Title: Excitatory to inhibitory transition in GABAergic currents guides circuit formation of cortical interneurons

Authors: *K. ZAVALIN[1], A. HASSAN[2], Z. KHERA[1], E. DELPIRE[2], A. H. LAGRANGE[2]; [1]Vanderbilt Univ., Nashville, TN; [2]Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Introduction:
Excitatory GABA is a crucial developmental cue that guides perinatal neuronal migration, synaptogenesis, and circuit formation. The switch from embryonic depolarizing GABA to mature hyperpolarizing responses is mainly determined by the onset of KCC2 expression. Previous work by other groups has found that prematurely upregulated KCC2 function produces dramatic abnormalities in brain development, especially in GABAergic cortical interneurons (INs). However, few studies address the repercussions of delayed onset of hyperpolarizing GABA. Here, we investigate how indefinitely-prolonged depolarizing GABA responses in INs adversely affect cortical circuit development using an IN-specific knockout (KO) mouse - DLX5:cre-IRES-eGFP; $KCC2^{flox}$.
Hypothesis:
We hypothesize that GABAergic interneuron migration and inhibitory circuit formation is critically dependent on the timing of hyperpolarizing GABA onset. We expect an anachronistic excitable physiology and altered distribution/circuit integration in $KCC2^{-/-}$ KO INs.
Results/Discussion:
KO mice exhibit abnormal neurological development, including: spontaneous seizures, a 45% faster onset of fluorothyl-induced seizures, reduced body weight, and late postnatal mortality, but normal gross and histological anatomy of organs, including feeding structures and the brain. We observe the earliest cortical KCC2 expression in layer 5 (L5) INs, as early as E16-18 in wild-type mice. We thus expected these cells to be the most affected by loss of KCC2, but instead found comparable densities of cells in both maturing (Dlx5:GFP+) and all INs (pan-IN marker) in L5 of KO and sibling. In addition, inhibitory synapses are roughly similar in quantity and $GABA_A$ receptor subtype composition.
We then postulated that the effects of KCC2 loss might be specific to IN subtypes, which in L5 consist mainly of somatostatin (SST) and parvalbumin (PV) INs with distinctly different circuit

functions and developmental sequences. We found a 24% increase in L5 density of SST INs in KO, but no change in PV IN density. Accordingly, we found no change in frequency of L5 principal cell sIPSCs, which reflect somatic and proximal dendrite input of predominantly PV IN projections. Hence, while a timely KCC2 expression in INs is vital for cortical circuit functionality, our preliminary data suggest that only the L5 SST INs, but not the L5 PV INs, are affected in the KO. We are now investigating (1) the circuit-level repercussions of abnormal SST IN development in the KO, and (2) if an earlier IN developmental trajectory is particularly sensitive to KCC2 loss.

Title: Effect of body weight and breeding position within the uterine horn on the hippocampus of the Wistar rat

Authors: *B. RUIZ VELÁSQUEZ[1], R. HUDSON[2], I. JIMÉNEZ[3], P. PACHECO[1], M. ALVARADO[1];
[1]Neurobiología del Desarrollo, Inst. De Neuroetología, Univ. Veracruzana, Xalapa, Veracruz, Mexico; [2]Inst. de Investigaciones Biomédicas, UNAM, Mexico, Mexico; [3]Dept. de Fisiologia, Biofisica y Neurociencias CINVESTAV-IPN, Mexico, Mexico

Abstract: Introduction: In the rat, the body weight of the individual is important during the first postnatal ages (P), in the obtaining of resources and in the development of the systems. The pupps have been classified as heavy, intermediate and light. It has been shown that before birth, the position of the offspring within the uterine horn (UH) and the neighboring brothers affect the hormonal levels of the breeding. They influence spatial memory capacity in adult ages, where mainly the hippocampus is one of the structures involved. Objective: To determine the number of hippocampal cells in the fetuses that presented differences in body weight (heavy/light) and their position in the UH on embryonic day 21 (E21). Methods: Seven litters were obtained from pregnant females, who underwent cesarean section in E21 to obtain the fetuses. The following biological parameters were taken into account: body weight, sex and position of the offspring within the UH (O, close to the ovary, M middle region and C near the cervix). By litter the heaviest and lightest brood of each sex was selected (n=7 in each group). Heavy male: HM; light male: LM; heavy female: HF; light female: LF. The histological process and Nissl staining were performed. The hippocampus was analyzed with the ImageJ program to obtain cell density. For

the statistical analysis, correlations were made (r=≥0.50) and a hierarchical analysis was carried out where Fisher's post hoc test was carried out (P=0.05). Results: the heavy offspring; HM and HF, were located in 90% in C, being the first to be born. The HF of the left uterine horn obtained values between 13000µm2 to 15000µm2, those of the right UH show valuesbetween 6000µm2 to 8000µm2. The HM, present values around 15000µm2. Regarding the correlations, it was observed that the pupils located in O, when increasing the body weight, the total number of cells in the hippocampus was higher (r=0.51). Significant differences were found between HM and HF in the total number of hippocampal cells; HM $\bar{x}$=5878.0 ± 753.1 and HF $\bar{x}$=4780.9 ± 846.1 (P=0.04). Conclusion: The heavy offspring are the first to be born. The body weight and sex of the individual, affect the development of the hippocampus from prenatal ages.

Title: Effect of the intake of blue tortilla additioned with organic acids and processed with microwave, on the development of hipocampo in Wistar rat

Authors: *P. GONZÁLEZ NIETO[1], M. ALVARADO[2], J. CHÁVEZ SERVIA[3], R. GUZMÁN GERÓNIMO[4];
[1]Inst. De Neuroetologia, Xalapa Veracruz, Mexico; [2]Inst. de Neuroetologìa, Univ. Veracruzana, Xalapa Veracruz, Mexico; [3]CIIDIR-Unidad Oaxaca, Inst. Politécnico Nacional, Oaxaca, Mexico; [4]Inst. de Ciencias Básicas, Univ. Veracruzana, Xalapa Veracruz, Mexico

Abstract: During pregnancy, the adequate supply of nutrients is essential for the proper development of the fetus. Basic foods such as corn (Zea mays) and specifically blue corn contain anthocyanins (antioxidants) that are bioactive compounds that help stimulate neurogenesis. However, the process of nixtamalization degrades anthocyanins. This work explored the effects of nixtamalization and alternative processes to maintain their biological properties. The nixtamalization by microwaves added with gallic acid was selected to continue with the biological test, obtaining 479.79 ± 0.06 mg total polyphenols Eq of gallic acid/100g and of anthocyanins 61.02 ± 1.80 mg C3G/100g with an increase of 43% and 69% respectively compared to traditional nixtamalization. The effect on the dentate gyrus of the hippocampus was evaluated, which participates in learning processes, memory, spatial perception and especially neurogenesis; process that takes place in the prenatal stage and continues in adulthood in this area. It was developed in 5 groups with Wistar female rats (control, traditional nixtamalization

with and without acid and nixtamalization by microwaves with and without acid) the fetuses were extracted on day 20 of gestation. The fetuses used were obtained from 6 average litters of each one a male was selected. The histological process was performed on the brains of the fetuses, afterwards the count of the number of cells per unit area (cells / mm²) of the dentate gyrus was carried out. The group of tortilla nixtamalizada by microwaves added with gallic acid predominated with values of 7305.09 ± 515.23 cells/mm² having an increase of 33% compared with the control which obtained 5465.02 ± 267.27 cells / mm² and an increase of 23% compared to the traditional nixtamalization without acid having values of 5900.28 ± 202.65 cells / mm². Further, the use of microwaves favors the cells size, the range < 30 μm² the use of the microwave and the favorable ranges ≥ 30 μm² microwaves doubled the cells size, while in the ranges greater than 60, without the addition of acid stimulated the increase. These data suggest that the process of nixtamalization by microwaves and added with gallic acid retains a greater quantity of anthocyanins and improves its biological activity.

Title: Generation of vascularized brain organoid and a model of brain angioenesis

Authors: *X. SUN;
Inst. of Neurosci., Shanghai, China

Abstract: Brain organoids derived from human pluripotent stem cells (PSCs), including induced PSCs (iPSCs) and embryonic stem cells (ESCs), can self-organize to form distinct brain regions and have been used to recapitulate developmental programs of human fetal brain, model developmental brain diseases. However, the lack of vasculatures composed mainly of endothelial cells (ECs), which have been shown to regulate embryonic neurogenesis, brain disorders, and aging process, limits its applications. During embryonic development, endothelial progenitor cells arise from migrating vascular progenitors (VPs) derived from mesodermal cells, while the ectodermic neural fate is triggered by the inhibition of BMP signaling, which makes it difficult to generate brain and vascular simultaneously. In this study, we develop the sequential induction approaches for vascular and brain organoids respectively, which could be fused together to generate the vascularized brain structures. Meanwhile, the blood-brain-barrier(BBB) structures could be detected in cultured brain organoids.

Title: Unexpected role of imprinted Cdkn1c genomic locus in cortical development

Authors: *R. BEATTIE[1], S. LAUKOTER[1], F. M. PAULER[1], K. I. NAKAYAMA[2], S. HIPPENMEYER[1];

Abstract: Developmental programs regulating the generation of cortical projection neurons by radial glia progenitor (RGP) cells need to be precisely implemented and regulated. However, the cellular and molecular mechanisms that underlie concerted RGP lineage progression and the control of neuron output remain unclear. The cyclin-dependent kinase inhibitor $p57^{KIP2}$ is encoded by the imprinted *Cdkn1c* locus, exhibits maternal expression, and is essential for cortical development. Here we employed Mosaic Analysis with Double Markers (MADM) technology to genetically dissect the level of cell-autonomy of *Cdkn1c* gene function in corticogenesis. We found that the previously described 'growth-inhibitory' function of *Cdkn1c* is a non-cell-autonomous one, acting on the whole organism and thus also entire cortex level. Our experiments also provide *in vivo* genetic evidence for a novel 'growth-promoting', rather than inhibiting, function of *Cdkn1c* which at the mechanistic level mediates nascent projection neuron survival. Strikingly, the newly identified growth-promoting function of *Cdkn1c* is highly dosage sensitive but not subject to genomic imprinting. Collectively, our results suggest that the *Cdkn1c* locus regulates cortical neurogenesis and growth through distinct cell-autonomous and non-cell-autonomous mechanisms. More broadly, our study highlights the importance to probe the relative contributions of cell intrinsic gene function and extrinsic tissue-wide mechanisms to the overall phenotype in health but also in neurodevelopmental disease conditions.

Title: AP-4 modulates ApoER2 secretory trafficking and reelin induces denditic development

Authors: *M. O. CARACCI, V. MACIAS, M.-P. MARZOLO;
Biologia Celular y Mol., Pontificia Univ. Catolica De Chile, Santiago, Chile

Abstract: Adaptor Protein Complex 4 (AP-4) an heterotetrameric complex (β4, σ4, μ4 and ε) which regulates protein trafficking from the TGN to endosomes and the plasma membrane. Each subunit has been associated to hereditary spastic paraplegia (HSP). The μ4 subunit directly recognizes tyrosine-based motif through structurally distinct canonical and non-canonical binding pockets. Few transmembrane protein cargos have been described, among them the Amyloid Precursor Protein (APP) and the Autophagy-related protein 9A (ATG9A) have received considerable attention. In the present work we show that ApoER2 secretory trafficking is disturbed by AP-4 deficiency. First, we followed the secretory pathway of ApoER2 using FM4-ApoER2-GFP co expressed with μ4 WT or binding defective mutant for the canonical and non-canonical binding pockets of μ4 in hippocampal neurons and HeLa cells. We found that expression of defective canonical binding pocket lead to a delayed exit from the TGN in HeLa cells and to differential ApoER2 distribution in hippocampal neurons. We further confirmed these observations using previously described HeLa ε KO cells where we found again a delayed release from the TGN. Surface expression of tagged ApoER2 was also reduced in HeLa KO cells compared to WT, further suggesting AP-4 complex regulates ApoER2 secretory pathway. Since ApoER2 is a bonafide Reelin receptor we tested if expression of WT or binding defective mutants affected Reelin mediated enhancement or primary dendrites. Surprisingly we observe that the effect of Reelin is greatly reduced in defective canonical binding pocket expressing neurons while expression of μ4 WT and defective non-canonical binding pocket expressing neurons showed enhanced Reelin induction of primary dendrites. All together our results show that ApoER2 is a potential novel protein cargo of the AP-4 complex, ascribing a role for this receptor and for Reelin signalling pathway in the development AP-4 associated neurodevelopmental disorders such as HSP.

Title: A role of autism related Chd8 in normal cerebellar development and motor functions

Authors: *C. XIANG[1], C. DONG[2,1], Y. LIN[1], W. ZHOU[1], R. Q. LU[2];
[1]Children's Hosp. of Fudan Univ., Shanghai, China; [2]Cancer and Blood Dis. Institute, EHCB, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: Autism spectrum disorder (ASD) is a complex neurodevelopmental disease defined by deficits in social interaction, repetitive and restrictive behaviors. Motor impairment and developmental co-ordination disorder, the cardinal feature in ASD, are among the earliest signs of an autistic phenotype. Cerebellum is essential for the spatial accuracy and temporal coordination of movement. Abnormal cerebellar pathology has been observed in autistic individuals. Recent studies indicate that *CHD8* represents one of the most high-risk susceptibility genes in ASD. A cohort of ASD patients exhibit cerebellar hypoplasia and develop ataxia, however, the underlying mechanisms of *Chd8* in regulation of cerebellum development remain poorly understood. Here, we find that *Chd8* is broadly expressed in the developing cerebellum. The mice with *Chd8* deletion in cerebellar neural progenitor cells exhibit severe malformation in cerebellar cytoarchitecture and lamination, as well as develop locomotion defects. In addition, genetic inactivation of *Chd8* in cerebellar granule neuron progenitors (GNP) leads to cerebellar hypoplasia and GNP dysgenesis in mice. The Chd8 mutant mice develop ataxia detected by rotarod test and beam walking test. Transcriptome profiling further indicate that *Chd8* regulates a set of GNP-associated genes and signaling pathways. Our studies reveal that *Chd8* is necessary for GNP development and cerebellar formation.

Title: Single-cell RNA sequencing of cell populations in the forebrain of embryonic chickens

Authors: *L. L. BRUCE[1], Y. ZHANG[1], S. KURAPATI[2], N. J. CHOI[1], J. ZUO[1];
[1]Biomed. Sci., [2]Pharmacol., Creighton Univ., Omaha, NE

Abstract: The neural plate of all vertebrates is believed to be composed of homologous cell populations of pluripotent progenitor cells. During embryonic development these progenitor cells gradually become specialized and acquire distinct functions and morphologies. The chicken forebrain is generally subdivided into pallium (cortex- and hippocampus-like) and subpallium (striatum- and pallidal-like) regions. The goal of this project is to investigate the dynamics and timing of molecular specification of chicken neuronal populations within pallium and subpallium regions at early developmental time periods. We will test the hypothesis that each forebrain region is born from a distinct progenitor region rather than from continuous gradients. Forebrain tissue was removed from euthanized chicks at embryonic day 5 and cells were dissociated using papain. Single cell RNA sequencing was performed using a 10X Genomics Chromium single cell 3' reaction, followed by DNA sequencing using an Illumina HiSeq X platform. A tSNE plot and heat map for 2 samples of 3000 cells each (3 forebrains per sample) was used to visualize cell clusters. Combinatorial gene expression patterns identified major clusters as red blood cells, collagen producing cells, neural crest cells, and brain-related cells. Within the brain-related cell cluster, cells were further clustered according to their developmental state, based on genes strongly expressed in (1) mitotic progenitor, neuroepithelial, and glial cells and (2) in young, maturing neurons. Forebrain cells were identified based on FoxG1+ expression. Of these, 23% of the FoxG1+ forebrain cell progenitor population expressed one or more pallium-specific genes (Emx1, Emx2, Tbr1, Eomes; 9%) or subpallium-specific genes (Dlx1, Dlx2, Dlx5, Isl1, Lhx6, Lhx8, Shh; 11%), or both (3%), whereas 94% of the maturing neuron population expressed pallial (18%), subpallial (71%) specific genes, or both (3%). Thus, during chick development, the forebrain regional specification begins at progenitor stages and is well established in young

maturing neurons. Combinatorial expression of transcription factors will be used to identify further clustering within these populations and to reconstruct the transcriptional trajectories of cell populations.

Title: Large scale death of retinal astrocytes during normal development mediated by microglia

Authors: V. M. PUNAL[1], C. E. PAISLEY[1], F. BRECHA[1], M. A. LEE[1], R. PERELLI[2], E. G. O'KOREN[1], C. R. ACKLEY[3], D. R. SABAN[1], B. E. REESE[4], *J. N. KAY[1];
[2]Neurobio., [1]Duke Univ., Durham, NC; [3]Univ. of California, Santa Barbara, Santa Barbara, CA; [4]Neurosci. Res. Inst., Univ. of California, Santa Barbara, CA

Abstract: Naturally-occurring cell death is a fundamental developmental mechanism for regulating cell numbers and sculpting developing organs. This is particularly true in the central nervous system, where large numbers of neurons and oligodendrocytes are eliminated via apoptosis during normal development. Given the profound impact of death upon these two major cell populations, it is surprising that developmental death of another major cell type - the astrocyte - has rarely been studied. It is presently unclear whether astrocytes are subject to significant amounts of developmental death, or how it occurs. Here we address these questions using mouse retinal astrocytes as our model system. We show that the total number of retinal astrocytes declines by over 3-fold during a death period spanning postnatal days 5-14. Surprisingly, these astrocytes do not die by apoptosis, the canonical mechanism underlying the vast majority of developmental cell death. Instead, we find that microglia kill and engulf astrocytes to mediate their developmental removal. Genetic ablation of microglia inhibits astrocyte death, leading to a larger astrocyte population size at the end of the death period. However, astrocyte death is not completely blocked in the absence of microglia, apparently due to the ability of astrocytes to engulf each other. Nevertheless, mice lacking microglia showed

significant anatomical changes to the retinal astrocyte network, with functional consequences for the astrocyte-associated vasculature leading to retinal hemorrhage. These results establish a novel modality for naturally-occurring cell death, and demonstrate its importance for formation and integrity of the retinal gliovascular network.

Title: Timing and specificity of Emx2 in area patterning

Authors: R. PANDEY, B. ALROBAEI, N. SINGH, H. TIEWAH, A. MEKONNEN, E. GALLMEIER, M. DELBRUNE, J. VIGILANT, K. ACCILIEN, *A. M. STOCKER; Biosci., Minnesota State Univ. Moorhead, Moorhead, MN

Abstract: All developmental processes are tightly regulated with respect to onset, cessation, as well as the specificity of actions undertaken. Transcription factors (TFs) are often utilized in the coordination and regulation of these processes, and homeobox TFs in particular regulate patterning of tissues and organs during development. Emx2 is a homeobox TF that has been previously demonstrated to regulate the patterning of functional areas in the developing telencephalon (area patterning), in particular the primary visual area (V1). Recent data and the development of novel approaches allowed for better exploration of the timing of Emx2's role in area patterning. Most early cortex-specific deletions have been performed utilizing the Emx1-IRES-Cre mouse line to mediate the enzymatic removal of floxed target genes. However a Cre-driver mouse line utilizing the Foxg1 promoter (i.e. Foxg1-IRES-Cre) has been generated which allowed a target gene to be deleted one day earlier than the Emx1 Cre-driver line. Through this comparison we determined that Emx2 function in area patterning occurred at the onset of expression as earlier deletion of Emx2 caused a larger reduction in V1 size in comparison to deletion at the later time point. In addition to timing we also explored the specificity of Emx2 function. Recent research has demonstrated that deletion of Emx1 yields an area patterning phenotype similar to the cortex-specific deletion of Emx2. The similarities in phenotype paired with the similarities in evolutionary origin, expression pattern, and timing of expression suggested that some functional redundancy might exist. We employed a multiple allele deletion approach to assess whether there is a gene dosage effect of the Emx genes on area patterning. Our results indicated that the actions of Emx1 and Emx2 were distinct, as double heterozygous

mutants did not exhibit a significant change in V1 size, while single gene homozygous mutants did. Additional Emx allelic deletion combinations were also generated and the area patterning phenotypes observed were consistent with the initial finding that the actions of Emx1 and Emx2 are distinct.

Abstract: This study aims to uncover the transcription network that regulates cortical regional patterning. Using *in situ* hybridization, we screened the expression of around 700 transcription factors (TFs) at E11.5 in the mouse, and identified around 30 that are expressed in rostrocaudal and/or dorsoventral gradients in the ventricular zone. Next, we tested whether their cortical expression was altered in CoupTF1, Emx2 and Pax6 mutant mice, and classified their phenotypes according to their change of expression in the context of abnormal regional architecture. Next, to assess whether their expression changes were due to direct regulation by CoupTF1, Emx2 and Pax6, we performed TF ChIP-seq, in conjunction with assays for epigenomic marks, DNA accessibility and chromatin-looping conformation in wild-types and mutants. This enabled us to map potential regulatory enhancers around the genetic loci of the 30

TFs of interest. We provide evidence that these TFs are combinatorially regulated by CoupTF1, Emx2 and Pax6.

Abstract: The brainstem ocular motor neurons (OMNs) mediate eye movements and are differentially affected compared with other motor neuron (MN) groups in some disorders. Specific subsets of OMNs show disrupted or aberrant innervation in congenital cranial dysinnervation disorders (CCDDs). In contrast, OMNs continue to function in Amyotrophic Lateral Sclerosis (ALS), while spinal and other brainstem MNs degenerate. Here we define unique developmental gene expression patterns among OMNs, and generate a toolbox of genetic markers to help study these disorders. We isolated and compared seven distinct motor neuron populations: the three ocular motor nuclei (CN3, CN4, CN6) and the other primary MN types (CN5, CN7, CN9/10/12 in the brainstem, and spinal cord MNs). We used microdissection and fluorescence-activated cell sorting (FACS) from multiple mouse lines to follow their developmental trajectories: embryonic days E9.5-E12.5 (*Islet-1:GFP, Hb9:GFP)*, E13.5-E14.5 (*Isl1^{Cre};Rosa26^{tdTomato}*), and E14.5-E18.5 (*Chat^{Cre};Rosa26$^{tdT\text{-}2A\text{-}H2B\text{-}GFP}$*). Pooled RNA-seq analysis at E10.5-E11.5 (Genesifter, DESeq2) was combined with single cell and single nuclei

RNA-seq at E9.5-E18.5 (plate- and droplet-based; Cell Ranger, Seurat, SPRING). Gene expression was validated with database analysis and *in situ* hybridization. We co-labeled for BrdU/EdU after injection on different developmental days (E8.5-E11.5) to correlate the gene expression differences with cell age. Each MN population showed unique gene expression patterns, including novel markers of OMNs, providing a genetic fingerprint of developing MNs for future studies. Spatially- and temporally-distinct subpopulations were identified within the ocular motor nuclei, corresponding to specific divisions of the oculomotor nerve, selectively affected in some CCDDs. The single nuclei FACS RNAseq protocol offers a new tool to enrich for small populations with unique gene expression at late embryonic/postnatal times when it is difficult to collect intact neurons. These data uncover distinct developmental gene expression patterns and markers of the various cranial motor neurons and provide new tools to study their selective vulnerability in the CCDDs.

Genet., [2]Genome Sci. and Technol., Univ. of British Columbia, Vancouver, BC, Canada; [3]Mol. and Cell Biol., Univ. of California, Berkeley, Berkeley, CA; [4]Univ. de Rennes 1, Brittany, France; [5]RIKEN Japan, Yokohama, Japan; [6]Med. Genetics; U of BC, Ctr. for Mol. Med. & Ther., Vancouver, BC, Canada

Abstract: The generation of diverse cell types in the brain is governed by sequential expression of genes. To elucidate the underlying gene regulatory cascades that produce cerebellar cell types, our lab and FANTOM5 consortium collected a dynamic transcriptomic dataset of cerebellum across embryonic (E) and neonatal (P) timepoints (E11-P9). Gene regulatory network analysis of this dataset has identified novel candidate transcription factors that have not previously been associated with cerebellar development. One of these genes, Pou3f1, is highly expressed during gastrulation and in developing mouse brain, and has been suggested to play a role in neural

differentiation, but its role in cerebellar development is unclear.
Our FANTOM5 data indicates that in mouse cerebellum, Pou3f1 transcript expression peaks at E12. *In-situ* hybridization demonstrated that Pou3f1 transcript is localized to the newly generated progenitors that arise from the rhombic lip and during their migration along the subpial surface of the cerebellum at E11-12. The expression pattern of Pou3f1 suggested that these cells may be glutamatergic cerebellar nuclear (CN) neurons. To test this hypothesis, we examined the Pou3f1-expressing cells in a mutant that lacks all glutamatergic lineages in the cerebellum, i.e. the *Atoh1*-null cerebellum. Pou3f1^{+} cells are missing in the *Atoh1*-null cerebellum indicating that these are glutamatergic neurons. We previously found that Pax6 is another key molecule expressed during the development of glutamatergic CN neurons and regulates the survival of these cells. Examination of Pou3f1 and Pax6 in wildtype E13 cerebellum shows that the two molecules are not co-expressed. To further examine the relationship between Pax6 and Pou3f1, we studied Pou3f1 expression in the *Pax6*-null Small Eye (*Sey*) mutant. Surprisingly, Pou3f1 expression is observed in the *Sey* mutant cerebellum. The lack of co-staining between Pou3f1 and Pax6 in the CN neuron progenitors, as well as the presence of Pou3f1-expressing cells in the *Sey* mutant suggests that Pou3f1^{+} nuclear neurons are a novel subtype of glutamatergic CN neuron. To map the position of Pou3f1^{+} CN neurons in the cerebellum, we examined the expression pattern of Pou3f1 with other CN neuron markers such as Tbr1, Brn2 and Irx3 in the E18 cerebellum. While Tbr1^{+} glutamatergic CN neurons reside in the fastigial nuclei, the GABA-ergic CN neurons (Brn2^{+} and Irx3^{+}) are found in the interposed and lateral nuclei. Pou3f1 largely co-labeled with Brn2 and Irx3. Our findings reveal that Pou3f1 marks a novel subtype of glutamatergic CN neurons and revises the lineage map of CN neurons distribution.

Title: Characterizing Msx genes in mouse cerebellar development

Authors: *I. GUPTA[1], F. CONSORTIUM[2], J. YEUNG[1], *D. GOLDOWITZ[1];
[1]Med. Genet., Univ. of British Columbia, Vancouver, BC, Canada; [2]RIKEN, Yokohama, Japan

Abstract: The cerebellum accounts for 80% of the neurons in the brain. Developmental defects of the cerebellum impair fine motor functions (Ataxia) and cognitive functions (ASD, Schizophrenia, ADHD). During embryogenesis, the cerebellar anlage is influenced by multiple signaling centers including the adjacent fourth ventricle roof plate, which secretes Bmp, Wnt,

and retinoic acid. Cerebellar neurons are then produced from two distinct progenitor zones: the **rhombic lip (RL)** and **ventricular zone (VZ)**. Bmp signaling activates the Msx (muscle segment homeobox) family of genes that has conserved homeodomains. They have been studied in fruit fly development and are implicated in mammalian CNS patterning, but their exact function is unknown. Different functional studies inactivating BMP signaling components in cerebellum have resulted in the loss of, or defects in, RL stem cell specification, and reduced number of Purkinje cells and interneurons. In mice and humans, the Msx family has 3 members - Msx1, Msx2 and Msx3. Our aim is to characterize these 3 genes in cerebellar development in the mouse. We participated in the FANTOM5 consortium to create a transcriptomic expression dataset, which was collected from the developing cerebellum tissue at 12 timepoints - embryonic days (E) 11.5 to E18.5 and postnatal days 0, 3, 6 and 9 - through cap analysis of gene expression (CAGE) sequencing. Temporal expression patterns for the 3 Msx genes obtained from this dataset show that they are expressed highest in early embryonic ages, and *in situ* hybridization (ISH) on these early age tissue shows their expression being limited to the progenitor zones. This suggests their involvement in early developmental processes like proliferation, specification and migration. We found that Msx1 and Msx2 are co-expressed with Atoh1 in the RL, which marks all glutamatergic lineages that arise from the RL. While Msx1 is more limited to RL, Msx2 expression is also seen in the VZ albeit more weakly. Msx3 is very strongly expressed in the VZ at E11.5 and E12.5. At these ages, Msx3 is expressed beyond the Ptf1a positive domain, while still being limited to the VZ. Interestingly, at E13.5 and E14.5, Msx3 shows compartmentalized expression within the VZ along with lateral-medial differences. This pattern imitates that of Olig2, a marker for Purkinje cell progenitors. Olig2 and Gsx1 are known to control the temporal identity transition of VZ progenitors by virtue of their compartmentalized expression pattern, and Msx3 may also be involved. To test this, we will study the loss-of-function effect of Msx3 on Olig2 and Gsx1 expression by knocking down the gene in an organotypic cerebellum tissue culture system at E11.5.

Title: Understanding the development of spinal sensory interneurons through *in vitro* differentiation of mouse embryonic stem cells

Authors: *S. GUPTA;
UCLA, Los Angeles, CA

Abstract: Spinal cord injury (SCI) patients can lose somatosensation, the ability to sense the environment when sensory interneurons (dI1-dI6) are damaged. These six classes of interneurons arise in the developing dorsal spinal cord from distinct progenitor pools (dP1-dP6), that are marked by the expression of specific transcription factors. The identities of these neurons are dependent on roof plate derived-Bone Morphogenetic Protein (BMP) family members and somite derived-Retinoic Acid (RA). However, it remains unresolved how RA and BMP signaling direct a variety of dI fates in the spinal cord. To resolve this question, we have differentiated mouse embryonic stem cells (mESCs) in the presence of either RA or RA+BMP4. We have observed that RA alone is sufficient to direct ESCs towards the Lhx1/5^{+}/Pax2^{-} dI2 (unknown function) and Lhx1/5^{+}/Pax2^{+} dI4 (pain-sensing) neural fates, while treatment with RA+BMP4 suppresses dI2/dI4 fates and concomitantly induces Lhx2^{+} dI1 (proprioception) and Isl1^{+} dI3 (mechanosensing) neurons. The simultaneous occurrence of either dI2/dI4 or dI1/dI3 neurons in our protocol suggest these neurons have a shared developmental origin. We hypothesize that RA and BMP4 activate different transcriptional networks to drive ESCs towards an as yet unidentified bipotential progenitor (dP2/dP4 and dP1/dP3), which then differentiates into either the dI2/dI4 or dI1/dI3 fates. We are evaluating this model using RNA-Seq analysis of mESCs undergoing dI differentiation to identify the RA and RA+BMP4 specific transcriptional networks. We are characterizing the progenitor types induced by RA and RA+BMP4 in mESCs by single-cell RNA-Seq to identify the novel bipotential progenitors of dI neurons. This analysis aims to provide fundamental insights into how specific classes of sensory interneurons are generated in the dorsal spinal cord. This information will shed light on our ability to design clinically relevant ESC protocols to derive specific dI neurons that can be used as cell replacement therapies to treat SCI.

Abstract: Neural progenitor proliferation, neuronal migration, areal organization and pioneer axon wiring are critical events during early forebrain development, yet remain incompletely understood, especially in human. Here, we studied forebrain development in human embryos aged 5 to 8 post conceptional weeks (WPC5-8), stages that correspond to the neuroepithelium/early marginal zone (WPC5), telencephalic preplate (WPC6 & 7) and incipient cortical plate (WPC8). We show that early forebrain neurons are formed at the neuroepithelial stage and originate from dorsal radial progenitors and possibly from the olfactory placode. At the preplate stage, forebrain organization is quite similar in human and mouse in terms of areal organization and of differentiation of Cajal-Retzius cells, pioneer neurons and axons. Like in the mouse, axons from pioneer neurons in prethalamus, ventral telencephalon and cortical preplate cross the diencephalon-telencephalon junction and the pallial-subpallial boundary, forming scaffolds that could guide thalamic and cortical axons at later stages. In accord with this scaffold guidance model, pioneer neurons express CELSR3 and FZD3, two molecules with key roles during mouse forebrain wiring. Furthermore, at the early cortical plate stage (WPC8), corticofugal axons cross the pallial-subpallial boundary and run in ventral telencephalon in close contact with scaffold neurons.

Title: Engineering cortical layers to enhance engraftment of neurons

Authors: *A. QUEZADA, N. IFEDIORA, J. M. HEBERT;
Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Several neurodegenerative disorders result in the loss of cortical neurons and ultimately the impairment of essential neural functions such as sensory processing or controlling movement. Neural stem cell (NSC) transplantation is a promising therapeutic strategy to replace neurons and repair damaged neural circuits. In this study, we plan to devise novel approaches to

replace lost or dying neurons in the cortex using NSC transplantation. First, to test if human vascular cells and neurons can integrate with the mouse host vascular and neural networks, we transplanted undissociated human fetal cortical tissue (gestational week 19) into a lesioned area of the cortex of immunocompromised mice (*NSG*, age 6-8 weeks). At one month post engraftment, we performed immunohistochemistry to assess graft survival and development. We observed both human and mouse blood vessels within the transplant as well as fusion of mouse and human blood vessels. This indicates that the mouse vasculature infiltrated the human graft and anastomosed with the human fetal derived blood vessels. Future experiments will include assays to demonstrate functionality of the blood vessels located within the graft. In addition, electrophysiological recordings will be performed to determine neural development of transplanted neural precursors and synaptic integration with the host. Since we now validated human cortical transplantation in mice, we will continue optimization using a more practical source of cells - human embryonic stem cells (hESC). We plan to do this using two complementary methods. First, to increase long-term survival of transplanted cells, the transplants will contain human vascular endothelial cells that spontaneously develop an integrated blood vessel network, as a method of pre-vascularization. Furthermore, to encourage repair of damaged neural circuits, cortical pyramidal neurons derived from hESC will be organized by cortical layers prior to transplantation in order to promote local circuit formation. Thus, we will compare transplants that are unvascularized and contain a disorganized mix of cortical neurons to transplants that are pre-vascularized and are organized by layers. Following transplantation into the motor cortex of immunocompromised mice, immunohistochemistry will be used to assess cell survival and structure of the transplant. Viral tracings will be performed to map out the axonal projections of transplanted neurons, while two-photon calcium imaging will be used to determine neurophysiological maturation of the graft.

Abstract: Interspecies chimeras are an emerging method that can be used to disentangle the roles cell autonomous programs versus environmental factors play in neural circuit development. Furthermore, this tool may provide a means to test the function of cells from less accessible species, such as humans, in a genetically-modifiable, whole-brain system. Despite recent advances in producing chimeras amongst rodents and other species, the extent to which different neuronal subtypes can develop, integrate, and contribute to circuit function and behavior remains poorly understood. Here, we have successfully produced rat-mouse chimeric animals (mRats) by injecting fluorescently-labeled rat pluripotent stem cells into mouse blastocysts. Using whole-brain imaging, we identify the contribution of rat cells to diverse cellular subtypes and circuits throughout the mouse brain. To assess the capacity of these rat neurons to function within the mouse, we have taken advantage of transgenic models in which specific neurons in the mouse olfactory system are ablated or silenced. These experiments demonstrate that rat olfactory sensory neurons can be produced during embryogenesis and are sufficiently specified to form glomeruli in the mouse olfactory bulb. However, when mouse olfactory sensory neurons are ablated, the rat neurons' ability to form glomeruli is compromised. In contrast, silencing mouse sensory neurons while maintaining their structural viability permits rat sensory neurons to form robust glomeruli and elicit activity in downstream neurons, suggesting the possibility of functionally replacing the mouse's olfactory sensory capacity with that of the rat. By quantifying the neural circuits to which neurons of other species can and cannot contribute and establishing the rules by which they integrate, these mRat chimeric studies will inform our understanding of evolutionarily conserved mechanisms of neural circuit development and plasticity applicable to species and circuits beyond the rodent olfactory system.

Title: An anatomical reference atlas of developing human brain at middle gestation: Segmentation based on a combinatorial expression of marker genes

Authors: *S.-L. DING[1], J. ROYALL[1], P. LESNER[1], B. A. C. FACER[1], K. A. SMITH[1], L. NG[1], N. DEE[1], R. DALLEY[1], S. M. SUNKIN[1], J. W. PHILLIPS[1], M. HAWRYLYCZ[1], I. A. GLASS[2], A. R. JONES[1], C. KOCH[1], A. BERNARD[1], E. S. LEIN[1];
[1]Allen Inst. For Brain Sci., Seattle, WA; [2]Univ. of Washington, Seattle, WA

Abstract: Prenatal development of the human brain is a dynamic and complex process that includes cell proliferation, differentiation, migration, target finding, synaptogenesis and maturation. Unlike adult brain, very few anatomical references are available to accurately describe the complex developmental anatomy in human brain. To provide a helpful and accurate reference tool that reflects structural organization in early development, we present, as a first step, a digital anatomical reference atlas of the developing human brain at post-conceptional week 15. In contrast to typical anatomical atlases based mainly on conventional Nissl and myelin stains, this atlas combinatorically incorporates in situ expression data from 46 marker genes and Nissl-stain histology from the same whole brain. A total of 236 structures were annotated in this atlas, including major cortical areas, developing cortical lamina, many transient structures (e.g. ganglionic eminences, rostral migratory stream and callosal sling), permanent subcortical nuclei, and major white mater tracts. This atlas represents the first detailed anatomical reference atlas for whole human brain at middle gestation, and can serve as a baseline reference for studies of abnormal development in neurological and psychiatric diseases as well as a guide for new techniques for cellular-level analysis of human brain development.

Title: Normal brain development and impaired exploratory behavior in transgenic mice overexpressing the polysialyltransferase ST8SiaIV in neuron

Authors: *S. NGAMLI FEWOU[1], I. RÖCKLE[2], H. HILDEBRANDT[2], M. ECKHARDT[3]; [1]Fac. of Hlth. Sciences, Univ. Des Montagnes, Bangangte, Cameroon; [2]Inst. für Klinische Biochemie, Medizinische Hochschule Hannover, Hannover, Germany; [3]Inst. für Biochemie und Molekularbiologie, Univ. Bonn, Bonn, Germany

Abstract: A large body of literature has demonstrated that the polysialic acid (polySia) modification of the neural cell adhesion molecule (NCAM) is a key regulator of cellular interactions during brain development, maintenance, and plasticity. To properly fulfill these functions, polySia concentration has to be carefully controlled. This is done by the regulation of the expression of the two polySia synthesizing enzymes ST8SiaII and ST8SiaIV. From this point of view we and others have demonstrated that downregulation of ST8SiaIV during oligodendrocyte differentiation is a prerequisite for efficient myelin formation and maintenance. Here, we addressed the question whether the prevention of polySia downregulation in neurons affects brain and particularly myelin development and functioning. For this purpose, we developed transgenic mouse lines overexpressing the polysialyltransferase ST8SiaIV in neurons. Transgenic expression of ST8SiaIV prevented the postnatal downregulation of polySia and most of the polySia in the forebrain and brain stem of adult transgenic mice was associated with NCAM-140 and NCAM-180 isoforms. Structural examination of the brain revealed no overt abnormalities of axons and myelin. In addition, ultrastructural and Western blot analyses indicated normal myelin development. However, behavioral studies revealed reduced rearing activity, a measure for exploratory behavior, while parameters of motor activity were not affected in transgenic mice. Taken together, these results suggest that a persisting presence of polySia in neurons has no major effect on brain structure, myelination and myelin maintenance, but causes mild behavioral changes.

Title: Characterization of nesprin-3 in mammalian neural stem cells

Authors: *T. PORTER[1], C. S. MORROW[1], K. AKO-ASARE[1], H. J. HEO[1], A. SONNENBERG[2], D. L. MOORE[1];
[1]Neurosci., Univ. of Wisconsin - Madison, Madison, WI; [2]Cell Biol., The Netherlands Cancer Inst., Amsterdam, Netherlands

Abstract: Throughout life, hippocampal neural stem cells (NSCs) generate new neurons in a process referred to as neurogenesis, contributing to cognitive flexibility. The mechanisms regulating adult neurogenesis are still being established. Recently, we have shown that dividing NSCs asymmetrically segregate protein cargoes, including the intermediate filament vimentin, between the two resulting daughter cells. The daughter cell inheriting these cargoes has a reduced proliferation, while the other “clean” daughter remains unaffected. Disruption of the nuclear envelope (NE) leads to symmetric cargo segregation, suggesting NE proteins may be involved in the molecular mechanism underlying cargo segregation. Interestingly, vimentin can interact with nesprin-3, an outer NE protein, whose function in the brain is unknown. Using multiple *in vitro* and *in vivo* techniques, we have characterized nesprin-3 and its interaction with vimentin in NSCs, within the developing and adult mammalian brain.

Title: Early generated interneurons regulate neuronal circuit formation during early postnatal development

Authors: C.-Z. WANG, J. MA, Y.-Q. XU, S.-N. JIANG, ***Y.-C. YU**;
Fudan Univ., Shanghai, China

Abstract: A small subset of interneurons that are generated earliest as pioneer neurons are the first cohort of neurons that enter the neocortex. However, it remains largely unclear whether these early-generated interneurons (EGIns) predominantly regulate neocortical circuit formation. Using inducible genetic fate mapping to selectively label EGIns and pseudo-random interneurons (pRIns), we found that EGIns exhibited more mature electrophysiological and morphological properties and higher synaptic connectivity than pRIns at early postnatal stages of the

somatosensory cortex. In addition, when stimulating one cell, the proportion of EGIns that influence spontaneous network synchronization is significantly higher than that of pRIns. Importantly, toxin-mediated ablation of EGIns after birth significantly reduce spontaneous network synchronization and decrease inhibitory synaptic formation during the first postnatal week. These results suggest that EGIns can shape developing networks and may contribute to the refinement of neuronal connectivity before the establishment of the adult neuronal circuit.

Title: Effects of neonatal exposure to an anesthetic midazolam on neural stem / progenitor cell behavior in the adult mouse hippocampus

Authors: *H. DOI[1,2], T. MATSUDA[1], K. YAMAURA[2], S. HOKA[2], K. NAKASHIMA[1];
[1]Stem Cell Biol. of Med., Grad. Sch. of Med. Sciences,Kyushu Univ., Fukuoka, Japan;
[2]Anesthesiol. and Critical Care Med., Grad. Sch. of Med. Sciences, Kyushu Univ., Fukuoka, Japan

Abstract: Adult neural stem/progenitor cells (aNS/PCs) in the subgranular zone (SGZ) of the adult hippocampal dentate gyrus (DG) proliferate and give rise to new neurons continuously throughout life to maintain hippocampus-dependent cognitive functions. Recent studies have demonstrated that gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter in the adult brain, suppresses aNS/PC proliferation in the SGZ. Midazolam, a $GABA_A$ receptor agonist, is widely used in clinical and surgical procedures, such as induction and maintenance of anesthesia, and sedation. Although previous studies indicated that neonatal exposure to $GABA_A$ receptor agonists including midazolam causes cognitive deficits later in life, mechanisms underlying these deficits have not been fully understood. In this study, we investigated whether exposing neonatal mice to midazolam affects NS/PC behavior and consequently impairs cognitive deficits in adulthood.
Postnatal day 7 (P7) mice received an injection of midazolam intraperitoneally for 3 consecutive days. We found that neonatally midazolam exposure decreased proliferation of NS/PCs and differentiation into neurons in the hippocampus in early postnatal stages. Interestingly, we also observed reduction of hippocampal NS/PC proliferation and neuronal differentiation in midazolam-exposed mice, even in the adulthood, associated with hippocampus-dependent cognitive deficits. Moreover, RNA sequencing of EGFP-positive hippocampal NS/PCs isolated from midazolam-exposed Nestin-EGFP mice revealed that neonatal midazolam exposure affects

expression genes involved in NS/PC proliferation in adulthood. These data suggest that midazolam has long-lasting adverse effects on NS/PC behavior and consequently causes cognitive deficits. Taken together, our findings may serve as a clue to elucidate the mechanism of anesthetic effects on neurogenesis and its association with memory dysfunctions.

Title: Ganglioside GD3 is required for maintenance of mitochondrial dynamics and neuronal morphogenesis in adult neurogenesis

Authors: *F. TANG, J. WANG, Y. ITOKAZU, R. K. YU;
Med. Col. of Georgia, Augusta Univ., Augusta, GA

Abstract: Gangliosides are abundantly expressed in the nervous system and are known to play important roles in neurodevelopment. We previously demonstrated that GD3 is a predominant ganglioside species (>80% of the total gangliosides) in mouse neural stem cells (NSCs). The presence of GD3 in NSCs coincides with its ability to facilitate EGF-induced cell proliferation and maintains NSC pools in adult brain. Notably, GD3 expression is not confined to NSCs but is observed throughout the adult DG, raising the possibility that GD3 have a function in later steps of the adult neurogenic sequence. Here, we describe deletion of GD3 from the hippocampal neurogenic lineage not only impairs stem cell maintenance, but also alters the dendritic structure as well as the number of excitatory synapses of adult-generated DG neurons. When examining the behavioral phenotypes of these animals, GD3-depleted mice display impairment in recognition memory. To gain insight into its cellular function, we examined GD3 binding partners from mouse-brain extract by using GD3 specific antibodies, followed by LC-MS/MS analysis and identify mitochondrial fission protein-Drp1 as a new GD3 binding protein. Biochemical and imaging analyses revealed aberrant mitochondrial fragmentation in GD3-depleted DG neurons. These results thus demonstrate GD3 may not only play a critical role in the regulation of NSCs function, but may also function during later stages of neurogenesis.

Title: The cellular and molecular attributes of adult neurogenesis and brain regeneration in zebrafish

Authors: *S. ANAND, A. MONDAL;
Sch. of Life Sci., Jawaharlal Nehru Univ., New Delhi, India

Abstract: In recent years, the adult zebrafish brain, owing to its tremendous neurogenic and regenerative ability, has emerged as a useful vertebrate model to study adult neurogenesis and brain regeneration. Several studies in recent years have been undertaken to characterize the cellular and molecular factors that mediate adult neurogenesis and brain regeneration in zebrafish. Many researchers have experimentally induced injury in the telencephalon in order to determine the cellular and molecular changes occurring in the brain during regeneration. Understanding reparative neurogenesis in the adult zebrafish brain may hold the key to the treatment of neurodegenerative diseases. Brain regeneration results from the proliferation and differentiation of adult neural stem cells (aNSCs). In a normal uninjured brain, the aNSCs spontaneously undergo cell division and differentiation to produce new cells, which replace the older dying cells in specific brain regions. In this study, we performed immunohistochemistry in 6 to 12 months old ASWT zebrafish brain to determine the precise location of the proliferating neural progenitor cells in the telencephalon of adult zebrafish brain. This was followed by double immunostaining experiments to characterize the proliferating progenitors using different differentiated and intermediate neuronal and glial cell markers. We then evaluated the response of these proliferating progenitors in a stab wounded adult zebrafish brain and how this response is mediated via the BDNF/TrkB signalling cascade using the selective TrkB receptor antagonist ANA-12. We found that the proliferating neural progenitors were distributed in distinct pallial and subpallial telencephalic regions with majority of them localized in the sub-pallium. Based on the results of double immunostaining experiments, we concluded that the progenitor cell population in the telencephalon, is not a homogenous cell population, rather it is a heterogeneous

cell population. When a stab wound injury was induced in the middle of the right telencephalic hemisphere, the proliferation of neural progenitors increased. However, the increase in proliferation was more or less eliminated when the injured zebrafish were treated with ANA-12. This suggests a major role of BDNF in mediating the brain regeneration process in zebrafish. This knowledge will contribute to the overall understanding of adult neurogenesis and brain regeneration in the zebrafish model.

Title: Jedi-1 is a novel regulator of postnatal neurogenesis

Authors: *K. A. KATDARE[1], M. N. TUGEND[1], F. E. HICKMAN[1], R. A. IHRIE[2], B. D. CARTER[1];
[1]Vanderbilt Brain Inst. Dept. of Biochem., [2]Vanderbilt Brain Inst. Dept. of Cell and Developmental Biol., Vanderbilt Univ., Nashville, TN

Abstract: Jedi-1 is an engulfment receptor involved in phagocytosis of apoptotic neuron corpses in the developing peripheral nervous system. However, Jedi-1 is also expressed in the brain and mRNA was detected in neurosphere cultures derived from perinatal ventricular-subventricular zone (V-SVZ) tissue. Previous studies indicated that neural progenitor cells (NPCs) in the V-SVZ could be phagocytic. To determine whether Jedi-1 contributes to this phagocytosis, we analyzed the uptake of carboxylated microspheres in NPCs derived from *jedi-1*$^{-/-}$ and *jedi-1*$^{+/+}$ perinatal mice. Although we confirmed the phagocytic ability of these cells, no difference was detected between *jedi-1*$^{-/-}$ and *jedi-1*$^{+/+}$ NPCs. However, we noted a marked increase in proliferation of the *jedi-1*$^{-/-}$ NPCs. Specifically, V-SVZ tissue was isolated from early postnatal mouse brains, dissociated and cultured for 7-10 days until neurospheres were formed. Neurospheres were then dissociated and plated as a monolayer and tested for EdU incorporation following a period of mitogen withdrawal. After 2-3 days of mitogen withdrawal, there was a 116% increase in proliferating cells from *jedi-1*$^{-/-}$ mice relative to *jedi-1*$^{+/+}$. At 2 days, most cells in culture were GFAP+ and Nestin+ indicating a neural progenitor identity. We are currently identifying which subtype of NPCs is the proliferating cell. The NPCs from both genotypes maintained their collective multipotency, generating neurons, astrocytes and oligodendrocytes after 14 days in culture. We are currently investigating whether there is any difference in the

proportions of these cell types generated from *jedi-1*$^{-/-}$ vs *jedi-1*$^{+/+}$ neurospheres. To examine the effects of *jedi-1* deletion on neurogenesis *in vivo*, 4-week-old *jedi-1*$^{-/-}$ and *jedi-1*$^{+/+}$ mice were injected with EdU (25mg/kg) and the brains isolated after 1 hour. EdU labelling and Ki67 immunostaining were quantified on sections sampled at every 50μm through the entire lateral ventricle. Surprisingly, in contrast to the *in vitro* results, we detected a 70% decrease in EdU+/Ki67+ cells in the V-SVZ of the *jedi-1*$^{-/-}$ mice relative to *jedi-1*$^{+/+}$. Current studies are aimed at quantifying proliferation at earlier ages, to determine whether there is depletion of the NPC pool by 1 month in the *jedi-1*$^{-/-}$ brain. We are also exploring the mechanisms by which Jedi-1 modulates NPC proliferation. Together, our results reveal that Jedi-1 is a novel regulator of postnatal neurogenesis.

Title: Divergent recombination of floxed sequences undermines the accuracy of stop-floxed reporters as indicators of global genetic recombination within single cells: Implications for studies of cell autonomous effects of gene knockdown

Authors: *T. J. DAUSE[1], E. D. KIRBY[2];
[1]Dept. of Psychology, [2]Dept. of Psychology, Dept. of Neuroscience, The Chronic Brain Injury Program, Ohio State, Columbus, OH

Abstract: A common question in cell biology is whether expression of a specific gene regulates cellular physiology autonomously or via paracrine effects. While gene function can be generally inferred from the effects of genetic ablation, determining whether gene knockdown impacts cells autonomously or via neighboring cell interactions requires a method to identify cells in which a target gene has been excised or suppressed versus those that are intact. To identify cells in which a gene has been knocked down, it is common practice to use Cre-lox system transgenic mouse models where flanking of essential exons of a target gene with loxP sites is combined with a stop-floxed fluorescent reporter under a universal promoter. Use of these models to determine cell autonomous effects of gene knockdown assume that recombination of both target and reporter genes occur simultaneously in the same cells with high probability. Because gene recombination in two loci are separate events, it is possible they may not correlate well cell by

cell. To our knowledge, this assumption--that recombination in one gene accurately predicts recombination in another at the single cell level--has not been tested. To test this assumption, we quantified co-expression of 2 separate Cre-dependent fluorescent reporters (Rosa EYFP Jackson #006148; Rosa tdTomato Jackson #007909) in the commonly used tamoxifen-sensitive NestinCreERT2 mouse line (Jackson #016261). In NestinCreER^{T2} mice, tamoxifen treatment activates Cre-mediated recombination in floxed sequences within adult neural stem and progenitor cells (NSPCs) with high specificity and efficiency. We analyzed fluorescent reporter recombination in NSPCs of the subventricular zone and dentate gyrus in NestinCreERT2(het);Rosa(EYFP/tdTomato) mice and found that EYFP recombination was a poor predictor of tdTomato recombination and vice versa. EYFP and tdTomato reporters recombined at different rates and in divergent NSPCs. These data imply that using inducible recombination of a fluorescent reporter to infer recombination of another gene at the single cell level is not a reliable methodology. It is important to weigh these limitations when considering the use of a transgenic mouse model where recombination of a target gene is inferred via the recombination of a fluorescent reporter on another gene.

Title: The role of microglia in neuroblast migration in the olfactory system

Authors: *S. J. MELLER, E. MARTÍN-LÓPEZ, T. LIBERIA, C. A. GREER;
Dept. of Neurosurg., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Understanding the mechanisms of neuroblast migration and integration into olfactory circuits will not only pave the way for therapies following smell loss, but may also have implications for the treatment of perinatal brain injury. The continued neurogenesis of the immature brain may provide opportunities for intervention by allowing recruitment of migrating neural precursor cells (neuroblasts) to sites of injury and functional recovery. Indeed, previous work has shown that migrating neuroblasts may be diverted from their migratory path to areas of injury where they can establish functional synapses with neighboring cells. We are interested in whether microglia, which are brain-resident immune cells, may help direct migrating neuroblasts during normal development and contribute to the recruitment of these cells to areas of injury. Microglia are first-line responders to brain injury and infection, but recent evidence indicates that

microglia are also critical for normal neurodevelopment. Microglia are involved in the formation of neural circuits through synaptic pruning, regulation of neurogenesis in stem cell niches, and promotion of myelin development. In addition, we are testing the hypothesis that microglia may influence neuroblast migration. In mice neuroblasts are generated in the subventricular zone throughout life and migrate long distances in the rostral migratory stream (RMS) to the olfactory bulb where they differentiate in interneurons. We find that microglia interact with migrating neuroblasts in the developing RMS prior to the establishment of the vascular and astrocytic scaffold that later guides neuroblasts. We also have evidence that microglia respond to a model of neuron injury in the olfactory bulb with an increase in the migration of neuroblasts to the areas of injury. In ongoing work we are developing strategies to eliminate microglia from migratory paths and investigating the molecular mechanisms mediating the effects of microglia on neuroblast migration, including the potential contribution of secretory factors. We hope that this work will eventually suggest new therapeutic strategies to promote normal neurodevelopment in infants following perinatal injury.

Title: Microglia and complement signaling in dendritic morphogenesis and behavioral output of adult-born neurons

Authors: *K. MCDERMOTT, M. FRECHOU, E. WOOD, J. GONCALVES;
Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: The dentate gyrus (DG) of the hippocampus, one of the few locations of adult neurogenesis, provides an opportunity to study new cells integrating into an existing circuit. The dendrites of dentate granule cells (DGCs) develop through trial and error, but the underlying mechanisms and functional implications of this growth process are not known. Microglia, the resident immune cells in the brain, prune synapses and eliminate apoptotic newborn neurons through phagocytosis. While microglia are known to affect adult neurogenesis, studies have focused on their role in cell survival rather than the development of adult-born neurons. Their contribution to the dendritic development of these neurons is not well understood. We hypothesize that microglia are necessary for the proper morphological and functional maturation of adult-born neurons in the dentate gyrus. We are investigating the role of microglia in adult-born DGC development through a combination of cell labeling, ablation, and *in vivo* imaging.

First, we are studying the effects of microglia ablation on the dendritic complexity of adult-born DGCs. We are also exploring the molecular mechanisms that underlie pruning in the DG through the complement pathway, which has been implicated in synaptic pruning in other brain areas. Finally, we are investigating how microglia and complement contribute to DG-dependent behavior. Our data suggest that ablation of microglia and loss of complement component C3 affect the dendritic growth of adult-born neurons. We also have preliminary data suggesting that C3 affects DG-dependent behavior.

Title: Assessment of neurogenesis and brain connectome in MPS I mice with iduronidase deficiency

Authors: *C. PEARCE, W. ZHU, P. HACKETT, W. CHEN, X.-H. ZHU, W. C. LOW; Univ. of Minnesota, Minneapolis, MN

Abstract: Mucopolysaccharidosis type I (MPS I, a.k.a. Hurler's Syndrome) is a genetic disease caused by mutations in the gene that encodes the enzyme alpha-L-iduronidase. This enzyme is required for the degradation of glycoaminoglycans (GAGs), and mutations result in lysosomal accumulation of GAGs in neurons and cognitive deficits in children with this disorder. Heparan sulfate is a GAG that binds to FGF receptors to form a trimer with FGF, and this trimer is required for signaling in neural stem cells for proliferation and differentiation during development. We therefore postulate that alpha-L-iduronidase deficiency may lead to decreases in neurogenesis and alterations in brain connectivity as underlying causes of cognitive impairment. To test this hypothesis, we have studied the brain connectome in MPS I mice using resting-state fMRI (rs-fMRI) to evaluate the connectivity of the hippocampal formation and other brain regions and neurogenesis using the X-CLARITY system coupled with immunohistochemistry to visualize neural cell proliferation in whole-brain preparations. In these studies, we observed diminished brain connectivity between the hippocampus and other regions of brain in MPS I mice vs. WT controls. Quantification of neurogenesis presented in the context of the brain connectivity observations provides a more clear understanding of mechanisms responsible for cognitive impairment in MPS I-affected individuals.

Title: Cdk1 is essential for long-term maintenance of neural stem cells in the postnatal hippocampus

Authors: *R. VANDENBOSCH[1,2], Q. MARLIER[1], S. VERTENEUIL[1], P. KALDIS[3], M. BARBACID[4], D. SANTAMARIA[5], L. NGUYEN[1], B. MALGRANGE[1];

Nacional de Investigaciones Oncológicas (CNIO), Madrid, Spain; [5]Univ. of Bordeaux, INSERM U1218, ACTION Laboratory, IECB, Pessac, France

Abstract: In contrast to the majority of neurons of the mammalian CNS, which are born during embryogenesis, hippocampal dentate granule neurons are continuously produced from mid-gestation to old age, including in humans. Postnatally born hippocampal neurons develop locally from neural stem cells (NSCs) anchored in a specialized niche of the dentate gyrus (DG), the subgranular zone (SGZ). We have previously shown that cyclin-dependent kinase (Cdk) 6, an important regulator of G1 progression, specifically drives the expansion of transit-amplifying progenitors in the postnatal hippocampus. However, it is not clear yet which Cdk is involved in the proliferation and long-term maintenance of hippocampal NSCs. Here, we investigated the role of Cdk1, an essential Cdk for M-phase, in postnatal hippocampal neurogenesis. Consistently with the crucial role of Cdk1 in the cell cycle, our results demonstrate that conditional loss of Cdk1 in hippocampal NSCs dramatically reduce their proliferation rate. Moreover, the total number of $Sox2^+$ NSCs rapidly declines upon Cdk1 deficiency, and this is accompanied by a concomitant increase in the number of newborn neurons produced. Surprisingly, we also observed that the loss of one allele of Cdk1 was sufficient to phenocopy most of the phenotypes encountered in the complete absence of Cdk1. These results suggest a role for Cdk1 beyond cell cycle regulation, where Cdk1 dosage regulates hippocampal NSC fate choice between neuronal differentiation and stem cell maintenance. We are actually investigating the mechanisms by which Cdk1 control cell fate in hippocampal NSCs.

Title: A role for polycomb repressive proteins in acquisition of the mature NMDAR phenotype at hippocampal synapses

Authors: ***H.-R. BYUN**[1], J.-Y. HWANG[2], B. COURT-VAZQUEZ[1], R. ZUKIN[1];
[1]Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY; [2]Dept. of Pharmacol. and Neurosci., Creighton Univ. Sch. of Med., Omaha, NE

Abstract: NMDARs (N-methyl-D-aspartate receptors) mediate excitatory transmission and are critical to synaptogenesis, formation of neural circuitry and to higher cognitive functions. A hallmark feature of NMDARs is a developmental switch in receptor phenotype from primarily GluN2B- to GluN2A-containing during the critical period of postnatal brain development. This is significant in that the GluN2B subunit restricts the number of AMPARs, decreases the threshold and increases the magnification of LTP. The gene silencing transcription factor REST is critical to the developmental switch in NMDAR phenotype at hippocampal synapses (*Noh, Hwang, Proc Natl Acad Sci USA*, 2012). The polycomb repressive protein Enhancer of zeste homolog 2 (EZH2) is a gene-silencing factors and member of a large macromolecular complex known as polycomb repressive complex 2 (PRC2) that is predicted to coordinate with REST to silence >500 neuron-specific target genes. A fundamental mechanism by which EZH2 and REST silence genes is by epigenetic remodeling. EZH2 is a histone-lysine N-methyltransferase that confers a tri-methyl mark on histone H3 at lysine 27, a mark of gene repression. Moreover, EZH2 recruits the DNA methylation machinery, which confers methyl moieties at the 5'-position of cytosines within the DNA, consistent with the concept that EZH2 induces enduring repression of target genes. However, a role for polycomb proteins in the developmental regulation of synaptic proteins is as yet unclear. Here we show that EZH2 and other components of the PRC2 (EZH1, SUZ12, and EED) are developmentally regulated in the hippocampus during the first two weeks postnatal and are recruited to the *grin2b* promoter, prior to the switch in NMDAR phenotype at P15. In addition, H3K27m23, the functional readout of EZH2, is enriched at the *grin2b* promoter at P15, where it remains as late as P60. Moreover, DNMT1 and 3a, proteins that mediate DNA methylation, are recruited to the *grin2b* promoter, where DNA methylation is prominent at P15 and continues to increase as late as P30, the latest time point examined. We

further show that acute knockdown of EZH2 increases GluN2B expression in DG neurons. These findings demonstrate that EZH2 is casually related to *grin2b* repression and the switch in NMDAR phenotype. We are currently examining a possible causal role for EZH2 in the recruitment of REST and the DNA methylation machinery and the long term stabilization of the mature NMDAR phenotype at hippocampal synapses.

Title: Control of neural stem cell specification in the postnatal forebrain by antagonist function of Vax1 and Pax6

Authors: *N. CORÉ, A. ERNI, C. BÉCLIN, H. CREMER;
IBDM CNRS-UMR7288, Marseille, France

Abstract: Neural stem cells (NSCs) in the postnatal mouse ventricular/subventricular zone (V/SVZ), that generate different types of interneurons for the olfactory bulb, are highly heterogeneous. Depending on their location along the ventro-dorsal axis of the lateral ventricles, they preferentially give rise to distinct neuronal subclasses with defined positions, connectivity or neurotransmitter phenotypes. Understanding the molecular mechanisms that determine the generation of the distinct neuron populations at the NSC level will be essential for directing the differentiation of NSCs into defined neuronal cell populations in therapeutic contexts. We found that the homeodomain transcription factor (TF) Vax1 is expressed in the lateral V-SVZ stem cell compartment in a ventro-dorsal gradient, suggesting a role in stem cell patterning and determination of neuronal phenotype. We used postnatal *in vivo* electroporation to miss-express Vax1 in the dorsal NSC aspects of the V-SVZ. Overexpressing Vax1 in dorsal or dorso-lateral NSCs led to a decrease in the dopaminergic interneuron population in the olfactory bulb. This phenotype is accompanied by a reduction of the pro-dopaminergic TF Pax6 in the stem cell compartment, suggesting that dopaminergic fate repression by Vax1 occurs through repression of Pax6. Moreover, conditional inactivation of Vax1 in NSCs along the lateral SVZ led to a reduced number of Calbindin+ neurons, showing that Vax1 is necessary for the production of this sub-set of OB neurons. This shows that antagonistic interactions between Vax1 and Pax6 control neuronal phenotype along the dorso-ventral axis of the forebrain stem cell compartment. If these interactions are direct or implicate intermediate regulators like, for example, miR-7a is currently under investigation.

Abstract: The brain growth occurs before birth or during childhood but it undergoes extensive remodeling in the adolescence period. Accumulating data from epidemiology and genetic to basic neuroscience showing that adolescence is a high-risk period for the onset neuropsychiatric diseases such as schizophrenia (SZ). Interestingly animal and human postmortem studies suggest that alterations in GABA interneurons contribute to neuropathological and clinical features of SZ. Inhibitory signaling from parvalbumin positive GABA interneurons (INsPV+) is a critical regulator of adult neurogenesis in the dentate gyrus. Recently in a pharmacological model of hypofunction of NMDA receptors through adolescence ketamine treatment (ket-teatment) that induce symptoms of SZ, we have observed a strong decrease of number of INsPV+ and a decrease of GABA transmission in prefrontal cortex but without effect on the ventral hippocampus. Considering that the contribution of the hippocampus in different brain functions varies along its septal-temporal axis, we used a immunofluorescent and electrophysiology approach to determine if adolescence ket-treatment, impairs the GABAergic synaptic transmission and decreases the adult hippocampal neurogenesis in rat dorsal dentate gyrus (DDG). Our results show that adolescence ket-treatment induced a strong decrease in the number

of INsPV+ and reduced spontaneous and evoked GABAergic transmission between INsPV+ and mature dentate granule cells (mDGC) in the DDG. Also, we observed that the ket-treatment did not affect the passive or active membrane properties of the mDGC. Using the expression level of BrdU/Ki67 and DCX markers, we found that the adolescence ket-treatment induced a significantly reduction of the proliferation rate and adult neurogenesis in the DDG. These results suggest that INsPV+ GABAergic transmission plays a key role in the synaptic and structural plasticity in DDG, and that the hypofunction of the INsPV+ in the adult DDG could be key to understand the pathogenesis of SZ

Title: Effect of cannabinoid exposure during gastrulation on neuronal development in zebrafish

Authors: *M. AMIN, K. AHMED, D. ALI;
Biol. Sci., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Marijuana is one of the most commonly used illicit recreational drugs. It is reported that up to 14% of pregnant females aged between 12-44 have used cannabis during their first trimester. In this study we wanted to determine the effect of brief exposure of cannabinoids (THC, CBD and CBN) during early development. To do this, we exposed zebrafish embryos to different cannabinoids for 5 hours during a stage of development known as gastrulation (5.25 hr-10.75 hr). Cannabinoid exposed embryos exhibited a dose-dependent reduction in survival, body length, hatching and heart rates. Treated fish were less responsive to touch whereas controls exhibited robust escape responses upon touching the head or tail with forceps. Because the movement of treated fish was severely limited, we examined motor neuron (MN) development, muscle fiber morphology and activity at the neuromuscular junction (NMJ). Fluorescent labelling of primary and secondary MNs indicated a change in branching patterns and a reduction in the number of axonal branches in the trunk musculature. Further, to look at the structural details of muscle fiber morphology, we performed TEM (transmission electron microscopy) imaging of longitudinal sections of muscle fibers and observed the presence of large-sized mitochondria in several muscle layers in treated embryos but not in controls. Next, we found that whole cell recording of mEPCS from white muscle fibers were less frequent in

cannabinoid treated embryos vs controls. To determine if cannabinoid treatment altered the ability of fish to respond to sound at 5 dpf, we examined the C-start escape response in larvae. We found that larvae treated with cannabinoids exhibited a drastic reduction in the number of C-start escape responses to sound stimuli. To examine how cannabinoids mediate their activity, we carried out co-exposure of cannabinoids with the CB1R blockers AM251, CP9455 or the CB2R blockers AM630 and JTE907. Our results suggest that the effects of δ^9(-) THC occur largely (but not exclusively) through CB1R whereas the effects of CBD and CBN occur mainly (but not exclusively) through activation of CB2Rs. These findings suggest that cannabinoids alter neuronal development via acting through either CB1R or CB2R.

Title: Regulated intramembrane proteolysis of neuregulin 1 is important for postnatal hippocampal neurogenesis and neuronal development

Authors: *A. JONE[1], P. M. RAJEBHOSALE[2], L. W. ROLE[3], D. A. TALMAGE[4];
[1]Neurobio. and Behavior, [2]Ctr. for Nervous Syst. Disorders, [3]Neurobio. & Behavior, [4]Pharmacol. Sci., Stony Brook Univ., Stony Brook, NY

Abstract: The Neuregulin 1 (Nrg1) gene encodes a family of versatile signaling proteins extensively involved in neural development and synaptic plasticity. One neuron-specific isoform, Type III Nrg1, is critical for neuronal survival, neural fate determination, receptor trafficking, axon myelination, and synaptic transmission. Genetic deletion of Type III Nrg1 in mice results in deficits in synaptic plasticity and behavioral deficits involving working memory and sensorimotor gating. Upon ErbB4 binding or neuronal depolarization, Type III Nrg1 undergoes regulated intramembranous proteolysis (RIP), mediated in part by γ-secretase cleavage, to generate a carboxyl-terminal fragment. This soluble intracellular domain (ICD) of Type III Nrg1 is capable of translocating to the nucleus, where it possesses strong transcriptional transactivation properties. *In vitro*, a valine residue in the transmembrane domain (position 321) is necessary for proper RIP of Type III Nrg1 and appropriate dendritic arborization. Interestingly, a single-nucleotide polymorphism that has been associated with psychosis and schizophrenia in a human population in Costa Rica results in the substitution of a leucine for this valine residue.

We generated a valine-321-leucine (V321L) mouse line and asked whether this point mutation affects Nrg1 RIP and disrupts developmental events *in vivo*. We show through subcellular fractionation that Nrg1 RIP and subsequent ICD nuclear translocation are impaired by the V321L mutation. Because the ICD has been previously demonstrated to regulate neural stem cell proliferation and fate specification *in vitro*, we asked whether neurogenesis is affected by disruptions in Nrg1 RIP *in vivo*. Our results indicate that mice with the V321L mutation have aberrant hippocampal neurogenesis, with reduced cell proliferation, altered cell cycle dynamics, and disproportionate fate specification in the dentate gyrus compared to wild-type littermates. Furthermore, newborn neurons in V321L mutants appear have impaired dendritic arborization. These results suggest that Nrg1 RIP plays an important role in regulating neural stem cell development and neuronal maturation in the hippocampus.

Title: PITPNA and PITPNB cooperate in maintaining neural stem cells self-renewal via GOLPH3-dependent notch signaling during mouse brain development

Authors: *S. K. HUR[1,2], V. BANKAITIS[2];
[1]Ctr. for Neurodegeneration Research, Pathology and Lab. Med., Univ. of Pennsylvania, Philadelphia, PA; [2]Mol. and Cell. Med. Department, Col. of Med., Texas A&M Univ., College Station, TX

Abstract: Phosphatidylinositol (PtdIns) transfer proteins (PITPs) stimulate PtdIns-4-P synthesis and signaling in eukaryotic cells. However, the precise nature of the associated signaling pathways, and of the biological outcomes associated with PITP activities remain unclear. Herein, we show that two type-1 START-like PITPs, PITPNA and PITPNB, cooperate in maintaining neural stem cell (NSC) self-renewal via a PtdIns-4-P and GOLPH3-dependent mechanism that promotes Notch signaling in embryonic NSCs. We have exploited an *in utero* electroporation approach to investigate the role of PITP-dependent inositol lipid signaling in the embryonic NSC pool. By silencing *Pitpnb* with shRNA in a *Pitpna* null mouse line we evoked a dramatic depletion of the NSC pool achieved through acceleration asymmetric differentiation of cell

division in the embryonic brain. *In utero* electroporation delivery of plasmids isogenic to wild-type PITPNA or PITPNB rescued the NSC depletion resulting from eviction of both PITPs. However, a PITPNA mutant clone deficient in phosphatidylinositol or phosphatidylcholine binding failed to rescue NSC depletion. Moreover, neither Sec14p, the major yeast PITP, which possesses the same lipid-binding/transfer activities but is structurally unrelated to type1 PITPs, nor PITPNC1, a homolog of PITPNA/PITPNB that also shows PtdIns-transfer activity but which uses a different second lipid, PtdOH, restored the NSC pool. These data reveal that PITPNA/PITPNB are specifically required for maintaining the NSC pool and additionally demonstrate that the function role of PITPNA/PITPNB in NSC self-renewal cannot be accounted for by simple PtdIns-4-P transfer as proposed in PtdIns-gradient models. We observed GOLPH3-dependent Golgi positioning which was required for controlling NSC self-renewal, and for maintaining the NSC pool. Furthermore, we confirmed that PITP deficiencies evokes a significant reduction of the Notch intracellular domain (NICD) in embryonic NSC. We propose a mechanism where PITPNA/PITPNB drive PtdIns-4-P-dependent recruitment of GOLPH3 to Golgi membranes so as to promote an asymmetric Golgi network where the Notch receptor matures to control NSC self-renewal.

Title: A conditional knockout mouse model to study the specific role of cyclin D2 in brain development, adult neurogenesis and human brain pathologies

Authors: V. GOYAL[1], S. A. ZAHRA[1], C. HENNINGS[3], G. ZIMMER-BENSCH[4], C. BEETZ[2], *C. W. SCHMEER[1], C. HUEBNER[3], O. W. WITTE[1], **A. URBACH**[1];

Abstract: Cyclin D2 (D2) is one out of three homologous D-cyclins implicated in cell cycle progression and malignant transformation. D2 becomes detectable during gastrulation and shows dynamic expression patterns during neurulation and brain development. Loss- or gain-of-

function mutations of D2 have been associated to circumscribed neurodevelopmental deficits resulting in loss of interneurons, microcephaly or megalencephaly. We previously showed that depletion of D2 impairs formation of the adult hippocampal stem cell pool, which is the source of lifelong neurogenesis. Our studies further suggest that D2 is critical for the proliferation of adult neural stem and progenitor cells. However, because of the aforementioned deficits and other developmental defects of conventional D2 knockout (D2KO) mice, the precise role of D2 in adults, e.g. for regulating neurogenesis, could not be evaluated so far. To bypass the limitations of the conventional D2KO, we engineered a mouse line in which exons I and II of the *ccnd2* gene are flanked by loxP sites, to enable a spatiotemporally controlled deletion of D2. In order to test the efficiency of the line, we crossed these animals to Cre deleter mice to achieve a ubiquitous conditional D2 knockout (cD2KO). In situ hybridization as well as Western blot analysis of D2-expressing tissues confirmed the lack of D2 transcripts and protein in homozygous cD2KO mice. Macroscopic evaluation and brain volumetry revealed that cD2KO mice display a phenotype equal to that of constitutive D2KO mice: Compared to wildtype siblings, we observed a 17% reduction in total brain volume, with atrophies becoming most prominent in the dentate gyrus (38% smaller), the olfactory bulb and the cerebellum. Moreover, incorporation of the S-phase label Bromodeoxyuridine into hippocampal precursor cells was reduced by 90%, indicating a severe impairment of adult neurogenesis. Heterozygous cD2KO mice were normal for all evaluated parameters, despite having an intermediate neurogenesis phenotype (approx. 35% less Bromodeoxyuridine incorporation). Taken together, we generated and validated a new conditional D2KO mouse model useful for investigating the contribution of D2 to brain development, stem cell self-renewal, adult neurogenesis and disease processes such as tumorigenesis.

Title: Differential effects of cyclin D2 ablation on the self-renewal capacity of postnatal and adult hippocampal stem cells and dynamic expression of D-cyclins during precursor differentiation *in vitro*

Authors: A. SYEDA ZAHRA, O. W. WITTE, ***A. URBACH**;
Hans Berger Dept. of Neurol., Jena Univ. Hosp., Jena, Germany

Abstract: The neurogenic potential of the adult dentate gyrus (DG) relies on a pool of quiescent neural stem cells (NSCs) that become activated to generate new granule cells on demand. Our studies on cyclin D2 knockout (D2KO) mice suggest that cyclin D2 is required for the establishment of the adult NSC pool during the second to third postnatal week, and that cyclin D2 becomes increasingly important for hippocampal neurogenesis during this period. We showed that cyclin D2 is the only D-type cyclin of adult NSCs, suggesting an important role for their proliferation and self-renewal. On the contrary, developmental NSCs in the postnatal hilar germinative matrix as well as in the emerging subgranular zone also express cyclin D1, which might compensate for the loss of cyclin D2 during postnatal neurogenesis. To further examine these findings, we isolated neural precursors from postnatal day 7 (P7) and adult mouse dentate gyri and cultured them as neurospheres. We found that neurospheres could be established from both, P7 and adult D2KO precursors. However, precursors from D2KO mice formed less and in adults also smaller spheres during primary culture as compared to wildtype mice. The spheres of P7 D2KO mice were able to expand exponentially over at least ten passages, demonstrating that their DG contains *bona fide* self-renewing NSCs that do not require D2 for proliferation. On the contrary, the precursor population from adult D2KO mice displayed no long-term neurosphere-forming capacity and stopped growing after the third passage, suggesting that it is composed of only progenitor cells. Proliferation of D2KO precursors is likely accomplished by cyclin D1 which is expressed in spheres of both, P7 and adult mice (qRT-PCR and Western blot). To further evaluate the dynamics of D-cyclin expression during adult neurogenesis, we cultured DG precursors from wildtype mice as monoadherent cultures (with FGF2 and EGF) and differentiated them in mitogen-free media for 96 hrs. We observed similar quantities of cyclin D1 and D2 transcripts and proteins which were high in proliferating cultures and sharply decreased during the first 24 hrs of differentiation, simultaneously with a drop of the proliferation marker Ki67 and increasing levels of differentiation markers DCX, Fox3 and GFAP. Together, these findings confirm our *in vivo* data suggesting that cyclin D2 is dispensable for proliferation of developmental NSCs but required for the formation and maintenance of the adult NSC population.

Title: Postnatal development and spatial distribution of neuromuscular junctions and innervated nerves in mouse skeletal muscles

Authors: *J. XU[1,2], T. YU[1,2], Y. LI[1,2], Y. YAO[1,2], D. ZHU[1,2];

Abstract: Neuromuscular junction (NMJ) is the typical chemical synaptic connection between lower motor neurons and muscle fibers, and control voluntary muscles contraction. NMJ is also a classical model of synapse development, which can provide references for the development of central nervous system. They are functional at birth and undergo numerous alterations postnatally, especially the change of innervation pattern (polyneuronal innervation to mononeuronal innervation) resulted from synapse elimination. And axon loss not only simplifies motor unit size, but also may influence the number of NMJs due to synapse elimination without takeover. However, the studies on NMJ development mainly focused on individual NMJ or a few NMJs innervated by a single motor neuron, which makes it difficult to understand the influence of synapse elimination for NMJ development in whole skeletal muscle. Currently, combining with optical clearing techniques, whole-mount analysis of the distribution and number of NMJs has been frequently used as an experimental paradigm. Here, combined this paradigm with the study of NMJ development, all NMJs and axon branches were detected and analyzed quantitatively in mouse skeletal muscles at different time points during postnatal development. We found that the spatial distribution pattern of NMJs and nerve branches was consistent after

birth, but the number of NMJs in gastrocnemius and tibialis anterior increased continually during early postnatal development and reaches equal level to the adulthood at about P10. In addition, a phenomenon was observed by high-magnification confocal imaging that some new nerve terminals sprouting from the nerve branches would “share” with neighboring acetylcholine receptor (AChR) clusters, which would lead to the division of the neighboring AChR clusters. The above results indicated that NMJ formation still occurs in some muscles during the early postnatal stage, and synapse elimination do not reduce the number of NMJs in whole muscles, on the contrary, it could be associated with an increase in NMJ number.

Title: Thalamocortical axons regulate neurogenesis in sensory areas of the mouse neocortex

Authors: *T. R. MONKO, J. STOLLEY, S. DABRUZZI, P. GONCHAROV, Y. NAKAGAWA;
Neurosci., Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: Connectivity between the mammalian thalamus and the neocortex is important for proper brain functioning and has been proposed to have an instructive role in shaping the structural and functional differences among neocortical areas. Thalamocortical axons are known to refine the dendritic arbors of upper layer neurons to produce unique cytoarchitectural features, such as barrels in rodent primary somatosensory cortex, and distinct areal borders such as those found between striate and extrastriate in primate visual cortex. These axons control gene expression patterns across areas of the thalamo-recipient layer 4 of neocortex, but it is unknown if thalamocortical axons are important in the generation of the increased number of upper-layer neurons in primary sensory areas. Axons from the thalamus reach the neocortex when upper layer neurons are being produced and may therefore have a role in spatiotemporal regulation of progenitor proliferation and differentiation. We address this by analyzing neurogenesis in thalamus-specific Gbx2 mutant mice, which lack thalamocortical axons. In these mice, the number of upper-layer neurons in primary somatosensory and visual areas was reduced in postnatal cortex. In addition, the number of radial glia and intermediate progenitor cells were reduced in putative sensory areas of the embryonic cortex. These results indicate that thalamocortical axons enhance production of upper-layer neurons in primary sensory areas by

interacting with progenitor cells. In addition, we investigate a molecular mechanism unique to sensory areas by examining the role of Vgf, which encodes a set of neuropeptides expressed specifically in principal sensory nuclei of embryonic thalamus. In thalamus-specific Vgf knockout mice, the number of dividing intermediate progenitor cells was reduced in putative sensory areas with a concomitant decrease in upper-layer neurons. These results collectively suggest that thalamic afferents play multiple complex roles in controlling neurogenesis in sensory areas of the neocortex. Because one of the Vgf-encoded peptides has a receptor exclusively expressed by microglia, our results may indicate an indirect role of the resident immune cells that mediate the thalamic regulation of neocortical neurogenesis.

Title: Cord blood-derived exosomal contactin-2 and BDNF: Biomarkers for brain health of neonates at risk for iron deficiency?

Authors: *T. M. MATVEEVA[1], P. MARELL[1], S. BLOHOWIAK[1], P. KING[1], M. GEORGIEFF[1], P. V. TRAN[2];
[2]Dept. of Pediatrics, [1]Univ. of Minnesota, Minneapolis, MN

Abstract: Iron deficiency anemia (IDA), which affects approximately 20-30% of all pregnant women and their offspring worldwide, causes long-term impairments in cognition and socio-emotional behaviors in adulthood despite iron therapy following IDA diagnosis in infancy. The persistent abnormalities constitute a significant cost to society in terms of education attainment, job potential, and mental health. The underlying pathobiology for the persistent abnormalities has been ascribed to abnormal neural development and function (e.g., metabolism, dendritogenesis, and synaptogenesis) during critical periods in early life that are carried forward into adulthood. However, accumulating evidence also implicates iron-dependent epigenetic mechanisms, by which early-life ID induces long-lasting dysregulation of genes critical for neural function in adulthood. The epigenetic modifications can be mitigated with a methyl donor supplement, choline, suggesting therapeutic efficacy of the adjunctive diet. As such, it is important to establish early biomarkers that can index brain health of infants at risk for IDA. Given that iron is prioritized to the red cell production to support tissue oxygenation, when IDA is diagnosed using available blood-based markers (e.g., Ferritin, zinc-protoporphyrin [ZnPP]) the brain has already been deprived the severely needed iron for growth during critical periods of

development. We have explored the use of exosomes, which are secreted by cells and carry proteins and nucleic acids for cell-cell communication, from cord blood to identify potential brain-specific biomarkers. Our findings suggest Contactin-2, a neural specific cell-surface protein critical for axonal growth and myelination, and Brain-derived Neurotrophic Factor (BDNF), an important growth factor for neural development during fetal and postnatal life, as potential sex-specific markers that are remarkably correlated to infant iron status based on cord blood ferritin and ZnPP. Additional analyses of Contactin-2 positive exosomes from cord blood will potentially identify additional markers that can be readily translated into clinical tools for assessing developing brain health in neonates.

Title: iPSC derived engineered cerebral organoids as *in vitro* models of tauopathy

Authors: *C. E. J. LOVEJOY[1], A. ALATZA[1], C. ARBER[1], J. HARDY[1,2,3], S. WRAY[1,2]; [1]Inst. of Neurol., UCL, London, United Kingdom; [2]Queen Square Inst. of Neurol., London, United Kingdom; [3]UK Dementia Res. Inst. at UCL, London, United Kingdom

Abstract: Introduction: Hyperphosphorylated, insoluble aggregates of the microtubule associated protein tau are a pathological hallmark of a range of clinically diverse neurodegenerative diseases termed tauopathies. Mutations in the tau gene (MAPT) cause Frontotemporal Dementia, and a subset of these mutations disrupt splicing of the MAPT gene. Induced pluripotent stem cell (iPSC) carrying MAPT mutations have been differentiated into neurons to study tau expression. However, iPSC-neurons closely resemble foetal neurons and predominantly express 3R tau isoforms rather than equimolar amounts of 3R/4R tau observed in the adult human CNS. We examined tau expression and splicing 3D cerebral organoids to test the hypothesis that 3D cultures mature quicker in vitro, and therefore express 4R tau earlier than 2D neurons. Methods: iPSC lines with the MAPT 10+16 mutation were used to generate 3D engineered cerebral organoids (EnCORs) using the protocol described in (Lancaster et al., 2017). Tau expression, splicing and phosphorylation were examined using RT-PCT and western blot. Results: Successful differentiation of iPSC into 2D and 3D cultures was confirmed by staining

for the neuronal markers phospho-vimentin, FOXG1, TBR1, and βIII-tubulin. Control EnCORs expressed predominantly 3R tau, while both 3R and 4R tau was expressed in cultures containing the MAPT 10+16 mutation. Tau isoform diversity increased over time, and a direct comparison of 2D and 3D cultures revealed a robust expression of 4R tau in 3D cultures from controls after 200 days in vitro, which was absent in 2D cultures. Tau was phosphorylated at multiple epitopes in EnCORs but no differences were observed between control and mutant genotypes. Conclusions: 2D and 3D neuronal models predominantly express the 0N3R foetal tau isoform. Multiple isoforms of tau are expressed after extended in vitro culture time points, and the appearance of 4R tau occurs earlier in 3D cultures than 2D cultures. The presence of the MAPT 10+16 splicing mutation results in expression of both 0N3R and 0N4R isoforms in both 2D and 3D. Cerebral organoids therefore provide a physiologically-relevant culture system to study the consequences of tau splicing.

Title: Repeat associated non-AUG translation of dipeptide repeat proteins in C9orf72 ALS/FTD patient iPSC-derived neurons

Authors: *S. E. SALOMONSSON[1,2], K. M. WILSON[1,2], B. MURALIDHARAN[1,2], I. GLARIA[1,2], M. BICTASH[3], A. MONAGHAN[3], P. J. WHITING[3], A. M. ISAACS[1,2];
[1]UK Dementia Res. Inst. at UCL, [2]UCL Queen Square Inst. of Neurol., Univ. Col. London, London, United Kingdom; [3]Alzheimers Res. UK UCL Drug Discovery Inst., London, United Kingdom

Abstract: Introduction
A G_4C_2 repeat expansion in the gene C9orf72 is the most common known cause of frontotemporal dementia and amyotrophic lateral sclerosis. Transcription of sense and antisense repeat mRNA leads to intraneuronal nuclear RNA foci and production of five dipeptide repeat proteins (DPRs), through non-canonical repeat-associated non-AUG (RAN) translation. DPRs form neuronal aggregates in the patient brain. Previous studies using overexpression cell models showed that activating the integrated stress response upregulated RAN translation. Furthermore, eIF4A inhibition reduced RAN translation in such models. We investigate if these factors also

regulate endogenous RAN translation in patient induced pluripotent stem cell (iPSC)-derived neurons.
Methods
N=3 patient iPSC lines with paired CRISPR/Cas9 corrected isogenic controls were used. Differentiation of motor neuron progenitor cells and mature spinal cord motor neurons was induced through a 2D dual SMAD inhibition protocol. iPSC-derived motor neurons were transiently treated with vehicle or sodium arsenite to activate the integrated stress response. Poly-GP RAN translation was quantified through an MSD immunoassay. Rocaglamide was used to inhibit eIF4A activity in patient iPSC-derived neuronal progenitor cells, to examine its potential for inhibiting endogenous RAN translation.
Results
Baseline poly-GP expression was greater in neuronal progenitor cells than in the iPSCs they were derived from. Baseline levels of poly-GP RAN translation differed among the patient lines but did not correlate with repeat length. There were donor-dependent differences in response to eIF4A inhibition. Preliminary data suggest that poly-GP translation was upregulated following transient activation of the integrated stress response in patient iPSC-derived motor neurons.
Conclusion
Baseline poly-GP levels were donor-dependent and neuronal differentiation increased RAN translation. The patient lines responded differently to Rocaglamide, which may be due to differences in DPR turnover rates, or sense versus antisense RAN translation of poly-GP. Sensitive DPR quantification in C9orf72 patient cells with endogenous RAN translation is a potential tool in the search for therapeutic targets.

Title: Profiling bioenergetics in iPSC-derived brain cells from Alzheimer's disease patients and non-demented control individuals

Authors: *W. RYU[1], R. A. HEALY[1], M. BORMANN[1], L. WANG[1], M. SHEN[1], B. M. COHEN[1], K. C. SONNTAG[2];
[1]Mclean Hospital/Harvard Med. Sch., Belmont, MA; [2]McLean Hospital, Harvard Med. Sch., Belmont, MA

Abstract: Although toxic molecules, such as beta amyloid peptides (Aβ) and phosphorylated tau (*p*-tau) have been suggested as critical mediating factors in Alzheimer's disease (AD), the underlying cause of sporadic or late-onset AD (LOAD) is still not known. Bioenergetics is the production of energy through metabolism of organic compounds in living organisms. Neural activity is heavily dependent on energy production and substantial changes in bioenergetics have been observed in aging and neurodegenerative diseases, including LOAD. A major energy product is adenosine triphosphate (ATP) which cells make through several processes, predominantly glycolysis and mitochondrial respiration, the latter consisting of the tricarboxylic acid (TCA) cycle and oxidative phosphorylation. In a previous study on skin fibroblasts derived from LOAD patients and non-demented control individuals, we found an increase in glycolysis and a decrease in oxidative metabolism in the patients'-derived cells. We have continued our investigations using induced pluripotent stem cell (iPSC)-derived neural cells, which would be more suitable to define neuronal defects and adapt potential therapeutic developments. We focused our investigations on LOAD and control iPSC-differentiated proliferative cells, including neural precursor cells (NPCs) and astrocytes. NPCs are multipotent progenitors that can be differentiated to any brain cell type. Astrocytes, play important roles in brain metabolism, including energy production. In particular, they produce lactate which is used by neurons as a substrate for mitochondrial respiration. Therefore, the investigation of iPSC-derived astrocytes could be important in understanding the role of bioenergetics in LOAD. To this end, we characterized NPCs and astrocytes from n=5 control and n=7 LOAD iPSCs. To confirm their bioenergetics profiles, we screened the cells using Seahorse XFp Cell Mito Stress Tests. The tests showed that mitochondrial respiration, glycolysis, and ATP production were elevated in both LOAD NPCs and astrocytes but their mitochondrial mass was similar to controls. The growth rates of NPCs and astrocytes, however, were slower in the LOAD patients'-derived cells than in cells from non-demented controls. These data suggest that bioenergetics changes also occur in brain cells from patients with LOAD and may be inherent pathophysiologic features in LOAD. Altogether, we have developed a cellular platform consisting of "personalized cell systems" to identify changes in key metabolic pathways that may be LOAD-specific. These models can lead to the development of novel diagnostic and/or therapeutic strategies.

Abstract: Multifocal Motor Neuropathy (MMN) is a rare chronic inflammatory neuropathy characterized by asymmetrical weakness in distal limbs. It shares important features with the Acute Motor Axonal Neuropathy (AMAN) form of Guillain-Barré syndrome (GBS), namely conduction block in motor axons, and autoantibodies against the ganglioside GM1 which is abundant in neuronal membranes. We have previously established the first disease model for MMN by treating iPSC-derived motor neurons (MN) from control donors with patient sera, and showed that IgM-anti-GM1 raised intracellular Ca^{2+}levels by itself, and produced structural damage by activating the classical complement pathway. More recently we have performed a more detailed characterization of the model, investigated the mechanism of antibody pathogenicity in MMN, and expanded the application to the related neuropathies GBS, Lewis Sumner Syndrome (LSS) and Chronic Inflammatory Demyelinating Polyneuropathy (CIDP). Comparison of ganglioside expression in iPSC-derived motor- and sensory neurons did not reveal differences in antigen expression that could explain MN specificity in MMN, indicating there may be a MN-specific disease mechanism downstream of antibody binding. Motor- and sensory neurons also displayed equal expression of the complement-inhibiting proteins CD46, CD55 and CD59, but we did find common genetically encoded differences in protein expression between control iPSC donors that might have a disease-modifying effect in patients. MN-binding IgM autoantibodies were also detected in sera from GBS, LSS and CIDP patients, at varying subcellular localizations. Intracellular antibodies were even detected in some controls, but seemed particularly prevalent in CIDP. It is unclear whether such antibodies could be pathogenic. While Ca^{2+}-imaging previously indicated that IgM-anti-GM1 from MMN patients could influence MN function, it was unclear how the cytosolic Ca^{2+}-increase was induced, what effect it had on electrophysiological properties, and how this would relate to conduction block observed in patients. A pilot high-resolution microelectrode array experiment (MaxWell Biosystems) allowed simultaneous recording of multiple neurons individually, visualizing action potential propagation and measuring conduction velocity. Interestingly, we observed that different neurons in the culture responded differently to the addition of MMN serum, which should be followed up with post-recording correlation with neuron identity. If MN-specific conduction abnormalities are conserved in the model, it would greatly strengthen its reliability for diagnostic or drug testing purposes.

Abstract: The Indiana University Genetics Biobank (IUGB) was established in 1990 and currently houses more than 20,000 lymphoblastoid cell lines and peripheral blood mononuclear cells. In partnership with the National Institute on Aging (NIA) through the National Centralized Repository for Alzheimer's Disease and Related Dementias (NCRAD) and the Michael J. Fox Foundation (MJFF), the IUGB has been funded to create a centralized repository of human pluripotent stem cells (hPSCs) and fibroblasts. These cell lines are derived from patients with Alzheimer's disease and related dementias (ADRD), Parkinson's Disease (PD) and healthy controls. hPSCs provide a remarkable tool to study early human development, disease modeling, and drug development. However, much variability exists between hPSC lines, which is compounded by the diversity of culture conditions that exist among laboratories. Additionally, many labs do not have the resources to perform thorough quality control measures on cell lines or to distribute high demand lines to other investigators. Due to these factors, the IUGB works to centralize hPSC and fibroblast lines in one location and perform rigorous quality control to ensure cells can be offered in a standardized manner to researchers worldwide. hPSCs are first screened for multiple species of mycoplasma and other sources of bacterial and yeast contamination. A 94 single nucleotide polymorphism (SNP) fingerprint is obtained to assign an identity to every cell line. G-band karyotype is performed to assess genetic stability. hPSCs are differentiated to each of the three germ layers. Pluripotency as well as differentiation efficiency is determined by qRT-PCR analysis of more than 20 genes corresponding to each lineage. Additional quality control measures performed on NIA funded lines include pluripotency

confirmation by immunocytochemistry. Any pathogenic mutations are verified by PCR amplification followed by Sanger sequencing. Lines that pass all quality control measures are made available to approved researchers. Through these efforts, the IUGB has established a standardized facility to advance the study of neurodegenerative disorders through the distribution of hPSCs and fibroblasts.

Title: Generation of two different human microglia cells separately from iPSC derived primitive or definitive hematopoietic progenitors

Authors: *K.-D. CHOI[1], M. L. HENDRICKSON[2], Z.-W. DU[2];
[1]Brainxell, Madison, WI; [2]BrainXell, Inc., Madison, WI

Abstract: Human microglia are vital residents of the brain, where they play important roles in development, injury and disease, such as Alzheimer's (AD) disease. Arising from yolk sac primitive progenitors that colonize in the brain during embryogenesis, microglia are unique among tissue macrophages in that they are thought to remain primitive progenitors derived throughout life, without contribution from the definitive hematopoiesis. After insults such as stroke and neurodegenerative disease, however, microglia dramatically change their phenotype and are joined by infiltrating macrophages from blood. These definitive hematopoietic progenitors-derived occupants can resemble microglia in morphology and surface marker expression but appear to participate differently in disease pathogenesis, making it essential to further clarify their functions. Currently, there is no method reported to generate these two microglia cells from the same iPSCs. To understand how naive microglia and infiltrating microglia cells affect the brain in disease condition, we developed a novel protocol to efficiently produce two different microglia cells separately from primitive or definitive hematopoietic progenitors. By manipulating WNT signaling and Activin-Nodal signaling, human iPSCs were first induced to separate hematopoietic fates, primitive hematopoietic progenitors ($CD43^+$, $CD235a^+$) and definitive hematopoietic progenitors ($CD34^+$, $CD43^-$, $CD235a^-$). Next, these two hematopoietic progenitors were grown in serum-free differentiation medium containing CSF-1 and IL-34 to differentiate into macrophages, then cocultured with our BrainXell cortical neuron

and astrocyte mixed culture to induce microglia identity. We identified the different gene expression between these two microglia cells by RNA-seq profiling, and validated by qPCR, immunostaining and FACS analysis. In summary, two different microglia cells, derived separately from iPSC derived primitive or definitive hematopoietic progenitors, will provide useful models to understanding microglia function in neurological diseases like AD disease.

Title: Maturation of iPSC-derived dopaminergic and cortical neurons with Neuro MQ medium, in a model of Parkinson's disease

Authors: *J.-P. RICHARD[1], I. SILVA[1], L. REN[1], M. HONDA[2], Y. OKUDA[2], S. EMINLI-MEISSNER[3], R. MODALI[1], M. RAO[1];
[1]REPROCELL USA, Beltsville, MD; [2]REPROCELL Inc, Yokohama, Japan; [3]REPROCELL Europe Ltd, Glasgow, United Kingdom

Abstract: Neurodegenerative diseases such as Alzheimer's disease, ALS or Huntington Disease, affect millions of people worldwide. They are usually characterized by treatments available only to alleviate symptoms and no therapies to cure, and by a critical lack of biomarkers. Here, we focused on Parkinson's disease, which is affecting mainly the dopaminergic neurons of the substantia nigra. The etiology of Parkinson's disease is still unclear and genetic causes are usually estimated to represent 10% of cases, while most cases are sporadic (mix of environmental and genetic factors). This diversity explains that animal models don't fully represent the disease spectrum and research involving induced Pluripotent Stem Cells (iPSCs) disease modeling capabilities are filling that void.
REPROCELL uses a unique cocktail of non-modified RNAs, immune evasion mRNAs and double stranded microRNAs in our reprogramming 3rd generation kit (stemRNA) to reprogram primary cells into high quality iPSC, in a short time (as short as 10 days) and with an efficiency of up to 4%. Our reprogramming platform is GMP compatible to produce clinically relevant iPS cells and can be easily used to reprogram commonly isolated cell types (fibroblasts, endothelial progenitor cells and urine-derived cells). We present full characterization of the primary fibroblasts from a Parkinson's disease patient and a control individual with no known neurological diseases (including Whole Exome Sequencing) and fully characterized the iPSC

lines generated.
We differentiated iPSC lines to dopaminergic neurons and astrocytes to assess differentiation potential. We kept dopaminergic neuronal monocultures for 8 weeks after the beginning of differentiation and we compared adapted published protocols with and without maturation with Neuro MQ medium. Neuro MQ medium helped neuronal cultures to mature faster, a very important feature when investigating late onset neurodegenerative diseases. Neuro MQ medium induces electrophysiological activity earlier in neuronal monocultures. To further investigate the maturation of neurons, we are using gene expression panels and neurite outgrowth assays and compare control and Parkinson's disease cultures. We are also comparing maturation obtained via direct coculture with astrocytes.

Title: 3D midbrain floorplate model for differentiation of PSC-derived dopaminergic neurons

Authors: *R. E. JOSEPHSON[1], J. SAGAL[1], S. SHIN[2], M. DERR[1], D. KUNINGER[1]; [1]Thermo Fisher Scientific, Frederick, MD; [2]Primary and Stem cell Systems, Thermo Fisher Scientific Inc, Frederick, MD

Abstract: Accurate *in vitro* modeling of neurological diseases requires multiple cell types of the brain to interact and develop toward mature functionality. When human pluripotent stem cells (PSC) undergo neural differentiation in 3D, self-organization of progeny cells results in organoids with brain-like structures and functions that are not observed in 2D culture. However, the increased complexity of neural organoids often comes with the costs of low throughput and poor reproducibility. Disease models for drug discovery may therefore have to temper self-organized complexity with inductive specification of desired cell types. To model Parkinsons Disease (PD), we have developed a method for differentiation of human PSC to midbrain

dopaminergic (DA) neurons that combines elements of 2D dissociated culture and 3D organoid culture. Cells are efficiently specified as midbrain floor plate (FP) in 2D via an established protocol using a combination of small molecules and growth factors. FP cells are then seeded into suspension culture in defined numbers for spheroid formation and expansion, then maintained in suspension for two to five weeks of differentiation. Early differentiation of the 3D cultures is marked by morphological change and the appearance of NurrI- and tyrosine hydroxylase (TH)-expressing DA neurons at the organoid surface. Single-cell analysis demonstrates that many neurons co-express Sox6 and TH and thus resemble midbrain DA neurons of the Substantia Nigra pars compacta (SNc). Replating of spheroids on extracellular matrix results in neurite outgrowth and outward migration of DA neurons. Multielectrode array (MEA) recording of replated spheroids shows spontaneous burst activity within a relatively short time, followed by gradual refinement toward coordinated rhythmic bursting. To test disease modeling in the hybrid 2D/3D system, CRISPR was used to make PD-related mutations (LRRK2 G2019S and SNCA A30P) in a Cas9-expressing iPSC line. These lines were differentiated to generate DA neurons as above, and to demonstrate sensitivity of the mutant SNc-like DA neurons to oxidative stress. In short, a hybrid 2D/3D culture system for iPSC-derived midbrain floor plate improves maturation of DA neurons and makes promising steps toward a reproducible *in vitro* disease model for Parkinsons.

Title: Integration of clinical WGS supported by patient specific hiPS cell-based disease modeling and functional genomics translational approach for decoding of unknown neurodevelopmental disorders (UNDs)

Authors: M. WYPCHLO[1,3], T. HAHN[4], M. RYDZANICZ[2], A. PRIGIONE[4], R. KUHN[4], A. RYBAK-WOLF[4], S. DIECKE[4], R. PLOSKI[2], *P. LISOWSKI[4];

Medicine, Med. Univ. of Warsaw, Warsaw, Poland; [4]Max-Delbrück-Center For Mol. Med. (MDC), Berlin, Germany

Abstract: BACKGROUND: Neurodevelopmental disorders (NDs) are characterized by the lack of effective diagnostic procedures and therapeutic strategies, due to limited knowledge of the underlying pathogenetic mechanisms. Whole-Genome-Sequencing (WGS) is the state of the art approach for detecting rare-disease-causing variants. However results interpretation and then functional verification is a daunting task.
AIM: Thus, we aim to establish a clinical diagnosis for patients with undiagnosed NDs (UNDs) applying clinical WGS. To support WGS studies functional significance is addressed by extensive transcriptome and epigenome profiling of the iPS and their isogenic controls along the neuronal lineage.
METHODS AND RESULTS: To support the interpretation of the WGS results allowing to find novel causative genetic variants, we developed hiPSCs technology platform by generation of mutation-specific neuronal subtypes, *in vitro* for whole genome transcriptome and methylome screening of patients derived neurons to unravel deregulation in genes expression and explain the genetic basis of rare neurodevelopmental diseases. This is achieved through genomic datasets integration from patient derived stem cells, neuronal precursors and matured neuronal cells including 2D neurons and 3D brain organoids. Experimental confirmation are finally carried out on the hiPSC-derived isogenic controls after correction of putative mutations specified by combination of WGS, transcriptomic and DNA methylation profiles.
CONCLUSIONS: Proposed approach for decoding of UNDs by integration of clinical WGS supported by patient specific induced pluripotent stem cell based modeling, transcriptomic and epigenomic translational approach, and finally in-vitro validation, is applicable to establish an efficient and effective methodology for genomic biomarkers discovery and plausible treatment of investigated undiagnosed neurodevelopmental diseases.

Abstract: Human forebrain development is characterized by a series of highly synchronized cellular events, which, if perturbed, can cause neurodevelopmental disease. To chart the regulatory activity that may coordinate these events, we generated a map of accessible chromatin in human stem cell-derived 3D neural cultures. In particular, we probed glial and neural cell lineages from 3D organoids resembling either dorsal or ventral forebrain over ~20 months of *in vitro* differentiation. We found that, at matched developmental time points, accessibility in forebrain organoids closely resembled that in primary tissue. We integrated accessibility with transcriptomics to infer specific transcription factors that regulate lineages and identify putative enhancers for developmentally expressed genes. Moreover, we used this resource to map genetic risk for neurodevelopmental disorders to specific lineages and developmental stages, and uncovered sequence motifs enriched in human-specific regulatory DNA regions. Overall, this organoid platform brings novel insights into chromatin regulatory dynamics of inaccessible stages of human forebrain development and could be used to model neuropsychiatric disorders and study human brain evolution.

Abstract: Fragile X syndrome (FXS), an X-linked disorder, the most common form of inherited intellectual disability and autism, is caused by the silencing of the *FMR1* gene. Data from rodent models of FXS indicate that loss of FMRP leads to an increase in neuronal excitability. In order to assess whether increased excitability is present in human neurons we generated cortical neurons from human pluripotent stem cells and using whole-cell patch-clamp recording techniques assessed whether loss of FMRP expression leads to altered network activity of these excitatory neurons. We have recorded from two control induced pluripotent stem cell (iPSC) lines, three FXS iPSC lines and a pair of isogenic embryonic stem cell line in which we deleted 5'UTR and exon 1 of the *FMR1* gene using CRISPR/Cas9. For each set of 'control' or 'FMRP-lacking' lines the data were internally consistent and data reported here are from the isogenic pair, $FMR1^{+/y}$ and $FMR1^{-/y}$. In current-clamp recordings $FMR1^{+/y}$ neurons displayed spontaneous firing of bursts of action potentials with mean duration of 50.4 ± 2.9 s (n=16 cells). The mean number of such events observed (in 10 minutes) was 5.0 ± 0.65. In contrast $FMR1^{-/y}$ neurons displayed burst durations that were significantly shorter in duration (12.8 ± 0.8 s, n=15 cells; $P<0.0001$) but which occurred more frequently with an average number (in 10 minutes) of 22.5 ± 2.6 ($P<0.0001$). We hypothesize that this altered network excitability in FXS neurons may potentially be due to altered activity of persistent sodium conductance (Na_P) and/or large conductance calcium activated potassium channel dysfunction (BK_{Ca}). To confirm this we assessed the effect of riluzole (persistent Na_P blocker) and paxilline (BK_{Ca} blocker) on the burst properties. Burst properties of $FMR1^{-/y}$ neurons did not show significant change in *presence* of blockers with mean burst duration of 15.2 ± 2.0 s (n=5 cells; $P=0.69$) and mean burst number (in 10 minutes) of 30.8 ± 4.2 ($P=0.32$). In *presence* of riluzole and paxilline $FMR1^{+/y}$ neurons displayed a decrease in mean burst duration 19.2 ± 2.1 s (n=7 cells; $P = 0.017$) and increase in mean burst number 11.3 ± 1.0 (P=0.0011) thereby resembling the bursting profile of $FMR1^{-/y}$ neurons. Current density measurements of Na_P and BK_{Ca} channels from $FMR1^{-/y}$ neurons show a decrease in persistent sodium (INa_P at -40 mV: $FMR1^{+/y}$ -0.96 ± 0.13 pA/pF, n=18 cells; $FMR1^{-/y}$, -0.3002 ± 0.03 pA/pF, n=18 cells; $P < 0.0001$) and BK_{Ca} (IBK_{Ca} at +40 mV: $FMR1^{+/y}$ 13.1 ± 1.8 pA/pF, n=11 cells; $FMR1^{-/y}$, 4.48 ± 0.76 pA/pF, n=11 cells; P=0.0003). These findings suggest that lack of FMRP leads to Na_P and BK_{Ca} channel dysfunction causing aberrant network excitability in human stem cell derived cortical neurons.

Title: Characterization of the activity-dependent development of IPSC-derived neurons from fragile X patients

Authors: *G. MAUSSION, C. ROCHA, V. SOUBANNIER, T. M. DURCAN;
Montreal Neurolog. Inst., Montreal, QC, Canada

Abstract: Fragile X syndrome is a form of syndromic autism whose genetic causes have been relatively well uncovered. It is actually mainly caused by a CGG triplet expansion in the 5' UTR sequence of *FMR1* gene, affecting mostly men. *FMR1* encodes a mRNA binding protein which is involved in the regulation of local translation at the synaptic level. The mechanisms leading from such gene mutations to a neurodevelopmental disorder still need to be investigated. While several studies have shown that the neuronal development is driven by cellular activity and connectivity, we aim to further investigate the effect of *FMR1* repression on the neuronal activity taking advantage of IPSC-derived neurons from patient's cells.
IPSC-derived neurons will be investigated through calcium imaging to characterize their pattern of spontaneous activities, as well as their capability to respond to neurotransmitter through extra-synaptic receptors. A multi-electrod array approach is going to be used to analyse the overall network activities.
Those studies should provide further information on the impairment of activity-dependent neuronal development in Fragile X syndrome.

Title: Analysis of neuronal development in patients with KCNJ11/Kir6.2 mutations using cerebral organoids

Authors: *G. DALGIN[1], A. J. GARCIA, III[2], A. K. TRYBA[3], A. COHEN[4], L. PHILIPSON[1], S. A. W. GREELEY[1];
[1]Kovler Diabetes Ctr., Univ. of Chicago, Chicago, IL; [2]Emergency Med., [3]Pediatric Neurol., The Univ. of Chicago, Chicago, IL; [4]Rosalind Franklin Univ., North Chicago, IL

Abstract: The fundamental question in brain research is to understand how the complex human brain is developed. Recent advancements in human induced pluripotent stem cell and 3D cell culture technologies made it possible to generate cerebral organoids. This technology made it possible to explore the human brain development in a dish, and increased our opportunities for personalized medicine. Neonatal diabetes mellitus (NDM) is a rare type of monogenic diabetes that is caused by a single gene abnormality and patients develop diabetes early in life. Heterozygous activating mutations in the ATP-sensitive potassium (K_{ATP}) channel gene *KCNJ11* are the most common cause of permanent NDM. In addition to diabetes patients exhibit range of neurodevelopmental dysfunctions, from learning disorders to cognitive dysfunction and seizures. Our clinical data suggest that neurodevelopmental disorders in KCNJ11 mutant patients may start during fetal and postnatal brain development that is largely inaccessible for direct molecular and functional analysis. To model KCNJ11 dependent brain development and to understand the pathophysiology of neurodevelopmental disorders in patients we developed patient induced pluripotent stem cell derived cerebral organoids. The molecular and electrophysiological signatures of cerebral organoids developed from non-pathogenic/normal ipscs suggest that these organoids established a stable neural network with synchronized bursting. In contrast extracellular recording of local population activity revealed decreased activity of KCNJ11 mutant brain organoids. Therefore, we developed a reliable platform to analyze brain organoids from patients with neurological disorders to predict the outcome and determine personalized treatments. We are testing potential therapeutics that may improve outcome and examine how genetic variations affect the phenotype.

Title: Probing the role of astrocytes in fragile X syndrome using human induced pluripotent stem cell-derived astrocytes

Authors: *B. REN[1], Y. JUNG[2], B. OLDHAM[2], A. ARMSTRONG[2], R. GOUGH[2], P. RAGUNATHAN[2], A. DUNAEVSKY[2];

Abstract: Fragile X syndrome (FXS), the most common monogenic cause of autism spectrum disorder, results from the hypermethylation of CGG expansion in the FMR1 gene locus, transcriptional silencing of the gene and the absence of fragile x mental retardation protein (FMRP). The fmr1 mutant mice have been useful in elucidating the mechanisms of neural impairments, however, attempts to translate outcomes to humans have been challenging. Here we investigate the role of human astrocytes in the pathogenesis of FXS by differentiating human induced pluripotent stem cells (hiPSCs), derived from fibroblasts of FXS patients, to astrocytes. We found that FXS astrocytes showed altered transcriptional and functional properties, including shortened cell cycle duration and enhanced calcium signaling. To examine the phenotypes of FXS astrocytes in the brain, we generated a chimeric mouse model by neonatal implantation of hiPSC-astrocytes expressing a fluorescent protein. Three months post engraftment, transplanted cells maintained astrocytic lineage. Analysis of astrocyte morphologies revealed that FXS astrocytes have longer processes and altered complexity in different brain regions. Analysis of astrocyte morphologies at 6 and 9 months post-engraftment is ongoing. Preliminary data suggest that FXS astrocytes exhibit altered Ca^{2+} signaling properties in cortical slices four months post engraftment. To further understand whether structural synaptic plasticity is altered, repeated in vivo imaging of hiPSC-astrocytes and dendritic spines in the chimeric mice is performed. Our studies suggest the contribution of human astrocytes in FXS pathogenesis and provide therapeutic targets for personalized FXS treatment.

Title: Exploring Smith-Magenis syndrome-associated phenotypes in induced pluripotent stem cell (iPSC) - derived neural cells

Authors: *B. K. ENGLAND, F. J. GORDOVEZ, J. CROSS, N. AKULA, W. R. CORONA, A. SMITH, *S. D. DETERA-WADLEIGH, F. MCMAHON;
NIH, Bethesda, MD

Abstract: Smith-Magenis Syndrome (SMS) is a rare neurodevelopmental disorder characterized by behavioral, neurocognitive, circadian rhythm, and craniofacial abnormalities. The majority of cases are caused by a heterozygous deletion on 17p11.2. Non-deletion cases carry damaging mutations on *RAI1*, a gene that is encoded by this region. *RAI1* is highly expressed in brain and is thought to function as a transcription factor although its exact biological role remains to be well defined. To dissect the genetic and phenotype features of SMS, we are studying a family that includes parents, a daughter with SMS and her unaffected sister. Sanger sequencing of the region that includes the SMS mutation in all four family members confirmed the presence of a frameshift mutation in the patient and its absence in her parents and sister. To identify potential defects in the entire coding region we are conducting whole exome sequencing on all family members. SMS symptoms that include behavioral problems and intellectual disability strongly suggest defects in brain function. We chose to study iPSC-derived neural cells to reveal defects in neurobiological mechanisms associated with *RAI1* mutation. Peripheral blood mononuclear cells (PBMCs) from the entire family are reprogrammed to iPSCs. After assessing karyotype and pluripotency, three iPSC clones from each subject are differentiated into neural progenitor cells. Initial studies will involve RNA-sequencing and evaluation of cellular morphology. These results will be used to guide future research, including differentiation into other cell types, such as neurons and astrocytes. Ultimately, this study aims to further elucidate the function of RAI, with the potential of illuminating the role of this gene in other neuropsychiatric illnesses.

Abstract: Pitt-Hopkins Syndrome (PTHS) is a rare neurodevelopmental disorder caused by an autosomal dominant mutation or deletion in the gene transcription factor 4 (*TCF4*). TCF4 is a basic helix-loop-helix (bHLH) transcription factor that plays a critical role in neuronal development through known interactions with other proneural bHLH proteins. Human *TCF4* expression peaks during corticogenesis and patients with *TCF4* mutations have Pitt Hopkins Syndrome (PTHS), which is characterized by profound developmental delays and autistic behaviors. To study the role of TCF4 in human cortical development, we have developed a platform to differentiate PTHS patient and control induced pluripotent stem cells (iPSC) into human neural progenitor cells (NPCs). In this study, we have reprogrammed iPSCs and differentiated NPCs from 6 control individuals and from 4 PTHS patients with a point mutation in the bHLH domain of TCF4 and 2 PTHS patients with large truncations of TCF4. Differentiation of NPCs was validated with immunocytochemistry and Fluidgm qPCR. Over the course of 20 days of NPC differentiation, we have identified over 500 differentially expressed genes (DEGs) between PTHS and controls. GO-term enrichment analysis of these DEGs has identified a downregulation in terms associated with axonal development along with additional up-regulation/down-regulation of terms associated with cellular metabolism, trafficking, and respiration in PTHS NPCs. We have performed metabolomic analysis of PTHS and control NPCs to further assess specific molecular pathways identified by our GO-terms analysis. With this stem cell-based platform, we aim to better understand the role of TCF4 in cortical development and underlying pathophysiology of PTHS in a human context.

Title: The role of KIAA0319 in neuronal development and developmental dyslexia

Authors: *S. PANIAGUA, B. CAKIR, Y. XIANG, I. H. PARK, J. R. GRUEN;
Yale Univ., New Haven, CT

Abstract: Reading Disability (RD), also known as dyslexia, is defined as difficulty in processing written language in individuals with normal intellectual capacity and educational opportunity. The prevalence of RD is between 5% and 17% (Shaywitz, SE et al., 2013) and the heritability ranges from 44% to 75% (DeFries, JC et al., 1987; Hart, SA et al., 2010). Genetic linkage analysis and genome-wide association studies (GWAS) have identified several genes and regulatory elements linked to RD and reading ability, although their functions and molecular mechanisms are not well understood. Prominent among these are *DCDC2* and *KIAA0319*, two genes encoded in the DYX2 locus of human chromosome 6p22 (Eicher, JD et al., 2014). Association of both genes has been independently replicated in multiple independent studies and languages (Fisher, SE, DeFries, JC, 2002; Thapar, A et al., 2015; Stergiakouli E, Thapar, A, 2010; Carrion-Castillo, A et al., 2013). Rodent models suggest that both genes are involved in neuronal migration, but their precise function is unknown (Paracchini, S et al., 2016). Additionally, glutamatergic synaptic transmission is elevated in *Dcdc2*-mutant mice, and this elevation is at least in part through an NMDAR-mediated, presynaptic mechanism at layer 4 synaptic connections (Che, A et al., 2016).
The goal of this study is to determine the mechanisms by which *KIAA0319* and *DCDC2* influence reading and language performance. We hypothesize that both genes play a critical role in neuronal development. To test this hypothesis, we knocked down mRNA expression of targets using CRISPRi in a human embryonic stem cell line in which a doxycycline-inducible dead Cas9 (dCas9) gene has been stably integrated. We then examined changes in morphology through immunofluorescence, synaptic signaling by electrophysiology, and neuronal differentiation through qRT-PCR targeting genes specific to neuronal subtypes and cortical layers. Preliminary data from *KIAA0319* knockdown showed an increase in neuronal morphology and a decrease in proliferation compared to controls, after 20 days of neuronal differentiation through an extracellular-factor protocol. These results are consistent with previous studies in rats and mice (Franquinho, F et al., 2017), implicating *KIAA0319* in regulating neuronal development by acting as an inhibitor of terminal differentiation. In aggregate, these studies suggest that differential expression of *KIAA0319*, within cortical layering and neuronal cell types, plays a crucial role in regulating brain development and affecting reading performance.

Title: Quantitative characterization of variability in cortical neurons between healthy human induced pluripotent stem cell lines

Authors: *R. A. THOMAS[1], E. CAI[2], X. C. CHEN[1], N. ABDIAN[1], E. A. FON[1], T. M. DURCAN[1];

Abstract: When studying developmental neurological diseases such as autism spectrum disorder, human tissue samples are only available postmortem. The breakthrough advances allowing reprogramming of human blood or skin cells into pluripotent stem cells (iPSCs), which can be differentiated into numerous cell types including neurons and astrocytes, allow for human cell models of neurodevelopmental disorders. However, iPSC are difficult to maintain and many different protocols for culturing and differentiation have been developed. How different cell lines behave under different culturing conditions has not been compared in parallel. To be able to compare between patient lines and controls there needs to be a bench-mark of normality. Standardized reproducible quality control checks must be established and shared across different research groups. Quantitative characterization of iPSC lines and neurons is critical to detecting disease phenotypes and identifying the sources of disease etiology. Here, we aim to create a panel of measurements using automated analysis programs to characterize 12 iPSC control lines. We characterize 2 commercial and 10 in house lines, analyzing 5 different stages. We quantified markers of pluripotency and cortical neurons using custom scripts. Additionally, we compared two types of growth media and two neuronal induction protocols. We find variation in rates of differentiation between protocols and between iPSC lines. The amount that iPSCs aggregate together, the proportion of non-neuronal cells in cultures and many markers vary across cell lines. We summarize the variation across iPSC and provide analysis tools and a reference data set for the range of normality in healthy iPSC and their differentiation into cortical neurons. We conclude, that to be confident in phenotypes found using iPSCs from patients, multiple control lines should be included and iPSC quality control characterization should always be performed for each line.

Abstract: Down syndrome (DS) associated with trisomy of chromosome 21 is a developmental disorder characterized by brain hypotrophy, intellectual disability and high risk for developing Alzheimer's disease (AD) later in life. Approximately one in every 700 births worldwide is diagnosed as DS. Tissue culture and mouse models have yielded significant insight regarding the pathological phenotypes of DS. However, species differences between mouse and human and the limited utility of tissue cultures hamper advances in elucidating the mechanisms given rise to DS, and thereby hamstring the development of effective therapeutic interventions. Recent advances in generating human induced pluripotent stem cells (iPSCs) from individuals with DS provide a powerful platform that might better recapitulate certain DS phenotypes. We have used DS patient-derived iPSCs and its isogenic iPSCs disomic for chromosome 21 to investigate how the extra chromosome 21 affects brain development. We reported that our DS organoid model recapitulates multiple relevant phenotypes. Moreover, single-cell RNA sequencing identifies different cell population clusters and signature transcription factors unique to DS organoid compared to its isogenic disomy. We are using this DS organoid model to investigate the effect of trisomy 21 on the development of various brain cell types and pathological hallmarks of AD, and as potential platform for therapeutic interventions.

Title: Exploring the role of UBE3A in electrophysiological phenotypes of human Dup15q syndrome neurons

Authors: *M. ELAMIN, T. M. ROBINSON, J. JAMES, E. S. LEVINE;
Neurosci., Univ. of Connecticut Sch. of Med., Farmington, CT

Abstract: Autism is one of the most prevalent developmental disorders worldwide. Affected children often display impairments in communication, difficulties in social interactions, repetitive behaviors, and learning disabilities. One of the most common genetic variations associated with autism is duplication in the 11.2-13.1 region of the long arm of chromosome 15. Children carrying this duplication develop Dup15q syndrome, a distinct neurodevelopmental disorder characterized by autism, epilepsy, and a range of intellectual and motor deficits. Using neurons derived from patient-specific induced pluripotent stem cells (iPSCs), we found that Dup15q neurons had an increased frequency of excitatory synaptic events and increased spontaneous action potential firing, as well as increased dendritic protrusions, compared to unaffected controls. It is important to note that only maternal duplications of this region result in Dup15q syndrome, while paternal duplications do not. There are many genes in the duplicated region, but only UBE3A, which encodes a ubiquitin ligase, is paternally imprinted in neurons and therefore only expressed from the maternal allele. This strongly affirms the relevance of UBE3A to Dup15q syndrome. Although UBE3A overexpression has been used to model Dup15 syndrome in mice, the contribution of UBE3A to the cellular phenotypes identified in human neurons is unknown. The goal of the present study is to define the role of increased UBE3A expression in the development of Dup15q cellular deficits. Antisense oligonucleotides (ASOs) will be used to lower UBE3A levels and the electrophysiological and morphological phenotypes will be examined during *in vitro* development. Preliminary data obtained in 15-week old Dup15q neurons indicate that reducing UBE3A to control levels rescues the elevated synaptic activity and spontaneous action potential firing rate. Decreasing UBE3A below control levels also disrupts neuronal and synaptic development, as seen in Angelman syndrome neurons, suggesting that appropriate regulation of UBE3A is critical for neuronal development. Elucidating the relationship between UBE3A and these electrophysiological phenotypes may shed light on the relevant downstream targets of UBE3A and provide a basis for exploring potential contributing

roles of other duplicated genes in the affected region. Overall, these studies may identify novel therapeutic targets for treating Dup15q and related neurodevelopmental disorders.

Systems, Sacramento, CA; [4]Genome Center, MIND Institute, and Biochem. and Mol. Med., Univ. of California, Davis, CA

Abstract: Jordan's syndrome is a rare neurodevelopmental disorder arising from *de novo* missense mutations in protein phosphatase 2 regulatory subunit b'delta (*PPP2R5D*). *PPP2R5D* encodes for B56δ, a protein that regulates protein phosphatase 2A (PP2A) substrate specificity and catalytic activity at serine/threonine sites. Dephosphorylation at these sites requires three structural subunits to complete the heterotrimeric PP2A enzyme: a scaffolding (PR65) and catalytic subunit (PPP2CA) form the core holoenzyme which interacts with variable regulatory subunits, such as B56δ. While studies have shown B56δ is highly expressed in the brain and genetic variants arising in its gene (*PPP2R5D*) are linked to Jordan's Syndrome, appropriate disease models are necessary to understand neuronal dysfunction and subsequently employ novel techniques to target the variant. Targeting the mutant *PPP2R5D* transcript is a promising avenue to assess the consequence of these variants on B56δ and PP2A function. In our proof of principle studies, we have implemented small interfering RNAs (siRNA) and the dCas13b-ADAR2$_{DD}$(E488Q/T375G) system to reduce and edit the mutant *PPP2R5D* transcript,

respectively. *PPP2R5D* siRNA resulted in a potent knockdown of mutant and healthy *PPP2R5D* mRNA suggesting that the seed region was not able to discriminate the variant RNA. Interestingly, we observed an increase in *PR65* and *PPP2CA* expression when siRNA were targeted to *PPP2R5D* in patient-derived fibroblasts. These preliminary studies by our group support a dominant negative mechanism of action, where variants in *PPP2R5D* affect PP2A holoenzyme subunits. To achieve allele specificity, we used dCas13b fused to an RNA adenosine deaminase, $ADAR2_{DD}$ (dCas13b-$ADAR2_{DD}$E488Q/T375G) paired with a guide RNA (gRNA) to edit the mutant *PPP2R5D* transcript. We have employed this RNA editing system in patient-derived fibroblasts and induced pluripotent stem cells (iPSCs) and started assessing on-target editing efficiency. Our future work is focused on understanding the developmental implications of *PPP2R5D* variants in iPSC-derived neural progenitor cells (NPCs) and neurons by analyzing the underlying molecular mechanisms giving rise to altered signal transduction pathways and neuronal dysfunction in Jordan's syndrome. These studies support the potential for RNA targeting strategies to enable molecular rescue and advance precision therapeutics for individuals with neurodevelopmental disorders such as, Jordan's syndrome.

Title: Modelling synaptic mechanisms of autism-associated neuroligin-3 mutations using human neurons

Authors: *L. WANG[1,2], V. R. MIRABELLA[1], Z.-P. PANG[1];
[1]Neurosci. and Cell Biol., Child Hlth. Inst. of NJ, New Brunswick, NJ; [2]Ctr. for Med. Genet., Sch. of Life Sciences, Central South Univ., Changsha, China

Abstract: Synaptic transmission controls information flow in the brain and synaptic dysfunction is likely a biological basis for several neurodevelopmental disorders including autism spectrum disorders (ASDs), Down syndrome, and neuropsychiatric disorders such as schizophrenia. Recent human genetic studies revealed that an increasing number of mutations in neuroligins (NLGNs) and neurexins, synaptic cell-adhesion proteins, are linked to ASDs and schizophrenia. The first defined gene mutation identified in idiopathic autism was an arginine (R) to cysteine

(C) missense mutation at position 451 of NLGN 3 (NLGN3 R451C). Numerous studies using knock-in animals and heterologous overexpression systems have suggested that NLGN 3 R451C may act as both a loss and gain-of-function mutation, however the detailed molecular mechanism(s) by which it causes behavioral pathology and synaptic dysfunction remain unclear. Recent advances in stem cell biology have allowed the efficient conversion of human stem cells into defined neural subtypes and we hypothesized that studying the R451C mutation using this simplified and species-specific approach may yield new insight into its molecular etiology. To test this hypothesis, we have generated isogenic knock-in human embryonic stem cell lines harboring NLGN 3 R451C allele. Initial characterization showed no major impact of NLGN3 R451C on isolated excitatory synaptic transmission in relatively homogeneous glutamatergic human neuronal cultures, suggesting the possibility that the NLGN3 R451C mutation could preferentially impact subtype-specific neuronal crosstalk between excitatory and inhibitory neurons, overall network properties and E/I balance. Ongoing experiments are defining correlating functional, morphometric and biochemical parameters in co-cultured excitatory and inhibitory human induced neurons to determine a molecular and synaptic basis for NLGN3 gene association with the pathogenesis of autism.

Abstract: Rationale: Smith-Magenis syndrome (SMS; MIM 182290, incidence 1/25000) is a complex genetic disorder characterized by multiple congenital anomalies, including dysmorphic craniofacial features, brachydactyly, hypotonia, developmental delay and sleep abnormalities. Usually after puberty, SMS patients develop mood instability and anxiety that worsen during adolescence. Most individuals present a moderate range of intellectual disability; however, the substantial deleterious behaviours leads to altered adaptive function (communication and socialization) and a lower perceived cognition. Autistic features and/or autistic spectrum disorder have been reported in as many as 90% of subjects affected by SMS and the severity ranges from mild to severe autism. SMS has been associated to 4-Mb deletion Copy Number Variation on chromosome 17p11.2. More recently it has been shown that rare nucleotide mutations in RAI1 gene - in the absence of Chr17p11.2 deletions - reproduce 21 out of 30 SMS features. Thus it was recognized that RAI1 haploinsufficiency by itself is the primary cause of the syndrome. Little is known about RAI1 molecular function and its role in neural development. **Methods**: We investigated the role of the novel RAI1 mutation (NM_030665.3:c.1194) on the functional properties of human patient's fibroblasts derived from a SM patient and, subsequently, of Neural Stem Cells generated upon fibroblast reprograming followed by neural differentiation (SMS-hiNSCs). **Results**: The mutation generated a RAI1 protein incapable of entering the nucleus and acting as transcription factor. Fibroblasts analysis showed a strong alteration in circadian cycle associated with an impairment in cell growth caused by an altered metabolism. Based on these results, we produced induced pluripotent stem cells and differentiated them into SMS-hiNSC in order to evaluate how the truncated form of RAI1 might influence the cell fate, the proliferation and differentiation pattern of these cells *in vitro* and *in vivo,* by transplanting the SMS-hiNSCs into the brain of immundeficient mice, in long term experiments. Our results showed that hiNSC cells carrying RAI1 mutation showed a low ability to differentiate, compared to the control lines, both *in vitro* and *in vivo,* consistent with the SMS phenotype.

Abstract: Experimental models of the human brain are needed for basic understanding of its development and disease. Human brain organoids hold unprecedented promise for this purpose; however, they are plagued by high organoid-to-organoid variability. This has raised doubts as to whether developmental processes of the human brain can occur outside the context of embryogenesis with a degree of reproducibility comparable to the endogenous tissue. Here, we show that an organoid model of the dorsal forebrain can achieve reproducible generation of a rich diversity of cell types appropriate for the human cerebral cortex. Using single-cell RNA sequencing of 166,242 cells isolated from 21 individual organoids, we find that 95% of the organoids generate a virtually indistinguishable compendium of cell types, through the same developmental trajectories, and with organoid-to-organoid variability comparable to that of individual endogenous brains. Furthermore, organoids derived from different stem cell lines show consistent reproducibility in the cell types produced. The data demonstrate that reproducible development of complex central nervous system cellular diversity does not require the context of the embryo, and that establishment of terminal cell identity is a highly constrained process that can emerge from diverse stem cell origins and growth environments.

Abstract: Progress towards a better understanding of schizophrenia (SZ) etiology, and in developing novel treatments has been hindered by a lack of animal models with high validity for the disorder. Moreover, current animal models cannot effectively model polygenic risk contributing to schizophrenia. The advent of induced pluripotent stem cell (iPSC) provides a unique opportunity to study human cells that retain the entire genetic architecture of schizophrenia risk, thus opening the door to developing *in vitro* models that can improve our ability to develop novel treatment strategies. We have established a systematic and quantifiable iPSC platform to model common risk variation associated with SZ. To help overcome heterogeneity associated with common variation, we generated iPSCs from 16 SZ patients with high polygene risk scores (PRS) and 16 neurotypical individuals with a low PRS. To control for technical variability, iPSCs underwent four independent rounds of directed differentiation into cortical neurons, a process that was monitored at each stage using a variety of quality control assays, including qPCR and immunocytochemistry followed by high-content imaging. To identify phenotypes between SZ cases and controls an array of assays were performed on neural progenitor cells (NPCs) and cortical neurons in a double-blind manner. These assays include immunocytochemistry, electrophysiology, $^{Ca2+}$ imaging, metabolomics, qPCR, and RNA sequencing. This varied approach for measuring functional and dynamic properties associated with neuronal development will assist in the identification of phenotypic variation between SZ cases and controls. Overall, we have established a robust *in vitro* platform to study polygenic risk for schizophrenia, and we anticipate this model system will advance our ability to identify therapeutic targets for drug development.

Abstract: Patient-derived IPS cell models present invaluable opportunity to gain insights into human nervous system development, function and mechanisms underlying its disorders. Many neuropsychiatric disorders, including Bipolar Spectrum Disorder (BSD), are believed to be associated with altered neuronal excitability and synaptic connectivity, which require disease models to recapitulate electrophysiological properties of mature human neurons. Existing neuronal differentiation protocols generate neurons that express appropriate neuronal markers and appear to be relatively mature. However, their ability to reproduce firing behavior observed in tissue from human brains has been difficult to obtain. We showed previously that vitamin E (vit E) improves health and maturation of the membrane properties of neurons derived from control individuals and from patients diagnosed with the BSD. Interestingly, vit E treatment also improved firing properties of both types of neurons, which were further significantly improved by addition of the docosahexaenoic acid (DHA), but not by other omega-3 or omega-6 fatty acids. In the present work we further demonstrate effects of vit E and DHA on functional maturation of IPS cells-derived neurons with particular focus on synaptic connectivity and major conductances underlying proper electrophysiological function. Human neural progenitor cells (NPCs) were derived from IPS cells via dual inhibition of BMP and TGFβ. Neuronal differentiation was induced by culturing NPCs in complete BrainPhys supplemented with vit E, DHA or the combination of both. Electrophysiological recordings and high spatial/temporal resolution calcium imaging were performed after 8 weeks of differentiation in 2D neuronal cultures. We performed patch-clamp recordings in the voltage clamp mode to detect sodium and potassium currents by using a series of voltage steps from -80 to +100 mV. Spontaneous glutamatergic postsynaptic currents were monitored by clamping Vm at -60 mV. We also examined spontaneous and evoked Ca^{2+} transients using high resolution Ca^{2+} imaging. The effects of vit E, DHA and the combination of both were compared to control conditions. Results indicating higher ionic conductances similar to those observed in adult neuronal tissue and more frequent and/or higher amplitude synaptic events were interpreted as improved neuronal maturation. Further studies are necessary to establish the mechanisms by which DHA and vit E promote neuronal maturation *in vitro*. Our results demonstrate the utility of culture media augmentation with vit E and DHA in studies of patient-derived neurons in which biophysical properties are of primary interest.

Title: Omega 3 fatty acid and vitamin e promote maturation of neurons derived from induced pluripotent stem cells of bipolar disorder patients

Authors: *C. DELONG[1], K. GLANOWSKA[2], G. G. MURPHY[3], K. O'SHEA[1];

Abstract: Bipolar disorder (BD) is a hereditary neuropsychiatric disorder that is characterized by pathological fluctuations in mood from mania to depression, due to an underlying dysfunction in neuronal excitability that may in part be due to abnormal synaptic properties in neurons. The use of induced pluripotent stem cells provides a model to study neuronal excitability, however current protocols lack the ability to generate a majority of mature neurons that reflect those of the adult human brain. Neurons in the brain are enriched with long chain polyunsaturated omega 3 fatty acids, in particular docosahexaenoic acid (DHA), that are necessary for normal brain development, and previous studies in mouse neurons suggest that DHA enhances synaptic properties. We therefore looked at the effect of DHA or other fatty acids in the presence of the antioxidant alpha-tocopherol on passive and active electrophysiological properties and synaptic density in human neurons. Neural precursor cells (NPCs) were derived from iPSC via inhibition of BMP and TGFbeta signaling using Dorsomorphin and SB431542. Neuronal differentiation was induced by culturing NPCs in complete BrainPhys medium, which was supplemented once a week for 8 weeks with alpha-tocopherol alone or with oleic acid (OA), arachidonic acid (AA), eicosapentaenoic acid (EPA), or DHA. In all conditions, the ratio of GAD67-positive to vGlut1-positive cells was approximately 1:4, and the percentage of non-neuronal cells was 3-5%, suggesting a similar composition of cell types across conditions. In control and bipolar neurons, the enrichment of media with alpha-tocopherol alone improved both passive and active electrophysiological firing properties over control, several of which were further improved by the addition of DHA, but not OA, AA, or EPA. Synaptic density (number of synapsin 1+ puncta/micron of neurites) was increased over control by all treatments, with the greatest increase by alpha-tocopherol and alpha-tocopherol+DHA. Current studies are focused on DHA +/- alpha-tocopherol treatment of control vs bipolar neurons to measure effects on fatty acid

composition, single-cell and network electrophysiological properties, gene expression, neurite outgrowth, and calcium signaling.

Title: Human induced pluripotent stem cell (hiPSC) derived GABAergic and glutamatergic neuron development and function in bipolar disorder

Authors: *D. J. SCHILL[1], K. F. CAMPBELL[1], K. M. GLANOWSKA[2], C. J. DELONG[1], M. G. MCINNIS[3], G. G. MURPHY[4], K. O'SHEA[1];

Abstract: Bipolar I Disorder (BP) is a serious, recurrent mood disorder that is characterized by alternating episodes of mania and depression that affects nearly 5.7 million Americans. Considerable evidence suggests that changes in the development and function of several neural subtypes may be responsible for these shifts in mood state, however the underlying mechanisms remain unknown. There is an interplay in communication and network assembly governed by inhibitory GABAergic interneurons and excitatory glutamatergic neurons which modulate neuronal excitability during cortical differentiation. However, little is known about how these populations contribute to the BP phenotype. In the current investigation we have derived stem cells from BP patients who share a single nucleotide polymorphism, rs1006737, in the L-type calcium channel gene *CACNA1C* known to be associated with BP. We generated four independent lines of both C and BP human induced pluripotent stem cells (hiPSC) and differentiated them to GABAergic and glutamatergic neurons using dual Smad inhibition followed by exposure to dorsal or ventral patterning factors, harvesting cells at sequential stages of differentiation. GABAergic neural progenitor cells (NPCs) were > 90 % positive for the ventral marker Nkx2.1 and yielded > 80 % GABA+ neurons that co-express mature neuronal markers SV-2, Map2, and NeuN protein. GABAergic neurons robustly express *GAD67* and *SLC12A5* mRNA, indicative of a switch to an inhibitory state. Glutamatergic NPCs were > 90% Pax6, Nestin and FoxG1 positive while continued neuronal differentiation yielded > 90 % vGlut2 and vGlut1 positive neurons that co-express the mature neuronal marker NeuN. Interestingly, preliminary data suggests that BP glutamatergic NPCs display a premature

differentiation phenotype as compared to their Control counterparts in that glutamatergic NPCs express significantly more *EMX2*, *FOXG1* and *CACNA1C* mRNA. Electrophysiology, live cell calcium imaging, neurite outgrowth analysis, and RNA-seq of C and BP GABAergic and glutamatergic neurons is in progress. Understanding the developmental and functional differences in BP GABAergic and glutamatergic cortical neurons may help identify novel therapeutic targets to treat bipolar disorder.

Abstract: Bipolar I Disorder (BP) is a serious, recurrent mood disorder that is characterized by alternating episodes of mania and depression. To begin to identify novel approaches and pathways associated with BP, we have differentiated BP and undiagnosed control (C) induced pluripotent stem cells (iPSC) to astrocytes and performed RNA-seq. In comparing differentially expressed genes using hierarchical cluster analysis, “Exosome” was the most highly significant cluster identified. Astrocytes have been shown to release exosomes in culture and importantly, miRNAs have been shown to be differentially expressed in exosomes derived from BP vs C postmortem brain tissue. However, little is known regarding what transcripts and proteins are carried from astrocytes to neurons, how they regulate biological functions of the recipient cell, and in turn how that may be altered in mood disorders. Astrocyte-derived exosomes have been suggested to promote neuronal plasticity, as well as to remove toxic proteins in brain, and alterations in function or content may be involved in neurodevelopmental, neuropathological and neuropsychiatric conditions. To examine the characteristics of BP patient and Control exosomes, their cargo and interactions with neural precursor cells, astrocytes were differentiated from BP and C iPSC lines. Immunocytochemical analysis demonstrated that differentiated astrocytes expressed CD44, S100b, and GFAP. Supernatants from these cultures were collected, exosomes

were isolated using differential ultra-centrifugation, and analyzed using NanoSight technology, demonstrating that the mean size of exosomes derived from the bipolar media was significantly smaller than that of control astrocytes, but concentrations were similar. Western blot analysis demonstrated the presence of exosomal markers: CD63, HSP70, CD9, and CD81, and proteomic analyses of both spontaneously secreted exosomes and following stimulated release are in progress. Checkerboard analyses of exosome contribution to neuronal differentiation is being carried out by addition of BP and C astrocyte derived exosomes to BP and C neural progenitor cells (NPC). Neurite outgrowth, miRNA array, electrophysiology, and immunocytochemistry/RTqPCR for differentiation makers are being carried out on recipient cells. Utilizing PKH26 to fluorescently label exosomes demonstrates uptake by recipient NPC in both live cell imaging and immunocytochemical analysis. Additionally, proteomic analysis of exosomes isolated from peripheral blood of patients who contributed fibroblasts for stem cell derivation is currently underway.

Abstract: The developing nervous system is particularly sensitive to influence by environmental signals, including dysregulation by toxins. Polybrominated diphenyl ethers (PBDEs), one such type of toxins, are an environmentally pervasive class of brominated flame retardants that have been extensively used as coatings on a wide range of consumer products. Their environmental stability, propensity for bioaccumulation, and known potential for neurotoxicity have evoked interest regarding their effects on the developing nervous system. Concerningly, there is a growing body of evidence correlating human exposure levels to behavioral deficits related to neurodevelopmental disorders. Understanding the molecular and cellular mechanisms by which

PBDEs affect the developing brain may help clarify this association and provide insight into the disorders. Using primary cultures of cortical neurons from embryonic rats (*R. norvegicus*), we found that chronic exposure to a hydroxylated metabolite of BDE-47, one of the most abundant PBDE congeners, suppressed both spontaneous and evoked electrical activity. We also made the fortuitous observation that some ortho-hydroxylated metabolites share key structural similarities to Type-III non-ATP competitive MEK1 inhibitors. This led to the development of a mechanistic hypothesis for how these compounds may partially inhibit MEK1, a central kinase in the MEK-ERK pathway. Modeling of protein-ligand docking and observed attenuation of pERK induction and MAPK-driven gene transcription following acute PBDE exposures support this hypothesis. Further, when we exposed flies (*D. melanogaster*) via feeding, we found that both 6-OH-BDE-47 and the MEK1 inhibitor PD-0325901 caused increased frequency of mushroom body β-lobe midline crossing, a metric of axonal guidance *in vivo*. Our data support the hypothesis that certain ortho-hydroxylated PBDE metabolites can act as MEK1 inhibitors and disrupt spontaneous and evoked electrical activity, pre-synaptic composition, and axonal guidance. These data indicate that partial inhibition of MAPK signaling by specific ortho-hydroxylated PBDEs could impact neurodevelopmentally critical processes.

Title: Regulation of RNA splicing associated with environmental stimulation in the postnatal brain

Authors: *F. TSURUTA[1], J. KIM[1], T. TAKETOMI[2], C. HAMADA[2], J. NAKAMURA[1], B. SATO[1], T. CHIBA[1];

Abstract: In mammals, a wide variety of environmental stimuli play important roles in establishing the functions of the postnatal brain. During postnatal stages, these stimuli enforce the diversity and complexity of synaptic connectivity and neuronal circuit, resulting in affecting various critical periods. Recently, it has been reported that RNA splicing has effects on the brain

function a time- and region-dependent manner, regulating synaptic connectivity and neuronal circuit. However, it has not been elucidated the molecular mechanisms linking environmental stimuli to the neuronal function involved in RNA splicing after birth. Here, we report that ubiquitin specific peptidase 15 (USP15) is accumulated in the nucleus after visual stimulation. Previously we found that USP15 deubiquitinates Terminal Uridylyl Transferase 1 (TUT1), contributing U6-snRNA stabilization and proper RNA metabolism. In the brain, USP15 exists in both nucleus and cytoplasm in layer V cortical neurons. On the other hand, USP15 is not accumulated in the nucleus in the absence of light exposure under the dark condition. Using the microarray analysis, we identified substantial genes, which are involved in ER stress and membrane trafficking. One of the interesting candidates influenced by USP15 deficiency is a mutant of Hevin, which is a secreted protein from astrocyte and accelerate the synaptic formation. This mutant lacks a calcium binding domain, EF-hand at the C-terminal region. We also found that this mutation hampers the trafficking pathway and is accumulated in the endoplasmic reticulum in not only astrocyte but also specific neurons, inducing a mild ER stress. Taken together, our results suggest that visual stimulation during postnatal stages promotes USP15 accumulation in the nucleus in layer V cortical neurons, followed by controlling the proper RNA splicing in the nucleus. A defect in this machinery produce multiple splicing mutants like Hevin and causes neuronal dysfunctions. These finding may provide the possibility that USP15 act as a key mediator that link environmental stimuli to the establishment of the proper neuronal circuit.

Title: Structural and functional maturation profile of rat primary motor cortex layer 5b neurons

Authors: ***D. DANNEHL**[1,2], B. BENEDETTI[2], M. JANSSEN[1], C. CORCELLI[1], S. COUILLARD-DESPRES[2], M. ENGELHARDT[1];

[1]Inst. of Neuroanatomy, Med. Fac. Mannheim, Heidelberg Univ., Heidelberg, Germany; [2]Inst. of Exptl. Neuroregeneration, Paracelsus Med. Univ., Salzburg, Austria

Abstract: Layer 5b pyramidal neurons (L5bPN) are the major output population of the primary motor cortex (M1), playing a key role in motor circuit integration and initiation of voluntary movement. L5bPN are among the most active excitatory neurons in the CNS. However, axonal maturation patterns and firing properties of M1 L5bPN during development remain elusive. Here, we characterized the structural and functional maturation of the action potential (AP) initiation site, the axon initial segment (AIS), of rat M1 L5bPN. AIS maturation from P1 to P150 was investigated via morphometrical analysis applying confocal-based immunofluorescent detection of the AIS scaffolding proteins βIV-spectrin and ankyrin-G. The elongation rate of L5bPN AIS was highest during the first postnatal week (0.6 ± 0.1 µm/day, oneway ANOVA, $p<0.001$). At P10 to P15, the elongation rate began to slow significantly (0.4 µm ± 0.06 µm/day, $p<0.001$), until negligible AIS elongation was observed at adult age (< 0.06 µm/day). Recent studies have shown that AIS elongation contributes to increased neuronal excitability. Hence, we analyzed the relation between AIS maturation and cellular excitability via whole cell patch-clamp recordings in acute slices prepared from 5 age groups: (i) P2-5, (ii) P10-15, (iii) P20-25, (iv) P50-56, and (v) > P150 (average n = 20 cells per group). AP parameters indicated that with the exception of higher maximal firing frequencies, the overall excitability of M1 L5bPN decreased with age despite corresponding AIS elongation. Cells from older age groups showed a significantly decreased input resistance in comparison to the two youngest age groups (P20-25 = 371 ± 280 MΩ; P50-56 = 249 ± 69 MΩ; P>150 = 365 ± 242 MΩ, $p<0.001$; P2-5 = 1609 ± 878 MΩ; P10-15 740 ± 308 MΩ), correlating to higher rheobase and smaller gain. Remarkably, all significant physiological development occurred right after P2-5 or P10-15, namely at phases of fast or intermediate AIS elongation rate. Our data suggest that notwithstanding overall longer AIS, older neurons are not more excitable than younger neurons with significantly shorter AIS. Possibly, progressive elongation of AIS with age might have a function in counterbalancing the impact of decreased input resistance on the overall neuronal excitability to balance neuronal excitability in the developing cortical network.

Title: Dynamic regulation of synaptopodin and the cisternal organelle in the axon initial segment of retinal ganglion cells during postnatal development

Authors: M. JANSSEN[1], A. SCHLÜTER[1,2], S. ROSSBERGER[1,3], D. DANNEHL[1], S. VORWALD[1], J. HANNE[4], C. SCHULTZ[1], D. MAUCERI[2], *M. ENGELHARDT[1];

Abstract: The axon initial segment (AIS) is a key component of normal cellular function in neurons. The AIS constitutes the site of action potential generation and plays an important role for establishing neuronal polarity. In visual cortex pyramidal neurons, the AIS undergoes periods of activity-dependent structural plasticity during development. However, it remains unknown how AIS morphology is organized during development for downstream cells in the visual pathway, namely retinal ganglion cells (RGCs) and whether these AIS retain the ability to dynamically adjust to changes in network state in the retina. Here, we investigated the maturation of RGC AIS during mouse retinal development, and tested putative activity-dependent mechanisms by applying visual deprivation with a focus on the AIS-specific cisternal organelle (CO), a presumed Ca^{2+}-store. Whole-mount retinae from wildtype and Thy1-GFP transgenic mice were processed for multi-channel immunofluorescence using antibodies against AIS scaffolding proteins Ankyrin-G, βIV-spectrin and the CO marker synaptopodin (synpo). Confocal microscopy and morphometrical analysis of AIS length and position as well as synpo cluster size was performed. Data show that RGC AIS undergo dynamic length maturation during development, with longest AIS during the early postnatal phase (P10: 24.45 ± 0.42 µm SD, P15: 24.11 ± 0.28 µm SD), followed by a significant length reduction from P28 until adulthood (P21: 20.68 ± 0.36 µm SD; P28: 16.92 ± 0.28 µm SD; P>55: 16.82 ± 0.25 µm SD; oneway ANOVA, $p \leq 0.05$). Furthermore, a subset of RGC AIS contains synpo clusters and data show that the size, but not the number of synpo clusters in RGC AIS undergoes significant changes during retinal development (P21: 0.59 ± 0.01 μm^2 SD vs. P28: 0.50 ± 0.02 μm^2 SD and P35: 0.52 ± 0.004 μm^2 SD; oneway ANOVA, $p \leq 0.05$). Similar to previous data from visual cortex, we found that both RGC AIS and CO maturation seem to be activity-regulated events during retinal development, since both are impaired under visual deprivation conditions. Using superresolution microscopy, we addressed the subcellular localization of synpo in RGC axons. Similar to cortical neurons, RGCs show a periodic distribution of AIS scaffolding proteins. A previously reported scaffold-deficient nanodomain correlating with synpo localization is not evident in all RGC AIS. In summary, our work demonstrates a dynamic regulation of both the AIS and synpo in RGCs during retinal development and after visual deprivation, providing evidence that the AIS and CO in RGCs can undergo structural plasticity in response to changes in network activity.

Abstract: The axon initial segment (AIS) is the cellular compartment where most neurons integrate synaptic inputs and generate their primary output signal: the action potential. However, it was only recently that its structure and molecular composition have been untangled. Such studies mostly relied on immunofluorescent staining in fixed neuronal tissue using antibodies against elements of the AIS cytoskeleton. For example, the scaffolding proteins Ankyrin-G and βIV-spectrin cluster voltage-gated ion channels at the AIS and provide a cellular anchor between axonal membrane and cytoskeleton. Recent approaches allow life labeling of the AIS using antibodies against the extracellular domain protein neurofascin-186 or by using transfection of cultured neurons with AIS-specific constructs. However, these techniques are somewhat limited in their application and have, so far, only been established for *in vitro* applications.
Here we present and characterize a transgenic mouse line, in which the AIS is intrinsically labeled with a genetically encoded fluorophore. In this model, a modified sequence generates an Ankyrin-G-GFP fusion protein that is activated by Cre recombinase and only visualizes endogenous Ankyrin-G. This allows AIS labeling in subsets of neuronal populations and time-points in the living animal, depending on which Cre-line is selected as a cross or which virus is

injected.
We investigated whether the fusion of Ankyrin-G with GFP and its insertion at the AIS affects AIS morphology, development, molecular composition, and electrophysiological function after activation of the construct in different neurons (interneurons, excitatory neurons, dopaminergic neurons) and by different techniques (virus transfection, breeding). Using confocal and superresolution (STED) microscopy as well as whole cell patch clamp recording *in vitro*, *ex vivo* and *in vivo*, we confirm that the subcellular scaffold of the AIS and basic electrophysiological parameters of labeled cells are not changed after the fusion of GFP to Ankyrin-G. Now, we use this mouse line to study the time course of AIS development and plasticity in individual living neurons using confocal life imaging in combination with whole cell patch clamp recordings.

Title: Voltage-sensitive dye recording of glossopharyngeal nerve-related synaptic networks in the embryonic mouse brainstem

Authors: *K. SATO[1], Y. MOMOSE-SATO[2];
[1]Komazawa Women's Univ, Fac. of Human Hlth., Tokyo, Japan; [2]Dept. of Nutr. and Dietetics, Kanto Gakuin University, Col. of Nutr., Yokohama, Japan

Abstract: The glossopharyngeal nerve (N.IX) transfers motor and sensory information related to visceral and somatic functions, such as salivary secretion, gustation and the control of blood pressure. N.IX-related neural circuits are indispensable for these essential functions. Compared with the strenuous analysis of morphogenesis, we are still at the entrance to elucidate the functiogenesis of these neural circuits during ontogenesis. In the present study, we applied voltage-sensitive dye recording to the embryonic mouse brainstem, and examined the functional development of the N.IX-related neural circuits. First, we optically identified the motor nucleus (the inferior salivatory nucleus (ISN)) and the first-order sensory nucleus (the nucleus of the tractus solitarius (NTS)). We also succeeded in recording optical responses in the second/higher-order sensory nuclei via the NTS, including the parabrachial nucleus. Second, we pursued

neuronal excitability and the onset of synaptic function in the N.IX-related nuclei. The neurons in the ISN were excitable at least at E11, and functional synaptic transmission in the NTS was first expressed at E12. In the second/higher-order sensory nuclei, synaptic function emerged at around E12-13. Third, by mapping optical responses to N.IX and vagus nerve (N.X) stimulation, we showed that the distribution patterns of neural activity in the NTS were different between N.IX and N.X from the early stage of ontogenesis. We discuss N.IX-related neural circuit formation in the brainstem, in comparison with our previous results obtained from the chick and rat embryos.

Title: Exposure to nicotine during development disrupts synaptic network formation by inhibiting correlated spontaneous wave activity

Authors: *Y. MOMOSE-SATO[1], K. SATO[2];
[1]Kanto Gakuin University, Col. of Nutr., Yokohama, Japan; [2]Dept. of Hlth. and Nutr. Sci., Komazawa Women's Univ, Fac. of Human Hlth., Tokyo, Japan

Abstract: Correlated spontaneous activity propagating over a wide region of the central nervous system is expressed during a specific period of embryonic development. In a previous study using the optical imaging technique with a voltage-sensitive dye, we demonstrated that this wave-like activity, which we referred to as the depolarization wave, plays a fundamental role in the early process of synaptic network formation. We found that *in ovo* application of bicuculline/strychnine or *d*-tubocurarine, which blocked neurotransmitters mediating the wave, significantly reduced functional synaptic expression in the brainstem sensory nucleus. This result, especially for *d*-tubocurarine, an antagonist of nicotinic acetylcholine receptors, raised the possibility that prenatal nicotine exposure associated with maternal smoking affects the development of neural circuit formation by interfering with the depolarization wave. In the present study, we tested this hypothesis by examining the effects of nicotine on the depolarization wave and assessing the chronic action of nicotine on functional synaptic expression. The application of nicotine transiently increased electrical bursts and embryonic motility associated with the depolarization wave, but subsequently inhibited these activities.

Furthermore, chronic exposure to nicotine *in ovo* markedly reduced functional synaptic expression in the brainstem sensory nucleus, the parabrachial nucleus. This study suggested that prenatal nicotine exposure disrupts the initial creation of neural circuitry by inhibiting the correlated spontaneous activity.

Title: Morphological annotations reveal the trajectory of cerebellar interneuron diversification

Authors: W. X. WANG, ***J. L. LEFEBVRE**;
Mol. Genet., Hosp. For Sick Children/ U. of Toronto, Toronto, ON, Canada

Abstract: Inhibitory interneurons comprise diverse classes of cells that target specific subcellular compartments of their postsynaptic neurons. Even within the same class, interneurons exhibit significant heterogeneity in their morphological and electrophysiological features, suggesting that connectivity patterns are shaped by extrinsic cues during development. To investigate inhibitory interneuron diversification, we focused on the cerebellar cortex in which the sole projection neurons, the Purkinje cells, receive nearly all inhibitory inputs from one class of interneurons, the molecular layer interneurons (MLIs). MLIs derive from a common progenitor pool but give rise to divergent types that target distinct Purkinje cell compartments, including dendrites, somata, and axon initial segments. Based on these axon targeting motifs and other morphological characteristics, MLIs have classically been divided into two types, the stellate cells and the basket cells. However, observations of intermediate and overlapping morphologies have led to the alternate model that MLIs represent one class of interneurons with continuously varying characteristics. To assess MLI diversity, we established genetic strategies to label MLIs with single-cell resolution, sampling across birth dates and final laminar positions. We reconstructed the morphologies of 147 mature MLIs, including their complete dendritic and axonal arbors. Following unsupervised clustering of 24 morphological features, we show that the MLIs cluster into two subpopulations—basket cells and stellate cells. Interestingly, the stellate cell cluster is further represented by a continuum of differences, revealing a cellular heterogeneity within this population. We next analyzed the morphological trajectory of MLIs

during the first postnatal weeks to determine the progression of diversification. Using imaging-based pseudo time analysis of axonal features from 1001 reconstructed MLIs, we mapped the developmental bifurcation of MLIs into basket and stellate cells during the final stages of MLI migration. We demonstrate that MLIs undergo considerable remodeling to establish their final wiring patterns, and that cerebellar interneuron patterning is highly regulated by local signaling rather than by birthdate. Further studies bridging form to molecular signatures will set the stage to identify mechanisms that influence MLI identity and synaptic targeting.

Title: SCN heterogeneity revealed through developmental patterning of neuropeptide expression

Authors: *V. CARMONA-ALCOCER, K. E. ROHR, F. SAABEDRA, A. VALENCIA, N. BURRIESCI, J. A. EVANS;
Biomed. Sci., Marquette Univ., Marquette University, WI

Abstract: Neuropeptide signaling modulates the function of master clock neurons in the suprachiasmatic nucleus (SCN). Both arginine vasopressin (AVP) and vasoactive intestinal peptide (VIP) regulate the SCN network during adulthood, but when these two neuropeptides are first expressed during development has been difficult to establish precisely. To address this important issue, we used a transgenic approach to define the developmental patterns of neuropeptide expression across the SCN network. Specifically, we crossed *Avp-Cre*$^{+/-}$ or *Vip-Cre*$^{+/+}$ males to *Ai9*$^{+/+}$ females that express floxed tdTomato (tdT). In the offspring of this genetic cross, the fluorescent protein tdT is stably expressed after initiation of *Avp* or *Vip* transcription. Here we use this approach to profile the spatiotemporal patterning of neuropeptide expression by examining tdT expression at critical developmental time points spanning from embryonic age (E) 15.5 to adulthood. Our results indicate that the onset of neuropeptide transcription begins shortly after SCN neurogenesis is complete, with initiation of *Avp* and *Vip* transcription occurring in a cell-type specific manner. Further, this work reveals that there are spatial gradients in the developmental patterning of neuropeptide expression across the anteroposterior SCN. These results suggest that SCN neurons of the same neurochemical class can be distinguished into further sub-clusters, which may relate to functional differences detected along the anteroposterior axis of the mature SCN network.

Title: Non-ionotropic NMDAR signaling promotes spontaneous and evoked neurotransmitter release in the developing retinotectal system

Authors: ***M. VAN HORN**, L. TIMMINS, A. SCHOHL, V. HIGENELL, S. GLASGOW, P. KESNER, E. RUTHAZER;
McGill Univ., Montreal, QC, Canada

Abstract: The NMDA receptor plays an important role in activity-dependent refinement of sensory connections, which occurs during normal neural circuit development. Recently, presynaptic NMDA receptors (preNMDARs) have been found to regulate many forms of plasticity at several synapses. Here we investigated the potential role of preNMDARs on retinal ganglion cells (RGCs) in the developing *Xenopus laevis* tadpole visual system. To test for the presence of functional NMDARs in RGC axons, we performed two-photon imaging of RGC axon terminals in isolated whole-brain preparations from animals in which RGCs were expressing the genetically-encoded calcium indicator GCaMP6s. Using this preparation, where the RGCs were separated from their somata, we found application of NMDA produced Ca^{2+} transients in RGC axon terminals suggesting the presence of presynaptic NMDARs on RGC axons. Using whole cell electrophysiology, under postsynaptic NMDAR blockade, bath application of NMDAR antagonists, particularly targeting GluN2B-containing receptors, decreased miniature excitatory postsynaptic current (mEPSC) frequency. Moreover, the NMDAR antagonist APV resulted in a significant increase in paired -pulse ratios (PPRs). Interestingly, raising the tadpoles in MK801, to block Ca^{2+} influx through the ion channel of the NMDARs, did not prevent the APV-induced decrease in mEPSC frequency or the increase in PPRs. These results suggest that NMDARs can regulate both spontaneous and evoked synaptic release independent of Ca^{2+} influx through the ion channel. Additional studies are required to determine the downstream signaling pathways mediating these non-ionotropic mediated changes. Taken together these results suggest an unappreciated role of NMDARs on RGCs in the developing retinotectal system and identify a novel, non-ionoptropic mechanism by which NMDARs can modulate evoked and spontaneous neurotransmission and contribute to neural circuit development.

Title: Learning to see with closed eyes: Retinal waves tune cortical neurons before eye opening

Authors: ***A. S. HAMODI**, X. GE, M. C. CRAIR;
Yale Univ., New Haven, CT

Abstract: Development of neural circuits depends on a combination of molecular and activity-dependent mechanisms. The activity can be spontaneous—such as retinal waves that course across the mammalian perinatal retina—or sensory-evoked. Spontaneous waves provide essential instructions for the development and refinement of visual circuits, and disruption of early spontaneous activity has been implicated in numerous neuropsychiatric disorders, such as autism and schizophrenia. Although much is known about the retinal circuitry responsible for retinal wave generation, it is unclear how retinal waves shape the development of functional cortical architecture. It is also completely unknown which subtypes of neurons participate in waves in visual cortex and when they are recruited during development. Here we determine the roles and dynamics of excitatory and inhibitory neuron activity in visual cortex during the period of retinal waves (before eye-opening). To do this, we use simultaneous cellular-resolution calcium imaging of genetically defined neurons within a local circuit and mesoscopic imaging of neuronal activity across cortex to assess the function of retinal waves in cortical circuit formation in awake, head-fixed mice. In addition, we developed a novel method for ultra-fast whole-brain vector-driven gene delivery. Using this novel method to obtain pan-neuronal expression of GCaMP6s before eye-opening, we observe that all interneuron subclasses in visual cortex are recruited by retinal waves as early as P4. However, the degree of participation depends on the subclass of neurons, cortical layer, and developmental age. Additionally, we are using our dual-imaging approach to examine the role of retinal waves in emergence of functional receptive field properties already present at eye-opening, such as orientation- and direction-selectivity. To do this, we are directly linking retinal wave properties to the number and identity of cortical neurons

recruited, and testing whether retinal waves instruct the development of direction selectivity in cortical neurons prior to eye-opening. Our work enables the generation of novel insights into the role of specific populations of individual neurons in the development of functional organization of brain circuits in health and disease.

Title: Epigenetic modulation of auditory system critical period plasticity

Authors: *B. SCHWARTZ, W. WANG, S. BAO;
Univ. of Arizona, Tucson, AZ

Abstract: The critical period is a time of maximal plasticity within the cortex. The progression of the critical period is marked by experience-dependent transcriptional alterations in cortical neurons, that in turn shifts the excitatory-inhibitory balance in the brain and accordingly, reduces plasticity. Epigenetic mechanisms, such as DNA methylation, control the transcriptional state of neurons, and has been shown to be dynamically regulated during the critical period. Here we show that adult animals have a significantly higher concentration of DNA methylation than critical period animals. Pharmacological reduction of DNA methylation in adult animals re-establishes critical period auditory map plasticity. Furthermore, the reduction of DNA methylation in adult animals, reverted intrinsic characteristics of inhibitory synapses to an immature state. Our data suggests that accumulation of DNA methylation during the critical period confers a mature phenotype to cortical neurons, which in turn, facilitates the reduction in plasticity seen after the critical period.

Title: Functional frequency maturation across the perinatal time window

Authors: *J. CIARRUSTA, D. BATALLE, R. DIMITROVA, J. O'MUIRCHEARTAIGH, L. CORDERO-GRANDE, A. PRICE, E. HUGHES, D. MURPHY, J. HAJNAL, D. EDWARDS, G. MCALONAN, T. ARICHI;
King's Col. London, London, United Kingdom

Abstract: Adult neural activity as studied by resting state functional magnetic resonance imaging (rs-fMRI) occurs at a relatively low frequency spectrum (0.001 to 0.3Hz). In the first year of postnatal life, there is a drastic shift from global slow frequencies (0.025 Hz) to adult like peak frequencies (0.1 Hz) in rs-fMRI. However, whilst the spatial distribution of neural networks are known to rapidly evolve across the perinatal period, it is not known how changes in frequency may modulate network development. We used high temporal resolution fMRI data to characterise changes in frequency power in diverse cortical regions across the perinatal time window. A total of 150 term born neonates were recruited as part of the developing human connectome project and were scanned at median age 41.57 postmenstrual weeks. fMRI data were acquired using a 3T scanner and a multi-slice echo planar imaging sequence with multiband excitation (MB factor 9; TR 0.39s). Data pre-processing was performed using FSL. Signal artefacts were identified using independent component analysis and regressed out using FIX. Spatial distortion effects were then corrected. Power spectral density was calculated in native space for each subject and then warped into standard space. In-house scripts generated in matlab were used to calculate the fractional amplitude of lower fluctuations (fALFF). The proportion of spectral power in lower relative to higher frequencies was studied in 6 different frequency bands ranging from 0.0016 to 0.3 Hz. A general linear model was used to assess the effect of age in each frequency band in 7 different cortical regions. A significant effect (FDR corrected) of increasing power with age was seen in the somatosensory, motor and auditory cortices at 0.075 to 0.1 Hz (figure 1). Whole brain analysis revealed a significant increase of power in 0.05 to 0.075 Hz in posterior cortices. These results suggest early developing sensory networks are the first to acquire the ability to function at higher frequency ranges and indicate adult like frequency power follows a posterior to anterior maturation trajectory.

Title: Long lasting remodeling of hippocampal networks by adult neurogenesis

Authors: *A. I. GROISMAN, S. M. YANG, A. F. SCHINDER;
Leloir Inst. (IIBBA-CONICET), Capital Federal, Argentina

Abstract: Adult-born granule cells (GCs) are continuously generated in the dentate gyrus of the hippocampus of all mammals, including humans. They are known to participate in information processing in the dentate gyrus which is involved in memory and learning. Developing GCs undergo a period of high excitability that is regulated by the local GABAergic network, generating heterogeneous functional profiles. In order to better understand the integration dynamics between GCs and the different types of GABAergic interneurons, we built a spatio-temporal map from INs to GCs, and from GCs to INs. We combined presynaptic optogenetic stimulation and whole-cell recordings of fluorescently-labeled postsynaptic cells. GABAergic interneurons expressing parvalbumin (PV-INs) and somatostatin (SST-INs) were identified by genetic labeling. Retroviruses were used to transduce developing GCs. Optogenetic stimulation of PV-INs or SST-INs elicited postsynaptic responses with small amplitude and slow kinetics in young developing GCs, characteristic of immature synapses. Mature synapses were only observed in 6- to 8-week-old GCs, well beyond the critical period of high excitability. Development of GC outputs occurred at a slower pace, with synapses requiring up to 11 weeks to reach functional maturation. PV-INs formed perisomatic synapses onto GCs and contributed to both feedforward and feedback loops within the dentate gyrus, while SST-IN contacted proximal and distal dendrites in GCs and contributed to feedback but not feedforward inhibition. Thus, perisomatic inhibition arises both from feedforward and feedback loops, while dendritic inhibition comes primarily from feedback circuits, and it is the loop demanding the longest maturation time. These data demonstrate that integration of new GCs within the preexistent dentate GABAergic network is specific of each INs population and that adult neurogenesis takes a large period of time for remodeling and circuit integration.

Title: The rich get richer: Serial section electron microscopy reveals that climbing fiber-Purkinje cell synapse rearrangement in the developing mouse cerebellum is economical and begins with positive feedback addition of synapses

Authors: *A. M. WILSON[1], R. SCHALEK[2], A. SUISSA-PELEG[2], T. JONES[4], S. KNOWLES-BARLEY[5], H. PFISTER[2], J. W. LICHTMAN[3];
[1]Princeton Univ., Princeton, NJ; [3]NWL 249.50, [2]Harvard Univ., Cambridge, MA; [4]Broad Inst., Cambridge, MA; [5]Google, Seattle, WA

Abstract: During postnatal development, cerebellar climbing fibers become strong synaptic inputs to a subset of their original Purkinje cell targets, and eliminate their connections from the rest. As a result, in the adult cerebellum each climbing fiber innervates a small number of Purkinje cells (often separated by large distances of several mm in a sagittal zone). Furthermore, each Purkinje cell is innervated by a single climbing fiber. This remapping has been broken down into various stages (Kano et al., 2018). However, the processes responsible for the observed changes in climbing fiber-Purkinje cell synaptic connectivity have not been well described. In order to get insight about the nature of these processes, we reconstructed two serial section electron microscopy datasets from mice at different time points during the first postnatal week (190 x 120 x 50 μm3 at postnatal day 3 and 190 x 120 x 75 μm3 at postnatal day 7). Between postnatal days 3 and 7, Purkinje cells retract long dendritic branches while local dendritic processes grow. On this changing dendritic landscape, individual climbing fibers selectively add many synapses onto a subset of their Purkinje cell targets, without pruning synapses from their other Purkinje cell targets. The active zone areas for individual synapses associated with powerful versus weak connections are indistinguishable. These results show that increases in synapse number, rather than changes in synapse size, are the predominant form of early developmental plasticity. Finally, although multiple climbing fibers innervate each Purkinje cell in the first postnatal week, the number of climbing fiber axons and Purkinje cells in a local region of cerebellum appear to be almost the same (likely due to exuberant climbing fiber branching). Thus, over-innervation of Purkinje cells by climbing fibers in early postnatal development is economical: the number of axons innervating Purkinje cells within a local region is about the amount required to assure that each axon ends up with a postsynaptic target.

Title: Antenatal sFLT1 overexposure induces neurodevelopmental milestone delay, cortical thinning and synapse reorganization in juvenile offspring

Authors: D. EFFINGER[1], G. SEEDORF[2], A. J. LAW[3], S. H. ABMAN[2], ***C. PATERSON**[1]; [1]Dept. of Psychiatry, [2]Pediatric Heart and Lung Center, Dept. of Pediatrics, [3]Departments of Psychiatry, Cell & Developmental Biology, Med., Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Epidemiologic studies have shown that complications during gestation are strongly associated with an increased risk for neurodevelopmental and neuropsychiatric disorders in offspring. While maternal insults during pregnancy directly impact fetal development, mechanisms leading to abnormal offspring neurodevelopmental reprogramming are not fully understood. Clinical studies suggest that an imbalance of pro- and anti- angiogenic factors may be pathogenic in multiple gestational complications. Particularly evident are elevated maternal and fetal soluble fms-like tyrosine kinase 1 (sFLT1) levels; however whether elevated sFLT1 levels are sufficient to impair structure and function of the developing brain is uncertain. We have established a model of elevated antenatal sFLT1 levels via intra-amniotic injection of sFLT-1 in gestational day 20 male and female rat embryos. To determine the potential biological processes driving the association between antenatal sFLT1 elevations and increased incidence of neurological disorders in offspring, we examined neurodevelopmental milestone attainment as well as prefrontal cortex (PFC) structure and synapse marker expression at the juvenile stage. Behavioral milestone analysis from postnatal days (PND) 3-14 revealed that sFLT1 overexposure delayed offspring growth and neuroreflex attainment with a tendency to be more evident in male offspring. Histological analyses revealed that at the juvenile stage (PND 14) cortices of offspring exposed to sFLT-1 were thinner in specific lamina of prefrontal areas associated with cognitive outcomes than saline treated offspring. Moreover, we found an imbalance in cortical protein levels of excitatory and inhibitory synapse proteins in sFLT1 exposed offspring. Together these findings implicate that elevated antenatal sFLT1 levels are sufficient to cause sustained structural, behavioral and synaptic disruption of the juvenile rat brain that are reflective of clinical findings in offspring born from complicated pregnancies.

These data bring to attention the neurobiological importance of regulated gestational sFLT1 levels, and highlight the potential contribution of sFLT1 to high risk for neurodevelopmental and neuropsychiatric disorders.

Title: Examine the association between gluten sensitivity and the pathophysiology of autism

Authors: *L. ALZGHOUL;
The Univ. of Jordan, Amman, Jordan

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder. It characterized by a socio-communicational impairment with restricted or repetitive interest and activity. In addition, gastrointestinal (GI) disturbances are also noticed in many patients with ASD, leading to the suggestion that dietary sensitivity may play a role in the pathophysiology of ASD. Several studies have focused on immunological responses to dietary proteins, such as gluten and casein. One study found that peripheral blood mononuclear cells from children with ASD responded to gliadin by producing higher levels of inflammatory cytokines, compared with peripheral blood mononuclear cells from typically developing children. Studies looking at mucosal immune responses in children with ASD who have GI symptoms have shown increased infiltration of T-cell, monocyte, and eosinophil in the gut mucosa, prominent mucosal T-cell activation with increased TNF_ but lower IL-10 production, compared with non-inflamed control subjects or compared with children with celiac disease or inflammatory bowel diseases. **Hence the aim of this study was to examine the association between blood levels of anti gliadin antigens and autism in Jordan.** To study that, blood levels of anti-gliadin IgA and IgG as well as anti- Tissue transglutaminase IgA and IgG were measured in 120 ASD patient, 117 siblings, and 130 age and gender matched healthy controls using ELISA kits. Furthermore, the association between the levels of levels of antibodies and GI symptoms were also examined. Our data revealed 1) no statistically significant deffrence of anti-gliadin IgA, anti- Tissue transglutaminase IgA and anti-Tissue transglutaminase IgG levels were found between the three groups, 2) levels of anti-gliadin IgG that was statistically higher in the ASD group compared to healthy controls but not the

sibling group was also detected 30 no association between any of the tested markers with GI symptoms. These data suggest no role of gluten sensitivity in the pathophysiology of ASD.

Title: Prevalence, etiology, and treatment of sleep disorders in autism spectrum disorder

Authors: *B. CHANG, M. L. BAUMAN;
Dept. of Anat. and Neurobio., Boston Univ. Sch. of Med., Boston, MA

Abstract: Autism Spectrum Disorder is a range of neurodevelopmental disorders that typically manifest as social deficits, delayed or impaired communication skills, and repetitive behaviors in day-to-day life. Patients with Autism Spectrum Disorder (ASD) often present with other concurrent clinical disorders. Sleep disorders (SD) and sleep issues are highly prevalent in ASD children and rank as one of the most common concurrent clinical disorders. Sleep problems can have an impact on daytime health and may result in neurocognitive dysfunction and behavioral disruptions. Therefore, sleep disorders may have wide-ranging effects on daytime functioning, developmental progress, and quality of life for children with ASD. A literature review of studies, abstracts, and clinical trial data relating to ASD, SD, and other comorbidities observed in ASD was performed to provide a review of the research status of ASD, SD, the interplay between these two disorders, and therapeutic interventions that have been researched or are currently being investigated. Future areas of investigation based on the current state of autism research are also suggested. Current models and theories on the relationship between ASD and SD suggest that the underlying etiology of autism itself may contribute to sleep troubles, and might even have wide-reaching impacts on other unrelated aspects of ASD (Figure 1). Gastrointestinal, otolaryngologic, and psychiatric comorbidities are observed in autism and may affect sleep in these patients, but the mechanism by which this occurs is unclear. There are many treatments for sleep troubles in ASD such as melatonin and behavioral interventions, with varying success. Much work is required to understand the underlying mechanism between both autism and sleep disorders. There are multiple ongoing clinical trials underway which may have promising results, but there is still a need for more efficacious therapeutic interventions. Future studies should also incorporate robust data-collection instruments such as polysomnography to validate findings.

Title: A multicentric, randomised, single-blind phase 2 trial to evaluate the pharmacokinetics and PK/PD of trazodone in children and adolescents with neurodevelopmental disorders and insomnia

Authors: *F. CALISTI, V. TELLONE, A. DEL VECCHIO, M. ROSIGNOLI, R. PICOLLO, S. OLIVIERI, F. GAROFOLO, A. CATTANEO, S. TONGIANI;
Angelini RR&D (Research, Regulatory & Development) - Angelini S.p.A., Rome, Italy

Abstract: Background: Insomnia is the most common sleep disorder presented to paediatric healthcare providers and it is reported in otherwise healthy children as well as in children with a range of neurological conditions, including headache, epilepsy or neurodevelopmental disorders (NDDs). NDDs include attention deficit hyperactivity disorder (ADHD), Autism Spectrum Disorders.Good sleep practices and proven behavioural strategies are the first-line treatments. However, in the specific group of children with NDDs, there are children who do not respond to

behavioural interventions who are candidates for a pharmacological management for their insomnia. Trazodone (TZD) is a multimodal antidepressant, a serotonin antagonist and reuptake inhibitor, with a good safety profile. TZD has a clear and ameliorating effect on sleep architecture and can improve the quality of sleep in depressed patients. These characteristics may suggest that TZD is an ideal candidate to treat insomnia in patients with NDD. **Aim and Objectives:** The aim of this study is the characterisation of the PK parameters, the assessment of linearity in drug exposure and the collection of preliminary efficacy data for a pharmacokinetic-pharmacodynamic (PKPD) model. The primary objective of this study is to assess the PK of TZD after single and repeated oral doses in patients aged from 2 to ≤17 years.
The secondary objectives of this study are:
• PKPD relationship of TZD
• Concentration-QT interval correlation
• Dose rationale in children and adolescents
• Safety and tolerability
• Palatability
Study Design
Multi-centre, single-blind, parallel-group, randomised Phase II clinical trial designed to assess the PK and PD of 3 dose levels of TZD in children and adolescents with NDDs (autism, intellectual disability or ADHD). A minimum of 36 patients will be randomised to one of the following 3 treatment arms:
• Arm 1: 0.25 mg/kg/day
• Arm 2: 0.4 mg/kg/day
• Arm 3: 0.5 mg/kg/day
At the start of the screening period, an actigraphy device will be delivered to the patient and used for at least 1 week to ensure that the patient has become familiarised with the device use before treatment phase. Sleep latency and total sleep time will be recorded by actigraphy starting from 3 consecutive days prior to first drug intake to the end of the treatment.
Conclusions: Insomnia in patients with NDD is an unmet medical need with a substantial impact and burden on functioning and quality of life of both patients and caregivers. TZD is a reasonable candidate for the treatment of this condition based on its mode of action and safety profile. The results from this study will provide new information which may be relevant to further development programs.

Title: Maternal immune challenge enhances neural progenitor cell proliferation and increased hippocampus volume in neonatal rats

Authors: *Y. PANG, K. CARTER, M. LOAYZA, L.-W. FAN, A. BHATT;
Univ. of Mississippi Med. Ctr. / Dept of Pediatrics, Jackson, MS

Abstract: Epidemiological studies suggest that maternal infection is a risk factor for Autism Spectrum Disorder (ASD). A causative link is supported by experimental studies showing that maternal exposure to bacterial pathogen lipopolysaccharide (LPS) produce ASD-like behavioral characteristics in offspring animals. However, the underlying mechanisms by which LPS-triggered inflammatory response leads to abnormal brain development are not fully understood. Here we test a novel hypothesis that maternal LPS exposure disrupts cellular programs that controls neuron numbers, leading to excessive neurogenesis in the offspring, and this may explain why ASD infants experience a period of brain overgrowth. Pregnant rats at embryonic day 12.5 (E 12.5) were injected with LPS (50 ug/kg body weight, i.p.). On E17 and postnatal day 21 (P21), expression of microglial pro-inflammatory and anti-inflammatory markers, programmed neuronal death (PND), and neural progenitor cell proliferation were assessed. The sizes of hippocampus and striatum were assessed by stereology in Nissl-stained sections. Our data showed that maternal LPS significant suppressed PND in the hippocampal region at E17, which was associated with increased neural progenitor cell proliferation in the dentate gyrus of postnatal rats. LPS-induced microglia activation is characterized with a mixed M1 and M2-like phenotype, as low levels of both pro-inflammatory (iNOS, CD68 and MHC-II) and anti-inflammatory (TGFb and CD206) markers were detected by immunohistochemistry. Volume assessment showed that the size of hippocampal was specifically increased in male, but not female rats with maternal LPS exposure, whereas no changes were observed in the striatal volume. In conclusion, this study may provide a significant implication regarding underlying neurobiological mechanisms of brain overgrowth in ASD infants.

Abstract: Autism Spectrum Disorder (ASD) is a severe neurodevelopmental disorder characterized by deficits in social interaction and communication, stereotypic behaviors, restricted interests, and abnormal sensory processing. Its incidence has dramatically risen during the last few decades and many cases remain unexplained even after advanced genetic testing. *P*-cresol is an aromatic compound either of environmental origin or produced by specific gut bacterial strains. It is a known uremic toxin, able to negatively affect brain function. Urinary and foecal levels of *p*-cresol have been found significantly elevated in ASD children over matched controls in at least five published reports. In the present study, we have assessed the effects of a single acute injection of low- or high-dose (1 or 10 mg/kg i.v., respectively) *p*-cresol in BTBR mice, a reliable animal model of human ASD. Low-dose *p*-cresol significantly increased anxiety in the elevated plus maze ($P<.001$) and hyperactivity in the open field ($P<0.05$). In addition, high-dose *p*-cresol also produced stereotypic behaviors in the open field ($P<.001$) and complete loss of preference for social interaction in the three-chamber test ($P<.01$). No effect was recorded on object recognition. Significantly elevated tissue dopamine, HVA and DOPAC levels were found by HPLC in the amygdala ($P<0.05$) following low-dose *p*-cresol, as well as in dorsal ($P<0.001$) and ventral striatum ($P<0.01$) after high-dose *p*-cresol, while no effect was recorded in medial prefrontal cortex and hippocampus. Marginal effects on norepinephrine and 5-HT were recorded. Our study (a) supports a gene x environment interaction model, whereby *p*-cresol can acutely induce autism-like behaviors acting upon a susceptible genetic background; (b)

underscores dopaminergic roles in ASD, especially abnormal activation of the reward circuitry; (c) spurs ongoing follow-up studies to clinically characterize 216 ASD children and 58 unaffected siblings based on urinary *p*-cresol levels; (d) raises interest in the correction of chronic constipation and in microbiota transfer therapy as potential strategies to lower *p*-cresol absorption and clinically ameliorate autistic behaviors, anxiety and hyperactivity in young children with ASD.

Title: Gene-environment interactions in an experimental mouse model of neurodevelopmental disorders and stress

Authors: *M. L. PHAN[1], N. JADAV[1], T. LIU[1], C. YOHN[1], J. LUNDEN[2], X. ZHOU[2], M. VOLLBRECHT[2], E. M. DICICCO-BLOOM[2], B. A. SAMUELS[1];
[1]Rutgers Univ. Dept. of Psychology, New Brunswick, NJ; [2]Dept Neurosci & Cell Biol/ Pediatrics (Child Neurol. & Neurodevelopmental Disa, Rutgers Robert Wood Johnson Med. Sch., Piscataway, NJ

Abstract: Autism spectrum disorders (ASD) are pervasive neurodevelopmental disorders characterized by impairments in social interactions and the presence of repetitive or stereotyped behaviors and interests. Compounding these challenges are findings indicating that adults with ASD experience more stressful life events, greater perceived stress, and increased comorbidity with anxiety disorder and depression. Stress exposure contributes to multiple disorders, and chronic stress is a major risk factor for mood disorders. However, it is unknown whether adult exposure to stress can exacerbate the neurobiological and behavioral phenotypes associated with ASD. Using Engrailed-2 knockout (En2-KO) mice, we developed an innovative hypothesis to examine a novel gene x environment interaction with ecological validity for ASD at cellular, circuit, and behavioral levels. En2 genetic polymorphisms are associated with ASD in multiple

distinct human populations, and En2-KO mice display behavioral disturbances in social interaction assessments and memory tasks, as well as reductions in juvenile play, social sniffing, and aggressiveness. We exposed adult wild-type (WT) and En2-KO mice to either chronic social defeat stress (CSDS) or control and quantified the effects on social interactions, negative affective behaviors, and neuroanatomical changes. A social interaction test, following CSDS, showed that the En2-KO mice spend more time in a defined interaction zone surrounding a plexiglass enclosure when an aggressive mouse strain was contained as compared to an empty enclosure and that CSDS decreased the time spent in the social interaction zone. This altered behavior was accompanied by reduced noradrenergic axonal fibers in the nucleus accumbens and amygdala but not in the prefrontal cortex in En2-KO mice exposed to CSDS. These findings are consistent with our hypothesis that stress exposure alters not only behavior and stress hormones, but this effect may be mediated by altered LC fiber innervation into critical regions that underlie stress responses.

Title: IBA1 immunohistochemistry, peripheral cytokine levels and bacterial profiles in mouse models of ASD

Authors: ***S. M. PARKINSON**[1], B. BEASLEY[1], K. SCOTT[1], W. GILL[2], R. W. BROWN[3], M. CHANDLEY[1];
[1]Dept. of Hlth. Sciences, Col. of Publ. Hlth., [2]Dept. of Biomed. Sci., East Tennessee State Univ., Johnson City, TN; [3]East Tennessee State Univ. Dept. of Biomed. Sci., Johnson City, TN

Abstract: Autism spectrum disorder is a neurodevelopmental disorder marked by social deficits and repetitive actions. Communication is thought to occur between the bacterial collections known as the microbiota in the gut and the resident immune cells in the brain, microglia. It has been postulated that bacteria in the gut are capable of secreting signaling molecules that can indirectly induce peripheral inflammatory cytokine release or directly elicit microglia activation to alter neurotransmission in the brain. Tissues from male mice were used to determine if microglial activation, increased peripheral cytokine levels and altered fecal profile panels were

present in mice that demonstrate social behavior deficits. Brain tissue and blood were collected at postnatal day 21 from wildtype control mice (C57BL/6J) and maternal immune activation (MIA), valproic acid (VA), and BTBR mouse models. Behavioral, 16S, and fecal short-chain fatty acid profiles were evaluated in adult male mice from two models (VA and BTBR) and the wildtype control group. Immunohistochemistry in males for the microglial marker ionized calcium binding adaptor molecule 1 (IBA-1) found no difference in area fraction or microglia cell counts in the caudate or cingulate cortex between the wild type and social deficit groups (N=4). Peripheral cytokine analysis demonstrated that BTBR mice had increased IL-1 ($p<0.05$) and IFN- levels ($p<0.05$) that were statistically significant from the control group, but the valproic acid and MIA models did not differ in cytokine expression levels from the control group. Behavioral analysis of the adult mice revealed significantly reduced marble burying in all three models and decreased sociability time in the VA and the BTBR groups when compared to wild type control mice. Short chain fatty acid expression of acetate ($p<.001$, $p<.005$) and valerate ($p<.005$, $p<.05$) in feces were significantly different between wild type controls and social deficit groups (VA, BTBR). The 16S rRNA sequencing of fecal matter demonstrated differences in bacterial profiles between the BTBR and VA groups when compared to wild type control mice. These studies are instrumental in the creation of future mechanistic strategies or peripheral markers that may illuminate treatable signaling pathways for ASD.

Title: Examining a novel gene-environment interaction in autism spectrum disorder

Authors: *K. TESSEMA[1], L. ELAHI[1], R. GAU[1], J. A. MARTINEZ-AGOSTO[2], J. E. LE BELLE[3], H. KORNBLUM[4];
[1]Semel Inst., [2]Human Genet., [3]Psychiatry, UCLA, Los Angeles, CA; [4]UCLA Med. Ctr., Los Angeles, CA

Abstract: Autism spectrum disorder (ASD) accounts for a large individual, familial, and societal burden. The lives of patients and their families are also significantly impacted, as the biopsychosocial effects generally impair functioning in multiple settings. Currently, treatment approaches focus on behavioral therapy since developing biological treatments has been challenging due to the variability in causative mechanisms and lack of reliable biomarkers. To address this challenge, it is crucial to uncover common pathogenic mechanisms underlying

multiple ASD risk factors, as such understanding would help develop therapeutic strategies for larger groups of patients. One candidate pathway that has been studied in a subset of ASD patients is the PI3K-AKT-mTOR pathway. Evidence suggests that this pathway can become dysregulated in response to both genetic and environmental influences, often resulting in enlarged brains and abnormal connectivity. Here, we describe initial studies that investigate a novel gene-environment interaction that converges on the mTOR axis, specifically that of exposure to maternal inflammation *in utero* and heterozygous PTEN mutations. We observe that media conditions associated with maternal inflammation differentially affect proliferation in both 2-D (neural progenitor) and 3-D (organoid) cultures in heterozygous PTEN mutant patient-derived cell lines compared to familial control-derived cell lines. We are continuing to characterize this phenotype by comprehensively examining the consequences of mTOR dysregulation, currently focusing on single-cell proteomic and transcriptomic profiling to identify the specific molecular alterations underlying this effect.

Title: Oxytocin normalizes altered social circuit connectivity in the Cntnap2 knockout mouse

Authors: *K. Y. CHOE[1], M. SAFRIN[2], R. A. BETHLEHEM[3], N. G. HARRIS[4], D. H. GESCHWIND[1];
[2]Neurosci., [1]UCLA, Los Angeles, CA; [3]Dept. of Psychiatry, Univ. of Cambridge, Autism Res. Ctr., Cambridge, United Kingdom; [4]Neurosurg., Dept. Neurosurgery, UCLA, Los Angeles, CA

Abstract: Aberrant functional connectivity (FC) is frequently found in autism spectrum disorders (ASD), notably correlating with the degree of social impairment (Supekar et al., 2013). In our previous work, exogenous administration of oxytocin (OXT) or DREADD activation of paraventricular nuclei (PVN) OXT neurons improves social deficits in mice lacking an ASD risk gene, *Cntnap2* (Penagarikano et al., 2015). Given the ability of OXT to increase circuit signal-to-noise via modulating interneuron function (Owen et al., 2013), we hypothesized that OXT might exert its prosocial effects via rescuing alterations in FC potentially present in the *Cntnap2* KO

mouse. To test this, we used high field (7T) fMRI to measure resting-state FC at the baseline and after exogenously administered OXT in dexmedetomedine-sedated wild-type (WT) and *Cntnap2* KO mice (n=15/group). In line with observations made in individuals with ASD (Rudie et al., 2013), we observed significantly lowered mean FC between regions with established roles in social behavior in the KO mouse (e.g. PVN, nucleus accumbens (NAcc), medial prefrontal cortex; $p<0.001$ vs WT, Monte Carlo exact permutation test), and higher mean FC between these and other regions not typically involved in social functions (e.g. sensory cortices, thalamus) ($p<0.001$ vs WT). Strikingly, both FC phenotypes were normalized by i.p. administration of OXT, significantly elevating the mean FC between social regions and attenuating that between social and other regions ($p<0.001$). In-depth investigation using pairwise ROI and independent component analysis revealed that OXT induced a KO-specific modification of functional circuit connectivity involving the NAcc, a result that was confirmed by immunohistological quantification of neurons expressing c-Fos (immediate early gene product commonly used as a marker of increased neuronal activity). These results suggest that the observed social deficits in KO mice are potentially related to lowered FC between social brain regions, which can be temporarily normalized by OXT administration. To further investigate the functional significance of OXT-induced NAcc circuit activation in social rescue of the KO mouse, we are currently testing the impact of optogenetic activation of this circuit on FC with optogenetic fMRI as well as social behavior.

Institute, UCLA, Los Angeles, CA; [7]Intellectual Develop. and Disabilities Res. Center, UCLA, Los Angeles, CA

Abstract: Social behavioral difficulties are at the core of autism spectrum disorder (ASD). The loss of the brain-wide distributed *contactin associated protein-like 2* (CNTNAP2) is implicated in a syndromic form of ASD. Trans-synaptic structural scaffolding and facilitating neuron-glia interactions are major functions of the transmembrane protein CNTNAP2. Along with investigating the synaptic ultrastructure of social behavior implicated brain regions, we quantified glial-neuron interactions in the hypothalamic paraventricular nucleus (PVN). The PVN contains magnocellular oxytocin (OXT) producing cells. There is a growing body of evidence for OXT's involvement in neuropsychiatric disorders such as ASD. We used the parameter of astrocyte end-foot coverage of OXT neuron cell body to quantify neuron-glial interaction. We found significant differences in glial endfoot coverage of OXT neurons in Cntnap2 knockout (KO) mice as compared to WT. The marked structural difference in astrocyte endfeet - OXT neuron interactions in the KO PVN implicates a potential dysregulation in the synaptic and glial input to these neurons that may underlie the observed social deficits present in these mice. We reason that a potential alteration in the structural relationship between oxytocinergic neurons and their neighboring astrocytes in addition to marked differences in synaptic ultrastructure of socially implicated brain areas may serve as neuroanatomical correlates of underlying deficits in social behavior previously reported in the Cntnap2 KO mouse.

Title: Diminished sodium channels impair dendritic spike generation in layer 5 prefrontal neurons in fragile x syndrome

Authors: F. BRANDALISE[1], B. E. KALMBACH[2], E. P. COOK[3], ***D. H. BRAGER**[4];
[1]Basic Neurosciences, Ctr. Médical Universitaire, Geneva, Switzerland; [2]Human Cell Types, Allen Inst. For Brain Sci., Seattle, WA; [3]McGill Univ., Montreal, QC, Canada; [4]Neurosci., Univ. Texas at Austin, Austin, TX

Abstract: The prefrontal cortex (PFC) sits at the top of the hierarchy associated with cognitive function by exerting top-down control over numerous cortical and subcortical regions. Patients with Fragile X syndrome, the leading monogenetic cause of autism, suffer from cognitive impairment, including working memory and attention deficits, all directly related to functions of the PFC. Extratelencephalic-project projecting L5 neurons (ET) of the PFC project to multiple cortical and downstream structures including thalamic and brainstem nuclei and are therefore well positioned to integrate task-relevant sensory signals and guide motor actions. In ET neurons, distal synaptic inputs are too weak to overcome the dendritic filtering properties to influence the somatic membrane potential and produce action potential output. To overcome this, synaptic inputs in the distal dendrites are transformed into local dendritic Na^+ spikes, which can propagate to the soma and trigger action potentials. We investigated this dendritic input-output transformation in L5 ET neurons of the *fmr1*$^{-/y}$ mouse model of Fragile X syndrome. Using dual somatic-dendritic current clamp, we found that attenuation of both back propagating action potentials and subthreshold inputs was significantly greater in *fmr1*$^{-/y}$ neurons compared to wild type. Using either current injection or optogenetic stimulation, we found that the threshold for dendritic spike initiation was more depolarized in *fmr1*$^{-/y}$ neurons compared to wild type. Using a systems-based analysis, we found that the dendritic input that preceded dendritic spikes and somatic APs was larger in *fmr1*$^{-/y}$ neurons. Outside-out patch clamp recordings revealed that the dendritic sodium current was significantly smaller in *fmr1*$^{-/y}$ ET neurons compared to wild type. Together, these data suggest that a loss of dendritic sodium channel function in ET neurons of the PFC contributes to a fundamental breakdown in the input-output transformation process in Fragile X syndrome.

Title: Dysfunctional temporoammonic pathway LTP in a mouse model of fragile X syndrome

Authors: *G. ORDEMANN[1], R. A. CHITWOOD[2], D. H. BRAGER[3];
[1]Ctr. for Learning and Memory, The Univ. of Texas, Austin, TX; [2]Ctr. for Learning and Memory, The Univ. of Texas, Austin, TX; [3]Inst. for Neurosci., Univ. Texas at Austin, Austin, TX

Abstract: Fragile X syndrome (FXS) is the most common monogenetic cause of autism and intellectual disability. Although the genetic underpinnings of FXS are well understood, the neurophysiological basis for the intellectual deficits remain largely unknown. Our lab previously identified dendritic channelopathies in FXS affecting synaptic integration and Schaffer collateral (SC) synaptic plasticity in CA1 neurons of the hippocampus, a structure critical for learning and memory. Here, we use the *fmr1-/y* mouse model of FXS and a combination of somatic and dendritic current clamp recordings paired with 2-photon calcium imaging to investigate properties and plasticity of temporoammonic (TA) synapses from the entorhinal cortex onto CA1 neurons. Following theta burst stimulation, LTP at TA synapses in *fmr1-/y* CA1 neurons was significantly smaller (8.8 ± 21.8%) compared to wild type CA1 neurons (324.4 ± 74.4%). Using 2-photon imaging we found that dendritic calcium signals during 100 Hz burst stimulation of TA inputs was significantly smaller in *fmr1-/y* CA1 neurons (14.29% $\alpha F/F_0$) compared to wild type CA1 neurons (57.36% $\alpha F/F_0$). Using both calcium imaging and current clamp recordings, we found no significant differences in NMDA receptor function at TA synapses between wild type and *fmr1-/y* neurons. Interestingly, and in contrast in TBS, simultaneous pairing of both TA and SC synapses results in comparable levels of LTP between wild type and *fmr1-/y* neurons. This suggests that TA synapses in *fmr1-/y* neurons can be potentiated. Dendritic recordings of complex spikes were no different between wild type and *fmr1-/y* neurons. However in *fmr1-/y* neurons, unlike in wild type, complex spikes were relatively insensitive to high concentrations of extracellular Ni^{2+}, suggesting a difference in the functional expression of voltage gated calcium channels in *fmr1-/y* CA1 dendrites. We hypothesize that in *fmr1-/y* neurons, a combination of insufficient dendritic depolarization and activation of voltage-gated calcium channels, impairs LTP at TA synapses in *fmr1-/y* mice.

Title: Dysfunction of hippocampal inhibitory interneuron function in fragile-X syndrome

Authors: *L. T. HEWITT[1], D. H. BRAGER[2];
[1]The Univ. of Texas at Austin, Austin, TX; [2]Inst. for Neurosci., Univ. Texas at Austin, Austin, TX

Abstract: Fragile X Syndrome (FXS) is the most commonly inherited form of intellectual disability and the leading genetic cause of autism. Patients with FXS exhibit increased incidence of epilepsy, sensory hypersensitivity, and anxiety among other cognitive impairments. Recent data suggests that a lack of inhibitory/excitatory balance in the brain may be a major contributor to the debilitating cognitive deficits in FXS. While there is an extensive body literature investigating excitatory pyramidal neurons and synaptic transmission, the impact of aberrant inhibitory activity is largely unknown. We focused on two integral inhibitory interneuron subtypes in the hippocampus: *somatostatin expressing* (SOM) and *parvalbumin expressing* (PV) interneurons. SOM interneurons specifically target pyramidal cell dendrites and control synaptic plasticity, while PV interneurons target pyramidal cell bodies and control cell ensemble activation. Using whole-cell current clamp recordings, we measured subthreshold (i.e. input resistance, resting membrane potential) and suprathreshold (i.e. action potential threshold) properties of SOM and PV cells in wild-type and *fmr1-/y* mice. Preliminary data suggests that subthreshold and suprathreshold properties in SOM interneurons of the *fmr1-/y* mouse are altered with no apparent phenotype in PV interneurons. Due to their distinct connections, SOM and PV cells to contribute to different functional aspects of the hippocampal microcircuit and alterations of either interneuron subtype in FXS would impair information processing in the hippocampus.

Title: Sex-specific effects of prenatal omega-3 fatty acids on vocalization production in the Fmr1 knockout mouse

Authors: *S. O. NOLAN[1,3], S. L. HODGES[2], M. BINDER[1], P. D. WOMBLE[1], J. N. LUGO, JR[1];

Abstract: Isolation-induced ultrasonic vocalizations are considered an early indicator of behavioral dysregulation in many mouse models of Autism spectrum disorder (ASD). Previous studies in both our lab and others utilizing the *Fmr1* mutant model have demonstrated several quantitative and qualitative changes in vocalization production during early postnatal periods, ranging from postnatal days (PD) 8 - 12. The present study sought to determine the impact of prenatal high fat dietary manipulations on isolation-induced ultrasonic vocalization production in both male and female *Fmr1* mutants on PD9 using high-throughput analysis methods. For the dietary manipulation breeding pairs were assigned to one of three diet conditions prior to breeding and remained on the diet throughout gestation: standard lab chow, omega-3 fatty acid enriched chow, and a diet controlling for the fat increase. Resulting offspring (male WT, male KO, female WT, female HET and female KO pups) were maintained on this diet and genotyped prior to vocalization recording on PD9. On PD9 we used the maternal separation paradigm to elicit vocalizations from pups. The vocalizations were recorded using an Avisoft recording system. Results indicated that prenatal exposure to high omega-3's increased average fundamental frequency of calls in both male WT and KO mice. Exposure to omega-3 fatty acids restored the number of calls produced by *Fmr1* female HETs to levels similar to female wildtype mice. Moreover, diminished spectral purity in the female *Fmr1* homozygous mouse was rescued by exposure to high fat diets, though these effects were not seen in the male *Fmr1* knockout. These results are in line with data in adult *Fmr1* knockout males, showing that omega-3 fatty acids administered prenatally, attenuate a broad host of behavioral impairments in adulthood, such as deficits in prepulse inhibition and fear learning and memory. These data support future development of this dietary therapeutic for neurodevelopmental disorders.

Abstract: Fragile X syndrome (FXS) is the leading cause of inherited intellectual disability and a significant genetic contributor of Autism spectrum disorder. In addition to autistic-like phenotypes, individuals with FXS are subject to developing numerous comorbidities, one of the most prevalent being seizures. In the present study, we investigated how a single early-life seizure superimposed on a genetic condition impacts the autistic-like behavioral phenotype of the mouse. We induced status epilepticus (SE) on postnatal day (PD) 10 in *Fmr1* wildtype (WT) and knockout (KO) mice. We then tested the mice in a battery of behavioral tests during adulthood (PD90) to examine the long-term impact of an early-life seizure. Our findings replicated prior work that reported a single instance of SE results in behavioral deficits, including increases in repetitive behavior, enhanced hippocampal-dependent learning, and reduced sociability and prepulse inhibition. We also observed genotypic differences characteristic of the FXS phenotype in *Fmr1* KO mice, such as enhanced prepulse inhibition and repetitive behavior, hyperactivity, and reduced startle responses. Superimposing a seizure on deletion of *Fmr1* significantly impacted repetitive behavior in a nose poke task. Specifically, a single early-life seizure increased consecutive nose poking behavior in the task in WT mice, yet seizures did not exacerbate the elevated stereotypy observed in *Fmr1* KO mice. Overall, these findings help to elucidate how seizures in a critical period of development can impact long-term behavioral manifestations caused by underlying gene mutations in *Fmr1*. Utilizing double-hit models, such as superimposing seizures on the *Fmr1* mutation, can help to enhance our understanding of comorbidities in disease models.

Title: Cannabidiol attenuates behavioral and epileptiform deficits in a mouse model of CDKL5 developmental disorder

Authors: A. WIEST[1], M. YENNAWAR[1], *R. S. WHITE[2], J. WACKER[2], F. E. JENSEN[2]; [1]Pharmacol., [2]Neurol., Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA

Abstract: Cyclin-dependent-kinase-like 5 (CDKL5) mutation and loss of function result in a range of autistic-like behaviors, neurodevelopmental deficits, and often refractory seizures. Recent clinical studies with cannabidiol have shown efficacy in suppressing seizures in this population as well as other neurodevelopmental syndromes characterized by epilepsy, autistic-like symptoms, and intellectual disability. We used a CDKL5 mouse model where the protein is functionally knock (R59X). We have previously demonstrated behavioral and cognitive deficits and increased seizure susceptibility within this model (Yennawar, et al., J. Neurosci, 2019). Adult (P60-80) R59X mice and littermate WT mice were treated with vehicle (saline) or cannabidiol (CBD:100mg/kg) 1 hour prior to behavioral testing or chemoconvulsant (pentylenetetrazol (PTZ) 50 mg/kg) seizure induction. Cannabidiol treatment attenuated deficits in social choice with an average increase of 18.4±5.5sec spent at the social chamber (R59X veh: 21±1.5s vs R59X CBD: 39.4±4.3s; $p<0.01$). Treatment also helps with learning and memory, improving successful trials on the Y-maze test (R59X veh: 39.3±1.1s vs R59X CBD: 56.5±2.8.3s; $p<0.0001$) and long-term fear conditioning (R59X veh: 20.6±3s vs R59X CBD: 37.8±5.9s; $p<0.05$). In addition, CBD reversed the increase in seizure susceptibility to PTZ seizures in the R59X mice (R59X veh: 86.4±4.7s vs R59X CBD: 150.3±24.2s; $p<0.001$). In contrast, CBD treatment did not affect these parameters in WT mice.To begin to understand the potential therapeutic effects of CBD, we evaluated the developmental trajectory of protein expression of different known endocannabinoid pathway targets. We showed that CB_1 expression is significantly elevated in R59X mice at P50 in the hippocampus when compared to WT littermate controls (30.9±11% diff, $p<0.05$). We have also shown that CB_2 expression is significantly elevated in the cortex of R59X mice at P50 (60.9±16% diff., $p<0.01$). We are investigating other known targets of the endocannabinoid system (A1, TRPV1, TRPV2, and GPR55) to understand how protein expression is regulated during development in R59X mice to elucidate a mechanism of CBD in our mouse model. Taken together, these data suggest that cannabidiol may have therapeutic potential in rescuing not only seizure susceptibility but also the behavioral deficits in CDKL5 disorder and justify further study of the role of the endocannabinoid system as a target for treatment.

Title: IGF2 dependent paracrine signaling inpericyte and neuronal crosstalk

Authors: *Z. ZHAO[1], X. W. XIE[1], J. ZENG[2], Y. WU[3], **B. PLUIMER**[3];
[1]Physiol. and Neurosci., [2]Physiol. & Neurosci., [3]USC, Los Angeles, CA

Abstract: Neuronal functions and brain connectivity require a highly coordinated neurovascular unit (NVU). Neurons and vascular cells are not just adjacently located; they communicate with each other vigorously via different signaling modules. Pericytes are vascular mural cells of the endothelium and vital integrators of NVU functions, including maintaining the blood-brain barrier (BBB) and vascular integrity, regulating blood flow and tissue oxygenation, modulating neuroinflammation and supporting neuronal health. Pericyte injury and loss occur commonly in CNS diseases including Alzheimer's disease and dementia. Our current knowledge implicates a critical role of pericytes for neuronal functions, which calls for investigation of pericyte-neuronal communication for different neuronal functions in health and particularly in Alzheimer's disease. Using new 3D co-culture systems and novel transgenic models, we found that pericytes can directly regulate neurogenesis and neuronal functions, which can be attributed to pericyte-derived insulin-like growth factor 2. IGF2 is a peptide hormone with multiple roles in regulating metabolic functions and developmental processes. Patients carry IGF2 mutation and mice lacking IGF2 exhibited strong growth defects with abnormal neural development. IGF2 is produced locally in the brain; however, the roles of brain IGF2 in neurogenesis and neuronal dysfunction in CNS diseases are poorly understood. Our preliminary studies additionally indicated that IGF2 mediates pericyte-neuronal communication by activating a noncanonical IGF2R-Gαi-PLC pathway to enhance neuronal functions, as well as stimulating a canonical PI3K/Akt pathway to promote neurogenesis or suppressing Tau-phosphorylation. We hope to generate first evidence of functional pericyte-neuron crosstalk for brain function in health and diseases, and pinpoint the mechanism of this signaling at the molecular level for IGF2-mediated pericyte-neuron crosstalk. The outcomes may provide new insights to the IGF system and neurovascular interaction in the brain, and close an important gap between metabolic diseases and CNS neurodegenerative diseases such as AD.

Title: *In-vivo* tracking and biological function of engineered mesenchymal stem cell-secreted artificial transcription factors

Authors: *P. DENG[1], D. CAMERON[2], J. J. WALDO[2], J. A. HALMAI[2], U. BEITNERE[1], J. NOLTA[3], D. J. SEGAL[1], K. FINK[2];
[1]Genome Ctr., UC Davis, Davis, CA; [2]Neurol., [3]Stem Cell Program, UC Davis Med. Ctr., Sacramento, CA

Abstract: The advent of nuclease-deficient DNA binding domains (DBDs) such as zinc fingers and CRISPR/dCas9 for tunable gene expression have revolutionized approaches towards treating rare neurologic disorders. An effective delivery system that can traffic these proteins to target tissue remains a key barrier for translating gene modifying DBDs into the clinic. Cell-based delivery methods, such as mesenchymal stem cells (MSC), are an attractive delivery vehicle for DBDs due to their transient nature and ability to create favorable microenvironments through the release of trophic factors. Along with their strong clinical safety profile, MSCs can be readily reprogrammed to secrete large proteins and are not limited in their transgene packaging size like adeno-associated viral approaches. To evaluate this system, we have engineered bone-marrow derived MSCs to act as in-vivo biofactories that secrete DBDs into the extracellular space whereby the DBDs are uptaken by neighboring cells, and shuttled into the nucleus to alter gene expression.
Presently, we demonstrate the feasibility of this platform through in-vivo tracking of MSC-DBDs engineered to secrete a PET-reporter following multiple routes of cell administration: intranasal, intracerebral, and cisterna magna. Robust distribution of PET-reporter protein was observed along the spinal cord and in the brain of cisterna magna-transplanted mice.
Additionally, we evaluated the biological activity of secreted DBD following transplantation of MSC-DBD in a YFP-fused *Ube3a* reporter model of Angelman Syndrome. Significant activation of the YFP-fused *Ube3a* gene was observed 3- to 6- weeks following both cisterna magna and intracerebral transplantation as assessed by Western Blot and qPCR. Together, this is suggestive that an MSC-secretory system for DNA-binding domains can alter gene transcription in a durable fashion in mammalian organisms. Current ongoing experiments are evaluating the translational approach of this platform in non-human primates.

Title: Neural crest loss caused by Pak1ip1 mutation can be rescued by Tp53 inhibition

Authors: *A. A. PANOUTSOPOULOS[1,2], A. LEE[2,1], A. DE CRESCENZO[2,1], E. HELMKE[2], R. MARCUCIO[3], P. TRAINOR[4], K. ZARBALIS[2,1];
[1]UC Davis, Sacramento, CA; [2]IPRM - Shriners Children Hosp., Sacramento, CA; [3]Univ. of California, San Francisco, CA; [4]The Univ. of Kansas, Kansas City, MO

Abstract: Pak1ip1 has been characterized as a nucleolar protein required for ribosome biogenesis. Loss of Pak1ip1 stabilizes Tp53 by increasing the levels of freely circulating ribosomal proteins Rpl5 and Rpl11, which inhibit the Tp53 inhibitor Mdm2. In previous work, we have shown specific defects in cranial NC-derived structures in *Pak1ip1* mutant embryos, key amongst them midline facial clefting. These defects are apparently caused by increased neuroepithelial apoptosis and/or diminished proliferation during the formation and migration of cranial NC cells. Here, we show that pharmacological and/or genetic interference with Tp53 signaling can ameliorate or even prevent the mutant phenotype. Intriguingly, while pharmacological inhibition by Pifithrin-α(PFTα) can diminish phenotypic features and rescue NC cells, genetic*Tp53* inactivation has the capacity to completely prevent midline clefting. Rescue effectiveness is based on gene dosage with only homozygous *Tp53* loss leading to complete prevention of the median cleft. Morphological outcomes are associated with improvements in cell viability and proliferation within the neural plate and increased numbers of migrating NC cells in of *Pak1ip1; Tp53 compound* mutants compared to *Pak1ip1 mutant* embryos.

Title: Assessment of spine density and brain morphological phenotype in three rodent models of neurodevelopmental psychiatric disorders, poly(I:C): two-hit poly(I:C); and prenatal MAM rat model

Authors: *D. RADL[1], J.-C. BIZOT[2], S. DAVID[2], J. COMBEAU[2], F. MASSE[2], Y. OBAYASHI[1], N. CHEN[1], P. O'DONNELL[3], R. PETROSKI[4], O. TOURY[4], B. BUISSON[4], R. HODGSON[1];

[1]Takeda California, San Diego, CA; [2]Key-Obs, Orleans, France; [3]Takeda Pharmaceuticals, Cambridge, MA; [4]Neuroservice, Aix En Provence Cedex 3, France

Abstract: Prenatal infection and postnatal exposure to traumatizing experience are involved in the pathogenic processes of various neurodevelopmental psychiatric disorders such as schizophrenia. Dendritic spine number undergoes substantial changes during development. Spine density loss and cortical thinning is observed in patients with schizophrenia during adolescence. Excessive spine pruning is thought to underlie the reduced cortical gray matter volume in schizophrenia. The aim of the present study was to compare the morphological phenotype in young adult offspring of: 1. C57BL/6J mouse dams infected with polyriboinosinic-polyribocytidylic acid (poly I:C; 5 mg/kg ip on gestational day 15), 2. C57BL/6J mouse dams infected with a subthreshold exposure of polyriboinosinic-polyribocytidylic acid (1 mg/kg iv gestational day 9) that are exposed to stress, 3. Sprague-Dawley rat dams infected with methylazoxymethanol acetate (MAM). Cohort 2 was exposed to a sub-chronic unpredictable stress between post-natal day (PND) 35 and PND 43, a period which corresponds to the peripubertal period. Stress consisted of: Day 1 Electric foot shock (12 min 3 shocks), day 3 Restraint stress (45 min), day 5 Food deprivation (20 h: 12:00-08:00), day 7 Forced swimming test (18°C water, two 1-min FST 2 min apart), day 9 Repeated changing of home cage (5 changes irregular interval). A third cohort of pregnant rats received an IP injection of MAM (22 mg/kg) or saline on GD17. Rats of cohort 3 and mice of the cohort 1 were sacrificed at 9 weeks of age; mice of the cohort 2 were sacrificed at 6 weeks of age. The brains were harvested and used for several analyses: immunohistochemical analyses of inflammatory markers (IL1b) and glia morphology (CD11b, GFAP), spine analysis by Golgi staining and RNA extraction to analyze markers of inflammation (TNF-alfa, Il1b, IL6, C3, C4). These data provide a way to differentiate these three prenatal perturbation models of schizophrenia in terms of their impact on synaptic density and cortical thickness. These models will be further explored with behavioral and electrophysiological investigations for schizophrenia drug discovery programs.

Title: Longitudinal characterization of the *Cln8*$^{mnd-/-}$ mouse model of CLN8 Batten Disease - Fine motor performance, brain pathology and metabolic changes

Authors: K. LEHTIMÄKI[1], T. BRAGGE[1], *J. T. PUOLIVÄLI[1], J. RYTKÖNEN[1], P. POUTIAINEN[2], T. B. JOHNSON[3], J. T. CAIN[3], S. DAVIS[3], A. J. NURMI[1], J. WEIMER[3]; [1]Charles River Discovery, Kuopio, Finland; [2]Radiopharmacy, Kuopio Univ. Hosp., Kuopio, Finland; [3]Sanford Res., Sioux Falls, SD

Abstract: The naturally occurring *Cln8*$^{mnd-/-}$ mouse model of CLN8 Batten disease (B6.KB2-Cln8<mnd>/MsrJ, known also as Northern epilepsy) has been shown to exhibit progressive retinopathy, accumulation of autofluorescent lipopigment (stain positive for subunit c of mitochondrial ATPase), atrophy of neocortex and loss of cortical and hippocampal interneurons (Cooper JD et al. 1999, J Neurosci). However, relatively little is known on *in vivo* phenotype on neurometabolic profile in relation to brain atrophy and fine motor deficits. Here, we characterize the *Cln8*$^{mnd-/-}$ model from 2 to 8 months of age with a multimodal and longitudinal approach, combining advanced technologies such as kinematic gait analysis, MR based imaging techniques (T2 volumetry, DTI for white matter defects), spectroscopy (1H-MRS), and metabolic profiling (FDG PET). We have shown in our previous work in *Cln6*^{nclf} mice (bioRxiv, doi.org/10.1101/522011) that phenotypic fingerprint derived from longitudinal imaging and fine motor deficits can be identified and reduced to highly descriptive and significant metrics utilizing the contrastive PCA approach.
We used imaging, spectroscopic, and behavioral data collected from the same *Cln8*$^{mnd-/-}$ and wild type littermate controls (pooled and genders separated; 6 female and 6 male mice/genotype,) at 2, 4, 6 and 8 months of age. The data reduction and fusion were performed in two phases: first, PCA was applied separately to normalized parameter data from each modality. Then, the first phase PC scores were transformed into final scores using contrastive PCA (cPCA).
Data showed progressive nature of NCL resembling phenotype, with brain atrophy and neurometabolic disturbances obtained utilizing MR spectroscopy and PET-imaging. Abnormal motor performance was observed by fine motor kinematic analysis, and while declining motor performance is typical to Batten disease, the built-in motor neuron degeneration (mnd) origin in the mouse model is acknowledged. Contrastive PCA was capable of identifying the fingerprint typical to the model. Like we have shown in the previous works, this approach demonstrates how structural and functional readouts are connected using unbiased modeling and allows interventions with novel treatments with higher statistical window.

Abstract: **Rationale:** Bronchopulmonary dysplasia (BPD), a chronic lung disease, is the most common complication of prematurity. BPD is characterized by an arrest in lung growth and is an independent risk factor for adverse neurodevelopment. The potential implications of neural progenitor cells (NPCs), cells crucial for proper brain development, are unknown. Previously, we showed that intratracheal administration of umbilical cord-mesenchymal stromal cells (UC-MSCs), protects the lungs in a BPD rodent model. **We hypothesized** that NPCs are functionally impaired in experimental BPD, contributing to adverse neurodevelopment and further, that UC-MSC-derived exosomes can mitigate injury to NPCs in the brain. **Objective:** To asses NPC function in experimental BPD before and after UC-MSC administration. **Methods:** Two models of BPD were investigated. Neonatal C57/Black 6 mice were exposed to: i) 85% oxygen from postnatal day (P)0-P14 or ii) lipopolysaccharide at P7/8 and 8 hours of mechanical ventilation at P9/10, to mimic the conditions contributing to BPD in preterm infants. For treatment, mice (P9/10) were administered PBS or UC-MSC-derived exosomes intratracheally before ventilation. Exosomes were tracked using PKH26 staining. Age-matched control mice were housed in room air. NPC function was examined using sequential neurosphere assays. Mice were further assessed at 1 year for neurodevelopmental outcomes using a selection of motor, anxiety, and cognitive tests. **Results:** NPCs isolated from hyperoxia-exposed (n=5) and ventilated mice (n=7) formed significantly fewer secondary neurospheres compared to those isolated from control mice (P9/10, n=8; P14, n=5), indicating self-renewal impairments. One-year-old hyperoxia-exposed mice showed significant motor deficits on the rotarod test, a hypoanxiety phenotype on the light dark test, and learning and memory deficits during fear conditioning (controls, n=19; hyperoxia, n=12). NPCs from ventilated, exosome treated mice, formed significantly more secondary neurospheres compared to those isolated from PBS treated mice, indicating a rescue in self-renewal function (exosome, n=11; PBS, n=8). Labelled exosomes were identified in the lungs and NPC niche regions in the brain. No significant differences between sexes were observed. **Conclusions:** This study demonstrates that NPC function is impaired in BPD and that UC-MSC-

derived exosomes administered to target the lungs, results in remote organ protection, mitigating injury to NPCs in the brain. This critical research will strengthen the rationale for implementing UC-MSC therapy in the clinic, to reduce the life-threatening complications of preterm birth.

Title: 14-3-3gamma haploinsufficient mice display hyperactive and stress-sensitive behaviors

Authors: *C.-H. CHO[1], D. KIM[2], K. SIM[1], O. KWON[1], E. HWANG[3], H.-W. KIM[2], J.-Y. PARK[1];

Abstract: 14-3-3γ plays diverse roles in different aspects of cellular processes. Especially in the brain where 14-3-3γ is enriched, it has been reported to be involved in neurological and psychiatric diseases (e.g. Williams-Beuren syndrome and Creutzfeldt-Jakob disease). However, behavioral abnormalities related to 14-3-3γ deficiency are largely unknown. Here, by using 14-3-3γ deficient mice, we found that homozygous knockout mice were prenatally lethal, and heterozygous mice showed developmental delay relative to wild-type littermate mice. In addition, in behavioral analyses, we found that 14-3-3γ heterozygote mice display hyperactive and depressive-like behavior along with more sensitive responses to acute stress than littermate control mice. These results suggest that 14-3-3γ levels may be involved in the developmental manifestation of related neuropsychiatric diseases. In addition, 14-3-3γ heterozygote mice may be a potential model to study the molecular pathophysiology of neuropsychiatric symptoms.

Title: Phosphatidylinositol (4, 5)-biphosphate coordinates functional interactions in the dopamine transporter to promote amphetamine preference

Authors: *J. I. AGUILAR[1,2], S. J. MABRY[2], H. MATTHIES[2], A. GALLI[2];
[1]Vanderbilt Univ., Nashville, TN; [2]Dept. Surgery, Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: The psychostimulant amphetamine (AMPH) mainly mediates its pharmacological and behavioral effects by increasing extracellular dopamine (DA) availability. DA homeostasis is maintained by the dopamine transporter (DAT), a presynaptic membrane protein that mediates the high-affinity reuptake of released DA from the synaptic cleft. We have previously demonstrated that AMPH induces N-term phosphorylation of the DAT, which supports transport-mediated efflux of DA. Furthermore, we have shown that phosphatidylinositol (4, 5)-bisphosphate (PIP_2) directly interacts with the DAT and facilitates AMPH-induced DA efflux, but is not required for DA uptake. Specially, PIP_2 binds DAT through electrostatic interactions with positively charged DAT N-terminal residues. Disrupting the interactions between DAT and PIP_2 or depleting PIP_2 diminishes reverse transport (efflux) of DA. Previous studies on the human serotonin transporter show that non-N-terminal PIP_2 binding sites (within the fourth intracellular loop) modulate transporter function. Here, we show that a neutralizing substitution of residue R443 to Ala, which resides in the fourth intracellular loop of DAT, decreases DAT/PIP_2 interactions and AMPH-induced DA efflux, despite normal DA uptake. As such, this DAT variant dissociates forward transport (uptake) from reverse transport (efflux), allowing specific transport functions of the DAT to be studied independently. Using a coordinated genetic and pharmacological approach in *Drosophila melanogaster,* we translate our molecular discoveries *in vivo* to probe the physiological role for DAT efflux in motivated behavior. We uncover that residue R443 in the DAT regulates both AMPH-induced DA efflux and psychomotor behaviors, including preference.

Title: Subcellular localization of the dopamine transporter in nigrostriatal axons of the mouse medial forebrain bundle

Authors: K. BUCCHIN[1], J. BALCITA-PEDICINO[1], A. SORKIN[2], ***S. R. SESACK**[1]; [1]Neurosci., [2]Cell Biol., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The structure and function of the nigrostriatal pathway has been extensively examined at the level of midbrain dopamine (DA) cell bodies and their axons within the striatal complex. To date, no ultrastructural studies have visualized the axons that interconnect these regions within the medial forebrain bundle (MFB). Furthermore, we have previously reported the subcellular localization of the DA transporter (DAT) in the dorsolateral striatum (DLStr), showing that DAT is dominantly expressed on the plasma membrane of axons and minimally observed at internal sites: synaptic vesicles, small endosomes, and multivesicular bodies (Block et al., 2015 *J Neurosci* 35:12845). Here, in addition to investigating the morphological features of DA axons in the MFB, we sought to determine whether the transit of DAT through this region involves primarily diffusion in the plasma membrane or transport through intracellular organelles. Transgenic mice with a hemagglutinin (HA) tag incorporated into the DAT protein were used for these studies. Confocal immunofluorescence microscopy imaging of HA-DAT in the MFB showed axons of greater thickness than reported for the DLStr. Vesicular structures labeled for HA-DAT were also observed in MFB axons. The subcellular localization of HA-DAT in the MFB was further examined by immunogold-silver labeling and electron microscopy in 4 mice from the 2015 study. 166 axons labeled for HA-DAT were analyzed and had a mean diameter of 0.58 µm (± 0.02 µm, SEM), substantially larger than intervaricose axons in the DLStr (average of 0.24 µm; Descarries et al., 1996 *J Comp Neurol* 375:167) and larger as well than axon initial segments of nigral DA cells (average of 0.37 µm; González-Cabrera et al., 2017 *J Comp Neurol* 525:3529). Although the majority of immunogold-silver particles for HA-DAT were observed on the plasma membrane of these axons, the proportion of membrane gold was noticeably lower for the MFB than previously reported for the DLStr: 64% versus 84%, respectively. Of the 36% of HA-DAT detected intracellularly, roughly 37% was found in association with vesicles or slightly larger endosomes. The results indicate that nigrostriatal axons increase diameter as they travel through the MFB and that DAT is transported via both membrane diffusion and internal organelles. The findings have important implications for

understanding action potential conduction and trafficking of DAT within the nigrostriatal bundle in both the healthy state and in neurological disorders.

Title: Dopamine and adenosine signaling pathways are analyzed in striatal medium spiny neurons using kinase-associated neural phospho-signaling (KANPHOS) database

Authors: *X. ZHANG[1], T. NAGAI[2], K. KURODA[1], K. KAIBUCHI[1];
[1]Dept. of Cell Pharmacol., [2]Dept. of Neuropsychopharm. and Hosp. Pharm., Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan

Abstract: Protein phosphorylation is one of the most ubiquitous and essential mechanisms mediating intracellular signal transduction in various cellular processes. However, a large number of substrates that account for various kinases' function remain to be elucidated. To identify the specific substrates for the specific kinases, we have developed an in vitro approach termed the kinase-interacting substrate screening (KISS) method and an in vivo approach termed the kinase-oriented substrate screening (KIOSS) method. An online database system named KANPHOS (Kinase-Associated Neural Phospho-Signaling) were built, providing the phosphorylation signals identified by our methods. In the midbrain, dopaminergic neurons mainly project toward the striatum. Medium spiny neurons (MSNs) expressing dopamine D1 receptor (D1R) or D2 receptor (D2R) are major components of the striatum. Stimulation of D1R activates PKA through Gs to increase neuronal activity in D1R-MSN, while D2R stimulation inhibits PKA through Gi in D2R-MSN. By using KIOSS method, we found more than 100 PKA substrate candidates downstream of D1R including Rasgrp2 and Rap1gap, which are positive and negative regulators of the small G protein Rap1, respectively. We demonstrated that dopamine activates PKA to increase Rap1 activity through Rasgrp2 and Rap1gap phosphorylation in D1R-MSN. Rap1 activation increases D1R-MSN's neuronal excitability to enhance rewarding behavior (Nagai et al. Neuron, 2016). In D2R-MSN, adenosine A2A receptor

(A2AR) coupled to Gs is highly expressed. However, how dopamine and adenosine co-operatively regulate PKA activity remains largely unknown. Here, we measured Rap1gap serine 563 phosphorylation to monitor PKA activity and examined dopamine and adenosine signals in MSNs. We found that A2AR agonist CGS21680 increased Rap1gap phosphorylation, and pretreatment with the D2R agonist quinpirole blocked this effect in striatal slices. D2R antagonist eticlopride increased Rap1gap phosphorylation in D2R-MSN in vivo, and the effect of eticlopride was blocked by the pretreatment with the A2AR antagonist SCH58261. These results indicate that adenosine positively regulates PKA in D2R-MSN through A2AR, while this effect is blocked by basal dopamine in vivo. We propose that the shift from D1R-MSN to D2R-MSN or vice versa appears to depend predominantly on a change in dopamine concentration. In addition to Rap1 pathway, we also found some regulators of small G protein RhoA among PKA substrate candidates. We here discuss phospho-proteomic approach and our findings based on our database.

Title: Striatal dopamine in time and space: Effects of methylphenidate

Authors: M.-T. HSU[1], J. A. CHOUINARD[1], N. KITAMURA[1], K. LIYANAGAMA[1], L. TIAN[2], ***J. R. WICKENS**[1];
[1]Okinawa Inst. of Sci. and Technol., Onna, Japan; [2]Biochem. and Mol. Med., Univ. of California at Davis, Davis, CA

Abstract: Methylphenidate - a widely used and effective medication for attention-deficit hyperactivity disorder - is known to be a dopamine reuptake inhibitor at molecular level. However, its macroscopic effects are incompletely understood. We investigated the effects of methylphenidate on the spatiotemporal distribution of dopamine in the striatum. Using fast-scan cyclic voltammetry we measured the time-course of concentration changes at single locations after electrical stimulation (20 pulses at 10 Hz, biphasic, 2 ms per phase, 2-5V). When clearance of dopamine is reduced by bath application of methylphenidate (30 μM), the peak concentration of dopamine measured at a single distant point is delayed several tens of milliseconds after the end of the stimulation. This cannot be explained by a simple time delay due to diffusion time because there is no corresponding delay in onset of dopamine increase at the distant recording site. We hypothesized that the immediacy of the initial increase in dopamine can be explained by electrical current spread causing release at distant sites, while the delayed peak is due to

diffusion delays. A two-compartment model of dopamine concentration was implemented, in which electrically-stimulated release, reuptake and diffusion occurred in both compartments. Predictions of the model were compared to the experimental data and produced good quantitative fit. These findings partially support the two-compartment model. To test whether the model assumptions were correct, we obtained measurements of the spatiotemporal distribution of dopamine in two dimensions, using variants of the genetically encoded dopamine sensor, dLight, and epifluorescence imaging. These measurement showed that increases in dopamine concentration occurred simultaneously over the imaged area, consistent with an effect of current spread. The effect of methylphenidate on apparent diffusion distance of dopamine may be important for understanding its effects on processing of reward signals and its mechanisms of action in the treatment of attention-deficit hyperactivity disorder.

Title: High time resolution analyses in online microdialysis experiments for dopamine and serotonin

Authors: *H.-J. BROUWER[1], M. EYSBERG[2], L. VAN HEERWAARDEN[1], N. REINHOUD[1]; [1]Antec Scientific, Zoeterwoude, Netherlands; [2]Antec Scientific (USA), Boston, MA

Abstract: Microdialysis in vivo is an important sampling technique for continuous monitoring of neurotransmitter concentrations in the living brain. Extracellular fluid of the brain is sampled through a semipermeable membrane in a microdialysis probe, followed by HPLC analysis for quantification. However, HPLC analysis requires fractionation of the sample stream, and the size of the fractions will affect time resolution. Typical flow rates in microdialysis are 1 - 2 µL/min. In case of conventional HPLC, which require typical injection volumes of 10 µL - 20 µL, such samples represent a time resolution of 5 to 20 min. Such time resolution is not enough to accurately describe fast neural responses that take place within a few minutes. Therefore, decreasing the fraction size to a few microliters is necessary to enable measurements with a temporal resolution of 1 to 2 minutes. We developed a robust commercially available on-line solution for the simultaneous analysis of DA and 5-HT with high time resolution in microdialysis experiments. The solution is based on a UHPLC system equipped with a dual loop sampling valve in combination with the new DECADE Elite electrochemical detector and SenCell. Small samples with a volume of 1.5 µL were collected online into the dual loop sampling valve and

simultaneously analyzed (see figure 1). With this approach a temporal resolution of less than 2 minutes can be reached, with a detection limit of 100 pmol/L for both DA and 5-HT.

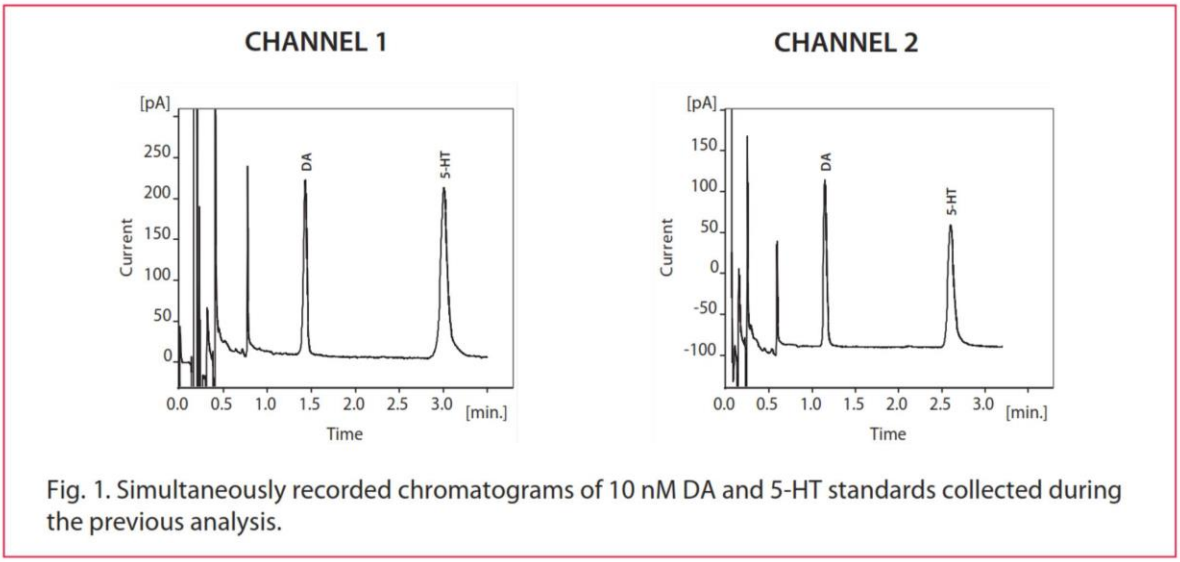

Fig. 1. Simultaneously recorded chromatograms of 10 nM DA and 5-HT standards collected during the previous analysis.

Title: Regulator of G protein signaling-12 modulates the expression and function of the serotonin transporter (SERT)

Authors: *A. N. WHITE[1], J. D. GROSS[2], S. W. KASKI[3], K. R. TREXLER[4], R. M. RODRIGUIZ[8], A. B. SCHROER[5], K. A. WIX[2], W. C. WETSEL[8], S. G. KINSEY[6], D. P. SIDEROVSKI[2], V. SETOLA[7];

Sch. of Med., Morgantown, WV; [4]Dept. of Psychology, [5]Dept. of Physiol. and Pharmacol., [6]Dept. of Psychology and Dept. of Neurosci., [7]Dept. of Neuroscience, Dept. of Behavioral Med. & Psychiatry, West Virginia Univ., Morgantown, WV; [8]Dept Psychiat & Behav Sci., Duke Univ. Med. Ctr., Durham, NC

Abstract: Regulators of G protein signaling (RGS) proteins inhibit G protein signaling by acting as GTPase accelerating proteins for the G-alpha subunits of G protein heterotrimers. G protein coupled receptors (GPCRs) constitute a significant portion of the druggable proteome and mediate responsiveness to multiple neurotransmitters; thus, a deeper understanding of the mechanisms by which particular, CNS-resident RGS proteins regulate G protein signaling could lead to the development of novel neuropsychopharmacologic agents. Our labs have previously shown that mice lacking RGS12 exhibit reduced hyperlocomotion in response to the dopamine system-dependent psychostimulant amphetamine (Gross, Kaski, *et al.*, 2018, *J Psychopharm*.). This prior finding led us to investigate whether RGS12 loss also attenuates behavioral responses to the serotonin system-dependent psychostimulant 3,4-methylene-dioxymethamphetamine (MDMA). Here, we report that these mice display a bimodal locomotor response to MDMA: hyperlocomotion to 10 mg/kg MDMA is markedly reduced in RGS12-null mice; however, RGS12-null mice exhibit augmented hyperlocomotion to a 30 mg/kg dose compared to wildtype littermate controls. To evaluate whether SERT expression and/or function of the serotonin transporter (SERT) is disrupted upon RGS12 loss, [^{3}H]citalopram binding and [^{3}H]serotonin (5-HT) uptake assays were performed. Increased numbers of [^{3}H]citalopram binding sites are found in the cortex and midbrain of RGS12-null mice, as well as increased citalopram-sensitive [^{3}H]5-HT uptake in the cortex, midbrain, and ventral striatum. In contrast, we observed no differences in [^{3}H]citalopram binding nor [^{3}H]5-HT uptake in the hippocampus or dorsal striatum, indicating that RGS12 loss engenders SERT dysfunction in a region-specific manner. These biochemical observations support the notion that basal serotonergic neurotransmission is disrupted upon RGS12 loss. To further elucidate this hypothesis, we are now testing RGS12-null mice and wildtype littermate controls in behavioral paradigms typically associated with/affected by SERT-acting drugs. Taken together, our data will demonstrate that RGS12 is a previously unidentified modulator of serotonergic neurotransmission.

Title: A mechanism of serotonin transporter regulation by cholesterol biosynthetic intermediates

Authors: *C. M. MITCHELL[1], B. K. YAMAMOTO[2];
[2]Pharmacol. and Toxicology, [1]Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: The serotonin transporter (SERT) is necessary for the regulation of serotonin in the brain through transport of extracellular serotonin (5HT) into neuron terminals. The activity of SERT is thought to be modulated in part by cholesterol and lipid rich microdomains within the plasma membrane where SERT localizes. These microdomains aid in SERT protein-protein interactions and post-translational modifications that modify SERT and modulate the amount and rate at which 5HT is removed from the synapse. However, experiments related to the mechanism of membrane cholesterol on SERT function in the brain has yielded conflicting results and no studies have examined the contribution of cholesterol biosynthetic intermediates in regulating SERT function. To investigate the role of cholesterol and its biosynthetic intermediates on neuronal SERT function, serotonergic RN46A-B14 cells were stably overexpressed with myc-tagged SERT. Simvastatin was used to block synthesis of cholesterol and cholesterol biosynthetic intermediates by blocking the rate limiting enzyme HMGCoA reductase. 5HT transport was assayed by measuring 5HT taken up by cells after incubation with exogenous 5HT. As expected, simvastatin treatment decreased total cell cholesterol. Unexpectedly, simvastatin increased 5HT uptake in a manner blocked by fluoxetine. Kinetic analyses showed a shift in the Km and Ki, but not the Vmax for 5HT. However, biotinylation studies demonstrated enhanced SERT and higher molecular weight SERT at the plasma membrane, suggesting the formation of higher order oligomeric SERT complexes induced by simvastatin. To demonstrate a role for cholesterol in simvastatin-mediated 5HT uptake, cholesterol was repleted during simvastatin treatment. Cholesterol repletion did not block simvastatin-enhanced 5HT uptake, but the addition of cholesterol biosynthetic intermediates farnesyl and geranylgeranyl pyrophosphate blocked the enhanced uptake. Lastly, our results are supported by *in vivo* studies showing enhanced 5HT uptake in the prefrontal cortex of rats administered 10 mg/kg/day simvastatin intraperitoneal for 7 days. These results indicate that simvastatin enhances 5HT uptake via SERT in a manner dependent on cholesterol biosynthetic intermediates, but independent of cholesterol per se.

Abstract: The neurotransmitter serotonin is important for modulating complex behaviors including appetite, mating, and sleep. The duration and intensity of serotonin signaling are mediated by the plasma membrane serotonin reuptake transporter (SerT). We used molecular techniques to 1) tag dSerT for subcellular localization mapping and 2) mutate dSerT to increase sensitivity to serotonergic drugs in the fruit fly *Drosophila melanogaster*. To map dSerT expression, we engineered a transgene containing dSerT cDNA with an N- terminal epitope tag hemagglutinin (HA). HA-SerT was expressed *in vitro* (insect cells) and *in vivo* (flies) to examine subcellular localization. SerT is found in both *Drosophila* and humans, however, dSerT is less sensitive to pharmacological inhibition. To bypass this, we have "humanized" dSerT by introducing a point mutation (M167I) into the *Drosophila* gene. The effect of this mutation on drug response was examined in both insect cell lines and *in vivo*. These tools allow us to pharmacologically control serotonin signaling and examine the molecular mechanisms of serotonergic neuromodulation.

Title: *Ex-vivo* dynamics of serotonergic fibers

Authors: *M. T. HINGORANI[1], A. M. VIVIANI[1], J. E. SANFILIPPO[1], S. N. SIU[1], J. C. CHIU[1], J. L. SELF[2], C. M. BATES[2], S. JANUSONIS[1];
[1]Psychological & Brain Sci., [2]Materials, Univ. of California Santa Barbara, Santa Barbara, CA

Abstract: Experimental evidence and computer simulations strongly suggest that brain serotonergic axons (fibers) perform random walks in their terminal fields. Since these walks are likely to underlie the self-organization of regional serotonergic densities, they have important

implications for fundamental and applied neuroscience. Pathological changes in the dynamics of fibers may lead to alterations in serotonergic signaling in a number of mental disorders, including major Depressive Disorder and Autism Spectrum Disorder.
Recently we have introduced several mathematical models that can reproduce the properties of serotonergic fiber trajectories in fixed brain tissue (Janusonis and Detering (2019) *Biochimie*, in press; Janusonis, Mays, Hingorani (2019) *ACS Chemical Neuroscience*, in press). However, the selection among these models is complicated by two problems: (i) little information is available about the spatial geometry of micro-obstacles serotonergic fibers have to navigate and (ii) no temporal information can be extracted from fixed preparations. This lack of experimental data significantly impacts theoretical analyses, especially those based on continuous-time processes (step-wise random walks are simpler but less realistic biologically).
In the study, we co-cultured mouse serotonergic neurons and rat glia to study the dynamics of serotonergic axons. We used standard culture conditions and also investigated the possibility of growing axons in artificial, structured spatial environments, such as hydrogels. These experimental approaches can provide key data for stochastic modeling of individual serotonergic fibers (e.g., using Fractional Brownian Motion), as they evolve in time, and can support predictive approaches to the self-organization of the brain serotonergic system.

Title: Transcriptomically polarized subtypes of median raphe serotonergic neurons have divergent bouton neurochemical phenotypes targeting distinct brain regions

Authors: *R. A. SENFT, M. E. FRERET, S. M. DYMECKI;
Harvard Med. Sch., Boston, MA

Abstract: The median raphe (MR), a brainstem nucleus enriched in neurons producing serotonin (5-hydroxytryptamine, 5-HT), is important in a variety of emotional and cognitive processes and behaviors. Serotonin neurons of the MR, while populating a single anatomical nucleus, arise developmentally from three distinct embryonic progenitor cell compartments - rhombomeres (r) - each transcriptomically unique and each generating 5-HT neurons transcriptomically distinct

from one another. Moreover, the MR 5-HT neuronal lineage arising from r2 can be further subdivided transcriptomically, as revealed by our recent single-cell RNAseq findings [Okaty et al., 2015; Okaty and Dymecki, 2019.]. One sub-sublineage is classically 5HTergic and referred to as *Pet1-Tph2*^{high}, while the other sub-sublineage appears more glutamatergic and is referred to as *Pet1-Tph2*^{low}. Unknown is how these mRNA profiles relate to the neurochemical phenotypes of their highly collateralized axons and boutons; equally lacking is an understanding of how neurotransmission may be differentially regulated across their numerous target regions. We performed immunohistochemistry and *in situ* hybridization in brain sections from mice expressing synaptophysin-GFP to mark boutons from r2-derived 5-HT neurons (referred to as *r2Hoxa2-Pet1* cells). We found region-specific neurochemical bouton distributions consistent with three types of innervation: primarily 5-HT-only, Vglut3-only, or a mixture of Vglut3-only and 5-HT/Vglut3 dual positive boutons, the latter suggestive of co-transmission. Dual positive boutons in the septum preferentially associated with pericellular baskets, a structure which coordinates dense axonal targeting to the cell soma, suggesting these boutons may be strategically located for temporally precise and highly effective control of target cell activity. Finally, we queried the cell identity of basket targets, finding different interneuron populations depending on bouton type and target region. These results suggest a model wherein 5-HTergic *r2Hoxa2-Pet1* cells innervate thalamic and hypothalamic regions and the olfactory bulb while putative glutamatergic cells innervate hippocampus, cortex, and the septum, with each subtype poised to modulate different populations of interneurons. Our results demonstrate the neurochemical heterogeneity and segregation of axonal boutons within a developmentally-defined 5-HT neuron subtype. This work enhances our understanding of Pet1 neuron neurochemical diversity and circuit interactions in the adult forebrain.

Title: Molecular diversity of 5-HT neurons of the mouse dorsal raphe nucleus

Authors: *B. W. OKATY, N. STURROCK, O. V. ALEKSEYENKO, K. A. LYON, S. M. DYMECKI;
Harvard Med. Sch., Boston, MA

Abstract: Serotonin (5-HT) is a monamine neurotransmitter released throughout the nervous systems of all organisms, where it regulates numerous biological processes crucial to health and survival. In vertebrates, brainstem neurons that synthesize and release 5-HT are often viewed as a single neuron type based on neurotransmitter identity, however 5-HT neurons display wide-ranging phenotypic diversity, including heterogeneous anatomy, morphology, hodology, electrophysiology, neurochemistry, and gene expression. These diverse molecular and cellular properties are likely critical determinants of the higher-order physiological, behavioral, cognitive, and affective functions supported by the 5-HT neuronal system as a whole. Recent findings by our group and others promote the hypothesis that phenotypically distinct 5-HT neuron subtypes modulate distinct functions. While 5-HT neuronal diversity is increasingly recognized by the field, a consensus framework for rigorously defining 5-HT neuron subtypes, linking these subtypes to specific functions, and understanding how micro-, meso-, and macro-scale properties of the 5-HT neuronal system interact is presently lacking. Here we present the results of our latest efforts towards these ends, focused specifically on mouse 5-HT neurons with cell somata located in the dorsal raphe nucleus (DR). We performed single cell RNA-seq of intersectionally labeled and sorted 5-HT neuron subgroups from microdissected subdomains of the DR followed by unbiased clustering and differential expression analyses to identify 5-HT neuron molecular subtypes. Specifically, we generated triple transgenic mice by crossing Pet1-Flpe mice (a pan 5-HT driver) with a number of Cre driver mice, including Npy2r-Cre, Crh-Cre, Slc17a8-Cre, Sert-Cre, and P2ry1-Cre, in combination with dual recombinase responsive fluorescent reporter lines. We found a relationship between molecularly and anatomically defined subtypes, with significant gene expression differences between 5-HT neurons located in dorsolateral, dorsomedial, ventromedial, or caudal subcompartments. We also found diverse molecular subtypes intermingled within a given anatomical subdomain, arguing against a simple anatomical organization of 5-HT neuronal diversity. We are currently working towards functional and hodological characterization of these molecularly and anatomically defined subtypes by intersectionally combining different marker and effector mouse lines and performing behavioral and physiological assays.

Title: Serotonin and histamine modulation in inflammation: Implications in depression

Authors: *M. HERSEY[1], S. N. BERGER[4], J. L. WOODRUFF[2], P. HASHEMI[4], L. P. REAGAN[3];
[2]Pharmacology, Physiol. and Neurosci., [3]Pharmacology, Physiol. & Neurosci., [1]Univ. of South Carolina Sch. of Med., Columbia, SC; [4]Univ. of South Carolina, Columbia, SC

Abstract: Neuroinflammation is associated with changes to the central nervous system (CNS) and plays a role in the pathology of depression and many other psychiatric diseases. By targeting the neurotransmitter systems of serotonin and histamine we aim to understand the neurochemical underpinnings of depression. Serotonin has long been hypothesized to play a role in depression as serotonin signaling is often impaired during depression. Histamine has a well-established role in peripheral inflammation and novel data showing that histamine release inhibits serotonin signaling justifies the need to consider the two neurotransmitters in tandem. In this work, fast-scan cyclic voltammetry (FSCV) is used to simultaneously measure the release and reuptake of histamine and serotonin, in the posterior hypothalamus and fast-scan controlled adsorption voltammetry (FSCAV) is used to measure ambient serotonin in the hippocampus of rodents following acute (peripheral injection of lipopolysaccharide) or chronic (high fat diet (45 kcal % fat) and chronic mild stress) neuroinflammation. Biochemical (for inflammation) and behavioral (for depression) analysis are correlated with neurochemical measurements. Our preliminary results allow us to hypothesize that inflammation corresponds to increased histamine release, thus increasing the inhibition of serotonin. We also find that the capacity of selective serotonin reuptake inhibitors (SSRIs), like escitalopram, to increase extracellular serotonin by inhibiting serotonin transporters (SERTs) is reduced in both inflammation models. However, a targeted decrease in histamine synthesis was able to increase SSRI efficacy. These results suggest that histamine plays a fundamental role in modulating serotonin during inflammation, thereby providing a novel therapeutic target as well as providing insights into the neurochemical basis for depressive illness.

Title: Inhibition of presynaptic monoamine transporters by the HIV-1 viral protein Tat in the prefrontal cortex: Evidence from a transgenic mouse model

Authors: *M. J. STRAUSS[1], B. O'DONOVAN[2], P. I. ORTINSKI[3], J. P. MCLAUGHLIN[4], J. ZHU[5];
[1]Univ. of South Carolina, Columbia, SD; [2]Pharmacology, Physiol. and Neurosci., [3]Pharmacology, Physiology, and Neurosci., Univ. of South Carolina, Columbia, SC; [4]Univ. of Florida, Gainesville, FL; [5]Drug Discovery and Biomed. Sci., Col. of Pharmacy, Univ. of South Carolina, Columbia, SC

Abstract: Abnormal dopaminergic transmission has been implicated as a mediating factor of HIV-1 associated neurocognitive disorders (HAND). Our laboratory has demonstrated that *in vitro* HIV-1 Tat protein reduces dopamine transporter (DAT) function via a direct allosteric interaction. This study determined whether the inhibitory effects of Tat on DAT function could be replicated in an inducible Tat transgenic (iTat) mouse model. Additionally, as the norepinephrine transporter (NET) is also responsible for the reuptake of dopamine in the prefrontal cortex (PFC), an area which has been linked to cognitive functioning, and shares a high level of homology with the DAT, effects of Tat on this transporter were also investigated. Following 7-day administration of doxycycline (Dox) or saline, the maximal velocity (V_{max}) of [^{3}H]dopamine uptake via the DAT and the NET in PFC of Dox-treated iTat mice was decreased by 27% and 34%, respectively, compared to their saline controls. 14-day Dox treatment demonstrated similar inhibition, as the V_{max} of [^{3}H]dopamine uptake via DAT and NET in the PFC was reduced by 34% and 22%, respectively. No differences in the V_{max} were found between Dox and saline treated control C57BL/6J mice. The reduction in DAT and NET function in the PFC was accompanied by a similar decrease in available substrate binding sites, with 7-day Dox treated mice displaying a 28% decrease in [^{3}H]WIN 35,428 binding to the DAT and a 36% decrease in [^{3}H]Nisoxetine binding to the NET. These decreases in function and substrate binding were not due to changes in total protein expression. Furthermore, whole-cell patch clamp recordings in layer V pyramidal neurons of the prelimbic cortex, which primarily project to subcortical dopaminergic structures such as the striatum and VTA, revealed a decreased action potential firing frequency from these neurons. Our findings demonstrate the extent to which

HIV-1 Tat may disrupt the presynaptic monoamine transport system and induce dysregulation of dopamine homeostasis, which ultimately may underlie the neurocognitive impairment evident in HAND patients.

Title: Examining monoamine oxidase inhibitor targets using *Caenorhabditis elegans*

Authors: M. J. VINCE[1], *J. S. DUERR[2];
[1]Dept. of Biol. Sci., [2]Ohio Univ., Athens, OH

Abstract: Monoamines (MA) are neurotransmitters and hormones in humans and *Caenorhabditis elegans* that are responsible for ionotropic and metabotropic signaling. MAs in humans include serotonin, dopamine, epinephrine and norepinephrine; C. *elegans* use serotonin, dopamine, octopamine, and tyramine. Changes in MAs are important in several psychological neurological disorders such as depression, Parkinson's disease, anxiety, and schizophrenia. Monoamine oxidases (MAO) are enzymes that degrade MA in presynaptic cells. Monoamine oxidase inhibitors (MAOIs) inhibit MAOs and generally increase MA signaling.
In our research, we are using the model organism C. *elegans* to examine the genetic targets of two prescribed MAOIs: tranylcypromine (prescribed for depression and anxiety) and phenelzine (prescribed for Parkinson's disease). In *C. elegans*, monoamines alter egg laying, metabolism, habituation, feeding, and movement. Mutations in the single identified MAO (*amx-2*) decrease, but do not eliminate responses to these MAOIs. Since these MAOIs are structurally similar to MAs, other possible targets for the drugs are MA receptors.
We have examined the responses to these drugs in mutants lacking MA synthesis and/or receptors. Our current work focuses on four genes. The gene *cat-2* encodes tyrosine hydroxylase, an enzyme required for synthesis of dopamine. *tdc-1* encodes tyrosine decarboxylase, an enzyme essential for synthesis of octopamine and tyramine. We have observed that *cat-2* and *tdc-1* mutants are behaviorally hypersensitive to both tranylcypromine and phenelzine. This may be due to the remaining MAs. On the other hand, mutants in *dop-3*, which encodes a dopamine type DRD2 receptor, are hypersensitive to tranylcypromine, but not phenelzine while mutants in *lgc-*

55, which encodes a tyramine gated chloride channel receptor, are hypersensitive to phenelzine, but not tranylcypromine. To test whether these receptors are likely to be direct targets of MAOIs, we have constructed mutants that knockout both monoamine synthesis and monoamine receptors and are examining their behavioral sensitivity to specific MAOIs.

Title: Behavioral and molecular analysis of a monoamine oxidase zebrafish mutant

Authors: *D. BARONIO, Y. C. CHEN, P. A. PANULA;
Univ. of Helsinki, Helsinki, Finland

Abstract: The monoamine oxidases (MAO) degrade biogenic and dietary monoamines and are key regulators of the monoaminergic systems. Disrupted functioning of these regulators plays a role in the pathophysiology of some brain disorders, such as schizophrenia and autism spectrum disorder (ASD). Zebrafish has become a valuable tool in neuroscience because it shares key genes with humans and possesses all main neurotransmitter systems. Differently than mammals, zebrafish possesses only one *mao* gene which shares some properties of both mammalian *MAO* genes. Surprisingly, *mao* zebrafish mutants remain uncharacterized and their relevance to study the pathophysiology of major disorders is uncertain. Thus, we characterized behavioral and molecular phenotype of *mao* zebrafish mutants. Neurotransmitter systems including catecholaminergic, serotonergic and histaminergic ones were analyzed by immunohistochemistry. qPCR was utilized to study genes relevant for ASD and neuropsychiatric disorders. Locomotor activity, sociability and anxiety-like behavior were evaluated. Surprisingly, *mao* knockout (KO) fish died within 2 weeks post-fertilization. At 10 days post-fertilization (dpf) they showed a hypoactive phenotype during a 24 hours locomotor activity evaluation, whereas heterozygous (HET) animals behaved similarly with the wild-type (WT) fish. KO animals presented strong intra- and extracellular brain serotonin immunoreactivity, which probably had a toxic effect towards other adjacent cell populations. This was indicated by the reduced number of histamine and tyrosine hydroxylase 1 (TH1)-positive cells. We also found strong GFAP immunoreactivity in the brains of KO animals that was confirmed by qPCR. The qPCR also

showed reduced levels of Mecp2 mRNA in HET fish at 10 dpf. Mecp2 expression is attenuated in different models of ASD. In a social preference test adult *mao* HET fish navigated more distantly from the social cue and showed a hyperactive phenotype during part of the trial. They also showed an anxious-like behavior in the novel tank test. These results indicate that the phenotype of *mao* zebrafish mutants resembles some of the molecular and behavioral features of brain disorders that have MAO deficiency as a feature. An in-depth analysis of this model is necessary to reveal in detail mechanisms behind the premature death of KO animals and the impaired behavior displayed by *mao* HET fish.

Title: New insights into amphetamine-induced efflux by employment of genetically encoded biosensors in dopaminergic neurons

Authors: *J. F. STØIER, S. H. JØRGENSEN, M. A. C. GREGOREK, A. T. SØRENSEN, F. HERBORG, U. GETHER;
Dept. of Neurosci., Univ. of Copenhagen, Copenhagen N, Denmark

Abstract: Amphetamines are widely abused as well as commonly prescribed for treating children with ADHD. The compounds are substrates for the dopamine transporter (DAT) and once inside the cell, amphetamines can indirectly reverse the transport of DAT through activation of intracellular signaling pathways. However, the current insights into how amphetamines activate such intracellular signaling in dopaminergic neurons is baffling with a majority of studies being performed in heterologous cells. Here, we employ genetically encoded sensors expressed in cultured midbrain neurons to achieve a better understanding of how amphetamines induce reversal of DAT function. To ensure selective expression in dopaminergic neurons, we used an adeno-associated virus to mediate tyrosine hydroxylase promotor driven Cre expression. This enabled the expression of different genetically encoded biosensors in the dopaminergic neurons using Cre-dependent constructs of the sensors. By expressing the recently developed green dopamine sensor dLight1.1 in the dopaminergic neurons, it was possible to directly visualize amphetamine-induced efflux. Addition of amphetamine to the culture caused a detectable increase in dLight1.1 fluorescence that was strongly amplified by preloading of the culture with dopamine. To assess in parallel putative changes in intracellular calcium levels in

response to amphetamine, the red calcium sensor JrGECO1a was co-expressed with dLight1.1. Amphetamine has previously been reported to elicit a calcium response and activate Ca^{2+}/calmodulin-dependent protein kinase II. However, we did not find any evidence for such an increase in intracellular calcium upon addition of amphetamine to the culture. In contrast, we observed large increases in intracellular calcium levels when stimulating NMDA-type ionotropic glutamate receptors and by activating G_q-coupled muscarinic receptors in the dopaminergic neurons. In conclusion, we have established an experimental set-up ideally suited for studying the cellular basis for amphetamine-induced efflux. Our current results strongly challenge the importance of intracellular calcium for amphetamine-induced efflux, underlining that further studies are required to unravel the complex actions of amphetamine in dopaminergic neurons.

Title: Rare genetic variants in monoamine transportes as a risk factor for neuropsychiatric disease? - Insights from a population based case-cohort sample

Authors: *F. HERBORG[1], V. APPADURAI[2], A. B. DEMUR[2], T. WERGE[2], U. GETHER[3]; [1]Dept. of Neurosci., Univ. of Copenhagen, Copenhagen, Denmark; [2]The Lundbeck Fndn. Initiative for Integrative Psychiatric Res., Copenhagen Univ. Hosp., Copenhagen, Denmark; [3]Fac. of Hlth. and Med. Sciences, Univ. Copen, Copenhagen N, Denmark

Abstract: The monoaminergic circuits of the brain have long been implicated in the aetiology and symptomatology of most common neuropsychiatric diseases. The monoamine transporters (MAT) are key regulators of monoaminergic neurotransmission and serve as principal targets for neuropsychiatric therapeutics. Nevertheless, it is unclear if MAT dysfunction can directly influence the risk of developing neuropsychiatric diseases. Using exome sequencing data from a cohort of ~20.000 controls and cases diagnosed with attention deficit hyperactivity disorder, (ADHD), autism spectrum disorder (ASD), schizophrenia, single or recurrent depression, or bipolar disorder, we investigated if rare genetic variants of monoamine transporters may contribute to the genetic architecture of neuropsychiatric diseases at a populational level. By

comparing the occurrence and allelic diversity of rare variants in genes encoding monoamine transporters among cases and controls we found new evidence supporting the monoamine hypothesis of neuropsychiatric disease by directly linking inherited changes to MAT function to an increased the risk of neuropsychiatric disease.

Title: Nanoscale distribution of the dopamine transporter assessed by super-resolution microscopy: Regulation by membrane potential

Authors: *M. D. LYCAS[1], J. F. STØIER[1], S. H. JØRGENSEN[1], A. T. SØRENSEN[1], M. SAUER[2], F. H. HANSEN[1], U. GETHER[1];
[1]Univ. of Copenhagen, Copenhagen, Denmark; [2]Univ. of Würzburg, Würzburg, Germany

Abstract: The dopamine transporter (DAT), a membrane protein present on dopaminergic neurons and responsible for the uptake of dopamine from the extracellular space, resides in discrete nanodomains on the plasma membrane of neuronal projections. Through direct stochastic optical reconstruction microscopy (dSTORM) on primary dopaminergic cultures and mouse brain slices, changes in the clustered, nanoscale distribution of DAT were observed upon manipulations affecting the neuronal membrane potential. The dynamic character of the clustered architecture was supported by dispersing of clusters following both NMDA receptor activation and nicotinic acetylcholine receptor activation. However, nanoclusters were not affected by the presence of the DAT inhibitor cocaine, nor was the NMDA induced declustering influenced by the inhibition of nitric oxide production. The declustering of DAT following NMDA receptor activation was muted through the sequesting of calcium by BAPTA-AM, and it was blocked by inhibition of voltage gated calcium channels, indicating the change in clustering is dependent on calcium influx. Interestingly, the changes in clustering architecture were also induced following viral transduction of ion channels into the dopaminergic neurons that caused the neuronal membrane to either hyperpolarize or depolarize. The data suggest that the dynamic changes in DAT clustering is a generalized phenomenon and is a response to membrane potential or neuronal activity in dopaminergic neurons. We also assessed the context for dopaminergic clusters by dual color dSTORM imaging of DAT with other presynaptic proteins, revealing concomitant declustering of some but increased clustering of other proteins. In order to observe if this phenomena takes place also in the developed brain, live mouse brain slices were treated

with NMDA, and the changes in DAT clustering were observed following dSTORM imaging of DAT in the striatum. In summary, DAT is organized into nanoscale clusters that are dynamic, and these clusters change in response to stimuli that influence membrane potential, indicating that the clustered distribution of DAT serves a functional role in dopaminergic neurotransmission.

Title: Calcium spike-dependent modulation of locus coeruleus excitability

Authors: *A. M. MCKINNEY, X. JIANG;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Noradrenaline-producing neurons in the locus coeruleus (LC), the largest noradrenergic nucleus in the central nervous system (CNS), project to all major CNS structures and play a crucial role in an array of behaviors and cognitive processes crucial to survival, including attention, arousal, and the stress response. The excitability of these densely-packed, large neurons is believed to be negatively controlled by noradrenaline release via α2 adrenoceptors (α2-mediated inhibition). However, using simultaneous recording of up to 12 LC neurons in pontine brain slices to examine the interactions within a group of recorded LC neurons, we found no evidence of lateral inhibition between LC neurons or self-inhibition via α2 adrenoceptors in neither juvenile (<P25) nor adult (>P60) mice, suggesting that this previously reported α2-mediated inhibition may only be active when a large population of LC neurons are activated. At the single-cell level, the main mechanism regulating LC excitability, instead, is a novel prolonged hyperpolarization that follows brief depolarization or phasic firing, which is mostly absent in neurons of the neocortex and hippocampus. This LC-specific self-inhibition persists in the presence of α2 adrenoceptor and galanin receptor antagonists, as well as sodium channel blockers which uncovered fast, prominent calcium spikes mediated by voltage-gated calcium channels (Ca_Vs). Further experiments with Ca_V channel blockers showed that it was not depolarization itself, but calcium influx from these spikes that drove this strong hyperpolarization of LC neurons. The hyperpolarization reversed at the potassium reversal potential and could be blocked or significantly reduced by K_{Ca}-specific blockers, suggesting that

the increase in intracellular calcium activated calcium-activated potassium channels (K_{Ca}) to hyperpolarize the neuron. To identify the Ca_V and K_{Ca} channels that mediate the novel hyperpolarization in LC, we are performing single-cell RNA-sequencing (scRNA-seq) to derive the single-cell transcriptome of LC neurons. Analysis is underway to determine which Ca_V and K_{Ca} channels are specifically expressed in the LC to mediate the novel hyperpolarization in LC neurons and how molecular variability underlies the organization of the locus coeruleus.

Title: Modulation of beta and gamma frequency oscillations in the rat anterior cingulate cortex (ACC) *in vitro* by group II metabotropic glutamate (mGlu) receptors (mGlu2/3)

Authors: B. H. DENNIS[1], *S. A. NEALE[2,1], F. E. LEBEAU[1], **T. E. SALT**[2,1,3];
[1]Inst. of Neurosci., Newcastle Univ., Newcastle upon Tyne, United Kingdom; [2]Neurexpert Limited, Newcastle upon Tyne, United Kingdom; [3]Inst. of Ophthalmology, Univ. Col. London, London, United Kingdom

Abstract: The anterior cingulate cortex (ACC) plays a role in remote spatial memory, attention and executive functions. These cognitive functions are associated with network oscillations in the beta (20-30 Hz) and gamma (30-80 Hz) range. We have recently demonstrated that both beta and/or gamma oscillations can be recorded *in vitro* either alone, or in combination, in the deep and superficial layers of ACC (Adams et al 2017 DOI: https://doi.org/10.1523/ENEURO.0313-16.2017). Changes in cortical beta and gamma frequency activity occur in patients in a range of neuropsychiatric and neurodegenerative diseases, and Group II mGlu receptors have been suggested as targets for diseases of both types. Therefore it is important to determine how these receptors participate in cortical network oscillations.
Following transcardial sucrose perfusion in anaesthetised rats ACC slices 450 µM thick were prepared. Slices were transferred to an interface chamber for recording. Network oscillations were evoked using bath application of kainate (800 nM) for 1-3 hours until oscillation magnitude stabilised.
Following application of kainate, beta activity (assessed over the 20-32.99 Hz frequency band) and gamma activity (assessed over the 33-80 Hz frequency band) were observed in ACC slices. Both beta and gamma activity were attenuated in the presence of the Group II mGlu receptor agonist LY354740. Following 60 mins application, LY354740 (3 µM) reduced the area under the curve (AUC) of gamma activity to 22.37 ± 6.59% (n = 4; p = 0.0013) of baseline levels and beta

was reduced to 49.25 ± 4.40% (n = 6; p < 0.0001). LY354740 (100 nM) reduced gamma to 61.3 ± 7.746% (n = 5; p= 0.0154) of baseline levels and AUC of beta activity was reduced to 94.77 ± 7.523% (n = 5). The effects of the LY354740 were reversed by bath application of the antagonist LY341495 (300 nM).
Gamma oscillations have been proposed to play a role in cortical local processing, while beta frequency activity is implicated in long range communication. Gamma activity showed a somewhat greater sensitivity compared to beta activity in response to mGlu2/3 activation. This could suggest differential roles for these receptors in modulating cortical function, and this may reflect localisation at certain synapses. Furthermore these results underline the importance of Group II receptors as potential targets for the treatment of neuropsychiatric and neurodegenerative diseases.

Title: Operant self stimulation of thalamic terminals in the dorsomedial striatum is constrained by metabotropic glutamate receptor 2

Authors: *K. A. JOHNSON[1], L. VOYVODIC[2], Y. MATEO[3], D. M. LOVINGER[4];
[1]Uniformed Services Univ., Bethesda, MD; [2]Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD; [3]Lab. for Integrative Neurosci., NIAAA, Bethesda, MD; [4]Chief, Lab. Integrative Neurosci, Natl. Inst. on Alcohol Abuse and Alcoholism Rockville Office, Rockville, MD

Abstract: The striatum plays a central role in the learning and performance of motivated behaviors. Cortical and thalamic glutamatergic inputs to the striatum are critical determinants of striatal neuron activity. In addition, both corticostriatal and thalamostriatal activation have been shown to elicit dopamine release, and thalamostriatal stimulation has recently been shown to support reinforcement of operant behavior. However, surprisingly little is known about how thalamostriatal transmission is regulated. Presynaptic G protein-coupled receptors such as group

II metabotropic glutamate ($mGlu_{2/3}$) receptors can robustly modulate the strength of transmission at many synapses. We previously demonstrated that activation of $mGlu_2$ dramatically decreases the strength of thalamically-driven glutamate and dopamine release in the dorsal striatum. Because both glutamate and dopamine could play roles in the reinforcing properties of thalamostriatal stimulation, we predicted that $mGlu_2$ manipulation would modulate this form of reinforcement. To test this, we established a thalamostriatal optical self-stimulation paradigm. We expressed channelrhodopsin-2 (ChR2) in striatum-projecting thalamic neurons in the intralaminar nuclei of the thalamus and bilaterally implanted adult male and female mice with optical fibers in the dorsomedial striatum. We trained the mice to press a lever for a brief (1 second, 5, 10, or 20 Hz) train of optical stimulation on an FR1 reinforcement schedule. Mice rapidly acquired lever-pressing behavior, and responding was readily extinguished. We then evaluated the effects of pharmacological manipulation of $mGlu_{2/3}$ receptors. Consistent with its ability to dampen thalamically-driven glutamate and dopamine release, the $mGlu_{2/3}$ agonist LY379268 (3 mg/kg, i.p.) robustly reduced the rate of pressing for thalamostriatal ICSS, and this effect was mimicked by the $mGlu_2$-selective positive allosteric modulator BINA (20 mg/kg, i.p.). Conversely, the $mGlu_{2/3}$-preferring antagonist LY341495 (3 mg/kg, i.p.) increased response rates. In contrast to the effects on thalamostriatal ICSS, LY379268 caused a very modest decrease in responding for a food reinforcer, whereas LY341495 robustly decreased rates of responding for food. Our findings suggest that group II mGlu receptors differentially influence operant behavior depending on the type of reinforcement.

Title: Identification of glutamatergic bidirectional synapses in the Portuguese man-of-war (*Physalia physalis*, hydrozoa)

Authors: *C. BOUCHARD[1], B. BOSERUP[3], N. BILL[1], R. H. JIANG[2];
[1]Col. of Sci. & Mathematics, Univ. of South Florida, Sarasota, FL; [2]Global and Planetary Health, Col. of Publ. Health, USF Genomics Program, Univ. of South Florida, Tampa, FL; [3]Dr. Kiran C. Patel Col. of Allopathic Med., Nova Southeastern Univ., Fort Lauderdale, FL

Abstract: The Portuguese man-of-war is a floating colony made up of polymorphic polyps. The animal belongs to the phylum Cnidaria, which includes animals such as hydra, sea anemone, coral and jellyfish. Modern day cnidarians are descendants of ancient metazoan lineages that were among the first animals to possess a nervous system. Understanding the function of cnidarian neurons that make up those nervous systems involves the identification of their transmitters as well as characterizing integral membrane proteins that bind to those neurotransmitters. One important taxonomic characteristic of cnidarians is the presence of stinging cells (cnidocytes). That a jellyfish must 'hear' a prey swim by its tentacles in order to catch it involves a sensory ability also present in humans and other vertebrate species who use hearing to communicate. When the cnidocyte detects a stimulus, the transduced vibrational stimulus is sent to pathways that control the release of a filament encapsulated within the stinging cell. This filament works like a harpoon to snare or perforate the prey's teguments. Because the discharge of the stinging cell is a one-time event, it is important that the discharge of the stinging cell occur when the chances of catching prey are high. Prior studies have identified glutamate as a player in the modulation of the cnidocyte discharge. However, the identity of neurotransmitters in cnidarians remains enigmatic. The goal of our study was to identify glutamatergic synapses associated with the cnidocytes. A transcript coding for a metabotropic glutamate receptor was isolated and a specific antibody was generated. Ultrastructural studies were not able to demonstrate the presence of synapses directly associated with cnidocytes, however bidirectional synapses in proximity to cnidocytes were shown to express the glutamate receptor.

Title: Nedd4 E3 ligase and beta-arrestins regulate ubiquitination, trafficking, and stability of the mGlu7 receptor

Authors: *S. LEE, S. PARK, H. LEE, S. HAN, J.-M. SONG, Y. SUH;
Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: The metabotropic glutamate receptor 7 (mGlu7) is a class C G protein-coupled receptor (GPCR) that modulates excitatory neurotransmitter release at the presynaptic active zone. Although post-translational modification of cellular proteins with ubiquitin is a key molecular mechanism governing protein degradation and function, mGlu7 ubiquitination and its functional consequences have not been elucidated yet. Here, we report that Nedd4 ubiquitin E3 ligase and β-arrestins regulate ubiquitination of mGlu7 in heterologous cells and neurons. Upon agonist-stimulation, β-arrestins recruit Nedd4 to mGlu7 and facilitate Nedd4-mediated ubiquitination of mGlu7. Nedd4 and β-arrestins regulate constitutive and agonist-induced endocytosis of mGlu7 and are required for mGlu7-dependent MAPK signaling in neurons. In addition, Nedd4-mediated ubiquitination results in the degradation of mGlu7 by both the lysosomal and proteasomal degradation pathways. These findings provide a model in which Nedd4 and β-arrestin act together as a complex to regulate mGlu7 surface expression and function at the presynaptic terminals.

Title: Neddylation of metabotropic glutamate receptor 7

Authors: *M. KANG, Y. SUH;
Dept. of Biomed. Sci., Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Metabotropic glutamate receptor 7 (mGlu7) is a G protein-coupled receptor (GPCR) that modulates synaptic transmission and synaptic plasticity by inhibiting glutamate release in the presynaptic terminals. It has been considered that posttranslational modification (PTM) is a major regulator of many GPCRs by triggering receptor internalization, recycling, or degradation. Previous studies have showed that SUMOylation and ubiquitination regulate mGlu7 trafficking

and stability in heterologous cells and neurons. However, Neddylation of mGlu7 in the C-terminal tail remains unknown. Neddylation is a PTM that covalently conjugates the ubiquitin-like protein Nedd8 (neural precursor cell expressed developmentally downregulated protein 8) to specific lysine residues on targeted proteins. This modification plays important roles in regulating several biological processes such as cell cycle progression, signaling cascades, and apoptosis. In addition, neddylation is shown to control axonal outgrowth and spine maturation in the mammalian CNS. Like ubiquitination, Nedd8 conjugation requires a series of enzymatic reactions catalysed by one Nedd8-activating enzyme complex (NAE1/UBA3 heterodimer), two E2 Nedd8-conjugating enzymes (UBE2F and UBE2M), and several E3 ligases. In this study, using cell biology and confocal imaging technology, we show that mGlu7 is a target of neddylation in HEK293T cells and cultured neurons. In addition, we identify neddylated lysine residues among the eight lysine residues at the C-terminal tail of mGlu7. We also explore the possibility that neddylation involves mGlu7 trafficking and agonist-induced signaling of mGlu7. These data will provide new insights into the function of mGlu7 in neurons.

Title: Characterization of n linked glycosylation of metabotropic glutamate receptor 7

Authors: *D.-H. PARK[1], Y. SUH[2];
[2]Dept. of Biomed. Sci., [1]Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Metabotropic glutamate receptor 7 (mGlu7) regulates neurotransmitter release at the presynaptic active zone in the mammalian brain. Regulation of mGlu7 trafficking in and out of the plasma membrane by binding proteins within the C-terminal tail of mGlu7 governs bidirectional synaptic plasticity. However, the functional importance of the extracellular domain (ECD) of mGlu7 has not been characterized. N-linked glycosylation is an abundant post-translational modification that plays crucial roles in proper protein folding in the endoplasmic reticulum (ER) and in forward trafficking to the plasma membrane. In addition to controlling trafficking, N-linked glycans can deliver intracellular signaling or modulate cell-cell

communications complexed with glycan-binding proteins. In this study, we report that mGlu7 is N-glycosylated at the asparagine (Asn) residues in the ECD in heterologous cells and in neurons. We found that deglycosylated mutations at the N-glycosylation site of mGlu7 caused a marked reduction in the surface expression of mGlu7, which resulted in retention of the receptor in the ER. In addition, the deglycosylated mGlu7 is degraded through the autophagy-lysosome degradation pathway. Furthermore, we evaluate whether N-glycosylation of mGlu7 could alter its pharmacological properties and downstream signaling. Taken together, these findings support the evidence that N-glycosylation contributes to surface expression and presynaptic function of mGlu7.

Abstract: A growing body of evidence indicates that type-2 metabotropic glutamate (mGlu2) receptors regulate pain transmission acting at multiple levels within the pain neuraxis, and are candidate drug targets for therapeutic intervention in inflammatory and neuropathic pain. N-Acetylcysteine (NAC) is an old drug marketed as a mucolytic agent and indicated for the treatment of acetaminophen poisoning and contrast-induced nephropathy. NAC activates the cystine/glutamate membrane antiporter (Xc^- system), thereby enhancing the synthesis of intracellular glutathione. However, this mechanism also enhances the export of glutamate, thereby facilitating the endogenous activation of presynaptic mGlu2 receptors. We have shown previously that NAC treatment causes analgesia in mouse models of inflammatory pain and in the chronic constriction injury model of neuropathic pain (Bernabucci et al., Mol. Pain, 2012). In addition, we were able to demonstrate that NAC treatment inhibits pain transmission in healthy human volunteers (Truni et al., Mol. Pain, 2015). We have now extended the study to a mouse

model of painful diabetic neuropathy, a condition which is often resistant to analgesic medication. Mice were injected i.p. with 200 mg/kg of streptozotocin (STZ), a nitrosourea that kills pancreatic β-cells causing diabetes. STZ-treated mice developed hyperglycemia and painful neuropathy, as shown by large reductions in mechanical pain thresholds. A single administration of NAC (100 mg/kg, i.p.) 14 day after STZ injection caused analgesia to the same extent as pregabalin (30 mg/kg, i.p.), a first line drug in the treatment of painful diabetic neuropathy in humans. Analgesia was also observed after repeated injections of NAC, indicating the lack of tolerance. NAC-induced analgesia was abrogated by a single injection of sulfasalazine or LY341495, which inhibit Xc^- and mGlu2 receptors, respectively. These findings suggest that NAC-induced analgesia in the STZ model was mediated by the sequential activation of the cystine/glutamate antiporter and the mGlu2 receptor. Finally, NAC treatment in diabetic mice normalized some biochemical correlates of nociceptive sensitization, e.g., MAP kinase activation in the dorsal horns of the spinal cord, and induced substantial changes in spinal cord protein levels, as assessed by proteomic analysis. Taken together, these data suggest that NAC caters the potential as an add-on drug in the treatment of painful diabetic neuropathy. The excellent profile of safety and tolerability of NAC encourages the use of the drug in clinical studies.

Title: Type-3 metabotropic glutamate receptors and Parkinson's disease: Preclinical studies and human genetics

Authors: L. DI MENNA[1], M. ALBORGHETTI[2], A. TRAFICANTE[1], J. A. MONN[1], M. SIMMACO[2], G. SPALLETTA[4], F. NICOLETTI[1,3], *G. BATTAGLIA[1,3], V. BRUNO[1,3], F. E. PONTIERI[2], M. BORRO[2];
[1]Mol. Pathology, I.R.C.C.S. Neuromed, Pozzilli, Italy; [2]Neuroscience, Mental Hlth. and Sensory Organs (NESMOS), [3]Physiol. and Pharmacol., Univ. Sapienza, Rome, Italy; [4]I.R.C.C.S. Fondazione S. Lucia, Rome, Italy

Abstract: Type-3 metabotropic glutamate (mGlu3) receptors exert pleiotropic functions in the CNS depending on their anatomical localization. Presynaptic mGlu3 receptors inhibit glutamate release, whereas postsynaptic mGlu3 receptors boost mGlu5 receptor signaling. In addition, activation of mGlu3 receptors in astrocytes stimulates the production of GDNF and TGF-β and

drives microglia towards an anti-inflammatory phenotype. We used the MPTP model of toxicological parkinsonism in mice to examine whether endogenous or pharmacological activation of mGlu3 receptors is neuroprotective. Chronic administration of MPTP (20 mg/kg, s.c., every other day) caused a substantial drop in dopamine (DA), DOPAC and HVA levels in the striatum observed at 15 and 30 days. At 15 days, MPTP induced DA depletion was slightly but significantly attenuated in mGlu2$^{-/-}$ mice, whereas an opposite trend was seen in mGu3$^{-/-}$ mice. At 30 days, the DA loss was significantly greater in mGlu3$^{-/-}$ mice as compared to their wild-type counterparts (94% vs. 84%). These findings support the hypothesis that activation of mGlu3 receptors is neuroprotective in models of parkinsonism whereas activation of mGlu2 receptors might be neurotoxic. We are currently performing studies with the selective mGlu3 receptor agonist, LY2794193, to further explore this hypothesis. We are also examining the association between polymorphic variants of GRM3 (rs12704290, rs13242038, rs1468412, rs1527768, rs187993, rs1989796, rs2228595, rs2237562, rs2282966, rs2299225, rs274622, rs6465084, rs724226, rs802457, rs906415, and rs917071) or GRM5 (rs60954128 and rs3824927) and Parkinson's disease (PD) and L-DOPA-induced dyskinesias in a large cohort of patients. *Ad interim* analysis suggests an association between the GRM3 variant, rs2228595, and PD. This polymorphism (exon 3; Ala293Ala) has been linked to schizophrenia (Marti et al., Am. J. Med. Genet., 2002; Egan et al., Proc. Natl. Acad. Sci., USA, 2004) and to a greater expression of a truncated form of the mGlu3 receptor (mGlu3Δ4) (Sartorius et al., Neuropsychopharmacology, 2008). These findings suggest that mGlu3 receptors might shape the balance between neurodegeneration and neuroprotection in PD and might be targeted by therapeutic intervention.

Title: Type-5 metabotropic glutamate receptors regulate the formation of perineuronal nets in the mouse cerebral cortex and cerebellum during postnatal development

Authors: G. MASCIO[1], S. NOTARTOMASO[1], P. SCARSELLI[1], D. BUCCI[1], M. CANNELLA[1], T. IMBRIGLIO[2], A. TRAFICANTE[1], G. BATTAGLIA[1,2], V. BRUNO[1,2], *R. GRADINI[3], F. NICOLETTI[1,2];

[1]Mol. Pathology, I.R.C.C.S. Neuromed, Pozzilli, Italy; [2]Physiol. and Pharmacol., [3]Exptl. Med., Univ. Sapienza, Rome, Italy

Abstract: Type-5 metabotropic glutamate (mGlu5) receptors are highly expressed and functional in the early postnatal development, when glutamate and other receptor agonists stimulate polyphosphoinositde hydrolysis to a large extent (Nicoletti et al., Proc. Natl. Acad. Sci. USA, 1986). In the first two weeks after birth, mGlu5 receptors are also found in cell types (e.g., cerebellar Purkinje cells), in which the receptor is absent in the adult life (Notartomaso et al., Sci. Rep., 2018). The precise role played by mGlu5 receptors in postnatal development is unknown. Here, we examined whether genetic deletion of mGlu5 receptors affects the formation of perineuronal nets (PNNs) in the CNS. PNNs represent a specialized form of the extracellular matrix surrounding cell somata and proximal dendrites of parvalbumin-positive (PV^+) interneurons and other neuronal types in different CNS regions. Chondroitin sulfate proteoglycans (CSPGs), hyaluronan, tenascin-R, and link proteins are major constituents of PNN. PNNs have been implicated in mechanisms of developmental plasticity, and PNN development and maintenance are altered in CNS disorders (Wen et al., Front. Mol. Neurosci. 2018). We could detect PNNs in the mouse cerebral cortex and cerebellum by fluorescent staining with WFA (Wistiria Fluoribunda Agglutinin). Interestingly, the number of neurons surrounded by PNNs was higher in the cortex of mice lacking mGlu5 receptors ($mGlu5^{-/-}$ mice) at postnatal day 16 (PND16), when PNNs begin to be fully expressed in the mouse cortex. Double fluorescent staining showed that a large proportion of neurons surrounded by PNNs were PV^+. The activity of type-9 matrix metalloproteinase, an enzyme involved in PNN degradation, was reduced in the cortex of $mGlu5^{-/-}$ mice suggesting that a reduced PNN turnover rate could at least in part account for the greater number of neurons decorated by PNNs in these mice. We extended the analysis to the cerebellum, finding that PNNs were increased in the cerebellar cortex (particularly those surrounding Purkinje neurons), but were reduced in deep cerebellar nuclei of $mGlu5^{-/-}$ mice at PND16. The two phenomena might be causally linked because Purkinje neurons project to deep cerebellar nuclei. We hypothesize that endogenous activation of mGlu5 receptors regulates formation and/or degradation of PNNs in the CNS during postnatal development. Experiments in which mGlu5 receptors are pharmacologically blocked or activated at different postnatal time windows are ongoing to examine this hypothesis in further detail.

Abstract: A growing body of evidence suggests that mGlu5 receptors are candidate targets for drug treatment of absence epilepsy. Pharmacological activation of mGlu5 receptors with the positive allosteric modulator, VU0360172, reduces spike-and-wave discharges (SWDs) in WAG/Rij rats, which show spontaneous absence seizures after 2-3 months of age. However, intrathalamic injection of VU0360172 causes a paradoxical enhancement of SWD frequency when combined with subthreshold doses of the GABA transporter (GAT-1) inhibitor, tiagabine (D'Amore et al, 2015). Here we explored the possibility that activation of mGlu5 receptors could protect against absence seizures by enhancing synaptic clearance of GABA in the thalamus. *Ex vivo* measurements of [^{3}H]-GABA uptake were performed in thalamic and cortical synaptosomes prepared from sympthomatic WAG/Rij rats receiving single or repeated s.c. injections of vehicle or VU0360172 (3 mg/kg). Both VU0360172 treatments significantly enhanced [^{3}H]-GABA uptake only in thalamic synaptosomes. Western blot analysis showed an up-regulation of GAT-1 in the thalamus of pre-symptomatic and symptomatic WAG/Rij rats, as well as in age-matched non-epileptic control rats, one hour after a single s.c. injection of VU0360172. In contrast GAT-1 mRNA levels were unchanged in rats challenged with VU0360172. Confocal microscopy analysis showed that the increase of GAT-1 expression in response to mGlu5 receptor activation occurred in neurons and there was no co-localization between GAT-1 and GFAP immunostaining. An up-regulation of GAT-1 could also be observed in thalamic slices challenged with the orthosteric mGlu1/5 receptor agonist DHPG or VU0360172, and this effect was abrogated by pharmacological inhibition of phospholipase-C. This suggests that activation of mGlu5 receptors enhances thalamic GABA re-uptake by increasing the stability of GAT-1 without changes in gene expression. Finally, we examined whether this effect has any impact on extrasynaptic $GABA_A$ receptor-mediated tonic inhibition in the thalamus by recording synaptic inhibition in the absence or presence of the extrasynaptic $GABA_A$ receptor blocker, gabazine. We found that addition of VU0360172 to thalamic slices caused a large reduction in tonic inhibition. Similar data were obtained in *ex vivo* experiments, in which tonic inhibition was largely reduced in thalamic slices of WaG/Rij rats treated systemically with VU0360172. Taken together, these findings demonstrate that activation of mGlu5 receptors enhances GABA

clearance and restrain tonic inhibition in the thalamus, thereby disclosing a novel potential strategy for the treatment of absence epilepsy.

Abstract: Type-5 metabotropic glutamate (mGlu5) receptors are highly expressed and functional in the early postnatal development (Catania et al., Neurosci. 1994 ; Nicoletti et al., Proc. Natl. Acad. Sci. USA, 1986). The function of mGlu5 receptors in developmental processes occurring after birth is unknown. Here, we examined the expression of genes related to GABAergic interneurons in the prefrontal cortex (PFC) and hippocampus of $mGlu5^{-/-}$ mice and their wild-type counterparts at postnatal day (PND) 9 and 21. PFC and hippocampal interneurons are dysfunctional in schizophrenia, and mGlu5 receptors are candidate drug targets for antipsychotic medication. At PND9, we were surprised to find an increase in parvalbumin (PV) mRNA levels in the PFC and hippocampus of $mGlu5^{-/-}$ mice, whereas PFC levels of the transcripts encoding for CB1 receptors and reelin were decreased. The transcript encoding for the NMDA receptor subunits and somatostatin were unchanged. These findings were divergent from those seen in mice lacking mGlu3 receptors in which a reduction in PV mRNA levels was consistently seen in both regions at PND9. In $mGlu5^{-/-}$ mice, the increase in PV mRNA levels persisted in the PFC but not in the hippocampus. Unexpectedly, we found large increases in the expression of the GluN1 subunit of NMDA receptors (both mRNA and protein levels) in the PFC of $mGlu5^{-/-}$ mice at PND21. This was associated with a significant increase in GluN2A mRNA levels, whereas the transcripts of the GluN2C and GluN2D subunits were unchanged. GluN1 protein levels were also substantially increased in the hippocampus of $mGlu5^{-/-}$ mice at PND21, and this was associated with an increase in the transcript of the GluN2C subunit. NMDA and mGlu5 receptors

are both expressed in GABAergic interneurons and they are physically linked by a chain of anchoring proteins. In addition, activation of mGlu5 receptors facilitates NMDA receptor function and *vice versa*. Thus, we hypothesize that the up-regulation of NMDA receptor subunits found in mGlu5$^{-/-}$ mice during development may represent a compensatory mechanism aimed at supporting synaptic activation of GABAergic interneuronsin the absence of mGlu5 receptors. This hypothesis warrants further investigation. We expect that, at least during early postnatal development, mice are more sensitive to drugs that interact with NMDA receptors. We are currently examining this possibility at behavioral level.

Title: TRPC3 channel is important for mGluR1-dependent Ca^{2+} and firing regulation in nigral dopamine neurons

Authors: *K. U. UM, M. PARK;
Dept. of Physiol., Sch. of Medicine. Sungkyunkwan Univ., Suwon-si, Chunchun-dong, Korea, Republic of

Abstract: Pacemaker dopamine neurons in the substantia nigra pars compacta (SNc) exhibit low-frequency spontaneous firing without any input stimuli and often produce high-frequency burst firing in response to strong glutamatergic afferent inputs. Since the tonic firing determines ambient dopamine levels, regulation of tonic firing rate is very important. Although activation of mGluR1 is reported to increase cell excitability via activation of some type of TRP channels, it is still unclear how mGluR1 regulates tonic firing activities in SNc dopamine neurons. In this study, we present that mGluR1 increases Ca^{2+} levels and tonic firing rate via TRPC3 channels in SNc dopamine neurons.
In SNc dopamine neurons, activation of mGluR1 inhibited spontaneous firing transiently but subsequently led to a slow increase in tonic firing rate. DHPG, a mGluR1 agonist, evoked two clear phases of Ca^{2+} elevations: the fast Ca^{2+} surge released from the endoplasmic reticulum (ER) Ca^{2+} store and then the following sustained Ca^{2+} influxes. When the intracellular Ca^{2+} store was emptied by caffeine or thapsigargin, we could not observe any Ca^{2+} influxes but DHPG induced a sustained Ca^{2+} influx, suggesting that DHPG induces Ca^{2+} influx regardless of store operated Ca^{2+} channels in dopamine neurons. Using the several TRP channel blockers, we found that DHPG-induced Ca^{2+} influx was dramatically reduced by pre-treatment of TRPC3 channel

blockers. In addition, we observed that DHPG-induced Ca^{2+} influx was inhibited by L-type Ca^{2+} channel blockers, but not by P/Q- or T- type channel blockers. Taken together, these data suggest that mGluR1 activate TRPC3 channels which induces Ca^{2+} influx by increased tonic firing rate and consequential activation of L-type Ca^{2+} channels. Therefore, we conclude that TRPC3 channels are a key player in mGluR1-induced cytosolic Ca^{2+} and tonic firing changes in SNc dopamine neurons.

Title: Analgesic activity of cinnabarinic acid in models of inflammatory and neuropathic pain

Authors: *F. FAZIO[1], S. NOTARTOMASO[2], S. BOCCELLA[3], M. ULIVIERI[2], N. ANTENUCCI[4], F. LIBERATORE[4], P. SCARSELLI[1], V. BRUNO[1,4], G. BATTAGLIA[1,4], L. LUONGO[3], F. NICOLETTI[1,4], S. MAIONE[3];

Abstract: L-Tryptophan (Try) has been involved in the regulation of pain, and tryptophan depletion in humans reduces morphine-induced analgesia (Abbott et al., Psychoph.,1992). It is generally believed that the action of Try on pain is mediated by serotonin. However, Try is the metabolic precursor of the kynurenine pathway, which generates a number of neuroactive compounds, such as kynurenic, quinolinic, and xanthurenic acids (Schwarcz et al., Nat. Rev. Neurosci., 2012). Metabolites of the kynurenine pathway have been implicated in the regulation of pain transmission (Godefroy et al., Brain Res.,1990; Heyliger et al., Pharmacol. Res., 1998). In the last few years, we have focused on cinnabarinic acid, a trace kynurenine metabolite which is formed by two joined molecules of 3-hydroxyanthranilic acid. We have found that cinnabarinic acid acts as an orthosteric agonist of mGlu4 metabotropic glutamate receptors (Fazio et al., Mol. Pharmacol., 2012), and this stimulated our interest for the study of cinnabarinic acid in pain models because drugs that activate mGlu4 receptors are known to cause analgesia (Vilar et al., J. Neurosci., 2013). We first examine the effect of cinnabarinic acid in mice injected s.c. with formalin in the hind paw. Low doses of cinnabarinic acid (0.125 and 0.25 mg/kg, i.p.) significantly reduced nocifensive behaviour in the second phase of the formalin test, which reflects the development of central nociceptive sensitization. In contrast, higher doses of cinnabarinic acid (0.5 and 3 mg/kg, i.p.) were inactive. We extended the analysis to the chronic

constriction injury (CCI) model of neuropathic pain, in which mechanical pain thresholds were assessed by von Frey filaments. Acute injection of low doses of cinnabarinic acid (0.25 mg/kg, i.p.) caused substantial analgesia two weeks after CCI induction. Analgesia was also observed after seven days of repeated administrations of cinnabarinic acid (0.25 mg/kg, i.p., q.d.), indicating the lack of tolerance. Taken together, these findings suggest that trace amounts of cinnabarinic acid are able to modulate pain transmission and induce analgesia in different models of pain. We are currently examining whether the analgesic effect of cinnabarinic acid is mediated by the activation of mGlu4 receptors or involves other mechanisms (e.g., the activation of aryl hydrocarbon receptors).

Title: Regulation of $GABA_B$ receptor trafficking and localization by APP, AJAP1 and PIANP

Authors: *P. REM, S. FRÜH, M. CHOO, M. GASSMANN, B. BETTLER;
Dept. of Biomedicine, Univ. of Basel, Basel, Switzerland

Abstract: $GABA_B$ receptors (GBRs) are key regulators of synaptic release, but little is known about mechanisms that localize GBRs at axon terminals. Presynaptic GBRs comprise the GB1a subunit that contains a pair of protein-protein interaction motifs termed ‘sushi domains’ at their extracellular N-terminus. One of these sushi domains interacts in a mutually exclusive manner with the three transmembrane proteins β-amyloid precursor protein (APP), AJAP1 and PIANP (Schwenk et al., Nature Neuroscience 19(2), 2016). Using heterologous assay systems we now show that complex formation of GBRs with APP, AJAP1 or PIANP does not allosterically influence G-protein signaling by the receptor. Bimolecular fluorescence complementation (BiFC) assays in neurons reveal that APP, AJAP1 and PIANP all interact with GBRs *in cis*. Using a hemi-synapse assay we show that AJAP1 also binds to GBRs *in trans*. We found that specifically APP transports GBRs to axon terminals and that lack of APP results in a significant deficit in presynaptic GBR-mediated inhibition. In line with this, axonal expression of GBRs is reduced in $APP^{-/-}$ but not in $AJAP1^{-/-}$ or $PIANP^{-/-}$ mice. However, expression of PIANP is essential for normal GBR-mediated inhibition of neurotransmitter release. We hypothesize that after delivery to the axon terminal, APP transfers GBRs to the higher-affinity binding sites of PIANP and AJAP1 that localize GBRs to presynaptic sites.

Title: Effect of angiotensin II type 1 receptor stimulation in the rostral ventrolateral medulla of normotensive rats: Interaction with glutamate and gamma-aminobutyric acid

Authors: *L. LEGAT, A. G. DUPONT, I. SMOLDERS;
VRIJE Univ. Brussel, Brussels, Belgium

Abstract: OBJECTIVE
The rostral ventrolateral medulla (RVLM), the so-called brainstem 'pressor area', is a key site for the regulation of sympathetic tone and blood pressure. The major source of excitatory sympathetic drive from the RVLM are spinally projecting glutamatergic neurons which receive tonic glutamatergic excitatory signals from the paraventricular nucleus of the hypothalamus (PVN), and gamma-aminobutyric acid (GABA)ergic inhibitory signals from the caudal ventrolateral medulla (CVLM). Brain angiotensin II (Ang II) increases mean arterial pressure (MAP) and sympathetic nerve activity through stimulation of AT1Rs on spinally projecting glutamatergic neurons located in the RVLM.
There is increasing evidence that glutamate and GABA interact within the RVLM to modulate the central regulation of blood pressure and sympathetic tone.
DESIGN and METHOD
The present study was designed to investigate whether the well established hypertensive response to local AT1R stimulation by Ang II is associated with changes in glutamate and GABA levels within the RVLM. *In vivo* microdialysis, for measurement of extracellular glutamate and GABA levels, was carried out in the RVLM of conscious normotensive Wistar rats while locally infusing Ang II (3 µg/µl/h). Glutamate and GABA levels were quantified by liquid chromatography.
RESULTS
Infusion of Ang II into the RVLM significantly increased glutamate levels ($P < 0.05$) and significantly decreased GABA levels ($P < 0.05$).
CONCLUSION
The results suggest that the well established hypertensive response to AT1R stimulation in the RVLM by Ang II is associated with enhanced glutamate release from glutamatergic projections originating in the PVN, possibly through stimulation of presynaptic AT1R on these nerve

endings. In addition, stimulation of AT1R located on inhibitory GABAergic nerve endings originating in the CVLM appears to reduce GABA release and subsequent disinhibition of the excitatory neurons driving the sympathetic tone within the RVLM. Further experiments with selective AT1R blockade are currently ongoing to assess the AT1R selectively of these responses.

Title: Beyond retigabine: Pharmacological characterization of novel neuronal Kv7 channel activators

Authors: *F. MICELI[1], P. NAPPI[1], L. CAROTENUTO[1], C. OSTACOLO[2], P. CAMPIGLIA[3], M. TAGLIALATELA[1];
[1]Dept. Neurosci., [2]Dept. of Pharm., Univ. of Naples "Federico II", Naples, Italy; [3]Dept. of Pharm., Univ. of Salerno, Salerno, Italy

Abstract: Retigabine is the only antiepileptic drugs approved for human use that acts by activating voltage-gated potassium channels belonging to Kv7 subfamily. Among this family, Kv7.2 and Kv7.3 subunits are mainly expressed in the neurons where they underlie a K^+ current (I_{KM}), which plays a fundamental role in controlling neuronal excitability. Because of poor selectivity for Kv7 subtypes, short half-life, poor brain penetration and chemical instability, leading to blue-gray skin discoloration, retigabine is no longer available on the market. In this work, we have tested a small library of retigabine derivatives by means of fluorescence-based assay and manual patch-clamp technique with the aim to indentify novel Kv7.2/3 channel modulators.
Stable CHO cell lines co-expressing Kv7.2 and Kv7.3 channel subunits were used for a fluorescence-based assay that uses Thallium (Tl^+) as a surrogate of K^+ ions and a fluorescent Tl^+-sensitive dye (FluxOR).

In Kv7.2/3 stable cell lines retigabine (0.1-100 μM) dose-dependently increased the maximal fluorescence and the initial slope of the fluorescent signal; both effects were abolished by the pan-Kv7 blocker XE991 (10 μM). The calculated EC_{50} for retigabine was 4.6±0.7 μM, a value similar to that calculated by electrophysiological techniques (EC_{50}= 1.9±0.2 μM). Some of the newly-synthesized retigabine analogues increased the maximal fluorescence and the initial slope of the fluorescent signal significantly more than retigabine. In particular, the compound CPRET-46 was at least 2000 times more potent than retigabine, showing an EC_{50} of 2.2±0.1 nM. Electrophysiological experiments corroborated such conclusion. In fact, in CHO cells expressing Kv7.2/3 channels, 100 nM retigabine failed to modify Kv7.2/3 channel gating; whereas, the same concentration of CPRET-46 negatively shifted Kv7.2/3 currents activation $V_{1/2}$ by about 23 mV. When compared to retigabine, CPRET-46 also showed a higher maximal efficacy; indeed, at the maximal concentration of 10 μM, the $V_{1/2}$ of Kv7.2/3 currents was shifted by 40 and 80 mV for retigabine and CPRET-46, respectively. In conclusion, we have identified a novel retigabine analogous showing higher potency over existing compounds.

Title: A novel role for Kv7/KCNQ potassium channels in synaptic strength

Authors: *G. C. TRACY[1], H. CHUNG[1,2];
[1]Dept. of Mol. and Integrative Physiol., [2]Neurosci. Program, Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Neuronal Kv7/KCNQ channels are voltage-gated, slow-activating, and non-inactivating potassium channels. They are critical in the regulation of neuronal excitability by limiting the repetitive firing of action potentials (APs) and modulating the resting membrane potential. Kv7 channels are composed of tetramers which, in the brain, are mostly heteromers of Kv7.2/KCNQ2 and Kv7.3/KCNQ3. In the excitatory pyramidal neurons of the hippocampus and cortex, Kv7 channels are enriched at the axon initial segment (AIS) and prevent intrinsic burst firing of APs. Ankyrins provide cytoskeletal support and organize membrane proteins to a macromolecular functional hub. AnkyrinG, a mammalian ankyrin protein, has multiple splice

isoforms which share ankyrin repeats but display different localization: the 480kD and 270kD AnkyrinG proteins are concentrated at the AIS whereas the 190kD AnkyrinG isoform is found in dendritic spines that harbors excitatory synapses. The AnkyrinG-480kD binding to Kv7.2 and Kv7.3 C-termini is required for their AIS localization. However, whether the AnkyrinG-190kD binds to Kv7 channels and regulates their expression remains unknown. In this study, we discover that Kv7.2, Kv7.3, and AnkyrinG-190kD in the postsynaptic density fractions of the rat hippocampus. In the rat primary dissociated culture of hippocampal neurons, Kv7.2, Kv7.3, and AnkyrinG-190kD are localized to the dendritic spines. Interestingly, acute inhibition of Kv7 channels using their blocker XE991 increases surface density of GluA2-containing AMPA receptors in the dendrites and dendritic spines. Activation of NMDA receptors upon a brief bath application of NMDA potentiated this effect by 1.36-fold. These findings suggest an exciting possibility that AnkyrinG-190kD may target Kv7 channels to the dendritic spines where they regulate excitatory synaptic strength. We are currently using biochemical, cellular, and electrophysiology approach to investigate the mechanism and physiological implication for Kv7 targeting to the dendritic spines.

Abstract: Mutations in *KCNQ2*, which encodes a pore-forming K^+ channel subunit responsible for neuronal M-current, have been associated with neonatal epileptic encephalopathy (NEE).

This complex disorder manifests as severe early-onset seizures and impaired neurodevelopment due to an imbalance in neuronal circuit activity in the brain. While the effects of *KCNQ2* mutations have been studied extensively in heterologous expression systems, their effects on the inherent properties of human neurons have not. Specifically, what remains unclear is how the likely defects in M-current affect the electrophysiological properties of human neurons during a critical period of neuronal maturation. Here we use KCNQ2-NEE patient-specific and isogenic control iPSC-derived excitatory neurons to elucidate the dynamic functional effects of a *KCNQ2* mutation.
We find that while patient-derived excitatory neurons exhibit reduced M-current early, they develop intrinsic and network hyperexcitability progressively over time in culture (using multi-electrode arrays and patch-clamp electrophysiology, respectively). This hyperexcitability is associated with faster action potential repolarization, larger afterhyperpolarization, and a functional enhancement of Ca^{2+}-dependent K^+ channels (BK and SK). These properties facilitate a burst-suppression firing pattern that is reminiscent of the interictal electroencephalography pattern in patients. Importantly, we were able to phenocopy these excitability features in control neurons only by chronic but not acute pharmacological inhibition of M-current. Our findings suggest that dyshomeostatic mechanisms compound KCNQ2 loss-of-function and lead to alterations in the neurodevelopmental trajectory of patient-derived neurons. Our work has therapeutic implications in explaining why KCNQ2 agonists may not be beneficial unless started at an early disease stage.

Title: Kir4.1 channels in NG2-glia play a role in potassium signaling and ischemia-related myelin loss

Authors: *X. TONG, F. SONG, X. HONG, J. CAO, J. WAN;
Shanghai Jiao Tong Univ. Sch. of Med., Shanghai, China

Abstract: The contribution of the inwardly rectifying K^+ channel subtype Kir4.1 has been focused mainly on astrocytes, where they play important roles in the maintenance of resting membrane potential, extracellular K^+ uptake and facilitation of glutamate uptake in the central nervous system. Here, we report the role of Kir4.1 channels in NG2-glia during brain development, potassium signaling and in an ischemic stroke disease model. Kir4.1 channels are widely expressed in NG2-glia during brain development. In the adult mouse hippocampus, Kir4.1 channels in NG2-glia constitute more than 80% of K^+ channels inward currents. This large portion of Kir4.1 channel currents exhibits a deficit in NG2-glia as an initial response in a transient ischemic mouse model (tMCAO). Further evidence indicates that Kir4.1 deficits in NG2-glia potentially cause axonal myelin loss in ischemia through the association with oligodendrocyte-specific protein (OSP / Claudin-11), which unravels a potential therapeutic target in the treatment of ischemic stroke.

Title: Exon2-deleted TWIK-1 KO mice are not an appropriate model for TWIK-1 defeciency

Authors: H.-G. JUNG[1], A. KIM[1], Y. BAE[2], J.-Y. PARK[2], *E. HWANG[1];
[1]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [2]Korea Univ., Seoul, Korea, Republic of

Abstract: TWIK-1 is a member of the two-pore domain K+ (K2P) channel family that plays an essential part in the regulation of resting membrane potential and cellular excitability. We recently reported that TWIK-1/TREK-1 heterodimeric channel mediates astrocytic passive conductance with gene silencing tools. However, this work was challenged by a report showing no alteration of astrocytic passive conductance in Exon2-deleted TWIK-1 mice (TWIK-1 ΔEX2 KO mice). Here we developed an antibody against C-terminus of TWIK-1 and we found that strong signals of immunohistochemistry was detected in hippocampal astrocytes of TWIK-1 ΔEX2 KO mice using this antibody. Molecular biological and biochemical experiments demonstrate TWIK-1 ΔEX2 KO mice expressed unsuspected TWIK-1 proteins showing an inflamed connection between Exon1 and Exon3 of TWIK-1. Targeting of gene silencing on

Exon1 or Exon3 of TWIK-1 showed clear reduction of astrocytic passive conductance in TWIK-1 ΔEX2 KO mice. In addition, heterologous co-expression of TWIK-1 ΔEX2 and TREK-1 in COS-7 cells shows a linear-like I-V relationship. Taken together, our data strongly suggested that TWIK-1 ΔEX2 KO mice is not a proper KO model for the study of TWIK-1 functions and reconfirmed the role of TWIK-1 as a molecular identity of astrocytic passive conductance.

Title: A 5' UTR GGN repeat sequence forms a stable G-quadruplex that controls translation initiation and neurite targeting of the potassium leak channel Task3 mRNA

Authors: ***C. J. MALTBY**[1], J. P. R. SCHOFIELD[1], I. M. O'KELLY[2], K. DEINHARDT[1], M. J. COLDWELL[1];
[1]Biol. Sci., [2]Sch. of Med., Univ. of Southampton, Southampton, United Kingdom

Abstract: Neurons are structurally complex, highly polar cells that exhibit spatial compartmentalisation of function. Activity-driven local translation of pools of translationally-repressed mRNAs underpins this functional compartmentalisation, allowing for distinct local proteomes to facilitate the dynamic synaptic remodelling attributed to normal cellular function. There has been growing evidence to suggest that cation-stabilised non-canonical secondary RNA structures, known as G-quadruplexes, within untranslated regions of mRNAs are key to regulating this translational control and distal transport of particular neuronal mRNAs, a process implicated in several neurodevelopmental and degenerative disorders.
2-pore potassium leak (K_2P) membrane channels maintain the resting membrane potential of neurons. Task3 is a hippocampal and cerebellar-enriched K_2P channel thought to play a role in maintaining neuronal excitability during long-term potentiation attributed to learning and memory. Minor aberrations in the levels of Task3 expression leads to neuronal dysfunction and mental retardation, though the mechanisms controlling the narrow physiological window of Task3 expression are largely unknown.
Through 5' Rapid Amplification of cDNA Ends (RACE), we revealed a 5' UTR cap-proximal $(GGN)_{12}$ repeat in human brain Task3 mRNA that is conserved across species. GGN repeat expansions have been implicated in Fragile-X mental retardation syndrome due to G-quadruplex formation *in vivo, and so* could be controlling physiological Task3 mRNA delivery and

expression in neurons. To investigate the nature of this GGN repeat, we employed circular dichroism (CD) and native PAGE assays, showing that under physiological K^+ conditions the $(GGN)_{12}$ repeat sequence forms a highly thermo-stable and K^+ dependent parallel G-quadruplex structure.
Through mutagenesis of this $(GGN)_{12}$ repeat sequence, we show *in vitro* that this G-quadruplex forming sequence inhibits translation of Task3 peptides, which is relieved upon overexpression of the brain-enriched G-quadruplex specific helicase, DHX36. We also find that endogenous Task3 mRNA is upregulated rapidly during neuronal activity and is present extensively throughout distal neurite projections. Using mutant 5' UTR reporter constructs, we find a strong correlation between the presence of this 5' cap-proximal G-quadruplex and distal mRNA localisation within axons and dendrites.
We therefore suggest that these G-quadruplex structures are central to regulating the delivery of Task3 mRNA to distal sites of translation, as well as the narrow window of Task3 expression levels attributed to normal cellular function.

Title: Structural molecular sites for local anesthetic modulation of TASK channels

Authors: *G. DU[1], Y. HOU[1], Y. HUANG[2];
[1]Translational Neurosci. Center, Dept. of Anesthesiol., West China Hosp. of Sichuan Univ., Chengdu, China; [2]Dept. of Anesthesiol., Affiliated Hosp. of Guizhou Med. Univ., Guiyang, China

Abstract: Introduction. TASK-1 (K2P3.1) and TASK-3 (K2P9.1), members of the K2P family, are widely expressed leak potassium channels responsible for maintenance of cell membrane potential and input resistance. TASK channels generate pH-sensitive, background K^+ currents. They are sites of action for a variety of modulatory agents and local anesthetics show inhibition of the channels. Our previous findings show TASK channels are important molecular targets for the CNS toxicity by local anesthetics. Inhibition of the TASK channels causes membrane depolarization and increases neuronal excitability, contributing to central local anesthetic

toxicity. However, the structural mechanism underlying local anesthetic acting on TASK channels remain elusive. **Methods**. Based on the crystal structures of human K2P channel subtype TREK1, homology models of TASK channels were created. We predicted candidate sites using the docking conformations for local anesthetic and TASK channels. Site-directed mutagenesis was constructed using mouse TASK-1-pcDNA3 and TASK-3-pcDNA3 wild type templates and Quikchange site-Directed mutagenesis kit (KAPA). Human embryonic kidney 293t cells were transfected with different mutations tagged with green fluorescent protein. Voltage commands were applied and currents recorded and analyzed with pClamp software. **Results**. Docking conformations for a local anesthetic within TASK channels were created. We predicted 15 different candidate sites involved in the local anesthetic modulation of TASK channels. Among the mutations, local anesthetics (bupivacaine, ropivacaine and lidocaine) showed more inhibition of the mutations T93A and F125R and less inhibition of the double mutation L122A-L239A, when compared with wild type TASK channels. **Conclusions**. T93, F125 and L122-L239 are potent and highly selective sites for local anesthetic modulation of TASK channels. Such structural molecular sites might be targets for development of new local anesthetic compounds with reduced toxicity in the future.

Title: Progressive myoclonic epilepsy-associated gene Kctd7 regulates retinal neurovascular patterning

Authors: *J. ALEVY, C. A. BURGER, N. E. ALBRECHT, D. JIANG, M. A. SAMUEL; Dept. of Neuroscience, Huffington Ctr. on Aging, Baylor Col. of Med., Houston, TX

Abstract: Homozygous mutations in the human potassium channel tetramerization domain-containing protein 7 (KCTD7) are associated with progressive myoclonic epilepsy. However, the molecular and neurological basis of this disease remains poorly understood. Using a high-throughput screening pipeline in murine retina, we recently identified *Kctd7* as a potential neural regulator. Here we show that mice deficient in *Kctd7* develop epileptic seizures and display neural activity defects in both the brain and the retina. Kctd7 is enriched in hippocampal and Purkinje neurons in the brain as well as in excitatory bipolar cells in the retina, and the absence

of *Kctd7* results in altered bipolar cell development. These defects are accompanied by specific alterations to vascular patterning that results in delayed vessel development and altered vascular structure. Together, these data identify a disease-inducing role for Kctd7 in the nervous system and establish a model for KCTD7-related progressive myoclonic epilepsy.

Title: Kv3.1 and Kv3.3 differentially contribute to action potential repolarization in principal neurons of the auditory brainstem

Authors: *N. CHOUDHURY[1], A. RICHARDSON[1], D. M. LINLEY[2], S. ROBINSON[3], M. ANDERSON[1], V. MARRA[1], C. KOPP-SCHEINPFLUG[4], J. R. STEINERT[1], **I. D. FORSYTHE**[1];

Abstract: The ‘delayed rectifier’ potassium current is mediated by Kv3 channels which open at voltages during action potential (AP)-mediated depolarisation and thus provide the repolarization drive to support high-frequency firing in neurons. Multiple Kv3 genes are co-expressed in several parts of the brain, either as hetero- or homo-tetramers but subunit specific roles are largely unknown. Neurons of the medial nucleus of the trapezoid body (MNTB) and the lateral superior olive (LSO), in the superior olivary complex (SOC) of the auditory brainstem, compute sound source localisation through integration of binaural stimuli. Both MNTB and LSO neurons express Kv3.1 and Kv3.3 subunits. We have used this neuronal network to investigate role of these subunits in generating functional Kv3 channels and during repolarization of the postsynaptic AP. The study was conducted on CBA/Ca mice, and on Kv3.1 knockout (KO), and Kv3.3KO mice backcrossed onto the same strain. Expression of Kv3 channels in the MNTB and LSO principal neurons was investigated by qRTPCR, western blot and immunohistochemistry. For *ex vivo* whole cell patch-clamp electrophysiology, transverse sections of SOC were used for

recording currents and voltages in the neurons under different biophysical and pharmacological conditions. Intracellular Ca^{2+} transients were studied by Fura-2 ratiometric fluorescence measurement. Statistical significance was determined using Student's t-test and one-/two-way ANOVA and expressed as mean ± SD.
The results obtained reveal that MNTB neurons effectively employed either Kv3.1 or Kv3.3 subunits in Kv3 channels, with similar whole-cell current amplitude; however, the fastest APs were achieved when both subunits were expressed together (AP halfwidth-WT: 0.29 ± 0.07ms, n=14; Kv3.1KO: 0.41 ± 0.11ms, n=11, p=0.0207; Kv3.3KO: 0.48 ± 0.06ms, n=11, p<0.0001). In the LSO, Kv3.3 subunits were essential; Kv3.1 mRNA was present, but somatic Kv3 channels must contain at least one Kv3.3 subunit, since Kv3.3KO mice had little or no TEA-sensitive Kv3 current (Kv3.3KO: 6.0 ± 2.5nA, n=11; with TEA: 5.0 ± 1.8nA, n=7), and AP halfwidths were increased compared to WT (WT: 0.28 ± 0.04ms, n=10; Kv3.3KO: 0.69 ± 0.15ms, n=7, p<0.0001). Measurement of whole-cell voltage-gated Ba^{2+} currents showed no change in the MNTB or LSO, but the longer AP duration in the KOs increased $[Ca^{2+}]_i$ in an activity-dependent manner. We conclude that Kv3 channels make major contributions to AP repolarization in both the MNTB and LSO. Kv3.1 and Kv3.3 subunits each contribute to Kv3 currents in the MNTB but Kv3.3 is crucially dominant for Kv3 channels in the LSO, while both of the subunits influence Ca^{2+} influx in these neurons.

Title: Characterizing electrophysiological properties of the nodes of Ranvier at motor never fibers using the *in situ* pressure-patch-clamp recording technique

Authors: *S. TONOMURA, K. HIROSATO, J. LING, J. G. GU;
Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: The nodes of Ranvier (NRs) are key sites for saltatory conduction, the rapid action potential conduction along myelinated nerve fibers. Saltatory conduction through NRs is often impaired under pathological conditions such as Multiple sclerosis and Guillain-Barre syndrome,

leading to sensory and movement dysfunctions. However, ion channel mechanisms underlying the saltatory conduction of action potentials at NRs are incompletely understood. In the present study, we investigated electrophysiological properties of NRs in spinal ventral root motor fibers using our newly developed *in situ* pressure-patch-clamp recording technique. We found that NRs of motor fibers displayed large non-inactivating outward currents that were not highly sensitive to the voltage-gated K^+ channel inhibitors TEA (20 mM) and 4-AP (1 mM). However, the outward currents were significantly inhibited by the two-pore domain potassium (K2P) channel blockers norfluoxetine. These results suggest that K2P channels rather than voltage-gated K^+ channels are principal type of K^+ channels present at NRs of rat motor nerve fibers. We also used the *in situ* pressure-patch-clamp recording technique to characterize other membrane and action potential properties at NRs. This is the first study to directly make whole-cell patch-clamp recordings from intact NRs of mammalian motor nerve fibers. This new study may help to understand ion channels and their functions at NRs in saltatory conduction along motor nerve fibers. The study was supported by NIH grants DE018661 and DE023090 to J.G.G.

Title: K2P channels are molecular machineries at nodes of Ranvier for saltatory conduction

Authors: ***H. KANDA**[1,2,3], S. TONOMURA[3], J. LING[3], K. NOGUCHI[2], S. MATALON[3], Y. DAI[1,2], J. G. GU[3];

Abstract: Timely sensory and motor responses are critical in life and largely rely on saltatory conduction of action potentials through nodes of Ranvier (NRs) along myelinated nerves. Impaired saltatory conduction occurs in many diseases causing sensory and motor dysfunctions. However, molecular machineries at NRs for saltatory conduction remain largely unknown at mammalian NRs. Here we show that two-pore domain potassium (K2P) channels are highly clustered at NRs. We demonstrate that 2P channels, but not voltage-gated K^+ channels, are required for action potential formation at NRs. We show that K2P channels control the speed and frequency of nerve impulses conducted through NRs. Furthermore, genetic knockdown of these

channels at NRs retards saltatory conduction and impair *in vivo* sensory behavioral responses. Collectively, K2P channels are molecular machineries at NRs for saltatory conduction in mammals, which may provide new insights into multiple neurological disorders.

Title: Distinguishing subunit-specific roles of Kv3 channels in action potential repolarization

Authors: *K. BONDARENKO[1], J. P. SMALLEY[2], M. S. ANDERSON[1], P. M. CULLIS[2], I. D. FORSYTHE[1];

Abstract: Voltage-gated potassium channels (Kv) of the Kv3 subfamily play key roles in generating short duration APs, which also permit firing at high frequency in many brain regions, including the auditory brainstem. We have shown that two subunits are of particular importance: Kv3.1 and Kv3.3. Histological studies show that both Kv3.1 and Kv3.3 subunits are expressed in principal neurons of the Medial Nucleus of Trapezoid Body (MNTB) and other nuclei of the superior olivary complex.
The aim of this study was to determine the role of each subunit in generating functional Kv3 channels. Four investigations have been performed: 1. Subcellular immunofluorescent labelling and localization of the Kv3 subunits; 2. Electrophysiological characterization of the outward potassium currents mediated by Kv3.1 or Kv3.3 subunits in MNTB neurons; 3. Examination of homozygous channels mediated by these subunits in cell lines. 4. Use of photo-activated pharmacology to identify the actions of different Kv3 channel subunits.
We show that Kv3.1 and Kv3.3 are localized in MNTB soma membrane axon initial segments. Whole-cell patch clamp was used to characterize outward potassium currents. MNTB neurons possessed Kv3 currents which were blocked by tetraethylammonium (TEA, 1mM), and comparable to Kv3 currents expressed in cell lines. The results show that Kv3.1 and Kv3.3 immunostaining were indistinguishable suggesting similar localization of both subunits in MNTB neurons. To test if these Kv3 channels were heteromers or homomers, we employed light-activated pharmacology based on the MAQ blocker (Fortin et al., 2011).

Single amino acid substitution using CRISPR/Cas9 was used to introduce a mutation at N484C of the Kv3.3 subunit in CBA mice. Preliminary results showed WT and mutant MNTB currents were similar. Whole-cell voltage clamp of N484C homozygous MNTB neurons showed moderate current reduction under 500 nm light following 90 min incubation in 300 uM MAQ (7-8%, n=3); currents were further blocked by 1 mM TEA.
Histology and electrophysiological studies show that MNTB neurons maintained Kv3.3 expression after genetic modification. Partial block of MNTB Kv3 channels by light-activated MAQ photo-switching was observed.

Title: Regulation of presynaptic Ca^{2+} microdomains and synaptic transmission by K^+ channel variants

Authors: *I. CHO[1], S. ALPIZAR[2], M. CHIN[1], L. PANZERA[3], M. B. HOPPA[2];
[2]Biol. Sci., [3]Biol., [1]Dartmouth Col., Hanover, NH

Abstract: Presynaptic terminals are fundamental computational units in the brain, and their dysfunction is associated with several neurological diseases. They mediate the transduction of incoming electrical signals (action potentials) into chemical signals (neurotransmitter release), and the efficiency of conversion determines the strength of circuits underlying memory and behavior. Many synapses in the hippocampus display frequency-dependent changes in transduction efficiency. The shape of the presynaptic action potential is of fundamental importance in determining the timing and magnitude of neurotransmitter release. However, the plasticity of action potential waveform shape during frequency dependent stimulation and a role in transduction efficiency is unknown. This is largely due to the fact that the *en passant* synapses that are prevalent in the hippocampus are difficult to measure with classic electrophysiology owing to their small size. To overcome these limitations in our current study we combine a genetically encoded far-red voltage indicator named QuasAr with quantitative measurements of presynaptic calcium and vesicle fusion by GCaMP and vGlut-pHluorin imaging, respectively.

We found significant frequency-dependent changes in presynaptic action potential shape even from paired pulse stimulation in primary cultured rat hippocampal neurons. Namely, a significant broadening of action potentials at excitatory synapses and narrowing at inhibitory synapses were shown. We determined that these changes were due to unique molecular identities and functional role of K^+ channels that can modulate the electrogenic properties of the presynaptic membrane at excitatory and inhibitory terminals. Our results indicate that $K_v\beta1$-induced inactivation of $K_v1.1/1.2$ channels underlies the broadening, while calcium-gated potassium channels underlie narrowing of the action potential for excitatory and inhibitory neurons respectively. Furthermore, while the changes in AP shape are strongly correlated with vesicle fusion probability, however they are independent of net calcium influx as classically predicted, suggesting a role for calcium-microdomain signaling. Taken together, these results suggest that variability in presynaptic K^+ channels may play a fundamental role in controlling frequency-dependent changes in synaptic strength.

Title: Regulation of neuronal ion channel activity by Polycomb and Trithorax group proteins in unexpected manners

Authors: *S. DAVE, T. LENG, Z.-G. XIONG, A. ZHOU;
Neurosci. Inst., Morehouse Sch. of Med., Atlanta, GA

Abstract: Polycomb Group (PcG) and Trithorax Group (TrxG) proteins are epigenetic regulators installing either repressive or activating marks, respectively, on histones. PcG proteins may potentially target nearly half of the known K^+ channel genes in addition to genes involved in cellular stress responses and cell cycle control. Previously we have shown that changes in cellular levels of selected PcG proteins, via gene silencing or over expression, can increase or decrease, respectively, K^+ currents in neuronal cultures. This led us to consider a potentially novel, previously undescribed role of PcG proteins in regulating neurophysiological properties of

neuronal cells, and whether TrxG proteins may act antagonistically in such regulation. The objective of this study was to determine: 1) Effects of pharmacologic inhibition of PcG proteins on K^+ channel activity; 2) Specific channel subtypes that may contribute to PcG-mediated changes in K^+ channel activity; and 3) Effects of inhibition of TrxG proteins on K^+ channel activity. Patch-clamp analyses were performed on differentiated, mouse brain-derived NS20Y neuroblastoma cells that were treated with one of the following inhibitors: 50 μM PRT 4165, or 100 μM MM-102, or 10 μM PFCBP-1 (antagonists of PcG protein BMI-1, TrxG protein MLL-1 and Creb Binding Protein(CBP, required for TrxG's activating transcription regulation), respectively). K^+ currents were recorded with or without appropriate channel blockers. Results to date showed that, inhibition of BMI1 resulted in an increase in whole cell K^+ currents, and an increase in negativity of the resting membrane potential (RMP). The afore-noted effects were masked by 100 nM alpha-guangitoxin 1E, suggesting the involvement of Kv2.1, 2.2 and 4.3. Inhibition of TrxG protein MLL-1, unexpectedly, also resulted in an increased K^+ currents but showed little effects on resting RMP, whereas inhibition of CBP resulted in a decrease in K^+ currents. Taken together, we conclude that the activity of neuronal K^+ channels are subject to repressive regulation by PcG proteins that can be achieved through changes in either the expression level or the biochemical activity of PcG proteins. The on-going study focuses on molecular mechanisms that underlie PcG protein-mediated regulation of K^+ channels, and characterization of the effects of PcG and TrxG proteins (MLL-1 and additional TrxG proteins) on other ion channels and neuronal excitability. Our ultimate goal is to investigate regulatory roles of PcG/TrxG proteins in neuronal stress response via regulation of ion channels.

Title: Mechanism of action of clinically relevant concentrations of 3,4-diaminopyridine at the neuromuscular junction

Authors: *K. S. OJALA[1], S. P. GINEBAUGH[1], M. WU[1], B. VUOCOLO[1], E. W. MILLER[2], S. D. MERINEY[1];
[1]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Chem. & Mol. and Cell Biol., Univ. of California, Berkeley, Berkeley, CA

Abstract: The most common treatment for the neuromuscular disease Lambert-Eaton Myasthenic Syndrome (LEMS) is the low dose administration of a potassium channel blocker, 3,4-diaminopyridine (3,4-DAP), which increases the magnitude of transmitter release from the neuromuscular junction (NMJ). The mechanism of 3,4-DAP action is canonically thought to be block of voltage-gated potassium channels, which is hypothesized to prolong the motoneuron action potential. However, a recent debate has centered on other potential effects of 3,4-DAP; namely, direct effects on voltage-gated calcium channels. In particular, it has been proposed that the action of 3,4-DAP on nerve terminal Cav1 type calcium channels may contribute to 3,4-DAP-induced increases in transmitter release; however, these previously published experiments were performed with substantially higher doses of 3,4-DAP than is clinically relevant. To address this debate, we performed a series of experiments. We expressed the most predominant presynaptic potassium channel present at the mammalian NMJ, Kv3.3 (human isoform), in HEK293 cells and used patch-clamp electrophysiology to characterize the concentration-dependent block of potassium current after application of clinically relevant doses of 3,4-DAP (0.5, 1.0, 1.5 uM). In addition, we showed that there was no effect on Cav2.1 or Cav1.2 calcium currents after application of 1.5 uM 3,4-DAP. Furthermore, the presence of the Cav1.2 calcium channel antagonist nitrendipine in ex vivo mouse and frog NMJs did not significantly alter the increase in transmitter release caused by application of 1.5 uM 3,4-DAP, measured via current clamp electrophysiology. Finally, we used a voltage-sensitive dye to measure the motor nerve terminal action potential and showed that ex vivo application of 0.5-1.5 uM 3,4-DAP significantly increased the duration of the presynaptic action potential in a dose-dependent manner in both mouse and frog NMJs. These results strongly support the hypothesis that improvements in neuromuscular function experienced by LEMS patients taking clinically relevant doses of 3,4-DAP are restricted to its mechanism of action on voltage-gated potassium channels and are not due to off-target effects on calcium channels.

Title: 3,4-diaminopyridine enhances muscle contraction strength by increasing asynchronous synaptic vesicle fusion to generate multiple muscle action potentials

Authors: *J. B. MACHAMER, K. T. PAGARIGAN, P. M. MCNUTT;
US Army Med. Res. Inst. of Chem. Def., Edgewood, MD

Abstract: Aminopyridines are a family of selective potassium channel antagonists that have been investigated as potential treatments for a variety of neurological diseases. Their therapeutic effects are believed to result from inhibition of Kv1 delayed rectifier channels and subsequent broadening of neuronal action potentials. In motor neurons, the extended period of presynaptic depolarization increases activation of voltage-gated calcium channels (VGCCs), resulting in larger Ca^{2+} currents, enhanced acetylcholine release, and greater depolarization of the muscle membrane. Firdapse, a form of 3,4-diaminopyridine (DAP), has received FDA approval for the treatment of Lambert-Eaton myasthenic syndrome (LEMs) and is in clinical trials for treatment of congenital myasthenic syndromes, myasthenia gravis and spinal muscular atrophy, and has been proposed as a treatment for botulism. In each of these diseases, muscle function is inhibited by reducing end-plate potential (EPP) amplitude below the threshold required to trigger muscle action potentials (mAPs) and muscle contractions. Aminopyridines are believed to therapeutically function by generating EPPs that exceed the muscle fiber threshold potential and thus generate mAPs and muscle contraction. However, aminopyridines enhance the contraction strength of undiseased neuromuscular preparations, suggesting that they promote muscle function through another mechanism. To better understand the mechanisms by which aminopyridines affect muscle function, we analyzed the effects of DAP on presynaptic release, postsynaptic mAP formation and postsynaptic mAP propagation. By inhibiting muscle contraction while maintaining mAPs using the myosin ATPase inhibitor 3-(N-butylethanimidoyl)-4-hydroxy-2H-chromen-2-one (BHC), we find that DAP enhances muscle contraction by generating multiple mAPs. The extra action potentials are not triggered by prolonged EPPs resulting from the synchronous fusion of increased numbers of synaptic vesicles, but instead are a consequence of large numbers of asynchronous vesicle fusions that induce stochastic depolarization of the membrane above the threshold potential required for mAP generation.

Title: The role of peptidoglycans receptors in the response to bacterial endotoxin LPS on synaptic transmission: NMJ and CNS

Authors: *C. R. BALLINGER BOONE[1], D. HARRISON[1], R. L. COOPER[2];
[1]Biol., Univ. of Kentucky, Lexington, KY; [2]Dept Biol, Univ. of Kentucky Dept. of Biol., Lexington, KY

Abstract: Gram-negative bacteria produce and release endotoxins in the form of lipopolysaccharides (LPS). The different forms of LPS produce varying secondary immune responses. The direct effect of LPS itself, which occurs in seconds, has not been well studied; however, the receptors which bind LPS were first identified in Drosophila which led to their discovery in mammals. We continue to use Drosophila as a model in these studies. Exposing the heart of larval Drosophila to LPS (500 µg/ml) from *Serratia marcescens* causes the heart rate to initially increase and then slow down. Whereas exposing the body wall muscle, while stimulating the motor nerve, results in hyperpolarization. Evoked as well as spontaneous excitatory junction potentials become depressed with the presences of LPS in high concentrations. Low concentrations can enhance evoked transmission. The decrease in synaptic transmission is likely due to the postsynaptic glutamate receptors being blocked by LPS. We set out to determine if there was an alteration in the rapid effects upon exposure to LPS in RNAi expressing lines for the peptidoglycan recognition proteins (PGRPs) PGRP-LC and PGRP-LE in body wall muscle, motor neurons and sensory neurons as well as cardiac muscle. Knocking down the receptor expression for PGRP-LC and PGRP-LE did not alter the acute effects of LPS exposure to the body wall muscle and effects on synaptic transmission or heart rate in larval Drosophila. The responses of LPS are not due to NOS, TEA sensitive K+ channels or K(ATP) channels as profiled by agonist and antagonist to these possibilities. We are still investigating CNS effects. Thus, it has yet to be determined the mechanism by which LPS and associated peptidoglycans are causing these rapid cellular changes. This is significant to address potential effects in human and other animals exposed to gram negative bacterial infections.

Title: Investigating the role of a synaptically targeted intronic lncRNA in memory

Authors: *E. GRINMAN, I. ESPADAS, Y. AVCHALUMOV, S. SWARNKAR, S. V. PUTHANVEETTIL;
Neurosci., The Scripps Res. Inst., Jupiter, FL

Abstract: Advances in next-generation sequencing have prompted increased attention to non-coding transcriptional elements in neurobiology, with long non-coding RNAs (lncRNAs) representing a significant portion within the central nervous system. However, despite their significance as regulators of transcription and translation, the functions of lncRNAs in long-term memory storage are poorly understood. Through next-generation RNA sequencing and qRT-

PCR, we have uncovered multiple lncRNAs that are enriched in mouse hippocampal synaptic fractions in a signaling pathway that mediates learning in the hippocampus: cAMP/PKA signaling. One such transcript was confirmed by fluorescence in situ hybridization to be transcribed, and targeted to distal processes in a microtubule and actin-dependent manner, and colocalizes with dendritic and synaptic proteins. This lncRNA, termed ADEPTR (Activity DEPendent Transported lncRNA), is intronic in its genomic origin but is expressed and transported independently of its protein-coding host gene. Functional and mechanistic experiments have demonstrated that this lncRNA 1) is rapidly and robustly expressed and dendritically targeted in a cAMP-dependent manner, 2) mediates cAMP-dependent changes in excitatory synaptic transmission and spine density, 3) is dendritically transported by Kif2a and binds proteins required for cytoskeletal reorganization 4) is expressed in the hippocampal CA1 subregion during contextual fear conditioning (CFC). Together, these results suggest that this lncRNA has a critical functional role in mediating hippocampus-dependent learning. This study is the first to demonstrate that an intronic lncRNA holds such potential to shape neurobiology; future work will elucidate its role in mediating learning *in vivo*. This may ultimately shape future study of lncRNAs in learning and memory and present intronic lncRNAs as worthwhile targets of memory-related disorders.

Title: Synaptic microRNAs and their role in major depressive disorder pathogenesis

Authors: *Y. YOSHINO[1], Y. DWIVEDI[2];
[1]Psychiatry and Behavioral Neurobio., Birmingham, AL; [2]Dept of Psychiatry, Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Major Depressive Disorder (MDD) is a debilitating disease affecting a large population all over the world. Several antidepressants that target monoamines such as serotonin, norepinephrine, and dopamine are available. These antidepressants work by adjusting levels of monoamines specifically in the synapse. The change of monoamine levels in synapse leads to alleviation of depression in patients. At the epigenetic level, microRNAs (miRNAs) are well studied and have emerged as a regulator of neural plasticity and higher brain functioning. Indeed, miRNAs changes have been reported in human blood and postmortem brain. To our knowledge, there is no report that focuses on miRNAs change in synaptosomes. This study aims to reveal the miRNAs changes in synaptosome of human postmortem brain related to MDD. The study was conducted in dorsolateral prefrontal cortex (dlPFC) of 15 non-psychiatric controls and 15 MDD subjects. The synaptic fraction was isolated by sucrose gradient and ultra-centrifugation methods. miRNAs were examined in both total and synaptosome fractions using small RNA sequencing. We found 13 miRNAs to be upregulated and 7 miRNAs were downregulated in the synaptic fraction from MDD subjects. From the pathway analysis, it appears that synaptic functions are significantly altered which occurs via changes in miRNAs. In addition, neuroinflammatory pathways were also detected. These pathways may provide new insight into how miRNAs may play a role in altering synaptic functions and their involvement in MDD pathogenesis.

Abstract: Deciphering the cellular and molecular mechanisms underlying learning and memory, in which inhibitory interneurons play a crucial role, is a fundamental goal in neuroscience. Epigenetic signatures execute transcriptional control and were shown to be dynamically remodeled in the adult nervous system. The emerging evidence for activity-dependent DNA methylation executed by DNA methyltransferases (DNMTs) and TET-mediated DNA demethylation in synaptic function irrevocably raises the question for the targeted subcellular processes and mechanisms.
Indeed, we found improved inhibitory synaptic transmission in electrophysiological recordings using a conditional DNMT1 knockout mice model specific for parvalbuminergic interneurons. Transcriptome and methylome analysis on FACS-enriched interneurons of wild-type and DNMT1 deficient mice as well as in vitro approaches provide evidence for differential modulation of processes involved in synaptic vesicle replenishment.
Further, the analysis of human brain samples suggests that this mechanism of synaptic function regulation by DNA methylation could potentially contribute to the pathophysiology of temporal lobe epilepsy. In summary, we here provide evidence for DNA methylation-dependent modulation of synaptic transmission in cortical interneurons by acting on synaptic vesicle replenishment.

Title: Cell type-specific action of the alternative splicing factor SLM2 for specifying synaptic properties

Authors: *L. TRAUNMÜLLER, E. FURLANIS, G. FUCILE, P. SCHEIFFELE;
Univ. of Basel, Basel, Switzerland

Abstract: Neuronal circuits consist of hierarchical assemblies of highly specialized neuronal cell types. The intrinsic properties of neurons and the functional specification of their synapses are fundamental for how circuits process information. However, how different classes of neurons orchestrate their synaptic and functional properties remains largely unclear. We are testing the hypothesis that post-transcriptional mechanisms, like alternative splicing, play a central role in the regulation of cell type-specific properties. We systematically mapped ribosome-associated transcript isoforms in genetically defined cell populations in the mouse neocortex and hippocampus. This approach revealed complex and highly distinct alternative splicing programs for the control of synaptic proteins and intrinsic neuronal properties- even within closely related classes of pyramidal cells and inhibitory neurons. Since alternative splicing is regulated by RNA-binding proteins, we further sought to identify cell type-specific RBPs that might regulate these distinct splicing programs. Interestingly, we found that different cell populations exhibit highly selective gene expression patterns for RBPs. This includes the alternative splicing factor SLM2 which is selectively expressed in subpopulations of excitatory and inhibitory neurons in the mouse brain. Cell type-specific loss-of function studies for SLM2 combined with cell type-specific transcript isoform profiling, indicate that SLM2 regulates alternative splicing of different transcripts in hippocampal somatostatin positive interneurons and CA1 pyramidal cells. Loss of SLM2 does not affect general neuronal properties but rather results in modulation of the functional specification of synapses. Thus, our work reveals a major role for cell type-specific alternative splicing programs in the genetic determination of neuronal circuit specificity and function.

Title: Adhesion GPCR Latrophilin-1 simultaneous coupling to both $G\alpha_s$ and $G\alpha_{i/o}$ proteins pathways is dictated by an intracellular alternatively splice insert

Authors: *J. C. OVANDO-ZAMBRANO[1], J. A. ARIAS-MONTAÑO[1], A. A. BOUCARD[2]; [1]Dept. de Fisiología, Biofísica y Neurociencias, [2]Dept. de Biología Celular, Ctr. de Investigación

y de Estudios Avanzados del Inst. Politécnico Nacional (CINVESTAV-IPN), Mexico City, Mexico

Abstract: ADGRL1/latrophilin-1 (Lphn1) is a member of the autoproteolytically-cleaved subfamily of adhesion G protein-coupled receptors (aGPCR) that participate in the formation of synapses through heterophilic interactions with its endogenous ligands such as neurexin-1β (nrx-1β) or fibronectin-leucine-rich transmembrane protein 3 (FLRT3), which allow the Lphn1-ligand complex to mediate intercellular adhesion. The gene encoding Lphn1 undergoes alternative splicing which results in receptor variants bearing a modification between two N-terminally located extracellular adhesion motifs (SSA) and within the C-terminal tail (SSB). These splicing events potentially affect receptor structure and consequently can also modify its function. While splicing at SSA has been shown to modify Lphn1 ligand-binding functions, the role of SSB in receptor functions remained elusive. However, because of its intracellular location SSB is likely to affect receptor trafficking to and from the cell membrane and/or its coupling to the cell signaling machinery. Thus, we analyzed the effect of SSB splicing on Lphn1 expression/trafficking, binding and signaling properties in HEK293T cells. Immunodetection of Lphn1 receptor variants revealed that SSB splicing did not affect their expression, their processing or their trafficking to the cell membrane, as steady state levels were identical for both proteins. Binding assays conducted with soluble ligands nrx-1β and FLRT3 unveiled that both SSB receptor variants possessed similar binding properties. Signaling properties of Lphn1 SSB variants were evaluated by measuring ligand-independent and ligand-dependent modulation of intracellular Ca^{2+} concentrations, activation of MAP kinases and regulation of cAMP levels. No changes between receptor variants were detected in both Ca^{2+} mobilization and MAP kinase activation assays. On the other hand, cAMP accumulation assays revealed that Lphn1+SSB expression constitutively and ligand-dependently increased intracellular levels of this second messenger in HEK293T cells while expression of Lphn1-SSB did not. Moreover, ligand-dependent inhibition of forskolin-induced cAMP production was observed for Lphn1-SSB and surprisingly for Lphn1+SSB expression, an effect that was mediated by the activation of $G\alpha_{i/o}$ proteins, thus suggesting that SSB splicing modulates Lphn1 dual activation of $G\alpha_s$ and $G\alpha_{i/o}$ proteins leading to opposite cAMP signaling profiles. These data bring a greater understanding of the role of Lphn1 in coupling adhesion to intracellular signaling which support synapse formation events.

Title: Rapid actions of anti-Müllerian hormone in regulating synaptic transmission and long-term synaptic plasticity in the hippocampus

Authors: K. WANG[1], F. XU[1], M. S. LAWSON[2], ***J. G. MAYLIE**[1], J. XU[1];

Abstract: Anti-Müllerian hormone (AMH) is a glycoprotein that was originally recognized as a fetal hormone generated by the testicular Sertoli cells to regulate sexual differentiation in mammalian species. Recent studies have shown that AMH acts as a neuroactive peptide factor in regulating neuronal viability and AMH-specific receptor AMHR2 is expressed in various brain regions including the hippocampus. However, little is known about the AMH effects on neuronal activities in hippocampus. In this study, we aimed to investigate AMH actions in regulating CA3-CA1 excitatory synaptic transmission and long-term synaptic plasticity in the hippocampus. Brain tissue was obtained from wild-type male and female CD-1 mice (6-8 weeks old). Following transcardial perfusion and post-fixation by 4% paraformaldehyde, mouse brains were frozen-sectioned for immunohistochemistry using anti-AMHR2 antibody. The direct actions of AMH on neuronal activities were examined by extracellular field recordings in hippocampal slices with and without 0.4 nM recombinant AMH protein addition. The efficiency of synaptic transmission is determined from plots of the slope of the extracellular field excitatory postsynaptic potentials (fEPSPs) against the amplitude of fiber volley (FV) evoked by synaptic stimuli of varying intensities. Whole-cell current-clamp recordings in hippocampal slices were used to determine AMH-mediated postsynaptic modulation of synaptic transmission. Data from female mice showed that AMHR2 was primarily localized in the hippocampal pyramidal neurons. Acute slices exposed to AMH displayed a robust increase in the efficiency of synaptic transmission relative to controls (0.61 ± 0.06 ms^{-1} versus 0.29 ± 0.03 ms^{-1}; $p < 0.001$). AMH addition also significantly boosted long-term synaptic potentiation, measured by the ratios of fEPSP slopes 5 minutes before and 15 minutes after delivery of high frequency train, compared to controls (168.9 ± 7.0 % versus 140.8 ± 6.6 %; $p < 0.01$). These results suggested enhanced information coding following AMH exposure. In addition, AMH treatment acutely increased excitatory postsynaptic potentials in CA1 pyramidal neurons (163.1 ± 16.3 %; $p < 0.01$). Male mice followed the same trend as females in AMHR2 expression and electrophysiological properties upon AMH exposure. Our findings provide functional evidence that AMH directly regulates synaptic transmission and long-term synaptic plasticity in the hippocampus. These data suggest a possible role of AMH in learning and memory, and the potential of AMH as a therapeutic target in preventing memory lost or treating cognitive diseases in the general population.

Title: Signaling by microglia-enriched cytokine tweak through the neuronal receptor Fn14 modulates synaptic neurotransmission and plasticity

Authors: *D. NAGY[1], K. ENNIS[2], S. SU[3], R.-F. GU[3], R. WEI[3], C. HINCKLEY[3], K. LI[3], B. GAO[3], M. HAJOS[3], L. C. BURKLY[3];
[1]Biomarkers, [2]Acute Neurol., [3]Biogen, Cambridge, MA

Abstract: Synaptic plasticity plays a critical role in the development of the CNS through synaptic strengthening and pruning, however these processes may become dysregulated or aberrant in the context of disease. While the molecular mediators of plasticity are not fully understood, emerging evidence may suggest bidirectional crosstalk between neurons and surrounding glia influence this neuroplasticity. We postulated that signaling by the microglia-enriched cytokine, TWEAK, through its neuronally-expressed receptor, Fn14, regulates synaptic physiology and pathophysiology based on the recent discovery of Fn14 as a molecular mediator of synaptic refinement in experience-dependent visual system development. Through the use of acute hippocampal (HC) brain slices and slice cultures, we demonstrate that recombinant TWEAK dose dependently dampens both basal synaptic neurotransmission (BSN) and long-term potentiation (LTP) while inhibition of endogenous TWEAK by an anti-TWEAK antibody augments these synaptic functions. We determined that the effects of TWEAK were Fn14-dependent by testing genetic Fn14 knockout (Fn14KO) mice as a tool to globally inhibit Fn14 signaling. We established that naïve adult Fn14KO mice do not exhibit any functional difference in normal synaptic physiology compared to wildtype control (WT) animals. In addition, we dissected the cell type specificity of the observed effects with the use of a hairpin targeted to knockdown Fn14. Hairpins were packaged into neuronal specific adeno-associated viruses and injected into WT animals, delineating that TWEAK modulates BSN and synaptic plasticity through neuronal Fn14. TWEAK treatment increased the paired-pulse ratio of excitatory postsynaptic potentials and decreased the frequency of spontaneous miniature excitatory postsynaptic currents while it had no effect on its amplitudes, suggesting that it modulates BSN through presynaptic mechanisms. To further understand the molecular mechanisms involved in the synaptic modulatory effect of the TWEAK/Fn14 pathway we ran phosphoproteomic analysis on TWEAK-treated acute HC slices from both WT and Fn14KO animals. We identified 243 Fn14-dependent TWEAK-induced phosphoproteomic hits, of which 68 (~27%) are synapse annotated. The broad impact of TWEAK/Fn14 signaling on the phosphorylation state of critical synaptic proteins supports a general role in synapse modulation. Activation of the pathway

dampens BSN and plasticity through presynaptic mechanisms while inhibition of the pathway improves synaptic physiology. We posit that inhibition of TWEAK/Fn14 signaling may be beneficial in diseases featuring synapse loss or reduced function.

Title: Inhibition of GluR current in microvilli of sensory neurons via Na^+-microdomain coupling among GluR, HCN channel and Na^+/K^+ pump

Authors: *Y. KANG[1], M. SAITO[2], Y. BAE[3], S. OH[4];
[1]Osaka Univ. Grad. Sch. Human Sci., Suita-Shi, Japan; [2]Dept. of Oral Physiol., Kagoshima Univ. Grad. Sch. of Med. and Dent. Scis., Kagoshima, Japan; [3]Sch. of Dentistry, Kyungpook Natl. Univ., Daegu, Korea, Republic of; [4]Sch. of Dent, Seoul Nat'l Univ., Seoul, Korea, Republic of

Abstract: Glutamatergic dendritic EPSPs evoked in cortical pyramidal neurons are depressed by activation of hyperpolarization-activated cyclic nucleotide-gated (HCN) channels expressed in dendritic spines. This depression has been attributed to shunting effects of HCN current (I_h) on input resistance or I_h deactivation. Primary sensory neurons in the rat mesencephalic trigeminal nucleus (MTN) have the somata covered by spine-like microvilli that express HCN channels. In rat MTN neurons, we demonstrated that I_h enhancement apparently diminished the glutamate receptor (GluR) current (I_{GluR}) evoked by puff application of glutamate/AMPA and enhanced a transient outward current following I_{GluR} (OT-I_{GluR}). This suggests that some outward current opposes inward I_{GluR}. The I_{GluR} inhibition displayed a U-shaped voltage-dependence with a

minimal inhibition around the resting membrane potential, suggesting that simple shunting effects or deactivation of I_h cannot explain the U-shaped voltage-dependence. Confocal imaging of Na^+ revealed that GluR activation caused an accumulation of Na^+ in the microvilli, which can cause a negative shift of the reversal potential for I_h (E_h). Taken together, it was suggested that I_{GluR} evoked in MTN neurons is opposed by a transient decrease or increase in standing inward or outward I_h, respectively, both of which can be caused by negative shifts of E_h, as consistent with the U-shaped voltage-dependence of the I_{GluR} inhibition and the OT-I_{GluR} generation. An electron-microscopic immunohistochemical study revealed the colocalization of HCN channels and glutamatergic synapses in microvilli of MTN neurons, which would provide a morphological basis for the functional interaction between HCN and GluR channels. Mathematical modeling eliminated the possibilities of the involvements of I_h deactivation and/or shunting effect and supported the negative shift of E_h which causes the U-shaped voltage-dependent inhibition of I_{GluR}.

Title: Cell type specific zinc modulation of excitatory synaptic transmission in mouse hippocampus

Authors: *J. N. TANG, G. SOLER-LLAVINA;
Novartis Inst. for Biomed. Res., Cambridge, MA

Abstract: Zinc is implicated in playing a vital role in neurophysiological homeostasis, with zinc dysregulation being associated with neurological and psychiatric disorders. Zinc in the brain is bound within proteins, where it plays catalytic, regulatory, and structural roles. In certain brain regions, 10-15% of zinc localizes to synaptic vesicles at excitatory terminals, where it is co-released with glutamate in an activity-dependent manner. Accumulating evidence establishes zinc as a modulator of synaptic transmission, plasticity, and information processing. However, how zinc modulates synaptic properties in specific cell types remains poorly understood. In this study, we use transgenic mouse lines to assess the role of synaptic zinc in modulating excitatory synaptic transmission at defined interneuron populations relative to pyramidal neurons in mouse hippocampal brain slices. We find that zinc differentially modulates synaptic transmission at specific synapses, suggesting that zinc plays an important role in controlling excitatory-inhibitory balance and ultimately network function.

Title: Heterosynaptic $GABA_B$ receptor function gates glutamatergic transmission in the nucleus accumbens

Authors: *K. M. MANZ;
Anesthesiol., Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: The nucleus accumbens (NAc) integrates distinct synaptic inputs to facilitate goal-directed motivational output. Medium spiny neurons (MSNs), segregated based on the expression of D1 or D2 dopamine receptors, mediate NAc output by projecting to functionally divergent brain regions. Glutamatergic afferents to the NAc drive feedforward inhibition mediated by parvalbumin (PV)-expressing interneurons (INs) and are critically involved in reward-related behavioral states, including those elicited by drugs of abuse. The $GABA_B$ heteroreceptor ($GABA_BR$), a $G_{i/o}$-coupled G protein-coupled receptor (GPCR), is highly expressed at glutamatergic synapses throughout the mesolimbic reward network, yet its physiological role and molecular mechanism at these synapses remains unknown. Here, we explored $GABA_BR$ function at glutamatergic synapses within PV-IN-embedded microcircuits in the NAc core. Using transgenic reporter mice, optogenetics, and whole-cell patch-clamp electrophysiology, we found that presynaptically-expressed $GABA_BR$ recruits a non-canonical SNAP-25-dependent signaling mechanism to reduce glutamatergic synaptic efficacy at D1(+) and D1(-) [putative D2] MSN subtypes. Furthermore, PV-INs heterosynaptically regulate glutamatergic transmission onto D1(+) MSNs by targeting presynaptic $GABA_BR$. Cocaine withdrawal abolished this plasticity and unmasked cell type-specific $GABA_BR$-induced long-term depression (LTD). These findings extend the current model of how PV-INs regulate NAc circuit function and refine mechanisms by which $GABA_B$ heteroreceptors modulate glutamatergic transmission in the NAc core.

Title: Alterations of CB1-mediated excitatory neurotransmission following chronic mild stress during adolescence at the CA1 dendritic layer

Authors: *A. R. FERRARO[1], P. A. WIG[1], S. M. O'SULLIVAN[1], N. M. AMADA[1], J. R. LOPEZ[2], B. HANER[2], Z. MALL[2], A. KEMP[2], C. G. REICH[1];
[1]Psychology, [2]Biol., Ramapo Col. of New Jersey, Mahwah, NJ

Abstract: Work in our lab demonstrated that hippocampal CB1 receptor (CB1R) levels are lower in female adolescent animals compared to males (Reich et al.,2009). Following 21-day exposure to chronic mild stress, CB1R density increased in females while decreasing in males; thus suggesting that hippocampal CB1 responds differentially to stress in a sex-dependent manner. Several other lines of converging evidence clearly indicate a functional sex difference in the endocannabinoid system and behavioral reactions to exogenous cannabinoids in both humans and animals (Rubino and Paralaro, 2011). However, there remains a paucity of data exploring how these sex differences are manifested physiologically following chronic mild stress in either sex. We, therefore, investigated adolescent sex and stress-dependent variance in rat endocannabinoid function throughout the CA1 dendrosomatic layer. Field excitatory postsynaptic potentials (fEPSPs) were recorded from CA1 in male and female adolescent Sprague-Dawley rats (40-60 d.o.) 400 μ;m hippocampal slices. All drugs were bath applied after a 10-min baseline with appropriate positive and negative drug controls as necessary. All sample sizes were greater than n=5, the size needed for 80% statistical power. The present data demonstrates that exogenous activation of CB1 (CB1 agonist, WIN 55-212-2) enhances excitatory neurotransmission (fEPSPs) in the CA1 area of female hippocampal slices, while it classically decreases excitatory transmission in males. The latter is due to a CB1-mediated suppression of glutamate release. In females, we provide evidence that CB1-modulation of excitatory neurotransmission results from enhanced CB1-mediated suppression of GABAergic neurotransmission (inhibitory) that is attenuated following CMS introduction during adolescence. Further observations suggest that the following contribute to the mechanism for augmented suppression of inhibition in females: 1) an attenuation of constitutive CB1 activity at GABAergic synapses, 2) the persistent presence of tonic 2-AG release irrespective of CMS induction and 3) the cessation of CB1-mediated estrogen receptor α-driven eCB production.

These results clearly demonstrate sex and stress-dependent differences in the dendritic layer of CA1 and further elaborate upon a multitude of sex differences found throughout the entirety of the CA1 dendrosomatic axis.

Title: Cholinergic gain control of the claustrum

Authors: *A. NAIR[1,2], M. GRAF[1], G. J. AUGUSTINE[1];
[1]Lee Kong Chian Sch. of Med., Nanyang Technological Univ., Singapore, Singapore; [2]Singapore Bioimaging Consortium, Agency of Science, Technol. and Res., Singapore, Singapore

Abstract: The claustrum is the most interconnected region of the brain and therefore requires mechanisms to distinguish and weight its myriad of inputs and outputs. Cholinergic signaling from the basal forebrain is hypothesized to discern and selectively enhance neuronal circuit output through the control of gain, i.e. the sensitivity of the output of individual neurons to their input. We therefore investigated the ability of cholinergic drive to modulate the gain of claustrum neurons. Whole-cell patch clamp recordings were used to measure claustrum neuronal responses to photostimulation of cholinergic inputs in brain slices prepared from a ChAT-ChR2 transgenic mouse line. Input-output (I-O) relationships were measured in individual neurons as the frequency of action potentials evoked by depolarizing currents of different intensities. Fluorescent retrogradely transported beads were injected into cortical and subcortical structures to identify claustrum neurons that project to these targets. We observed target-specific regulation of claustrum neurons by cholinergic input: this input evoked significantly larger polysynaptic excitation and significantly smaller polysynaptic inhibition in claustro-subcortical (CS) projection neurons in comparison to claustro-cortical (CC) projection neurons. Using synaptic blockers to isolate direct synaptic responses, we found that a sparse subset of CS neurons and VIP interneurons in the claustrum received excitation mediated by nicotinic receptors. This cholinergic excitation caused an increase in the slope of I-O curves, indicating an increase in the gain of these neurons. Remarkably, we also discovered a direct inhibition from cholinergic input that was mediated by $GABA_A$ receptors and preferentially targeted a sparse subset of CC projection neurons. This inhibitory input elicited a decrease in the slope of I-O curves, representing a reduction in gain of these neurons. In summary, cholinergic neuromodulatory input is capable of eliciting opposing, cell-type specific effects on neuronal gain in the claustrum.

We hypothesize that such gain control may provide a general mechanism for the claustrum to selectively process incoming signals and maintain discernibility of its outputs under behavioral states of high cholinergic drive such as directed attention.

Title: Adenosine protects neurosynaptic transmission against experimental ischemia, hypoxia, or hypoglycemia in the mouse hippocampus

Authors: M. KAWAMURA, Jr[1], *D. N. RUSKIN[2], **S. A. MASINO**[2];
[1]Pharmacol., Jikei Univ. Sch. Med., Tokyo, Japan; [2]Dept. of Psychology, Trinity Col., Hartford, CT

Abstract: Adenosine receptors are widely expressed in the brain and adenosine is a key bioactive substance for neuroprotection. Here, we clarify systematically the role of adenosine A_1 receptors during a range of timescales and conditions where large amounts of adenosine are released. Using acute hippocampal slices obtained from mice that were wild type or null mutant for the adenosine A_1 receptor we quantified and characterized the impact of varying durations of experimental ischemia, hypoxia and hypoglycemia on synaptic transmission in the CA1 subregion. In normal tissue, these three stressors markedly reduced synaptic transmission, and treatment of sufficient duration led to incomplete recovery. Whereas inactivation of adenosine A_1 receptors delayed and/or lessened the reduction in synaptic transmission during all three stressors, the lack of functional adenosine A_1 receptors resulted in incomplete recovery. We reproduced the differing responses to hypoxia and hypoglycemia by applying an adenosine A_1 receptor antagonist, validating the clear effects of genetic receptor inactivation on synaptic transmission. These studies clarify the neuroprotective role of the adenosine A_1 receptor during a variety of metabolic stresses, and reveal the consequences of adenosine A_1 receptor activation on synaptic transmission during the acute phase of ischemia, hypoxia or hypoglycemia, and during recovery from these events.

Title: Reactive oxygen species signaling modulates glutamate receptor transport

Authors: ***R. L. DOSER**[1], G. AMBERG[1], F. J. HOERNDLI[2];
[1]Biomed. Sci., [2]CVMBS, Colorado State Univ., Fort Collins, CO

Abstract: In neurons, changes in the subcellular localization and expression of the AMPAR sub-type of ionotropic glutamate receptors (AMPARs) is necessary for learning and memory. These receptors are primarily translated in the cell body and transported through neuronal processes to their destinations by molecular motors. This means that their localization, and therefore synaptic plasticity, requires proper intracellular transport to the synapse. Recent studies have determined that synaptic plasticity is abnormal in the presence of non-physiological levels of reactive oxygen species (ROS), byproducts of normal energy production. In some cell types, ROS are known to modulate voltage-gated calcium channels (VGCC). Our lab and others have shown that calcium signaling and CaMKII play an essential role in activity-dependent regulation of AMPAR transport. Together, these findings led us to ask: does physiological ROS-signaling modulate AMPAR transport and synaptic function *in vivo*? To visualize fluorescently tagged AMPARs *in vivo* in real-time we utilize the transparent genetic model *C. elegans*. This approach revealed that in the presence of increased ROS, AMPAR transport is decreased resulting in hindered AMPAR delivery and exocytosis at synapses. Using a genetic epistasis strategy, we determined that ROS regulate AMPAR transport by acting on or directly downstream of VGCC, but upstream of CaMKII. In addition, using the genetically encoded ROS sensor roGFP and calcium sensor GCaMP, we verified that pharmacological and genetic elevation of ROS leads to decreased intracellular calcium signaling*in vivo*. Using a combination of genetically-encoded tools and electrophysiology techniques, future experiments will determine if ROS regulate AMPAR localization via direct modulation of VGCC. Our *in vivo* studies will provide insight as to why elevation of ROS levels is correlated with abnormal synaptic plasticity and cognitive function in the aged and diseased brain.

Title: Cerebellar modulation of mesolimbic dopamine transmission is functionally asymmetrical

Authors: Z. R. HOLLOWAY, N. B. PAIGE, J. F. COMSTOCK, H. G. NOLEN, H. J. SABLE, *D. B. LESTER;
Psychology, Univ. of Memphis, Memphis, TN

Abstract: Cerebral and cerebellar hemispheres are known to be asymmetrical in structure and function, and previous literature supports that asymmetry extends to the neural dopamine systems. Using *in vivo* fixed-potential amperometry with carbon-fiber microelectrodes in anesthetized mice, the current study assessed hemispheric lateralization of stimulation-evoked dopamine in the nucleus accumbens (NAc) and the influence of the cerebellum in regulating this reward-associated pathway. Our results suggest that cerebellar output can modulate mesolimbic dopamine transmission, and this modulation contributes to asymmetrically lateralized dopamine release. Dopamine release did not differ between hemispheres when evoked by medial forebrain bundle (MFB) stimulation; however, dopamine release was significantly greater in the right NAc relative to the left when evoked by electrical stimulation of the cerebellar dentate nucleus (DN). Furthermore, cross-hemispheric talk between the left and right cerebellar DN does not seem to influence mesolimbic release given that lidocaine infused into the DN opposite to the stimulated DN did not alter release. These studies may provide a neurochemical mechanism for studies identifying the cerebellum as a relevant node for reward, motivational behavior, saliency, and inhibitory control. An increased understanding of the lateralization of dopaminergic systems may reveal novel targets for pharmacological interventions in neuropathology of the cerebellum and extending projections.

Title: The phosphorylation status of the Kv3.4 channel N-terminal inactivation domain regulates nociceptive signaling in the DRG and superficial dorsal horn

Authors: *M. COVARRUBIAS, **L. ZHI**, T. MUQEEM, T. ALEXANDER;
Neurosci., Sidney Kimmel Med. Col. of Thomas Jefferson Univ., Philadelphia, PA

Abstract: The Kv3.4 potassium channel shapes the repolarization of the action potential (AP) in nociceptors of the dorsal root ganglion (Ritter et al., J. Physiol., 2012), and thereby determines the strength of synaptic transmission in the superficial dorsal horn (Muqeem et al., J. Neurosci., 2018). This regulation depends on inactivation of Kv3.4, which is modulated by phosphorylation of four serines within the Kv3.4 N-terminal inactivation domain (NTID) (Covarrubias et al., Neuron, 1994). If the NTID is phosphorylated, Kv3.4 inactivation is slowed/eliminated, the AP is shortened and nociceptive signaling is dampened. However, whether or not this modulation impacts nociception *in vivo* remains unknown, and the translational potential of manipulating the Kv3.4 phosphorylation status and activity has not been explored. We are making Kv3.4 phosphorylation mutants and implementing an AAV-based approach to test the effects of manipulating inactivation on nociceptive signaling in vitro, using electrophysiological and optogenetic approaches, and *in vivo*, using behavioral protocols. Initial results have shown that the expression of the phosphomimetic Kv3.4 in embryonic DRG neurons increases the total high voltage-activating outward current, which exhibits an increased sustained level. Furthermore, expression of the phosphomimetic Kv3.4 induces shortening of the AP and accelerated maximum rate of AP repolarization in these neurons. Ongoing work is characterizing a Cre-dependent mouse line and the Kv3.4-null mouse to investigate the *in vivo* roles of Kv3.4 in nociception.

Title: Patterning interfaces at the nanoscale promotes axonal regeneration in lesion hippocampal organ cultures

Authors: *I. CALARESU[1], I. RAGO[2], L. BALLERINI[3], D. SCAINI[4];
[1]Intl. Sch. For Advanced Studies (SISSA), Trieste, Italy; [2]Elettra, Trieste, Italy; [3]Neurosci., SISSA-ISAS, Trieste, Italy; [4]Neurobio. Sector, Intl. Sch. For Advanced Studies, Trieste, Italy

Abstract: The ability of neurons to sense and adapt to environmental features at the nanoscale offers the opportunity to manufacture ad hoc substrate mechanical and topographical cues to investigate their role in promoting axonal regeneration and synapse formation. Among the variety of nanomaterials developed in these efforts, carbon nanotubes (CNTs) represent one of the more promising. In previous works we demonstrated that CNTs are excellent growth surfaces for neurons, boosting neuronal activity, synaptogenesis and enhancing neural signal transmission. We recently manufactured a novel CNT-based substrate, by growing CNTs as an ultrathin forest directly onto a fused silica substrate, resulting in a novel transparent interface enriched with CNTs (tCNTs); we further investigate tCNT ability in affecting hippocampal circuit formation in vitro. By using whole cell patch-clamp recording, we extensively explored neurons-material relationship with particular attention to the synaptic adaptation of dissociated hippocampal cells coupled to nanostructured substrates. Neuroglial and neuronal cell density and morphology have been investigated through immunofluorescence and confocal microscopy. We further exploited this interdisciplinary approach to test the ability of tCNT in interfacing more complex tissues, such as brain organ cultures. We used organotypic entorhino-hippocampal slice cultures, interfaced to tCNT intact (control) and upon a severe transection of the perforant path segregating the enthorinal cortex and hippocampal formation, which were co-cultured physically separated by a fixed distance (lesion). Simultaneous extracellular recordings were obtained by positioning two electrodes in the granule cells layer of the dentate gyrus and in the deep layers of the entorhinal cortex. Local field potential (LFP) were used to evaluate the degree of functional reconnection 10 days in vitro post lesion. We stimulated the superficial layers of the entorhinal cortex to evoke responses in the dentate gyrus and in the deep entorhinal cortex. Surprisingly, spontaneous LFPs from control and lesion cultures were always more synchronized when slices were interfaced to tCNTs, in respect to flat substrates. Evoked LFP were detected in 100% of lesion cultures on tCNT, indicating perforant path partial regeneration, through axons-nanomaterial interactions. This result is supported by a greater axonal regrowth when slices were interfaced to tCNT, measured by confocal microscopy. Such a multidisciplinary approach, combining surface nano-topography and neural cells assembly (dissociated and explant) may highlight new concepts for tissue engineering.

Title: Functional modulation of PV interneuron by sleep/wake cycle

Authors: F.-J. ZONG[1], Z. CHEN[2], X.-T. ZHANG[1], X. MIN[1], H. YAO[2], ***K.-W. HE**[1]; [1]IRCBC,Chinese Acad. of Sci., Shanghai, China; [2]ION,Chinese Acad. of Sci., Shanghai, China

Abstract: Parvalbumin positive (PV+) interneurons are the most abundant inhibitory neurons in cortices. They play pivotal roles in maintaining the stability of the neural network and increasing the computational power of the circuit. Dysfunction in PV interneuron is commonly associated with varied brain disorders, further underscoring its importance. However, how PV interneuron is regulated is far from clear. Here we found that both synaptic and neuronal function of PV interneurons are tightly modulated during the light/dark cycle, during which sleep and experience are critically involved. We further showed that such modulation have significant impact on the microcircuit properties and brain function, suggesting that it is a physiologically important regulatory mechanism.

Abstract: Apoptosis is the main type of programmed cell death, essential for the correct nervous system development. Even if in adult neurons apoptosis has been related to the pathology of neurodegenerative diseases, apoptotic machinery activation has been also described as necessary in non-lethal regulatory events, such as synaptic plasticity. Apoptosis activation, which culminates with activation of effector caspases, is modulated by hundreds of proteins. One of the regulators of apoptosis is the long isoform of Fas Apoptosis Inhibitory Molecule (FAIM-L), a neuronal specific death receptor antagonist shown capable to modulate neuronal caspase activation. FAIM-L carries out its anti-apoptotic activity by binding to X-linked Inhibitor of Apoptosis Protein (XIAP). XIAP is an inhibitor of caspases, and its levels are modulated by the ubiquitin-proteasome pathway. FAIM-L interaction with XIAP prevents its ubiquitination and degradation, allowing therefore its anti-apoptotic activity. This interaction also modulates non-apoptotic functions of caspases, such as the endocytosis of AMPA receptor (AMPAR), the main mechanism in long-term depression (LTD). To date consensus binding motifs of FAIM-L, which could shed light on its molecular mechanism of action, are unknown. Here, we performed a two-hybrid screening to discover novel FAIM-L-interacting proteins. We found a functional interaction of FAIM-L with the pro-apoptotic protein SIVA-1. SIVA-1 is a protein described as pro-apoptotic and able to interact with XIAP. In this work we show that SIVA-1 modulates FAIM-L function by disrupting the interaction of FAIM-L with XIAP, thereby promoting XIAP ubiquitination. Modulating the inhibitors of apoptosis XIAP and FAIM-L, SIVA-1 induces caspase-dependent neuronal cell death. Furthermore, we show SIVA-1 to be a novel modulator of synaptic plasticity. After induction of LTD in an *in vitro* neuronal model, SIVA-1 protein levels are rapidly increased, and SIVA-1 overexpression is sufficient to induce caspase-dependent internalization of AMPAR. In summary, our studies uncover a new functional partner of FAIM-L, SIVA-1. We propose SIVA-1 as a caspase modulator in neurons, and therefore to be a crucial regulator in neuronal cell death and synaptic plasticity.

Title: Effects of β-adrenergic receptor on long-term depression at parallel fiber to purkinje neuron synapses in the cerebellar flocculus

Authors: *T. INOSHITA, T. HIRANO;
Kyoto University, Grad. Sch. of Sci., Kyoto, Japan

Abstract: The cerebellum is involved in motor learning, and long-term depression (LTD) at parallel fiber to Purkinje neuron (PF-PN) synapses in the cerebellum has been regarded as a main mechanism for motor learning. On the other hand, the involvement of noradrenaline (NA) in motor learning has also been reported in several cerebellum-dependent learning paradigms. However, the relationship between NA and LTD at PF-PN synapses has not been clarified. Here, we examined effects of β-adrenergic receptor (β-AR) on the synaptic transmission and LTD at PF-PN synapses. Applying patch-clamp recording to slice preparations prepared from the cerebellar flocculus, we recorded excitatory postsynaptic currents (EPSCs) at PF-PN synapses. Cerebellar flocculus is known to regulate adaptation of oculomotor reflexes including optokinetic response (OKR) which works to stabilize an image on the retina during movement of visual field. We previously reported that the activity of β-AR in the flocculus is involved in OKR adaptation (Wakita et al., 2017). In addition, we also showed that LTD occurs at PF-PN synapses in the flocculus during OKR adaptation (Inoshita & Hirano, 2018). Thus, we focused on effects of β-AR activity on PF-PN synapses in the flocculus. In order to clarify whether activation of β-AR changes the transmission at PF-PN synapses, a selective agonist for β-AR isoproterenol (ISO) was applied to the slice preparation of the flocculus, which did not change EPSCs at PF-PN synapses. Next, we examined whether β-AR activity changes the threshold of LTD induction or not. In the ISO containing solution, LTD was induced by a relatively weak conditioning stimulation which did not induce LTD in the control solution. Effects of endogenous agonist of β-AR NA were also examined. NA did not change EPSCs at PF-PN synapse, and facilitated the LTD induction as ISO did. These results suggest that activation of β-AR does not affect the synaptic transmission but facilitates LTD induction at PF-PN synapses in the flocculus. Effects of ISO or NA on EPSCs and LTD at PF-PC synapse in the vermis will also be presented.

Title: Age dependent metabotropic glutamate receptor mediated long term depression

Authors: *A. J. IDOWU[1], M. SEGAL[2], A. KIRKWOOD[3];
[1]Physiol., Lagos State Univ. Col. of Med., Ikeja, Lagos, Nigeria; [2]The Weizmann Inst., Rehovot, Israel; [3]Mind Brain Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: Preserved cognitive function during normal aging in rats has been shown to be associated with metabotropic glutamate receptor (mGluR) mediated plasticity. Recently, neurobehavioral characterization of C57BL/6 mice showed significant age-dependent variations in cognitive functions between juvenile and adult mice. However, the unique functional properties of mGluR plasticity in the adult compared to juvenile C57BL/6 mice are yet to be described. We have now compared mGluR mediated long term depression in young (1 to 3 months; n=12 slices) and adult (6 to 8 months; n=12 slices) in the hippocampus of the C57BL/6 mice. We show an increase in the magnitude of mGluR long term depression between young and adult C57BL/6 mice (p&lt0.05). This finding suggests an age-dependent increase in mGluR plasticity in hippocampal slices between juvenile and adult C57BL/6 mice.

Title: Serotonin facilitates plasticity and associativity in hippocampal area CA2

Authors: *A. BENOY, N. ATHER, S. SAJIKUMAR;
Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Hippocampal area CA2 is a neuromodulatory hub of the hippocampal circuit, receiving inputs from several extra-hippocampal neuromodulatory centres including the serotonergic median raphe nucleus. CA2 also possesses a high density of inhibitory interneurons. This study investigates the modulation of synaptic depression, and synaptic tagging and cross-tagging mediated associative plasticity in hippocampal area CA2 under the influence of serotonin (5-HT). Using extracellular field potential recording in male Wistar rat (5-7 weeks old) hippocampal slices, we show that bath application of serotonin (10 µM) is able to transform weak low frequency stimulation (WLFS- 900 pulses (1 Hz, impulse duration 0.2 ms per half-wave, total number of stimuli 900)) induced transient early long-term depression (E-LTD) to protein synthesis dependent long-lasting late long-term depression (L-LTD) at the Schaffer collateral (SC) synapses onto CA2. Further, through synaptic tagging and capture of plasticity-related proteins (PRPs), the 5-HT facilitated L-LTD at SC synapses onto CA2 is able to transform WLFS induced E-LTD to L-LTD at the entorhinal cortical (EC) synapses onto CA2. In the absence of serotonin, WLFS only enables a short-lasting E-LTD at both the SC and EC synapses onto CA2. It was also shown that the 5-HT facilitated L-LTD at SC synapses onto CA2 enables weak tetanization (one 100 Hz train (21 biphasic constant-current pulses; pulse duration per half-wave, 0.2 ms)) induced early long-term potentiation (E-LTP) at EC synapses onto CA2 transform into long-lasting late LTP (L-LTP), through engaging in synaptic cross tagging and subsequent capture of PRPs. Furthermore, our results also suggest a role for BDNF in the 5-HT facilitated LTD at SC synapses onto CA2 as co-application of the BDNF scavenger, TrkB-Fc fusion protein with 5-HT inhibits LTD maintenance at SC synapses onto CA2. Blocking of 5-HT4 receptors abolishes the 5-HT facilitated LTD maintenance and agonists to 5-HT4 receptors alone facilitate E-LTD to L-LTD transformation at SC synapses onto CA2, pointing to a role of 5-HT4 receptors in the maintenance of LTD observed at SC synapses. Together, these findings reveal that serotonin facilitates long-term depression and associative plasticity in hippocampal area CA2.

Title: Altered perineuronal nets and synaptic plasticity in the hippocampus in neurofibromin deficiency in mice

Authors: *A. KAMALI TAFRESHI[1], S. ABDELMAGED[1], K. PRASAD[2], A. POLAVARAPU[1], N. LOZANO[1], C. KOCH[1], P. ALGEDIK[1], O. BOZDAGI[1];
[1]Psychiatry, Rutgers Univ., Newark, NJ; [2]Mol. Biol. and Biochem., Rutgers Univ., Piscataway, NJ

Abstract: Neurofibromatosis type 1 (NF1) is an autosomal dominant tumorigenic neurodevelopmental disorder associated with autism spectrum disorder (ASD) and intellectual disability (ID). Abnormalities in perineuronal nets (PNNs), a specialized extracellular matrix, have been linked to several neuropsychiatric conditions, but have not been investigated in mouse models of neurodevelopmental disorders associated with ASD and ID. In this study, we explored PNNs in the hippocampus in NF1 heterozygous mouse model ($Nf1^{+/-}$) compared to wild type controls. Because hippocampus is associated with synaptic plasticity, cognition and social behavior, we focused our analyses on CA1 and CA2 subregions of the hippocampus. Using lectin, Wisteria floribunda agglutinin (WFA) to label PNNs, we found increased WFA labeled PNNs in the CA2 of $Nf1^{+/-}$ mice compared to controls. Hippocampal gelatinase enzymatic activity, which remodels extracellular matrix proteins, is also reduced in $Nf1^{+/-}$ mice compared to wild type animals, associated with increased PNN formation. Additionally, we showed that Schaffer collateral-CA1 LTP is impaired in $Nf1^{+/-}$ mice, whereas long-term depression (LTD) is enhanced compared to wild type mice. Behavioral characterization suggests impaired long-term social learning and inhibitory avoidance learning in $Nf1^{+/-}$ mice compared to wild type controls. Our data show that PNN abnormalities might contribute to synaptic plasticity and behavioral deficits associated with ASD and ID.

Title: Characterizing long-term synaptic depression at the entorhinal to hippocampal CA1 synapse

Authors: *K. M. KEARY, III[1], Z. LI[2];
[1]Brown Univ. NIH GPP, Bethesda, MD; [2]NIMH, Bethesda, MD

Abstract: Long term synaptic plasticity is the cellular mechanism through which learning and memory are able to take place. Long term potentiation is responsible for strengthening active synapses, while long term depression is key for weakening or eliminating underused synapses. Both are necessary processes for maintaining overall circuit homeostasis and allowing for continual cellular changes. The hippocampal formation is a widely studied structure critical for learning and memory. CA1 is the primary output of the hippocampus, and while Schaffer collateral LTD at proximal dendrites has been extensively studied, the direct cortical input from entorhinal cortex to distal dendrites is far less represented in the literature. To fully investigate the plasticity at this synapse, we recorded field potentials from the Stratum Lacunosum-Moleculare of CA1 neurons in young (<P19) and adult (>P56) mice. Here we establish that LTD appears to take place at both the young and old entorhinal synapse, while Schaffer collateral LTD is abolished in adulthood. Entorhinal LTD appears to be blocked by administration of NMDA antagonist APV, implicating an NMDA dependent induction mechanism at the distal dendrites. Further pharmacological manipulations, as well as transgenic lines, will be utilized to fully explore the mechanism of Entorhinal to CA1 long term depression in the future.

Title: Targeted disruption of NMDAr-dependent synaptic plasticity by intermittent hypoxia

Authors: *A. ARIAS-CAVIERES[1], C. NWAKUDU[1], A. J. GARCIA, III[2];
[1]Univ. of Chicago, Chicago, IL; [2]Emergency Med., The Univ. of Chicago, Chicago, IL

Abstract: Long term potentiation (LTP) and long term depression (LTP) are two forms of synaptic plasticity whose underlying mechanisms regulate the efficacy of synaptic communication and serve as substrates central to learning and memory. Both LTP and LTD can be evoked through NMDAr dependent and NMDAr independent mechanisms.
Intermittent hypoxia (IH), a hallmark of sleep apnea, is known to impair spatial learning and memory. Although IH has been shown to impair LTP evoked by high frequency stimulation (LTPHFS), it is unclear whether IH targets specific forms of synaptic plasticity or alternatively, acts broadly to impair synaptic function. Here, we test the hypothesis that IH reduces the contribution of NMDAr causing a targeted disruption in NMDAr-dependent plasticity. Electrophysiological recordings were made in

hippocampal slices prepared from control mice (control) and mice exposed to ten days of IH (IH10). While LTPHFS and LTP evoked by theta burst stimulation (LTPθ) was reliability produced in control slice, LTPHFS was attenuated and LTPθ could not be evoked in IH10 slices. Similarly, both LTD evoked by low frequency stimulation (LTDLFS) and metabotropic glutamate receptor activation (LTDDHPG) was reliably elicited in the control; whereas, only LTDDHPG could be produced in IH10 slices. Our findings indicate that IH, associated with sleep apnea, causes targeted disruption to forms of NMDAr-dependent synaptic plasticity. Thus, the loss of NMDAr mechanisms supporting learning and memory is a principal consequence of IH which reduces the threshold for neurocognitive decline is sleep apnea.

Title: Impact on brain-derived neurotrophic factor on synaptic transmission and plasticity in the oval nucleus of bed nucleus of the stria terminalis

Authors: *D. FIEDLER[1], M. SASI[2], R. BLUM[2], C. KLINKE[3], M. ANDREATTA[3], H.-C. PAPE[1], M. D. LANGE[1];
[1]Inst. of Physiol. I, Westfälische Wilhelms-University, Muenster, Germany; [2]Inst. of Clin. Neurobio., Univ. Hosp. Wuerzburg, Wuerzburg, Germany; [3]Inst. of Psychology I, Julius-Maximilians-University, Wuerzburg, Germany

Abstract: The neurotrophin brain-derived neurotrophic factor (BDNF) is well known to regulate the differentiation of neuronal precursor cells and synaptogenesis and to contribute to neuronal growth and survival. In addition, BDNF modulates synaptic transmission and synaptic plasticity of neuronal networks, including the so-called fear circuits mediating fear learning and extinction. Specifically, BDNF is highly present in the bed nucleus of the stria terminalis (BNST), a key region contributing to stress-modulated fear. Here, we combined immunohistochemical and electrophysiological *in vitro* approaches to identify the role of BDNF in BNST circuits. The focus has been on intrinsic properties of BNST neurons, as well as synaptic transmission and plasticity in local BNST networks.
Immunohistochemically stainings revealed the existence and regional distribution of both BDNF and its main receptor Tropomyosin receptor kinase B (TrkB) within the BNST, with high levels in the oval nucleus (ovBNST). The influence of BDNF on ovBNST neurons was investigated by

performing electrophysiological whole-cell patch-clamp recordings. BDNF-TrkB interaction caused a significant hyperpolarizing shift of the membrane potential from resting values, associated with reduced excitability of ovBNST neurons. While no effect of BDNF on frequency or amplitude of spontaneous evoked postsynaptic currents (sEPSC) was detected, synaptic plasticity was found to be modulated by BDNF. Specifically, long-term depression (LTD, initiated by low-frequency stimulation of 10 Hz for 10 min) was abolished by the TrkB antagonist ANA-12 or by the kinase inhibitor K252a. Furthermore, LTD was absent when BDNF was captured by the BDNF scavenger TrkB-Fc chimera.
In summary, BDNF is functional in ovBNST synaptic networks. BDNF reduces LTD via TrkB receptors, with no effect on basal synaptic activity in ovBNST neurons. These findings suggest a synaptic entry point of the BDNF system to ovBNST-mediated regulation of stress and fear responsiveness.

Title: Inositol triphosphate receptors are required for DHPG induced LTD, but not low frequency stimulation induced LTD, in visual cortex

Authors: D. KALIKULOV, *Q. S. FISCHER, M. J. FRIEDLANDER;
Fralin Biomed. Res. Inst. At VTC, Roanoke, VA

Abstract: We evaluated the role of inositol triphosphate receptors (IP3Rs) and somatic calcium in the expression of long-term depression (LTD) induced by electrical verses chemical stimulation. We made whole-cell current-clamp recordings from layer 2/3 pyramidal neurons in acute slices (300 μm) of primary visual cortex from 6-12 day old tri-color guinea pigs. Pre-conditioning (baseline) and post-conditioning synaptic responses (postsynaptic potentials, PSPs) were evoked at 0.1 Hz using an extracellular stimulating electrode placed in L4. For conditioning, LTD was induced by either: 1) low frequency stimulation (LFS, 1 Hz, 15 min) of L4, or 2) chemical stimulation with (S)-3,5-dihydroxyphenylglycine (DHPG, 100 μM, 10 min bath application). Plasticity was calculated using a post/pre-conditioning ratio (mean evoked PSP peak amplitude between 20-30 min post-conditioning / mean evoked PSP peak amplitude during the 10 min pre-conditioning). We defined long-term depression (LTD) as a significant ($P<0.01$, t-test) decrease (≥15%) in post/pre ratios, long-term potentiation (LTP) as a significant increase in post/pre ratios, or no change as post/pre ratios that changed <15% and/or were not

significantly different (P>0.01, t-test). In some cases, the IP3R blocker Xestospongin C (XeC, 1µM) and/or the ratiometric calcium indicator Fura-4F was added to the recording pipette. LFS resulted in a mean 16% reduction in PSP amplitude (post/pre=0.84, N=17 slices). Moreover, LFS-LTD was unaffected by the addition of XeC to the recording pipette (post/pre = 0.83, N=11 slices; p = 0.99, KS-test). In contrast, DHPG-LTD resulted in a mean 41% reduction in PSP amplitude (post/pre = 0.59), which was significantly attenuated (to just 21%) by XeC in the recording pipette (post/pre=0.79, N=10 slices; P<0.05, KS-test). DHPG-LTD induction, but not LFS-LTD induction, was accompanied by a large calcium transient (resting baseline concentration=79±13 nM, N=12 slices; DHPG-LTD=600±95 nM, N=5) which was significantly attenuated by XeC (190±78 nM, N=5; P<0.01, t-test). Finally, the magnitude of DHPG-LTD, but not LFS-LTD was positively correlated with somatic calcium concentration. Together these data indicate a mechanistic difference in the induction/expression of LTD induced by LFS and DHPG.

Title: Spike-timing-dependent plasticity alters sensory network connectivity *in vivo*

Authors: *A. J. LUBE, X. MA, B. A. CARLSON;
Washington Univ. In St. Louis, St. Louis, MO

Abstract: How do sensory systems optimize detection of behaviorally relevant stimuli when the sensory environment is constantly changing? The adjustment of synaptic connectivity via spike-timing-dependent plasticity (STDP) has been found in circuits across diverse invertebrate and vertebrate organisms. Further, neuronal connectivity changes consistent with STDP have been observed during development, for example in the establishment of receptive fields and direction selectivity within the visual system. Although it is possible that STDP underlies rapid changes in neural connectivity that alter stimulus tuning, STDP has not been directly implicated *in vivo* under behaviorally relevant conditions. We hypothesize that STDP drives changes in sensory tuning in real-time that enable sensory systems to remain maximally responsive to a changing environment. Our study organism, mormyrid weakly electric fish, produce and receive electric organ discharges (EODs) used to electrolocate and communicate. Thus, spiking patterns themselves are the behaviorally relevant stimulus and the electrosensory system of these fish

allows us to precisely manipulate presynaptic spike timing using both sensory stimulation *in vivo* and afferent stimulation *in vitro*. Using whole-cell intracellular recordings *in vitro* and *in vivo* to repetitively pair afferent or sensory stimulation with intracellular current injection, we manipulated the relative timing of pre- and post-synaptic spiking in central sensory neurons. Using afferent stimulation *in vitro*, we found significant synaptic potentiation at pre- leads post-synaptic delays and significant depression at reversed delays. *In vivo*, we paired sensory stimulation with intracellular spiking at delays that resulted in potentiation and depression *in vitro*. We found that pairing with a sensory stimulus leading intracellular spikes significantly potentiated synaptic responses compared to the reverse delay condition and controls. Thus, our results suggest that STDP alters neural connectivity *in vivo*. Future studies will address how naturalistic patterns of activity in this network may drive changes in sensory tuning through STDP.

Title: The influence of LTP induction on back-propagated action potentials on dendrites: Analysis using optical imaging with voltage sensitive dye

Authors: *S. SUGIMOTO[1], M. KAWAI[1], M. KONDO[2], Y. R. TANAKA[1], T. AIHARA[1]; [1]Tamagawa Univ., Tokyo, Japan; [2]Grad. Sch. of Med., The Univ. of Tokyo, Tokyo, Japan

Abstract: The hippocampus has several functions that is related to the integration and storage of sensory information. Previous studies reveal that the dentate gyrus has the projections of spatial information (e.g. place) and non-spatial information (e.g. odor) at medial dendrite (MD) and distal dendrite (DD) in molecular layer, respectively. On the other hand, many researchers investigate that spike-timing dependent plasticity (STDP), the order and temporal interval between an excitatory post synaptic potential (EPSP) and a back-propagated action potential(bAP) decide the sign and magnitude of the plasticity, long-term potentiation (LTP) or depression (LTD). Our previous study showed that the amplitude and transmission distance of bAP, one of factors for STDP induction, were modulated by induction of LTP along dendrites in hippocampal CA1 pyramidal neurons. The result suggested that the association between the context information from CA3 and information through a direct pass from EC was facilitated by the modulated bAP. On the other hand, the influence of LTP induction on bAP modulation in hippocampal dentate granule cells was not investigated so that the integration of spatial and non-spatial information from EC projection to MD and DD on dentate gyrus granule cells was not

clear. In this study, to investigate the bAP modulation related to information integration of two inputs of dentate gyrus, we analyzed the amplitude of bAPs before and after LTP induction along dendrites in the granule cells, using optical imaging method with voltage sensitive dye. As the result, the bAP transmission distances were spread from MD to DD and the magnitude of bAP was increased at DD. The result suggests that the cooperative integration of place information and the other sensory information was influenced by the bap modulation based on the induction of synaptic plasticity on dendrites in dentate granule cell.

Abstract: Critical periods of synaptic plasticity facilitate the reordering and refining of neural connections during development, allowing the definitive synaptic circuits responsible for correct adult physiology to be established. Presynaptic spike timing-dependent long-term depression (t-LTD) exists in the hippocampus, which depends on the activation of NMDARs and that probably fulfills a role in synaptic refinement. This t-LTD is present until the 3rd postnatal week in mice, disappearing in the 4th week of postnatal development. We were interested in the mechanisms underlying this maturation related loss of t-LTD and we found that at CA3-CA1 synapses, presynaptic NMDA receptors (preNMDARs) are tonically active between P13 and P21, mediating an increase in glutamate release during this critical period of plasticity. Conversely, at the end of this critical period (P22-P30) and coinciding with the loss of t-LTD, these preNMDARs are no longer tonically active. Using immunogold electron microscopy, we demonstrated the existence of preNMDARs at Schaffer collateral synaptic boutons, where a

decrease in the number of preNMDARs during development coincides with the loss of both tonic preNMDAR activation and t-LTD. Interestingly, this t-LTD can be completely recovered by antagonizing adenosine type 1 receptors (A_1R), which also recovers the tonic activation of preNMDARs at P22-P30. By contrast, the induction of t-LTD was prevented at P13-P21 by an agonist of A_1R, as was tonic preNMDAR activation. Furthermore, we found that the adenosine that mediated the loss of t-LTD during the fourth week of development is supplied by astrocytes. These results provide direct evidence for the mechanism that closes the window of plasticity associated with t-LTD, revealing novel events probably involved in synaptic remodeling during development.

Title: A key role for metabotropic presynaptic NMDA receptor signaling in neocortical STDP

Authors: *A. THOMAZEAU[1], J. BROCK[2], P. SJÖSTRÖM[1];
[1]Brain Repair and Integrative Neurosci. Program, Ctr. for Res. in Neuroscience, Departments of Medicine, and Neurol. & Neurosurgery, The Res. Inst. of the McGill Univ. Hlth. Centre, Montreal Gen. Hosp., Montreal, QC, Canada; [2]Integrated Program in Neurosci., McGill Univ., Montreal, QC, Canada

Abstract: Postsynaptic NMDA receptors (NMDARs) are ideally suited for Hebbian coincidence detection, because they require both presynaptically released glutamate and postsynaptic depolarization to open, flux Ca^{2+}, and trigger plasticity. Recent evidence, however, questions this conventional view: NMDARs can signal metabotropically during Mg^{2+} block and without the need for ion flux, and there are also presynaptically located NMDARs (preNMDARs), neither of which suits Hebbian coincidence detection. We recently unveiled a double dissociation of preNMDAR signalling at visual cortex layer-5 (L5) pyramidal cell (PC) connections. Here, Mg^{2+}-sensitive preNMDARs rely on RIM1αβ to regulate release probability during high- but not low-frequency evoked release, while preNMDARs signal metabotropically via JNK2 to regulate spontaneous release independent of frequency. Timing-dependent long-term depression (tLTD) — which requires preNMDAR activation — also does not depend on frequency. We therefore

hypothesized that preNMDARs signal unconventionally in tLTD at L5 PC-PC connections. Using quadruple patch, we elicited tLTD at L5 PC-PC synapses in acute visual cortex slices using a spike-timing-dependent plasticity (STDP) protocol at 20 Hz with $\Delta t = \pm 25$ ms. RIM1αβ was genetically ablated by crossing flox-RIM1αβ and Emx1-Cre mouse lines, and compared to wildtype (WT) C57Bl/6 mice. We found that tLTD persisted after homozygous RIM1αβ ablation (65% ± 7%, n = 4 vs. tLTD in WT mice 65% ± 5%, n = 9, p = 0.95). The tLTD evoked in RIM1αβ ablation cells was expressed presynaptically, as determined by analysis of the coefficient of variation and paired-pulse ratio, just as in control tLTD experiments (RIM1αβ KO and WT tLTD pooled: $1/CV^2$ normalized = 42% ± 5%, n = 13, $p < 0.001$; $\Delta PPR = 0.12 \pm 0.02$, n= 13, $p < 0.001$ vs. zero). In contrast, the JNK2-selective inhibitor SP600125 prevented the induction of tLTD in WT mice (96% ± 2%, n = 8 vs. tLTD control 65% ± 5%, n = 9, p = 0.34). Here, paired-pulse ratio remained unaffected ($\Delta PPR = -0.07 \pm 0.05$, n = 8, p = 0.25 vs zero, but $p < 0.01$ vs WT tLTD $\Delta PPR = 0.13 \pm 0.03$, n = 9). In conclusion, our findings suggest a critical requirement for JNK2-mediated metabotropic preNMDARs signaling in neocortical tLTD. Our results contribute to the emerging view that NMDARs may signal metabotropically in pre- as well as postsynaptic compartments. The textbook view of NMDARs as ionotropic coincidence detectors may thus need reassessment.

Title: Input-specific excitatory and inhibitory stdp of layer 2/3 pyramidal neurons of mouse auditory cortex

Authors: *S. C. SONG, R. C. FROEMKE;
Skirball Inst., New York Univ. Langone Med. Ctr., New York, NY

Abstract: There are multiple forms of long-term synaptic plasticity in the cortex, and distinct inputs onto the same type of postsynaptic neuron can have qualitatively different learning rules (Maheux et al. 2016). There is growing evidence that cortical inhibitory synapses are also highly plastic, and a recent study in prefrontal cortex identified differences between cell-type-specific GABAergic inputs onto layer 2/3 pyramidal neurons (Chiu et al. 2018). Here we examined spike-timing-dependent plasticity (STDP) of different excitatory and inhibitory projections onto layer 2/3 pyramidal neurons of adult mouse auditory cortex in brain slices. STDP is a method for

inducing input-specific and long-term modifications of synaptic strength, and previously we showed that layer 5 pyramidal neurons of mouse auditory cortex can express STDP for both glutamatergic and GABAergic inputs (D'amour and Froemke, 2015). This mechanism might underlie the synchronization of stimulus-evoked excitatory and inhibitory input during development (Dorrn et al., 2010) and after conditioning or maternal experience (Marlin et al., 2015; Martins and Froemke, 2015).We utilized isolated expression of channelrhodopsin in various glutamatergic afferents and GABAergic interneurons in order to selectively activate these inputs. Whereas intracortical inputs seem to express STDP after a few minutes of pairing, glutamatergic thalamic inputs from the MGB were relatively aplastic. Similar to the results of Chiu et al. (2018) in prefrontal cortex, our data also indicate that individual inhibitory cell types might differentially express STDP after pre- and postsynaptic spike pairing, although the specific learning rules might vary across brain areas or cortical layers.

Title: *In vivo* verification of Hebb cell assembly hypothesis for perceptual memory

Authors: *X. YAN[1], D. ZHANG[2], M.-M. POO[3];
[1]Inst. of Neurosci., Shanghai, China; [2]Inst. of Neuroscience, CAS, Shanghai City, China; [3]Inst. of Neuroscience, SIBS, CAS, Shanghai City, China

Abstract: The nervous system can store and retrieve temporal sequence information, but the neural circuit mechanism for this ability remains largely unknown. Hebb has proposed that perceptual experience,including temporal sequence information,can be stored in selective cell assemblies, which are established by selective strengthening of synaptic connections among the neurons within the assembly. His postulate was supported by the discoveries of long-term potentiation (LTP) and spike timing-dependent plasticity(STDP),as well as findings of sequence learning in hippocampal place cells and the primary visual cortical neurons (V1), but direct evidence at the level of cell assemblies is still elusive. In this study, we used V1 of anaesthetized mice as a model system to study sequence learning and memory, and designed an experimental system for sequence stimulation, using optogenetic approaches and in vivo multi-electrodes recording. To directly test the role of sequential spiking of V1 neurons in storing sequence information, we expressed light activatable ion channel ChR2 in V1 neurons through viral

injection, built a customized scanning mirror to control the laser light for sequential light stimulation, and recorded in vivo neuronal activities from a linear array of neuronal groups in V1 to assay the firing sequence of the assembly of neuronal groups. Our results showed that ChR2-expressing neurons in V1 could be activated to fire in a sequential manner during sequential light stimulation. After 100 repeats of uni-direction moving-spot laser stimulation, spot stimulation only at the starting point of the sequence induced more sequential firing as compared to that found prior to the conditioning, whereas spot stimulation at the end point stimulation had no such effect. This effect can last for about 2.5 minutes, representing a form of short-term memory. We also investigated whether neuromodulator acetylcholine could affect the sequence learning and recall in V1 by optogenetic activation of diagonal band of Broca (HDB) during visual sequence stimulation and found that sequential learning was reduced by HDB stimulation, indicating neuromodulator acetylcholine can modulate sequence learning. Taken together, these results support Hebb's cell assembly hypothesis for perceptual memory formation and retrieval, and demonstrate that sequential firing of cortical neurons could imprint the sequence information into the cortical circuits.

Title: Optogenetic spike-timing-dependent plasticity over behaviorally relevant time scales

Authors: ***M. ANISIMOVA**, B. VAN BOMMEL, T. G. OERTNER, C. E. GEE;
Inst. for Synaptic Physiol., Univ. Med. Ctr. Hamburg-Eppendorf (UKE), Hamburg, Germany

Abstract: Spatial memory in rodents depends on hippocampal function and can last for many days. Lasting changes in synaptic strength after coincident activity in the pre- and postsynaptic neurons is a candidate mechanism for information storage; a process is commonly referred to as a spike-timing dependent plasticity (STDP). With electrophysiology alone it is not possible to follow the long-term consequences of STDP, since intracellular recordings can only be maintained for about one hour. Here we present a new all-optical method to induce STDP, thus separating the induction of plasticity from the electrophysiological read-out by a user-defined time period (e.g. 3 days). We induced STDP at Schaffer collateral synapses in rat organotypic hippocampal slices transfected with red-light-sensitive ChrimsonR (local virus injection in CA3) and blue-light-sensitive CheRiff (single cell electroporation in CA1). First, we verified that light-

induced spiking produces STDP while patched on the postsynaptic cell. We found that red light flashes (300@ 5 Hz) paired with bursts of 3 violet light flashes (50 Hz) induced LTP after causal pairing (pre before post) and LTD after anti-causal pairing (post before pre). We constructed illumination towers, each containing collimated red (630 nm) and violet (405 nm) high-power LEDs to induce controlled spike patterns in the incubator. At the read-out point (3 hours to 3 days), we sequentially recorded EPSCs from CA1, including at least 2 non-transfected neurons, while re-activating ChrimsonR-expressing CA3 neurons with a laser. To determine relative input strengths, the initial EPSC slope from each CheRiff neuron was divided by the average EPSC slope from the non-transfected neurons in that slice. At 3 hours after pairing, input strength was not significantly changed by either causal or anti-causal pairing. Surprisingly, 3 days after pairing, input strength to the CheRiff neurons was significantly larger in slice cultures that underwent causal or anti-causal pairing. Plasticity was abolished when NMDA receptors were blocked during pairing. Reducing the pairing frequency from 5 Hz to 0.1 Hz also prevented plasticity induction. When spontaneous activity was blocked with tetrodotoxin in the period from 3 hours to two days after causal pairing, input strength no longer increased. These experiments suggest that the synaptic memory of a short episode of coincident activity may be actively maintained and amplified in the cultures, perhaps by spontaneous reactivation of the networks once driven to synchronous activity.

Gemelli IRCCS, Rome, Italy; [4]Neurosci., Baylor Col. of Med., Houston, TX; [5]Dept. of Pharmacol. & Toxicology, Univ. of Texas Med. Br. at Galveston, Galveston, TX

Abstract: Chronic unpredictable mild stress (CUMS) is a clinically relevant model of major depressive disorder (MDD). Yet, the mechanisms of neuroplasticity underlying depression-like behaviors in the CUMS model are still poorly understood. Here, we identified glycogen-synthase kinase 3β (GSK3β) and voltage-gated K^+ channel Kv4.2 as key regulators of maladaptive plasticity in CUMS mice. We performed whole-cell patch-clamp recordings of medium spiny neurons (MSNs) in the nucleus accumbens (NAc), a brain region primary involved in the neurobiology of depression, and studied spike timing-dependent long-term potentiation (tLTP) in control and CUMS mice. We found that tLTP was increased in CUMS mice compared to control and that selective GSK3β knockdown in the NAc prevented these changes in tLTP. In addition, we found that A-type K^+ current density was decreased in MSNs from CUMS mice, an effect that was also prevented by GSK3β knockdown. Immunohistochemical, biochemical and pharmacological experiments revealed that the observed GSK3β-dependent changes in tLTP in CUMS mice were mediated by direct phosphorylation at Ser-616 of the Kv4.2 subunit, a molecular determinant of A-type K^+ currents. Furthermore, knockdown of GSK3β in the NAc ameliorated depressive-like behavior in CUMS mice measured as responses to forced swim test, elevated plus maze and sucrose preference. Collectively, our results identify GSK3β regulation of Kv4.2 as a molecular mechanism of MSN maladaptive plasticity underlying depression-like behavior and suggest that GSK3β/Kv4.2 axis may be an attractive therapeutic target for MDD.

Title: A modeling study of the cellular and circuit-level mechanisms of emotional memory consolidation in the prefrontal-amygdala network during REM sleep

Authors: *Y.-A. RHO, S. VIJAYAN;
Sch. of Neurosci., Virginia Tech., Blacksburg, VA

Abstract: Rapid eye movement (REM) sleep, the stage of sleep in which vivid dreams occur, has been implicated in the consolidation of emotional memories. Our recent work has found a candidate system for REM-related memory consolidation. During REM sleep, the frontal cortices, in particular the anterior cingulate cortex (ACC) and the dorsolateral prefrontal cortex (DLPFC), are dominated by theta (4-8 Hz) oscillations and by bursts of beta (15-35 Hz) activity,

and both beta and theta oscillations are coherent between the two regions. Experimental work has shown that theta power in the frontal cortex during REM sleep is positively correlated with the strengthening of emotional memories. Furthermore, studies suggest that rhythmic interactions between the frontal cortices and limbic structures, in particular the amygdala, play a critical role in the consolidation of emotional memories. However, the underlying mechanisms responsible for the consolidation of emotional memories during these rhythmic interactions during REM sleep remain unknown. We used biophysically realistic models of the prefrontal cortex (PFC) and amygdala (developed previously) to build a large-scale network and incorporated synaptic plasticity mechanisms into the connections between these two regions. We were able to reproduce the oscillatory dynamics observed in experimental studies and identify cell type specific synaptic changes caused by spike-timing dependent plasticity (STDP). The rhythmic activities observed in the PFC and the amygdala during REM sleep are generated under different physiological conditions than during the awake state since, for example, norepinephrine (NE) and serotonin (SE) are much lower during REM sleep. This has major implications for plasticity; indeed, experimental studies have revealed that neuromodulators modulate the expression of synaptic plasticity. Using our large-scale network model, we show how the levels of neurotransmitters such as NE and SE during REM sleep affect oscillatory dynamics and in turn influence the strengthening of connections related to emotional memories. To summarize, our network modeling provides us with a system level and cellular level mechanistic understanding of how emotional memories are consolidated during REM sleep.

Abstract: Vagus nerve stimulation (VNS) paired with behavioral experience promotes neuroplasticity which results in behaviorally relevant changes [1, 2]. VNS engages neuromodulatory systems in a temporally precise manner, which makes it a candidate for targeted plasticity therapy [5]. However, the mechanisms through which VNS promotes plasticity and enhances behavioral performance are not fully understood. We characterized how cortical stimulation-induced cortical plasticity, a form of activity-dependent synaptic plasticity [6], is affected by auricular (noninvasive) and cervical (invasive) VNS, in behaving monkeys. In three male macaque monkeys epidural and intracortical electrodes were implanted in prefrontal, pericentral (sensorimotor) and parietal cortical areas. The auricular branch of the vagus nerve (abVN) was stimulated with an earclip placed on either right or left cymba concha. One animal was also implanted with a bipolar cuff electrode on both left and right cervical VN (cVN). In order to induce cortical plasticity between 2 cortical sites, cortical stimulation (CS) in closed-loop mode was delivered to one site, triggered from the trough of beta oscillatory cycles (15-25 Hz) detected at the other site. Each experiment comprised 2 "conditioning" sessions, in random order: (a) only CS, (b) CS paired with VNS. Different VNS protocols (abVNS/cVNS, left/right, high/low frequency), at different time intervals relative to CS (before or paired with CS) were tested. In each experiment, the size of cortically evoked potentials (CEPs), a measure of cortical connectivity and cortical excitability, was measured before and after conditioning. We found that CEPs after 30-40 minutes of CS increased or decreased in size compared to pre-conditioning CEPs. When CS was paired with VNS, the difference in CEP size was reduced to zero. Even though additional controls are needed to established whether CS induced a change in cortical connectivity or it altered cortical excitability, the delivery of VNS seemed to suppress such an effect. This study adds new insights on the neurophysiology of VNS with regard to VNS timing, modality and dose. [1] Engineer et al., Nature 470: 101-104, 2011; [2] Clark et al. Neurobiol. Learn. Title: ERK phosphorylation is uncoupled from ERK activation in a cellular model of long-term plasticity

Authors: *N. KUKUSHKIN, T. J. CAREW;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Extracellular signal-regulated kinase (ERK) is a central hub of cellular signaling whose activity underlies many forms of long-term memory. As a member of the mitogen-activated protein kinase (MAPK) family, ERK is activated in a switch-like manner by double phosphorylation of a remarkably conserved, yet distinctly unusual TxY motif. Typically, phosphorylation of this motif is viewed as a reporter of ERK activity. However, ERK phosphorylation is distributed, meaning that the cellular population of pERK consists not only of active, dually phosphorylated enzyme (dualP-ERK), but also of singly phosphorylated and therefore inactive ERK (pT-ERK and pY-ERK). We show that stimulating *Aplysia* sensory neurons with 5HT, which mimics sensitization training in the intact animal, produces temporally and spatially distinct perturbations in these forms of pERK. In particular, an early surge of dually phosphorylated ERK in stimulated cells is followed by a later wave of pY-ERK, but not pT-ERK, at the time when dualP-ERK levels returns to baseline. The increase in pY-ERK is due to ongoing phosphorylation rather than dephosphorylation of dualP-ERK, since the MEK inhibitor U0126 prevents the later wave of pERK even when administered after the earlier one. Given the importance of ERK in repeated-trial learning, we hypothesize that the accumulation of inactive but biochemically primed pY-ERK represents a potential mechanism for intertrial interactions.

Title: Proteolytic processing of TGFβ provides a mechanism for precise temporal orchestration in long term memory formation

Authors: *P. MIRANDA[1], N. KUKUSHKIN[1], A. A. MIRISIS[2], M. SCHREIBMAN[1], T. J. CAREW[2];
[2]Ctr. for Neural Sci., [1]New York Univ., New York, NY

Abstract: While canonically viewed as hormone-like molecules operating with little temporal resolution, growth factors in fact play key roles in orchestrating the timing of molecular events

required to form a long-term memory (LTM). Specifically, in a two-trial training paradigm that induces LTM for sensitization in the marine mollusk *Aplysia californica*, the growth factor TGFβ is required during Trial 2 but not Trial 1, suggesting temporally specific inter-trial regulation of TGFβ's signaling cascade, either upstream or downstream of TGFβ release. Since TGFβ is necessary and sufficient to promote LTM, we hypothesized that it contributes to the inter-trial interactions that determine the temporally restricted outcome of repeated trial learning (Mirisis & Carew, 2019). However, the precise mechanisms that determine the differential requirement for TGFβ during two trial training remain unknown. To examine whether interactions between trials alter the magnitude of TGFβ signaling, we have developed a bioassay based on the nuclear translocation of Smad, a downstream target of the TGFβ cascade. Cultured *Aplysia* sensory neurons were treated with either one or two pulses of 5HT to mimic two trial sensitization training in the intact animal. We found that the rate of Smad nuclear translocation is indeed significantly increased after Trial 2 compared to Trail 1, suggesting differential activation of the TGFβ cascade during two trial training. To investigate the mechanisms underlying this effect, we monitored Smad translocation in the presence of BMP-1, a protease known to liberate secreted TGFβ from a latent state. While BMP-1 alone had no effect on Smad translocation, when it was combined with a single pulse of 5HT, it significantly enhanced Smad's redistribution. These data suggest a model in which the interaction between trials involves both temporally segregated stages of TGFβ release and proteolytic activation, the combination of which is required for the precise temporal processing of repeated trials during LTM formation.

Title: Nuclear export of the RNA-binding protein ELAV provides a candidate mechanism for mRNA localization during long-term memory formation

Authors: *A. A. MIRISIS, T. J. CAREW;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: In the marine mollusk *Aplysia*, signaling through distinct growth factor (GF) pathways is required for long-term memory (LTM) formation in unique temporal and spatial domains.

Specifically, in a two-trial sensitization training paradigm, TrkB signaling is required for gene expression of *apc/ebp*, an immediate-early gene, at 45 minutes following Trial 1, but prolonged *apc/ebp* gene expression necessary for LTM also requires TGFβ signaling during Trial 2 (Kopec et al., 2015). The *apc/ebp* transcript contains multiple AU-rich elements (AREs) in its 3' UTR, conferring increased susceptibility to degradation and/or stabilization due to the AREs' ability to bind various RNA-binding proteins (Yim et al., 2006). We have recently reported that the interaction between ELAV and *apc/ebp* is increased by Trial 2, and this interaction is required for LTM formation (Mirisis and Carew, 2018). Recent experiments have revealed that ELAV translocates from the sensory neuron nucleus into dendritic processes at 30 min following Trial 2. Moreover, this translocation is dependent on p38 MAPK activation downstream of TGFβ signaling. Taken together with previous findings of ARE-containing mRNAs in dendrites and at synapses (Alberini 2009; Meer et al., 2012; Arguello et al., 2013), this observation suggests a model in which ELAV-mediated transcript shuttling plays a critical role in LTM formation.

Title: NYX-458, a novel NMDA receptor modulator, improves age-related, hippocampal-dependent learning impairment and reverses changes in plasticity, spine morphology, and protein expression in rat hippocampus

Authors: *T. S. MATHARU[1], G. D. MORRISON[1], A. L. BARTH[1], C. J. KELLY[1], J. DUNNING[1], P. KANSARA[1], N. PUNCHARD[1], A. A. MOGHADAM[2], P. K. STANTON[2], J. R. MOSKAL[1,3], C. N. CEARLEY[1];
[1]Aptinyx, Evanston, IL; [2]Cell Biol. & Anat., New York Med. Col., Valhalla, NY; [3]Falk Ctr. for Mol. Therapeut., Northwestern Univ., Evanston, IL

Abstract: Age-related cognitive decline is a natural process that can particularly impact hippocampal function. This study was conducted to evaluate the effects of NYX-458, a novel N-Methyl D-Aspartate receptor (NMDAR) modulator with greatest affinity for NMDAR subtype NR2B, on hippocampal dependent cognitive function and associated cellular processes that contribute to cognitive decline with age. NMDARs have a critical role in hippocampal dependent learning and memory, and the depletion and dysfunction of these receptors are implicated in age-related cognitive decline. A single oral dose of NYX-458 (1 mg/kg) causes enhancement of hippocampal LTP that can be measured at both 24 hours and 72 hours post-dose in naïve young rats. In aged (26- to 27-month-old) rats, an oral dosing regimen of NYX-458 (1 mg/kg, daily) also improved performance in the hippocampal-dependent fixed-platform version of the Morris water maze. This dosing regimen also reversed the age-related deficits in hippocampal LTP and changes in spine morphology and enhanced the expression of proteins that regulate synaptic plasticity (specifically NMDAR2B, AMPAR1, and CAMKIIß). The long-term enhancement of hippocampal LTP and the reversal of age-related hippocampal impairments observed in the present study supports further investigation of NYX-458 in patients suffering from cognitive deficits associated with aging and for neurodegenerative diseases where synaptic plasticity and NMDAR function are impaired.

Title: The impact of PKA-dependent phosphorylation of GluN2B at Ser1166 on hippocampal plasticity and cognition

Authors: *M. W. PORCH[1], J.-Y. HWANG[2], A. E. CHAVEZ[3], R. ZUKIN[4];
[1]Albert Einstein Col. of Med., Bronx, NY; [2]Neurosci., Creighton, Omaha, NE; [3]Neurosci., Univ. De Valparaiso, Valparaiso, Chile; [4]Dept Neurosci, Albert Einstein Col. Med., Bronx, NY

Abstract: NMDA receptors (NMDARs) are glutamate-gated ion channels that are enriched at excitatory synapses, where they are strategically positioned to play a crucial role in regulation of synaptic function. A unique feature of NMDARs is their high permeability to Ca^{2+}. Ca^{2+} influx through NMDARs is essential for synaptogenesis, plasticity of neural circuitry, and higher cognitive functions, such as learning and memory. Emerging evidence reveals that PKA signaling represents a fundamental mechanism by which NMDAR-mediated Ca^{2+} influx is modulated in neurons. We recently identified serine 1166 (Ser1166) in GluN2B to be the molecular target of PKA phosphorylation relevant to PKA-dependent NMDAR Ca^{2+} permeability. Whereas the impact of Ser1166 on NMDAR Ca^{2+} permeability is well-established, its role in NMDAR-dependent synaptic plasticity and cognition is, as yet, unclear. To address this issue, we generated a mouse in which we knocked in GluN2B containing a single point mutation, S1166A, by means of CRISPR/cas technology. Whereas basal synaptic transmission and synaptic plasticity in the form of high frequency stimulation induced LTP (HFS-LTP) was normal in the knockin mice, theta-burst stimulation-induced LTP (TBS LTP) at CA1 synapses was greatly diminished in slices from knock-in vs. wild-type mice. A distinguishing feature of

spaced TBS- *vs*. condensed HFS-LTP at CA1 synapses is a requirement for the transient synaptic incorporation of GluA2-lacking AMPARs during the induction phase of LTP, which are subsequently replaced by GluA2-containing AMPA receptors. A hypothesis under consideration is that Ser1166 is critical for synaptic incorporation of Ca^{2+} permeable (but not Ca^{2+}-impermeable) AMPARs. We found that, upon induction of TBS-LTP, AMPARs EPSPs are inwardly rectifying and that the LTP is blocked by inhibition of Ca^{2+} permeable AMPARs with IEM-1460 and philanthotoxin 74. TBS LTP in KI mice was rescued by rolipram, which acts as a PKA activator and leads to the insertion of Ca^{2+}-permeable AMPARs to rescue LTP, and by a transient increase in extracellular Ca^{2+}. We further showed that visual cognition, assessed by means of the novel object recognition task, was markedly impaired in knockin *vs*. wild-type mice. Thus, loss of a single site within the GluN2B subunit not only eliminates PKA-induced Ca^{2+} signaling in spines, but greatly diminishes Ca^{2+}-permeable AMPAR-dependent synaptic plasticity in the form of TBS-LTP and hippocampal-based memory in the form of visual recognition.

Abstract: Synaptic plasticity is mediated by complex signaling cascades that transduce short-lived synaptic inputs into long-lasting changes of synaptic strength. The protein kinase C (PKC) family, consisting of more than 10 isozymes, has been shown to be involved in the induction, expression and maintenance of synaptic plasticity. However, poor isozyme discrimination, spatiotemporal resolution and sensitivity have limited our understanding of PKC function in

plasticity. Here, we have developed a suite of tools to discriminate the function of PKC isozymes through high resolution fluorescence resonance energy transfer (FRET) sensors optimized for 2-photon fluorescence lifetime imaging (2p-FLIM) and chemogenetic approaches. These tools reveal compartmentalized and isozyme-specific PKC activity and function during plasticity, clarifying the role of PKC in plasticity, learning and memory.

Title: Dynamic analysis of CaMKII activity switch in living cells using FRET/FLIM sensors

Authors: C. ZHANG, ***N. OTMAKHOV**, R. KEPHARD, L. GRIFFITH;
Brandeis Univ., Waltham, MA

Abstract: CaMKII plays a critical role in synaptic and behavioral memory. It has been suggested that its unique properties - operating as an activity switch and binding to multiple synaptic targets - are crucial for that role. *In vitro* studies demonstrated that CaMKII could undergo stable activation by means of its T286 autophosphorylation after a short pulse of Ca2+/CaM stimulation. It is also shown that binding to NR2B subunit of the NMDA receptor further supports this switch. The occurrence of a stable CaMKII switch, however, has not been demonstrated in living cells. Here we monitored CaMKII activity using the FRET/FLIM sensor Camui in Hela cells. Ca2+(i) transients, induced by Ionomycin application, resulted in a fast switch of Camui from a closed (‘inactive’) to an open (‘active’) state, which reversed back to its inactive state upon wash with EGTA/0 Ca2+/Ionomycin. Using different Camui mutants revealed that CaMKII T286 phosphorylation prolonged and T305/T306 phosphorylation shortened the reversal time, which was only 2 min longer than the reversal of Ca2+(i) transient. Adjusting the Ca2+(i) level at washout to match the basal level, prolonged the reversal time by 5-10 min. Inhibition of phosphatases with Calyculin A rendered a stable “active” Camui state for at least 15 min after Ca2+(i) reversal. The stable switch occurred in WT and 305A/306A but not in 286A or 286A/305A/306A Camui mutants indicating its dependence of T286 autophosphorylation. To test how binding to NR2B affects Camui activity switch, we

coexpressed Camui with the NR2B-C tail, which can bind CaMKII. We first coexpressed mls-NR2B-C, which binds the mitochondrial surface. Ca2+(i) transients produced translocation of Camui to mitochondria as observed by clustering. The Camui clustering, however, quickly disappeared upon wash with EGTA/Ionom. solution. Consistently, the Camui active state after Ca2+ stimulation lasted no longer than that without NR2B-C expression. For controls, we used GFPCaMKII, which also showed only transient clustering; the Camui (I205K) mutant, which does not bind to NR2B, did not cluster upon Ca2+(i) stimulation and its recovery from active state was not different from that of Camui WT. Since only a few subunits (of 12) in the CaMKII holoenzyme can bind to mitochondria-bound NR2B-C, our method might not resolve the effect of this binding. Therefore, we tested soluble GST-NR2B-C peptide, which should bind all subunits. Despite this, the Camui active state was not maintained beyond ~8 minutes after Ca2+ stimuli. Currently we are exploring different experimental conditions including more physiological Ca2+(i) stimulation to test the regulation of the CaMKII switch in living cells.

Title: Endogenous role for Rem2 inhibition of CaMKII in neuronal synaptic development and plasticity

Authors: *R. ANJUM[1], L. ROYER[1], J. J. HERZOG[1], K. M. KENNY[1], B. TZVETKOVA[1], J. C. COCHRANE[2], M. T. MARR, II[1], S. PARADIS[1];
[1]Biol., Brandeis Univ., Waltham, MA; [2]Mol. Biol. and Genet., Massachusets Gen. Hosp. and Harvard Med. Sch., Boston, MA

Abstract: In order to understand learning and memory at the molecular level, we must uncover the molecular mechanisms underlying synaptic development and plasticity. Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) is a well-studied serine-threonine kinase that is highly expressed at the post-synaptic density, and is required for multiple types of synaptic plasticity, including long-term potentiation (LTP). Our lab recently determined that Rem2, a Ras-like GTPase from the RGK (Rad/Rem/Rem2/Gem/Kir) protein family, is a potent endogenous inhibitor of CaMKII. Previously, we have characterized several neuronal functions of Rem2,

including promoting excitatory synapse formation, inhibiting dendritic branching, and regulating homeostatic plasticity in the visual cortex. Moreover, like other members of the RGK protein family, Rem2 overexpression inhibits voltage-gated calcium currents in heterologous cells and cultured neurons. Interestingly, CaMKII function has also been implicated in these biological processes including facilitation of calcium flux through voltage-gated calcium channels. In addition, our work shows that Rem2 inhibition of CaMKII regulates dendritic branching in cultured hippocampal neurons. Thus, we seek to determine if Rem2 inhibition of CaMKII plays a role in other neuronal processes in addition to dendritic branching. We have also developed a N-terminus mutant of Rem2, which cannot inhibit CaMKII.

Title: Interactions between CaM and Ng govern the dynamics of CaMKII as a leaky integrator

Authors: *M. ORDYAN[1,3], T. M. BARTOL, JR[2], M. B. KENNEDY[5], P. RANGAMANI[4], T. J. SEJNOWSKI[1];
[2]CNL-S, [1]Salk Inst., La Jolla, CA; [3]Inc, [4]Mechanical and Aerospace Engin., UCSD, La Jolla, CA; [5]Caltech, Pasadena, CA

Abstract: Calmodulin-dependent kinase II (CaMKII) has long been known to play an important role in learning and memory as well as long term potentiation (LTP). More recently it has been suggested that it might be involved in time averaging of synaptic signals, which can then lead to the high precision of the information stored at a single synapse. In this work, we adopt a rule-based modeling approach through Monte Carlo method to study the effect of Ca^{2+} signals on CaMKII phosphorylation in the postsynaptic densities (PSD). We study the differences between the CaMKII monomers and the dodecameric holoenzyme, as well as the effect of the scaffolding molecule neurogranin (Ng), which limits the availability of free Calmodulin (CaM), the protein which activates CaMKII in the presence of calcium. When Ng is present at significant concentration, we show that it plays an important modulatory role in CaMKII phosphorylation following a surge of high calcium concentration that is observed in the synaptic spines during an EPSP and back-propagating action potential due to the opening of NMDA receptors and voltage dependent calcium channels. We find a non-intuitive dependence of this effect on CaM

concentration that results from the different affinities of CaM for CaMKII depending on the number of calcium ions bound to the former. It has been shown previously that in the absence of phosphatase, CaMKII monomers integrate over Ca^{2+} signals of certain frequencies through autophosphorylation (Pepke et al, Plos Comp. Bio., 2010). We also study the effect of multiple calcium spikes on CaMKII holoenzyme autophosphorylation, and show that in the presence of phosphatase the CaMKII behaves as a leaky integrator of calcium signals, a result that has been recently observed *in vivo*. Our results also indicate the modulatory role the scaffolding protein Ng plays during signal integration: the area under the curve is significantly lower in the presence of Ng. Thus CaM scaffolds can make CaMKII phosphorylation a more robust process, resistant to noise in calcium signals.

Title: Deciphering IGF1 and insulin signaling within a single dendritic spine in long term potential

Authors: *X. TU, R. YASUDA;
Max Plank Florida Inst. For Neurosci., Jupiter, FL

Abstract: The insulin superfamily of peptides are well-known to regulate metabolism by regulating blood sugar levels, but only recently insulin and insulin-like peptides were shown to be crucial nervous system function as well. Decreased brain insulin levels or dysfunctional insulin and insulin-like growth factor 1 signaling are related to impaired learning, memory, as well as age-related neurodegenerative diseases. However, it remains unknown whether insulin receptor (IR) and insulin-like growth factor 1 receptor (IGF1R) are essential for synaptic plasticity and if so, when and how are they activated in dendritic spines during plasticity. To determine whether IR and IGF1R are required for plasticity, we assessed IR and IGF1R CRE-dependent knockout animals. We found that disruption of IGF1R or IR signaling in CA1 pyramidal neurons resulted in structural plasticity defects in those neurons. To further study the role of insulin and IGF1 signaling in plasticity, we developed fluorescence resonance energy transfer-based sensors for IGF1R and IR to measure the activity of the receptors during structural long-term potentiation (sLTP) in single spines. In response to sLTP induction, we discovered fast and sustained activation of IGF1R and IR in the stimulated spine. Elucidating insulin and IGF1 signaling mechanisms using two-photon fluorescence lifetime imaging microscopy in

combination with new biosensors will potentially allow to develop novel drug approaches to treat Alzheimer's disease or enhance learning and memory.

Title: Biochemically detailed single compartment model for neocortical postsynaptic long term plasticity

Authors: *T. MÄKI-MARTTUNEN[1], A. G. EDWARDS[1], G. T. EINEVOLL[2], K. L. BLACKWELL[3];
[1]Simula Res. Lab., Oslo, Norway; [2]Norwegian Univ. Life Sci., Aas, Norway; [3]Mol. Neurosci., George Mason Univ., Fairfax, VA

Abstract: Phenomenological models of plasticity have been widely applied in computational studies of cortical information processing. However, these models typically fall short of descriptions of molecular mechanisms behind the plasticity and are thus not useful for cellular-level or pharmacological studies of mental diseases that involve disruptions of plasticity. By contrast, biochemically detailed models for postsynaptic long-term plasticity exist for glutamatergic synapses in basal ganglia (Blackwell et al. 2019, Eur J Neurosci 49(6):768-783), cerebellum (Gallimore et al. 2018, Cell Rep 22(3): 722-733) and hippocampus (Jedrzejewska-Szmek et al. 2017, PLoS Comput Biol 13(7): e1005657). In this work, we combine previously described molecular pathways that are required for cortical plasticity into a biochemically detailed single-compartment model of a postsynaptic spine in the neocortex. Our model describes the dynamics of the signaling networks mediating β-adrenergic receptor-dependent potentiation as well as cholinergic receptor-dependent depression, and includes descriptions for the dynamics of the key signaling molecules PKA, PKC, and CaMKII. To determine Ca^{2+} inputs to the model, we employed a multi-compartmental model of layer II/III pyramidal cells from the database of Markram et al. (2015, Cell, 163(2):456-492) to predict the interaction between the time of a spike in the post-synaptic neuron and the magnitude of the Ca^{2+} inputs at the synaptic site. We show that our single-compartment model reproduces the induction of plasticity as observed in experimental studies of cortical pyramidal cells. In particular, we reproduced central features of the spike-timing dependent LTP and LTD of glutamatergic synapses in visual cortex (Seol et al. 2007, Neuron 55(6):919-929). Our model offers a unique method for examining

contributions of mental disorder-associated genes to the induction of synaptic plasticity. It also allows modeling the effects of candidate pharmacological treatments that could be used to maintain a baseline level of cortical LTP/LTD induction under altered disease conditions.

Title: Camkiig drives long term potentiation of parvalbumin positive interneurons, boosting network oscillations and memory

Authors: *X. HE, G. ZHOU, J. LI, J. YANG, H. MA;
Zhejiang Univ. Sch. of Medicine, Hangzhou,, Hangzhou, China

Abstract: Long-term potentiation (LTP) is fundamental for information encoding, processing and storage in the brain. Most studies have focused on LTP_{E-E}, the potentiation of excitatory synapses onto excitatory neurons, in which the "memory molecule" αCaMKII serves the central regulator. Inhibitory interneurons also receive excitatory synaptic input, but because these cells lack αCaMKII, it remains unclear whether, why and how LTP_{E-I} occurs. Here, we report that γCaMKII is the long-sought "αCaMKII-like" molecule that is enriched in inhibitory interneurons. Deleting γCaMKII in parvalbumin$^+$ interneurons spares LTP_{E-E}, but eliminates LTP_{E-I}, disrupts experience-dependent oscillation strengthening at gamma and theta bands, and impairs memory consolidation. Re-expression of γCaMKII in hippocampal parvalbumin$^+$ interneurons repairs memory defects, whereas optogenetically driving gamma and theta oscillations following learning also exerts similar rescue effects. Thus, γCaMKII is the critical mediator of LTP_{E-I}, and represents a novel synapse-specific target with unique roles in memory by linking synaptic activity to long-term network plasticity.

Title: Cannabinoid regulation of excitatory synaptic transmission at hippocampal TA-CA1 synapses

Authors: *A. FARAH[1], A. J. IRVING[2], J. HARVEY[1];
[1]Univ. of Dundee, Dundee, United Kingdom; [2]Univ. Col. Dublin, Dublin, Ireland

Abstract: It is known that cannabinoids produce their biological effects via activation of CB1 and CB2 receptor subtypes (Battista et al., 2012), however in the CNS, the predominant receptor is CB1. Numerous studies have examined the modulatory effects of cannabinoids on excitatory synaptic transmission at hippocampal Schaffer collateral (SC)-CA1 synapses. Moreover, increasing evidence suggests that hippocampal CB1 receptors play a role in learning and memory, and are also linked to neurodegeneration in Alzheimer's disease (AD; Hájos & Freund, 2002). However the effects of cannabinoids on excitatory synaptic function at the anatomically-distinct temporoammonic (TA) input to hippocampal CA1 neurons is not clear. Standard extracellular recordings were used to examine the effects of different selective agonists for CB1 receptors on excitatory synaptic transmission at juvenile TA-CA1 synapses. Recordings were made from transverse hippocampal slices (350μM) prepared from 12-18 day old rats, perfused with oxygenated aCSF. Statistical analyses were performed using paired *t* test (two-tailed; 95% confidence interval) or repeated-measures ANOVA for comparison between multiple groups. $P < 0.05$ was considered significant with n representing the number of slices used from different animals. Application of methanandamide (100nM; 15min) induced a long term increase (LTP; to 148± 5% of baseline; n=4; $p<0.001$) in excitatory synaptic transmission via activation of CB1 receptors, as application of a CB1R- antagonist blocked this effect (AM251; 102 ± 1.1% of baseline; n=4; $p>0.05$). CB1R-induced LTP has a postsynaptic locus of expression, and was NMDA receptor-dependent as 50 μM D-AP5 inhibited this effect (n = 4; $p>0.05$). These findings may be important as the TA pathway plays a role in episodic memory (Remondes & Schuman, 2004) and impairments in episodic memory is an early event in AD (Perry et al., 2000).

Title: AMPA receptor endocytosis enhanced by transient acidification in retrieval-induced lability of an aversive memory

Authors: *J. DU, **B. LIN**, F. S. NAGHAVI, E. E. KOFFMAN, C. M. KRUSE, K. SINGH; The Univ. of Toledo, Toledo, OH

Abstract: Being able to predict threat by recollecting fear stimuli is crucial for most animals such that one can behave adaptively to the dangerous environmental situation. However, since fear memories developed due to traumatic events may trigger mental health conditions, attenuating such memories could be a solution to its resulting psychiatric disorders. Pavlovian conditioning is a common method to develop a reflex response by training with repetitive actions. It was used to assess the ability of lab mice to learn and remember an association between a conditioned stimulus (CS, i.e. an auditory cue) and an aversive unconditioned stimulus (US, i.e. an electric foot shock), and how that memory can be modified. A retrieval cue (CS alone) can recall and destabilize the previously coupled US-induced aversive memory, and at this labile state, the memory is subjected to diminish by the following extinction process, in which the animal receives consecutive auditory cues without coupling with foot shocks. Our earlier studies demonstrated that transient acidification by exposing animals to CO2 in conjunction with the retrieval cue significantly enhanced labilization of the target memory and more effectively weakened the aversive memory after memory extinction. By electrophysiological techniques, we found that during retrieval, the rectification on AMPA receptors (AMPARs) was enhanced, suggesting a structural change of these neuroreceptors. CO2 inhalation induced acid-sensing ion channels (ASICs) to further energize this process. Switching Ca2+-impermeable to more excitatory Ca2+-permeable membrane-embedded AMPARs via ubiquitination, endocytosis and proteasomal degradation of AMPAR subunit GluR2 at glutamatergic synapses is essential for neuroplasticity. To dissect this mechanism, amygdalae from mice receiving fear conditioning/retrieval/CO2 or sham controls were harvested, processed and assessed for relevant molecular events. Western blot analysis showed an increased CaMKII phosphorylation, the central of signaling cascades mediating learning and memory, when retrieval was coupled with CO2 inhalation. Results of 20S proteasome activity assay and Western blot analysis of phosphorylation of the 19S regulatory particle Rpt6 suggested an increased proteasome activity

in mice exposed to CO2. Polyubiquitinated GluR2 was found more robust in mice exposed to CO2 compared to controls when a proteasome inhibitor was used to block the protein degradation. Supportively, knocking out predominant proton sensor ASIC1a to block CO2-induced signaling confirmed its regulatory effects on CaMKII phosphorylation, proteasome activity, and GluR2 ubiquitination.

Title: Assessing molecular mechanisms underlying NMDAR plasticity at hippocampal synapses

Authors: *S. LUTZU[1], K. ALVINA[2], P. E. CASTILLO[3];
[1]Albert Einstein Col. of Med., Bronx, NY; [2]Biol. Sci., Texas Tech. Univ., Lubbock, TX; [3]Albert Einstein Coll Med., Bronx, NY

Abstract: NMDA receptors (NMDARs) are crucial for synaptic transmission, plasticity, and cognitive processes such as learning and memory. Like AMPA receptors, NMDARs can also undergo bidirectional long-term plasticity (NMDAR-LTP/LTD) at several key brain areas, but the molecular basis of NMDAR-plasticity remains poorly understood. In the hippocampus, the mossy fiber-to-CA3 pyramidal cell (MF-CA3) synapse expresses bidirectional NMDAR plasticity which can be elicited by physiologically-relevant coincident pre-postsynaptic burst activity. Both NMDAR-LTP and LTD induction require postsynaptic $^{Ca2+}$ rise, but the $^{Ca2+}$ requirements differ -e.g. NMDAR-LTP, but not NMDAR-LTD, requires $^{Ca2+}$ release from internal stores. Different $^{Ca2+}$ dynamics could determine the bidirectionality of NMDAR plasticity. To test this hypothesis, we combined electrophysiology with 2 photon microscopy in acute rat hippocampal slices and measured postsynaptic $^{Ca2+}$ transients (CaTs) in CA3 pyramidal cells upon coincident pre-postsynaptic burst-activity used for the induction of NMDAR-LTP and LTD. At thorny excrescences (TEs), the postsynaptic target of MFs, CaTs were significantly larger during the induction of NMDAR-LTP than NMDAR-LTD. This difference was abolished by depleting $^{Ca2+}$ release from internal stores, or blocking type 5 metabotropic glutamate receptors (mGluR5), two manipulations known to abolish NMDAR-LTP. Conversely, mGluR1 blockade, a manipulation that impairs NMDAR-LTD, did not affect CaTs associated to

NMDAR-LTP and LTD, suggesting distinct functions for mGluR1 and mGluR5 at the MF-CA3 synapse. Moreover, mGluR5 blockade strongly reduced synaptically-induced CaTs, which are largely mediated by NMDARs. In contrast, mGluR1 blockade only elicited a slight reduction of synaptic CaTs, consistent with a different intracellular coupling of mGluR1 and mGluR5 at MF-CA3 synapse. MFs also contact hilar mossy cells (MCs) which play key role in hippocampal function and behavior. While MF-MC and MF-CA3 synapses share structural and functional similarities, it is unknown whether MF-MC synapses express NMDAR plasticity. We found that the MF-MC synapse expresses NMDAR-LTP but not NMDAR-LTD. Intriguingly, CaTs associated with NMDAR LTP and LTD induction protocols resembled those observed at MF-CA3, suggesting that some molecular difference likely accounts for the unique learning rules at MF-CA3 and MF-MC synapses. Our findings indicate that similar patterns of activity can have a significantly different impact on NMDAR function in a target-specific manner.

Title: The impact of rare human genetic variants of RGS14 on its binding to active $G_{\alpha i1}$ and Rap2A

Authors: *G. TERZIOGLU[1], C. MONTANEZ-MIRANDA[2], K. L. FOWLER[3], S. RAMINENI[4], J. R. HEPLER[1,2,3,4];

Abstract: The Regulator of G Protein Signaling14 (RGS14) is a multifunctional signaling protein that integrates G protein, MAPKinase, and Ca^{++}/CaM signaling pathways in host cells. Expressed primarily in hippocampal neurons, RGS14 is a natural suppressor of synaptic plasticity and long-term potentiation (LTP) in area CA2 neurons, and linked hippocampal-based learning and memory. The RGS14 domain structure consists of an RGS domain that binds active Gαi/o-GTP, an H-Ras and Rap1/2 binding domain (R1), and a GoLoco/GPR motif that binds inactive Gαi1/3-GDP. Genetic variations account for diverse traits and individual predispositions to disease. We have identified genetic variants of RGS14 that confer changes within functional

binding domains. Here we investigate the functional consequences of two human variants of RGS14, Q116P and K334N, on their interactions with related binding partners. Variant Q116P encodes a missense point mutation located in the RGS domain that may impact RGS14 interactions with active Gαi/o-GTP. Variant K334N encodes a missense point mutation in the R1 domain and that may alter RGS14 interactions with active Rap2A. To test this, wild type RGS14 or variant Q116P were co-expressed with Gαi1 in HEK cells in the presence of aluminum fluoride (AlF_4^-) and co-immunoprecipitated, followed by SDS-PAGE and immunoblotting. In parallel, we tested RGS14-Luciferase interactions with Gαi-YFP in live cells by bioluminescence resonance energy transfer (BRET). We found that wild type RGS14 and Q116P both interact with Gαi1 similarly, indicating the variant did not alter RGS14 function. By contrast, similar studies performed comparing RGS14 or variant K334N interactions with a constitutive active mutation (G12V) of Rap2(G/V) found that the K334N variant blocked RGS14's capacity to bind active Rap2A(G/V) as measured by both co-immunoprecipitation and BRET studies. Ongoing and future experiments will test the impact of K334N on RGS14 interactions with active H-Ras, hippocampal neuron physiology, and on synaptic plasticity, dendritic development and maintenance.

Title: Arc protein synthesis is promoted by secreted amyloid precursor protein-alpha in primary hippocampal neurons

Authors: *R. LIVINGSTONE[1], M. K. ELDER[4], M. BARRETT[1], C. WESTLATE[1], K. PEPPERCORN[2], W. TATE[2], W. C. ABRAHAM[3], J. M. WILLIAMS[1];

Abstract: Secreted amyloid precursor protein-α (sAPPα) is a neuroprotective and memory-enhancing molecule, however the mechanisms through which sAPPα generates these effects are not well understood. Recently, we have shown that sAPPα enhances cell-surface expression of glutamate receptors in a protein synthesis-dependent fashion. Activity-related cytoskeletal-

associated protein Arc (Arg3.1) is an immediate early gene (IEG) capable of modulating synaptic plasticity, through internalization of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors. Accordingly, we hypothesized that sAPPα may enhance synaptic plasticity, in part, by stimulating de novo synthesis of Arc mRNA and protein. Using FUNCAT-PLA and immunohistochemistry to quantify newly made and overall levels of Arc protein, we found that sAPPα (1 nM, 2 h) enhanced levels of Arc in primary hippocampal neuron cultures. Arc protein levels were increased in both the neuronal somata and dendrites in a Ca^{2+}/calmodulin-dependent protein kinase II-dependent manner. Additionally, dendritic Arc expression was dependent on activation of mitogen-activated protein kinase and protein kinase G. The enhancement of dendritic Arc protein was significantly reduced by antagonism of N-methyl-D-aspartate (NMDA) and nicotinic acetylcholine (α7nACh) receptors, and fully eliminated by dual application of these antagonists. These data suggest sAPPα-regulated plasticity within hippocampal neurons is mediated by cooperation of NMDA and α7nACh receptors to engage a cascade of signal transduction molecules to enhance the transcription and translation of Arc.

Title: Weak high-frequency synaptic stimulation induces persistent long-term potentiation in rat hippocampal slices if preceded or followed by a brief application of 4% sevoflurane

Authors: *P. TSOKAS[1], **L. M. RODRIGUEZ VALENCIA**[2], C. HSIEH[3], I. S. KASS[1], J. E. COTTRELL[2], T. C. SACKTOR[4];
[1]Physiol. and Pharmacology; Anesthesiology; The RF Furchgott Ctr. for Neural & Behavioral Sci., [2]Anesthesiol., [3]Physiol. and Pharmacology; The RF Furchgott Ctr. for Neural & Behavioral Sci., SUNY Downstate Med. Ctr., Brooklyn, NY; [4]Physiol. and Pharmacology; Neurology; Anesthesiology; Furchgott Ctr. for Neural & Behavioral Sci., SUNY Downstate, Brooklyn, NY

Abstract: In addition its role as a molecule maintaining memory, studies have shown that PKMζ--a brain-specific, autonomously active member of the atypical protein kinase C family--also serves a neuroprotective role. Specifically, sevoflurane preconditioning is associated with a *de novo* increase in PKMζ protein in hippocampal slices that confers neuroprotection by

mitigating the aversive effects of hypoxia on neuronal health (Wang et al., J Physiol. 590:4093, 2012). However, postsynaptic whole-cell infusion of PKMζ in CA1 neurons has been shown to cause potentiation of postsynaptic responses throughout the neuron. Such wide-spread increases in synaptic strength throughout the neuron would be expected to introduce noise that could corrupt memory traces, but interestingly no LTP is observed with sevoflurane. This suggests that the sevoflurane-induced newly synthesized PKMζ exerts its neuroprotective effects without affecting pre-existing synaptic pools of PKMζ, and that the integrity of pre-existing engrams in the hippocampus may be achieved via compartmentalization of PKMζ. To study the mechanisms that control compartmentalization of PKMζ we examined whether there is communication between different pools of neuronal PKMζ. We hypothesized that PKMζ synthesized by a brief sevoflurane application can be driven into the synaptic compartment by a subsequent weak, sub-threshold high-frequency synaptic stimulation (weak HFS), through a process similar to "synaptic tagging and capture". **Results:** We find that a 20 min application of 4% sevoflurane transforms a transient LTP induced by weak HFS into persistent LTP that lasts several hours, if the weak HFS is delivered 15, 45, or 75 min after sevoflurane washout, but not at 180 min post-sevoflurane. Remarkably, 4% sevoflurane can also transform transient into persistent LTP if the weak HFS precedes sevoflurane application by 15 or 45 min (but not 75 min). **Conclusion:** The underlying mechanism of this phenomenon could involve "synaptic capture" by the weakly tetanized synapses of new PKMζ synthesized in the dendrite in response to sevoflurane. Under normal physiological conditions PKMζ synthesized in response to sevoflurane is excluded from synapses and plays a role in neuroprotection without directly affecting synaptic output. This compartmentalization could break down due to pathological conditions, spontaneous ripple activity (resembling HFS) in the anesthetized brain, or during emergence from anesthesia. Breakdown of compartmentalization would corrupt pre-existing engrams by introducing noise, and may therefore contribute to post-operative cognitive dysfunction.

Title: Simulations suggest combined-drug treatments that enhance synaptic plasticity and potentially improve learning and memory

Authors: *P. D. SMOLEN[1], D. A. BAXTER[1,2], J. H. BYRNE[1];
[1]Neurobio. and Anat., McGovern Med. Sch. of UTHSC At Houston, Houston, TX; [2]Engin. & Med., Texas A&M Hlth. Sci. Ctr. – Houston, Houston, TX

Abstract: Genetic disorders such as Rubinstein-Taybi syndrome (RTS) and Coffin-Lowry syndrome (CLS) cause lifelong intellectual disability, including deficits in learning and memory. Can pharmacological therapies be suggested that improve learning and memory in these disorders? To address this question, we simulated drug effects within a computational model describing induction of late long-term potentiation (L-LTP). Biochemical signaling pathways impaired in these and other disorders converge on a common target, histone modification by acetyltransferases such as CREB binding protein (CBP), which facilitates induction of genes necessary for L-LTP. We focused on four classes of drugs: TrkB agonists, cAMP phosphodiesterase inhibitors, histone deacetylase inhibitors, and ampakines. Results suggested that each of these drugs alone may rescue, in part, deficits in L-LTP and learning. A potential disadvantage, however, was the necessity of simulating strong drug effects (i.e., high dosages), which could, in practice, produce adverse side effects. Thus, we also investigated the effects of the six drug pairs that use these four classes. These combination treatments normalized impaired L-LTP with substantially smaller individual drug 'dosages'. In addition, two of these combinations, using a cAMP phosphodiesterase inhibitor paired with a TrkB agonist or an ampakine, exhibited strong synergism in simulated L-LTP rescue. Drugs simulated in these combinations correspond to specific small molecules that are either clinically approved for other disorders, or have demonstrated effects in animal models. Therefore, we suggest these drug combinations are promising candidates for further empirical studies in animal models of genetic disorders that impair histone acetylation, L-LTP, and learning.

Title: Calcium dependent remodeling of PSD-95 by competitive binding for PDZ domains

Authors: *P. GIOLANDO, B. DAVIS;
Biomed. Engin., Purdue Univ., West Lafayette, IN

Abstract: Introduction: About 1 in 60 children in the US have been diagnosed with Autism Spectrum Disorder (ASD). Of the genes associated with ASD, those most correlated with the disorder produce proteins involved in synaptic function. Among these SYNGAP1 is a major

constituent and a downstream target of glutamate. Also highly expressed is the scaffolding protein PSD-95, which binds synGAP at all three of its PDZ domain. SynGAP has been found to occupy up to 15% of these domains at one time (1), potentially restricting the binding of other proteins to these sites including TARP and LRRTM proteins involved in regulating synaptic functions. To gain a full understanding of how synGAP competes for binding to PDZ domains, we present a computational model of the dynamic binding of synGAP and other key synaptic proteins (TARP, and LRRTM) with PDZ domains. Our model focuses on two events influencing the binding of synGAP to PDZ domains: binding of Ca^{2+}/Calmodulin (Ca^{2+}/CaM) to synGAP, and phosphorylation of synGAP by CAMKII. We hypothesize these events provide a mechanism for regulating the availability of PDZ domains at the synapse.

Materials and Methods: The dynamic interactions among synGAP, CaM, CaMKII, TARP, and LRRTM are modeled according to mass action kinetics. We define the time dependent binding for each protein by numerically solving a system of ordinary differential equations. Model parameters are derived from previous literature. To quantify model robustness, we use Latin hypercube sampling to perform a global sensitivity analysis.

Results and Discussion: To validate our model, we compared the concentration of synGAP bound to PSD-95 at basal conditions with known values and found synGAP bound up to 15% of the PSD-95 domains, in agreement with previous studies (Figure 1). The model accurately predicted the reduction in synGAP bound to PSD-95 by the activation of CaM and CaMKII, which previous *in vitro* studies determined to be 20% and 54% respectively.

To test whether phosphorylation of synGAP by CaMKII causes significant rearrangement of proteins bound to PSD-95, we stimulated activation of CaMKII by Ca^{2+}/CaM at 100 Hz Ca^{2+} spike frequency for 10 s, to mimic LTP and at 10 Hz for LTD. We find significant rearrangement in the binding pattern of synGAP, TARP and LRRTM occurs on the order of seconds and is thus on a timescale relevant for AMPAR receptor trafficking.

Figure 1. Rearrangement of proteins bound to PSD-95 during LTP stimulation (100 Hz), at 20 s for a duration of 10 s. Each protein is normalized to its steady state bound concentration.

Title: Aav shrna mediated pten knockdown in adult neurons leads to persistent activation of mtor, *de novo* neuron growth, and attenuation of activity dependent kinase activation and immediate early gene induction

Authors: *O. STEWARD[1], K. M. YEE[2];
[1]Univ. of California, Irvine, Irvine, CA; [2]Reeve-Irvine Res. Ctr., Univ. of California Irvine, Irvine, CA

Abstract: Conditional genetic deletion or knockdown of *PTEN* in neurons leads to persistent activation of mTOR, which enables regeneration of CNS axons and sprouting of intact axons after injury and induces *de novo* growth of cell bodies and dendrites of adult neurons in the absence of any injury. It is unknown how PTEN deletion, persistent activation of mTOR, and *de novo* growth affect the way neurons are activated in functional circuits in the brain. As a first step to address this question, we assessed consequences of PTEN knockdown in cortical neurons and granule cells of the dentate gyrus, focusing on activity-induced kinase signaling and immediate early gene (IEG) induction. Adult rats received unilateral injections of AAV expressing shRNA against PTEN and a reporter (either zsGreen or GFP) into the motor cortex or dorsal dentate gyrus. To assess IEG induction in response to intense neuronal activity, rats were anesthetized with urethane and prepared for acute neurophysiology. Rats with intra-cortical injections of AAVshPTEN received high frequency stimulation (HFS) to the side of the cortex that received AAVshPTEN. Stimulation was delivered via surface electrodes, and consisted of trains of 8 pulses at 400hz delivered 1/10sec for 10 minutes at an intensity sufficient to induce muscle twitch. Rats were perfused 20-60 minutes post-stimulation. For rats with injections of AAVshPTEN into the dentate gyrus, HFS was delivered as above via a stimulating electrode positioned in the entorhinal cortex to activate the performant path while monitoring performant path evoked potentials via a recording electrode positioned in the dentate gyrus. Rats were perfused 60 minutes after the initiation of HFS. Brains were prepared for immunocytochemistry using antibodies for PTEN to reveal the area of deletion, IEGs (Arc and c-fos), and phospho-specific antibodies for kinase signaling (p-ERK, p-S6). In rats with intra-cortical injections of AAVshPTEN, HFS of the cortex strongly induced IEG expression throughout the cortex on the side of the stimulation but IEG induction was attenuated in areas of PTEN deletion. In rats with injections of AAVshPTEN into the dentate gyrus, HFS of the perforant path massively induced Arc and c-fos expression throughout the dentate gyrus on the side of the stimulation, but this induction was almost completely abrogated in areas of PTEN deletion. Immunostaining for p-ERK and p-S6 revealed abrogation of both mTOR and ERK activation in PTEN-deleted granule cells, which may account for the abrogation of IEG induction. It remains to be determined whether how attenuation of activity-dependent kinase activation and IEG induction alter overall neuronal function.

Purpura Dept. of Neurosci., Albert Einstein Col. of Medecine, New York, NY; [4]Univ. of Castilla-La Mancha, Albacete, Spain; [5]Albert Einstein Coll Med., Bronx, NY

Abstract: The dentate gyrus, a major input area of the hippocampus, contains two types of excitatory neurons: dentate granule cells (GCs) and hilar mossy cells (MCs). MCs receive inputs from GCs and project back to GCs locally (intralamellar), contralaterally, and along the dorsoventral axis of the hippocampus, thereby establishing an associative positive-feedback loop (GC-MC-GC). However, how MCs contribute to dentate gyrus function remains poorly understood. We recently reported that MC-GC synapses express a robust form of presynaptic long-term potentiation (MC-GC LTP) that can increase the dentate gyrus output. Mechanistically, MC-GC LTP is NMDA receptor-independent and requires postsynaptic BDNF/TrkB and presynaptic cAMP/PKA signaling. MC-GC LTP also requires retrograde signaling but the identity of the retrograde signal remains unknown. To address this issue, we first determined whether postsynaptic firing alone could induce LTP in rodent hippocampal slices. We found that theta-burst firing (TBF) of a single GC by direct depolarization is sufficient to induce plasticity in an input-selective manner, namely, MC inputs but not neighboring medial perforant path (MPP) inputs undergo LTP. Using this single cell manipulation and selective pharmacology, we discarded a role for conventional retrograde messengers, such as endocannabinoids and nitric oxide. Given the requirement for presynaptic cAMP/PKA activity, we explored whether a G_s-coupled receptor could be involved. We discovered that activation of A_{2A} receptors is necessary and sufficient for MC-GC LTP, whereas activation of the $G_{i/o}$-coupled

A_1 receptor dampens LTP induction. In addition, using immunoelectron microscopy, we found that A_{2A} receptors are highly expressed at MC axon terminals but not at MPP axon terminals. Remarkably, interfering with adenosine release from GCs abolished LTP. Altogether, these results strongly suggest that adenosine may act as a retrograde messenger to mediate MC-GC LTP through activation of presynaptic, G_s-coupled A_{2A} receptors. By increasing the strength of MC inputs onto GCs, A_{2A} receptor-mediated LTP may contribute to memory formation and epilepsy.

Grad. Sch. of Med., Suita, Japan

Abstract: The essential involvement of phosphoinositides in synaptic plasticity is well-established, but incomplete knowledge of the downstream molecular entities prevents us from understanding their signalling cascades completely. Here, we determined that Phldb2, of which pleckstrin-homology domain is highly sensitive to PIP_3, functions as a phosphoinositide-signalling mediator for synaptic plasticity. BDNF application caused Phldb2 recruitment toward postsynaptic membrane in dendritic spines, whereas PI3K inhibition resulted in its reduced

accumulation. Phldb2 bound to postsynaptic scaffolding molecule PSD-95 and was crucial for localization and turnover of PSD-95 in the spine. Phldb2 also bound to GluA1 and GluA2. Phldb2 was indispensable for the interaction between NMDA receptors and CaMKII, and the synaptic density of AMPA receptors. Therefore, PIP_3-responsive Phldb2 is pivotal for induction and maintenance of LTP. Memory formation was impaired in our *Phldb2*$^{-/-}$ mice.

Title: Transcranial direct current stimulation induces hippocampal metaplasticity mediated by BDNF-dependent TrkB activation

Authors: ***T.-H. YU**[1], Y.-J. WU[2,3], M.-E. CHIEN[2], K.-S. HSU[1,4];
[1]Inst. of Basic Med. Sci., Natioanal Cheng Kung Univ., Tainan, Taiwan; [2]Dept. of Neurol., Natl. Cheng Kung Univ. Hosp., Tainan, Taiwan; [3]Inst. of Clin. Medicine, Col. of Med., [4]Dept. of Pharmacol., Natl. Cheng Kung Univ., Tainan, Taiwan

Abstract: Transcranial direct current stimulation (tDCS) is a non-invasive stimulation which can modulate brain function via applying electric fields. It has been used on several neurological disorders in humans. However, the detail cellular and molecular mechanisms is unclear. We investigated mechanism of the aftereffects after tDCS which can enhance the long-term potentiation (LTP) at Schaffer collateral-CA1 synapses, also can alter the performance of learning and memory. Anodal tDCS was applied using a constant current stimulator connected with a head electrode of 0.25 cm^2 on the skull over the hippocampus for 30 min at 0.25 mA. There were no significant changes on hippocampal EEG and neuronal excitation in tDCS-treated group by using electroencephalogram (EEG) and immunohistochemistry. Extracellular field potential recordings were used to examine the induction of LTP at hippocampal CA1 region. We found that hippocampal CA1 LTP were enhanced in tDCS-treated group compared to sham-treated group. This enhancement could be lasting for 12 hours and inhibit by the TrkB inhibitor ANA-12. It also increased brain derived neurotrophic factor (BDNF) protein levels which were measured with ELISA kit. To test whether tDCS influenced learning and memory, we compared memory performance in one-trial passive avoidance learning task between sham- and tDCS-treated group. Anodal tDCS enhanced memory performance in the behavior test. This

enhancement also could be inhibited by the TrkB inhibitor. Altogether, our results suggest that the aftereffects of anodal tDCS could facilitate the induction of hippocampal CA1 LTP and enhance the memory performance mediated by BDNF/TrkB pathway. These findings may give a further understanding on the cellular and molecular mechanisms of the aftereffects induced by tDCS and provide the therapeutic potential of tDCS for neurological disorders.

Abstract: Synaptotagmin-11 (Syt-11) is an uncharacterized member of synaptotagmin protein family that lacks apparent ability to bind calcium, phospholipids and SNARE proteins. Recent genetic studies suggest that mutations in the Syt-11 locus links to schizophrenia and Parkinson's disease. However, the biological role of Syt-11 in the mammalian brain still remains uncertain. Here, we demonstrate a detailed analysis of expression and localization of Syt-11 in cultured neurons and central nervous system, and phenotype of genetic mutant mice that lack Syt-11 either constitutively or in specific neuronal population. We observed that Syt-11 is broadly expressed in the mouse brain and distributed as a membrane constituent of mobile secretory vesicles that recycle in an activity-dependent manner. Importantly, while constitutive deletion of Syt-11 in all tissues resulted in early postnatal lethality, mice lacking Syt-11 in forebrain neurons exhibited normal lifespan but an impaired ability of spatial learning and memory. Moreover, ablation of Syt-11 had no effect on basal neurotransmission but blocked the induction of hippocampal long-term synaptic potentiation. Our findings indicate that Syt-11 acts on a secretory pathways essential for synaptic plasticity and memory, and provide important insights into the molecular mechanisms underlying neurological disorders.

Title: Cholinergic modulation of the corticostriatal synaptic plasticity in sub-group of stratal projection neurons

Authors: *A. TAMURA, J. A. CHOUINARD, K. KURIMA, Y. AKAMINE, J. R. WICKENS; Neurobio. Res. Unit, Okinawa Inst. of Sci. and Technol., Onna-son, Japan

Abstract: The cholinergic interneurons (CINs) of the striatum are crucial for behavioral flexibility. CINs of the dorsomedial striatum (DMS) play a role in strategy switching. However, how CINs modulate the neural circuitry underlying strategy switching is unclear. The glutamatergic afferents from the cerebral cortex to the striatum display activity-dependent plasticity in the corticostriatal synapses, and may be involved in certain types of learning. One hypothesis is that strategy switching may be realized by a modulatory effect of CINs on corticostriatal plasticity. Here, we investigated the effect of CINs on activity-dependent plasticity in the corticostriatal synapses. To control tonic firing of CINs, adeno-associated virus (AAV) encoding halorhodopsin (NpHR) was injected into DMS of ChAT-cre mice. AAV injected mice expressed NpHR in CINs and we can optogenetically inactivate CINs firing. We made whole-cell ex vivo slice recordings from spiny projection neurons (SPNs), which are the output neurons of the striatum, and recorded EPSPs induced by electrical stimulation of the corpus callosum. Activity dependent synaptic plasticity was induced by high-frequency stimulation under the Mg-free conditions. This conditioning stimulus combined with optogenetic inactivation of CINs during HFS induced long-term potentiation in some SPNs. However, other group of SPNs showed long-term depression in response to the same conditioning stimuli. These results might indicate that CIN activity modulates corticostriatal plasticity differentially in direct and indirect SPNs.

Title: A short episode of high intensity sound decreases BDNF levels in the hippocampus, which impairs LTP

Authors: J. L. DE DEUS[1], M. R. AMORIN[2], A. O. CUNHA[3], L. G. S. BRANCO[2], ***R. M. LEAO**[1];
[1]Physiol., [2]Morphology, Physiol. and Basic Pathology, [3]Univ. of Sao Paulo, Ribeirao Preto, Brazil

Abstract: Hippocampal neurons can respond to acoustic dimension clues, and that their function is affected by auditory stimulation and deprivation. High-intensity sound is a noxious stimulus, which can produce intense emotional reactions in animals and humans. We have previously found that a single minute exposure to a 110 dB sound inhibits Schaffer-CA1 LTP in hippocampal slices from rats. Here we investigate the possible mechanisms of this effect Whole-cell recordings were performed in hippocampal slices from rats sacrificed 2 hours after sound stimulation. We found that both GABAergic and glutamatergic (AMPA/kainate and NMDA receptor mediated) neurotransmission were unaffected by high intensity sound. Neurotrophins such as brain-derived neurotrophic factor (BDNF) are known to promote LTP in the hippocampus. We then measured the BDNF content in CA1 area using ELISA and found lower levels of BDNF in the CA1 from rats exposed to high intensity sound (2344 ± 89 pg/mg protein vs. 1732 ± 77 pg/mg protein, n= 8 and 7 respectively; $p<0.001$). We then studied whether BDNF can reverse LTP inhibition after a single episode of high-intensity sound. LTP was induced by 3 high-frequency stimulation trains (100 Hz; 1 second each) on the Schaffer-CA1 and then field postsynaptic excitatory potentials were recorded in the stratum radiatum of the CA1. BDNF (50 ng/ml) and the trk-B agonist, LM 22A4 (5 μM) were perfused for 5 minutes before and for 5 minutes after induction of LTP. LTP in animals exposed to a single sound stimulus is inhibited (1.04 ± 0.11, n = 5) in contrast to sham-stimulated rats (1.41 ± 0.11, n = 4; $p <0.05$). Perfusion with BDNF restored the LTP to its original levels (1.55 ± 0.12, n = 6). Application of BDNF in slices from sham-stimulated animals did not induced further potentiation of LTP (1.4 ± 0.07, n=7; p=0.9). The agonist of the BDNF target, the trk-b receptor, LM 22A4, also rescued LTP from sound-stimulated animals (1.62 ± 0.17, n = 5). Our results strongly suggest that the exposure to high intensity sound inhibits the BDNF production in the hippocampus, which could be the mechanism of the inhibition of LTP by high-intensity sound exposure.

Title: Modulation of synaptic plasticity in hippocampal CA1 region by basolateral amygdala

Authors: *Y. CHONG, C. GOH, S. SREEDHARAN;
Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Amygdala plays a vital role in emotional events which is known to affect memory consolidation. Hippocampus is a critical brain region involved in memory consolidation. Evidence has shown that a specific sub-region of amygdala, the basolateral amygdala (BLA), has reciprocal connections to ventral hippocampus proving that priming on the BLA alters the long-term potentiation (LTP) in hippocampus. To investigate time- and activity-dependent modulation of synaptic plasticity in the hippocampal CA1 region by the BLA and its underlying mechanisms, we used field electrophysiological recordings in acute horizontal brain slices from 5 to 7 weeks old C57BL/6J mice to study synaptic plasticity in the CA1 area under different BLA stimulation conditions. First, we studied the effect of timing dependence of the effect of BLA co-stimulation on synaptic plasticity in hippocampal area CA1. Co-induction of high frequency stimulation (100 Hz) in BLA and late-LTP in CA1 resulted in an elevated LTP while stimulation of BLA prior to late-LTP induction at a specific time scale (10 min and 30 min) suppressed late-LTP. No significant effect was observed when BLA stimulation was given 5 min prior to late-LTP induction in CA1. Next, we observed that the enhancement of late-LTP due to BLA co-stimulation (100 Hz) ameliorated LTP impairments in the synaptic competition phenomenon in CA1. However, stronger BLA co-stimulation (200 Hz) resulted in the impairment of late-LTP and associative plasticity in hippocampal area CA1. The modulation of BLA on synaptic plasticity in CA1 required protein synthesis and NMDAR as application of the inhibitors and antagonist, respectively, impaired late-LTP maintenance. The ongoing biochemistry study suggests that Arc protein level in CA1 was altered in the BLA co-stimulation conditions. Our finding confirms that amygdala has positive and negative influences on long-term synaptic plasticity in the hippocampus and it is time- and activity-dependent. Unravelling

its cellular mechanisms may provide insights into the mechanisms of emotional disorders such as post-traumatic stress disorder (PTSD).

Title: Long-term potentiation can be trans-synaptically evoked in the hippocampal formation

Authors: *M. T. ROMERO-BARRAGAN, J. M. DELGADO-GARCIA, A. GRUART;
Div. of Neurosciences, Pablo De Olavide Univ., Sevilla, Spain

Abstract: Long-term potentiation (LTP) evoked by high frequency stimulation (HFS) is a very well-known experimental procedure that shares certain mechanisms with learning and memory processes. LTP is a typical example of synaptic plasticity, which appears after applying an HFS train to the afferent pathway of a CNS synapse. Basically, the LTP consists in an increase of the synaptic response to a control stimulus following the presentation of the HFS trains. This technique was described for the first time in the hippocampus and it is still studied mostly there, since those synaptic connections are very susceptible to LTP induction. Besides, the highly laminar nature of the hippocampus provides a suitable model to study synapses with different ultrastructural dispositions. Although most of preceding studies have been performed *in vitro*, we have developed a new experimental approach to carry out these experiments in behaving animals. The main goal of this study was to ensure that there are synaptic changes in strength not only in the first synapse where LTP is induced, but also in those which are contiguous to it. Field excitatory post-synaptic potentials (fEPSP) evoked in five hippocampal synapses, located both ipsi- and contralateral hemispheres, were studied in alert behaving male mice. HFS was presented to the perforant pathway (PP) and recordings were carried out in the CA1 and CA3 areas of the ipsilateral hippocampus and in the CA1 area of the contralateral side. The five studied synapses were: PP-CA1i, PP-CA3i, PP-CA1c, CA3-CA1i, and CA3-CA1c. Animals were prepared for chronic recordings in the mentioned synapses following procedures described elsewhere (Gruart et al., J. Neurosci., 2006). We have characterized input/output curves, pair pulse facilitation (PPF) and LTP of these five synapses. Data from input/output curves and paired-pulse facilitation proved that the five studied synapses have similar basic properties, which makes their later comparison easier for subsequent histological, pharmacological, and genetic analysis. Importantly, regarding HFS of the PP, we observed the presence of significant

LTP both at the CA3-CA1c and PP-CA1c synapses. In conclusion, these results indicate that LTP can be evoked at synapses located far away from the stimulated afferent pathways.

Title: Effects of social isolation rearing and ketamine on hippocampal synaptic plasticity

Authors: *J. B. LOGUE[1], K. J. SCHOEPFER[1], Y. ZHOU[2], M. KABBAJ[1];
[1]Biomed. Sci., [2]Florida State Univ., Tallahassee, FL

Abstract: Social isolation rearing is a long-term stressor that produces lasting effects including memory deficits, cognitive impairments, and hippocampal functional and structural alterations. Ketamine (KET) is a non-competitive N-methyl-d-aspartate receptor (NMDAR) antagonist currently of interest for its antidepressant effects at subanesthetic doses. Previous work from our lab has shown that rats' sex and gonadal hormone status play critical roles in mediating sensitivity to the antidepressant-like effects of KET, as females behaviorally respond to a lower dose of KET (2.5 mg/kg, i.p.) than males (5 mg/kg, i.p.), an effect that requires both estradiol (E2) and progesterone (P4) on-board. However, electrophysiological correlates to this female-specific dose sensitivity remain unclear. This study aims to investigate the interaction between social isolation rearing stress and low-dose KET on hippocampal activity and synaptic plasticity in rats of both sexes. We hypothesize that: 1. The field excitatory post-synaptic potentials (fEPSPs) in dorsal hippocampus Schaffer collateral (CA3-CA1) synapses may be impaired by isolation stress in both sexes, 2. A single low dose of KET (2.5 mg/kg, i.p.) given *in-vivo* 3hr prior to slice recording may rescue stress-induced fEPSP deficits in females, but not males, 3. Female-specific KET rescue effects may be modulated by estrous stage (Proestrus: high E2/P4, Diestrus: low E2/P4), and 4. Stress-induced fEPSP deficits in both sexes may be ameliorated with a single treatment of 5 mg/kg KET (i.p.). Postsynaptic plasticity was evaluated by measuring tetanic stimulation-induced long-term potentiation (LTP), the responsivity of the synapse to electrical stimulation was measured by fEPSP input-output curves, and presynaptic transmitter release probability was measured by paired-pulse facilitation experiments. Completion of this project will generate insights into the interactions between gonadal hormones and KET at this synapse and the potential restoration of neural plasticity.

Title: Hippocampal long-term potentiation is modulated by exercise-induced alterations in dopaminergic neurotransmission in mice selectively bred for high voluntary wheel running

Authors: *K. D. PARFITT[1], J. M. PHAN[2], J. YI[4], J. H. A. FOOTE[1], S. K. OLSON[3], T. GARLAND, Jr[5];
[1]Dept of Neurosci., [2]Mol. Biol., [3]Biol., Pomona Col., Claremont, CA; [4]Neurosci., Washington Univ., Saint Louis, MO; [5]Biol., Univ. of California Riverside, Riverside, CA

Abstract: Mice from lines selected for high voluntary wheel-running activity (high-runner; HR) display behaviors that resemble features of human attention deficit hyperactivity disorder (ADHD). They exhibit increased motor activity and are highly motivated to run, running almost three times farther per day than non-selected control (C) counterparts. Our previous work revealed that HR mice with running-wheel access show significantly increased hippocampal long-term potentiation (LTP) compared to HR mice without wheel access, and to C mice with or without wheel access. Because hyperactivity and motivation are associated with alterations in dopaminergic neurotransmission, and because running is reduced in HR mice treated with methylphenidate, we were interested in possible changes in dopamine transporters and receptors in the brain of HR mice. Here, we examined the influence of this intense running on dopamine D1 receptors (D1R) and dopamine transporters (DAT) in hippocampus of HR vs C mice with wheel access. Pretreatment of hippocampal slices with the D1R agonist SKF-38393 prevented the elevated LTP seen in HR mice that had wheel access, such that it was similar to LTP seen in slices from C mice with or without wheel access; the magnitude of LTP in the absence vs presence of SKF was 83 ± 12% vs 41 ± 11% respectively ($p<0.05$), whereas the magnitude of LTP was not significantly different in SKF-treated or untreated C mice with wheels. SKF-38393 did not affect basal synaptic transmission. Using Western blot analyses, we also examined the expression of D1Rs and DAT in the hippocampus, prefrontal cortex, striatum, and cerebellum and found that hippocampal levels of D1Rs were significantly reduced in HR mice compared to C mice; levels of D1Rs were 30% lower in HR mice without wheels and 20% lower in HR mice with wheels, compared to C mice with or without wheels. Levels of DAT in hippocampus were elevated 21% in HR mice, with or without wheel access. D1R and DAT levels were not altered in other brain regions examined. Taken together, these results suggest that the increased hippocampal LTP seen in HR mice with wheel access may be related to alterations in

dopaminergic synaptic transmission that underlie the neurophysiological basis of hyperactivity and/or addictive behaviors.

Title: Computational analysis of cholinergic mechanisms for disinhibition of CA1 pyramidal cells and induction of hippocampal plasticity

Authors: *I. GUERREIRO[1], Z. GU[2], J. L. YAKEL[2], B. GUTKIN[1];
[1]Ecole Normale Superieure, Paris, France; [2]Natl. Inst. of Envrn. Hlth. Sci., Research Triangle Park, NC

Abstract: Studies of induction of hippocampal plasticity have shown that blockade of GABA inhibition can greatly facilitate the induction of LTP in excitatory synapses (Wingstrom and Gustafsson, 1983).
It was shown experimentally that repeated inhibition of hippocampal CA1 somatostatin-positive interneurons can induce lasting potentiation of Schaffer collateral (SC) to CA1 EPSCs, suggesting that repeated dendritic disinhibition of CA1 pyramidal cells plays a role in the induction of synaptic plasticity. It was also shown experimentally that repeated cholinergic activation enhanced the SC-evoked EPSCs through a7-containing nicotinic acetylcholine receptors (a7 nAChRs) expressed in oriens lacunosum-moleculare (OLMa2) interneurons.
We used a biophysically-realistic computational model to examine mechanistically how inhibitory inputs to hippocampal pyramidal neurons can modulate the plasticity of the SC-CA1 excitatory synapses. We found that locally-reduced GABA release (disinhibition) paired with SC stimulation could lead to increased NMDAR activation and intracellular calcium concentration sufficient to upregulate AMPAR permeability and potentiate the excitatory synapse. Repeated disinhibition of the excitatory synapses could lead to a larger increase of the AMPAR permeability. This results in the potentiation of the SC-CA1 excitatory synapse, which can be maintained when disinhibition period is over through repeated stimulation of the SC that keeps a balance between the down and upregulation of the AMPARs.
We then used our model to show how repeated cholinergic activation of a7 nAChR in stratum oriens OLMa2 interneurons paired with SC stimulation can induce synaptic plasticity at the SC-CA1 excitatory synapses. Activation of pre-synaptic a7 nAChRs in OLM cells activates these interneurons which, in turn, inhibit fast-spiking stratum radiatum interneurons that provide feed-

forward inhibition onto pyramidal neurons after SC excitation, and thus disinhibiting the CA1 pyramidal neurons and inducing synaptic plasticity.

Abstract: The dentate gyrus (DG), the main input region of the hippocampus, plays a critical role in memory formation by transforming patterns of cortical inputs into new patterns of output to the CA3 area. The DG includes two principal cells, hilar mossy cells (MCs) and dentate granule cells (GCs), which are reciprocally connected thereby establishing a GC-MC-GC associative circuit. Remarkably, MCs send extensive projections –intralamellar, contralateral and along the longitudinal axis of the hippocampus– that synapse onto GC proximal dendrites. Given this wide distribution, as well as the proximal localization of MC-GC synapses, activity-dependent plasticity of MC-GC transmission may contribute significantly to information processing and DG-dependent cognitive functions. Our lab recently reported that physiologically-relevant patterns of MC activity *in vitro* induce robust presynaptic LTP of MC-GC transmission. While MC-GC LTP requires postsynaptic BDNF/TrkB signaling, a pathway known to regulate protein synthesis, it is unknown whether BDNF is derived from the pre- and/or postsynaptic neuron, and the downstream signaling pathways remain poorly understood. Moreover, it is unclear whether this form of LTP can occur *in vivo*. Here, we combined electrophysiology and 2-photon live imaging in acute rodent hippocampal slices to investigate the molecular basis underlying BDNF/TrkB-dependent LTP at MC-GC synapses. Using the fluorescent BDNF sensor BDNF-pHluorin and cell-specific conditional knock-out for *Bdnf* and *TrkB*, we found that BDNF is released from both MC axonal boutons and GC proximal dendrites following repetitive activation of MCs, suggesting that both anterograde and retrograde BDNF/TrkB signaling are involved in MC-GC LTP. In addition, blocking protein synthesis (80

μM cycloheximide) during induction but not 20 min post induction abolished MC-GC LTP, indicating the involvement of fast protein synthesis. Lastly, we found that exposing mice to enriched environment for 2 weeks increased MC-GC synaptic efficacy and occluded MC-GC LTP, strongly suggesting that this form of plasticity can be induced *in vivo*. Altogether, our findings highlight a novel mechanism by which the DG processes information and may contribute to hippocampal-dependent learning and memory.

Title: Regulation of synaptic plasticity by BDNF-endocannabinoid interactions

Authors: F. LEMTIRI-CHLIEH, T. M. ROBINSON, ***E. S. LEVINE**;
Neurosci., Univ. of Connecticut Sch. of Med., Farmington, CT

Abstract: The goal of these studies is to explore the functional interactions between brain-derived neurotrophic factor (BDNF) and endogenous cannabinoids (eCBs) in regulating activity-dependent synaptic plasticity in the neocortex. Both BDNF and eCBs have been implicated in a diverse range of physiological processes, including sensory perception, motor coordination, memory, and cognitive abilities. Disruption of BDNF and/or eCB signaling may play a role in several neurologic and psychiatric disorders, including anxiety, depression, schizophrenia, and seizure disorders, and these neuromodulatory systems are currently major targets for the development of novel therapeutics. Although there is evidence for crosstalk between BDNF and eCB signaling, little is known regarding potential synaptic interactions. We have recently shown that BDNF suppresses presynaptic GABA release at cortical inhibitory synapses and this effect is mediated by the BDNF-induced release of eCBs from postsynaptic pyramidal cells that act as retrograde signals. We have also found that BDNF induces eCB release at cortical excitatory synapses, and the suppressive effects of eCBs on glutamate release can mitigate the direct enhancing effects of BDNF at these synapses. We are now poised to explore the functional relevance of these synergistic as well as antagonistic interactions in regulating activity-dependent synaptic plasticity. In the present studies, we examined the interactions between BDNF and eCB signaling at cortical layer 5 excitatory synapses, using a pharmacologically-induced long-term potentiation (LTP) protocol that increases intracellular cAMP and enhances NMDA receptor activation. We found that this chemical-LTP requires endogenous BDNF and TrkB signaling

because it was prevented by the TrkB antagonist ANA-12 or the Trk tyrosine kinase inhibitor K-252a. The response to this induction protocol was also impaired in mice engineered to express a common human variant in the BDNF gene (Val66Met) that reduces activity-dependent BDNF release. The role of eCB signaling will be explored through the use of CB1 receptor antagonists and inhibitors of eCB synthesis and metabolism. Release of eCBs at these excitatory synapses may diminish plasticity whereas eCB suppression at inhibitory synapses could enhance excitatory plasticity. Our overarching hypothesis is that the balance of BDNF and eCB signaling in specific circuits regulates the direction and magnitude of synaptic plasticity.

Abstract: All-trans retinoic acid (atRA) has been recently linked to the ability of neurons to express synaptic plasticity. It is involved in mediating the accumulation of AMPA-receptors at excitatory postsynapses during the expression of Hebbian and homeostatic plasticity. The precise mechanisms through which atRA mediates its effects on plasticity remain not well understood. In this study, we sought to test for the role of intracellular calcium stores in atRA-mediated excitatory synaptic plasticity. In organotypic tissue cultures treated for 3 days with 1 µM atRA an accumulation of AMPA-receptors at excitatory postsynapses of dentate granule cell is observed. These changes depend on protein synthesis and are impaired if intracellular calcium stores are blocked. As a result of atRA-mediated changes in AMPA-receptor composition of excitatory synapses, the ability of neurons to express synaptic plasticity is improved. Thus, we conclude that atRA promotes metaplasticity, i.e., it improves the ability of neurons to express plasticity via a mechanism that requires functional intracellular calcium stores.

Abstract: Transcranial magnetic stimulation (TMS) is a non-invasive brain stimulation technique used in clinical practice for diagnostic and therapeutic purposes. It is based on the physical principle of electromagnetic induction and allows for the activation of cortical neurons through the intact skin and skull. Despite its clinical use, the cellular and molecular mechanisms of TMS-based diagnosis and therapy remain not well-understood. Based on our previous work, which demonstrated that 10 Hz repetitive magnetic stimulation (rMS) induces structural and functional changes consistent with a long-term potentiation of excitatory neurotransmission, we here tested whether LPS-mediated neural inflammation affects the ability of neurons to express rMS-induced synaptic plasticity. Indeed, in three-week old entorhino-hippocampal tissue cultures treated with LPS for 3 days, 10 Hz-rMS-induced synaptic plasticity of CA1 pyramidal neurons is not observed. Mechanistically, these changes are accompanied by activation of microglia, changes in pro-inflammatory cytokines and neuronal plasticity markers. Hence, our results provide a biological basis for the diagnostic use of rTMS in the context of neural inflammation.

Title: Distinct role of mGluR1α and mGluR5 in synaptic plasticity of somatostatin positive interneurons in dentate gyrus

Authors: *G. GRIGORYAN, M. BARTOS;
Systemic and Cell. Neurophysiol., Inst. of Physiol. I, Univ. of Freiburg, Freiburg, Germany

Abstract: Experience-dependent modifications in excitation-inhibition balance enable a selected group of neurons to form a new cell association during learning, which represent the new memory trace. GABAergic inhibitory interneurons are proposed to play a key role in this process by influencing the activity of individual pyramidal cells and cell associations. However, how interneurons are recruited during learning is largely unknown. Here we addressed this open question in the dentate gyrus (DG), which is essential for the acquisition of new memories. The DG is characterized by a sparse activity, which is tightly controlled by synaptic inhibition. Somatostatin-expressing interneurons (SOMIs) are a major GABAergic cell type in the DG. DG-SOMIs receive synaptic inputs from granule cells (GCs), the so-called mossy fibers (MFs), and provide feedback inhibition onto GC dendrites. Here we studied the recruitment of DG-SOMIs by MF-inputs and the cellular and molecular mechanisms underlying long-term potentiation (LTP) at MF-SOMI synapses. We performed whole-cell patch-clamp recordings from morphologically and physiologically identified DG-SOMIs in acute hippocampal slice preparations. Synaptic plasticity was evoked by extracellular stimulation of pharmacologically identified MF synapses in association with action potential generation in SOMIs. An associative burst-frequency stimulation reliably induced post-tetanic potentiation followed by LTP in DG-SOMIs (151.88 ± 3.77 %, 7 SOMIs). Antibody labeling revealed that DG-SOMIs express group I mGluRs (mGluR1a/5). Incubating slices with LY367385 (10 µM), a selective mGluR1a antagonist, led to a complete abolishment of LTP (106.98% of baseline, 7 SOMIs) whereas MPEP (10 µM), a selective antagonist of mGluR5, increased LTP magnitude ($p<0.001$; 5 SOMIs). Examination of the paired-pulse ratio, CV analysis and failure rate revealed the presynaptic expression of LTP. Intracellular SOMI loading with the G protein inhibitor GDP-β-S (0.5 mM) or the protein kinase C (PKC) inhibitor PKC 19-36 (10 µM) resulted in a loss of LTP, indicating the importance of both downstream mediators in LTP induction at this synapse. Moreover, stereotaxic injection of rAAVs containing a shRNA expression cassette into the ventral DG of SOM-Cre-tdTomato mice confirmed the selective loss of mGluR1a-mediated LTP

at MF-SOMI synapses. Thus, we show that associative synaptic plasticity at MF-SOMIs synapses requires postsynaptic mGluR1a activation of G protein and PKC-mediated second messenger cascades, but the activation of mGluR5 is dispensable.

Title: Presynaptic increase in IP3 receptor type 1 concentration in the early phase of hippocampal synaptic plasticity

Authors: *H. RINGSEVJEN[1], H. UMBACH HANSEN[1], S. HUSSAIN[1], V. JENSEN[1], S. WALAAS[2], S. DAVANGER[3];

Abstract: The inositol 1,4,5-trisphosphate receptor (IP3R) subtype IP3R1 is highly enriched in the brain, including hippocampal neurons. It plays an important function in regulating intracellular calcium concentrations. Residing on the smooth endoplasmic reticulum (sER), the IP3R1 mobilizes calcium into the cytosol upon binding the intracellular signaling molecule IP3, whose concentration is increased by stimulating certain metabotropic glutamate receptors. Increased calcium may mediate synaptic changes occuring during long-term plasticity, which includes molecular mechanisms underlying memory encoding. The exact synaptic localization of IP3R1 in the central nervous system remains unclear. We hypothesized that IP3R1, in addition to its known expression in soma and dendritic shafts of hippocampal CA1 pyramidal neurons, also may be present in postsynaptic spines. Moreover, we hypothesized that IP3R1 may be present in presynaptic terminals as well, given the importance of calcium in regulating presynaptic neurotransmitter exocytosis. To test these two hypotheses, we used IP3R1 immunocytochemistry at the light and electron microscopical levels in the CA1 area of the hippocampus. Furthermore, we hypothesized that induction of long-term potentiation (LTP) would be accompanied by an increase in synaptic IP3R1 concentrations, thereby facilitating synaptic mechanisms of long term plasticity. To investigate this, we used quantitative immunogold electron microscopy to determine possible changes in IP3R1 concentration in sub-synaptic compartments before and five minutes after high frequency tetanizations. Firstly, our data confirm localization of IP3R1 in both presynaptic terminals and postsynaptic spines. Secondly, the concentration of IP3R1 after tetanization was significantly increased in the presynaptic compartment, suggesting a presynaptic role of IP3R1 in early phases of synaptic plasticity. It is therefore possible that IP3R1 is involved in modulating neurotransmitter release by regulating calcium homeostasis presynaptically.

Title: Acetylcholine mediated modulation of long-term plasticity at Schaffer-collaterals

Authors: R. SHARMA, *S. NADKARNI;
Biol., Indian Inst. of Sci. Educ. and Res. Pune, Pune, India

Abstract: Acetylcholine is a crucial neuromodulator in the brain that activates multiple receptors; triggering biochemical changes that affect signalling within neurons across various time scales. Blocking cholinergic receptors in the hippocampal formation has been shown to impair the encoding of new memories. Hippocampal pyramidal neurons primarily express M1 and M4 receptors. The M4 receptors are localized presynaptically, where their activation is shown to cause suppression of neurotransmitter release. On the other hand, M1 receptors are found on the soma and dendrites of pyramidal neurons. Activation of M1 receptors has been shown to cause increased neuronal excitability via suppression of potassium channels like KCNQ2/3 and calcium-activated potassium channels (SK channel). Separately suppression of SK channels in the spine has been reported to enhance LTP induction for a theta-burst protocol. Additionally, M1 activation also leads to calcium release via IP3 receptors by the way of triggering IP3 production. We have developed a detailed biophysical model that incorporates multiple signalling pathways associated with M1 and M4 activity to investigate acetylcholine-mediated modulation of synaptic signaling at a CA1 dendritic spine. The predicted change in membrane potential and calcium signal in response to a single vesicle release in our model is in quantitative agreement with experimental data. Schaffer-Collaterals typically undergo both LTP and LTD, with LTD induction taking place at low frequency sustained stimuli and LTP at short bursts of high-frequency stimulus. Upon M1 activation we report a clear change in this response and show enhanced potentiation. Further, we show that synapses are more likely to undergo LTP instead of LTD in the presence of acetylcholine, with the threshold for LTP getting reduced. We also show that concurrent activation of presynaptic M4 receptors, that suppresses neuronal release, can further modify the long-term plasticity profile in a stimulus-dependent manner.

Title: 17β-estradiol enhances long-term potentiation in the rat primary auditory cortex *in vivo*

Authors: *C. N. SOUTAR[1], P. GRENIER[2], M. C. OLMSTEAD[1,2], C. D. BAILEY[3], H. C. DRINGENBERG[1,2];
[1]Ctr. for Neurosci. Studies, [2]Psychology, Queen's Univ., Kingston, ON, Canada; [3]Dept. of Biomed. Sci., Univ. of Guelph, Guelph, ON, Canada

Abstract: The neuroactive steroid hormone 17β-estradiol (E2) is synthesized and released in the mammalian forebrain where it rapidly alters structural and synaptic plasticity in both males and females. A growing body of evidence from songbirds suggests that E2 synthesis within the auditory forebrain is regulated by auditory experience and that locally-synthesized E2 contributes to auditory processing and memory consolidation. Despite the established role of E2 as a modulator of synaptic activity and plasticity in the forebrain, as well as its role in auditory learning, the modulatory actions of E2 on long-term plasticity mechanisms underlying learning and memory have not been directly investigated in the auditory system. Thus, the objective of the current study was to investigate the potential role of E2 in gating long-term synaptic plasticity in the mammalian primary auditory cortex (A1). Specifically, we tested the hypotheses that the adult rat A1 is a site of E2 synthesis and that acute alterations in local E2 levels modulate long-term synaptic plasticity (long-term potentiation; LTP) in this region. To investigate E2 synthesis within A1, we performed immunohistochemistry (3,3'-diaminobenzidine and immunofluorescence) to probe for the expression of the estrogen synthetic enzyme aromatase. IHC experiments revealed that aromatase is widely expressed by A1 neurons across layers II-VI, with over 56% of NeuN-expressing cells being immunoreactive for aromatase. To test the effects of acute alterations in local E2 levels on LTP in A1, LTP was induced by theta-burst stimulation (TBS) of the medial geniculate nucleus *in vivo* during application of E2 or the aromatase inhibitor letrozole by reverse-microdialysis in A1. E2 application enhanced the magnitude of TBS-induced LTP in the thalamocortical auditory pathway, particularly at layer IV thalamorecipient synapses. In contrast, local reductions in E2 synthesis by letrozole application suppressed LTP induction in A1, particularly at layer II/III intracortical synapses. Ongoing experiments utilize whole-cell recording to investigate the effects of acute E2 manipulations on the electrophysiological properties of A1 pyramidal neurons, such as glutamatergic and

GABAergic receptor currents and spontaneous postsynaptic currents. Preliminary findings suggest that synaptic currents in A1 are sensitive to changes in E2 levels, with E2 application facilitating AMPA responses in layer II/III pyramidal cells. Collectively, these results indicate that the adult rat A1 is a site of E2 synthesis and that E2 functions as a modulator of synaptic activity and long-term plasticity in this region.

Title: The distribution of synaptic strengths and mechanism for synaptic plasticity in the model of inter-spine molecular transport of PSD-95 molecules

Authors: *D. TSIGANKOV[1,2];
[1]Massachusetts Eye and Ear, Harvard Med. Sch., Boston, MA; [2]Max-Planck Inst. for Dynamics and Self-Organization, Goettingen, Germany

Abstract: The scaffolding protein PSD-95 is the most abundant molecule in the post-synaptic density (PSD) located in the spine, where it forms a cluster to which the membrane synaptic receptors are bound. The amount of PSD-95 molecules inside an individual spine determines the size of the PSD cluster and is strongly correlated with the synaptic strength. It is observed that these molecules have high turnover rates and that neighboring spines are constantly exchanging individual molecules. Here we present a model of non-equilibrium molecular transport between spines in neuronal dendrites describing the dynamics of PSD-95 molecules. When the molecules interact with each other inside the spines of a dendrite due to binding to PSD cluster, the corresponding trapping times inside the spines depend on the size of the PSD cluster and become much longer than the diffusion times in the dendritic shaft. This allows us to obtain the stationary distributions of PSD cluster sizes that emerge from such inter-spine molecular dynamics. Our results suggest that spines are competing for a shared pool of PSD-95 molecules in a weak "winner-take-all" regime that is restrained by the finite lifetimes of the PSD-95 molecules. Furthermore, we propose that in the model non-equilibrium inter-spine dynamics of PSD-95 molecules can provide the basis for locally controlled synaptic plasticity through activity-dependent ubiquitination of PSD-95. Thus local rapid destruction of a fraction of the PSD-95 cluster can lead to its growth due to self-organization phenomena, providing the molecular mechanism for maintenance of late long-term potentiation (LTP) required for synaptic plasticity.

In this scenario, the geometrical filling fraction of the PSD cluster is suggested to be an important characteristic of the synapse that carries the information of the previous LTP events.

Title: Etomidate suppression of LTP does not depend on modulation of α5-$GABA_A$ receptors on Sst or OLM interneurons

Authors: *A. R. FRELKA[1], A. G. FIGUEROA[1], G. SURGES[1], M. PERKINS[1], K. KULLANDER[2], R. A. PEARCE[1];
[1]Anesthesiol., Univ. of Wisconsin, Madison, WI; [2]Uppsala Univ., Uppsala, Sweden

Abstract: $GABA_A$ receptors containing α5 subunits (α5-$GABA_A$Rs) are instrumental in controlling learning and memory. We previously reported that etomidate (ETOM) targets α5-$GABA_A$Rs of interneurons (INs) to suppress long-term potentiation (LTP) of the Schaffer collateral (SC) pathway in the CA1 region of the dorsal hippocampus (SFN abstracts 2018), but the specific interneuron types that contribute to this effect are unknown. Here, we tested whether α5-$GABA_A$Rs on Sst-INs, and more specifically on one subset of these cells (OLM-INs), are involved in ETOM suppression of LTP by selectively eliminating α5-$GABA_A$Rs and measuring effects on LTP *in vitro*.
We eliminated α5-$GABA_A$Rs in specific classes of INs by crossing Sst-IRES-Cre or Tg(Chrna2-cre)1Kldr mice with fl/fl-α5-$GABA_A$R mice. For LTP studies, coronal hippocampal slices were obtained from 60-100 day old Sst - and Chrna2-α5-KO and fl/fl-α5 (pseudo-wild type) mice. LTP of the SC pathway was induced using a theta-burst stimulus (TBS), and defined as the change in the mean field EPSP slope between 51-60 minutes post-TBS compared to baseline, in groups of 8 slices under each condition.
In Sst-α5-KO mice, the selective loss of α5-$GABA_A$Rs did not alter LTP under drug-free conditions (CTRL), nor did it influence the ability of ETOM (1μM) to suppress LTP (fl/fl-α5 CTRL 131 ± 6% vs. ETOM 109 ± 5%, p= 0.01; Sst-α5-KO CTRL 133 ± 7% vs. ETOM 112 ± 1%, p = 0.02). In Chrna2- fl/fl-α5 mice, ETOM (1μM) failed to suppress LTP even in the pseudo-wild type mice (fl/fl-α5 CTRL 122 ± 4% vs. ETOM 117 ± 4%, p = 0.33) and the loss of α5-$GABA_A$Rs did not influence LTP or its modulation by ETOM (Chrna2-α5-KO CTRL 115 ± 4% vs. ETOM 111 ± 2%, p = 0.66).

Our results indicate that α5-GABA$_A$Rs on Sst-INs are not essential to the ability of ETOM to suppress LTP *in vitro*. Therefore, ETOM either targets a different class of interneurons in the dorsal hippocampus to suppress LTP *in vitro*, or its action on any one of the multiple classes, including Sst-INs, suffices. The lack of effect of ETOM on LTP in the Chrna2-fl/fl-α5 (Cre^- pseudo-wild type) mice was a surprise and remains unexplained but does not alter our conclusions.

Title: Alternative splicing of synaptic adhesion molecules in human somatosensory neurons

Authors: *J. J. YOO, R. W. GEREAU, B. A. COPITS;
Anesthesiol., Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Processing external information from distinct sensory modalities is vital for generating the diversity of somatic sensations that we perceive. However, altered communication within these pathways can result in chronic pain states. While the plasticity of nociceptive circuits is well established, we possess a limited understanding of the molecular mechanisms that assemble sensory circuits, and how this connectivity may be altered in chronic pain. Neurexins (*Nrxns*) are presynaptic cell-adhesion molecules essential in coordinating synapse formation through trans-synaptic interactions with myriad post-synaptic ligands. Alternative splicing of *Nrxns* generates thousands of unique isoforms, which has been proposed to impart a "splice-code" for connectivity. Alternative splicing of *Nrxn* splice site 4 (SS4) is critical for regulating synaptic plasticity by altering binding affinity for different post-synaptic ligands, resulting in altered glutamate receptor content. In the central nervous system, *Nrxn* splicing has been shown to regulate synaptic properties critical to coordinating neuronal connectivity, yet *Nrxn* splicing in somatosensory circuits remains largely unexplored. Here, we found that *NRXN* alternative splicing of SS4 in sensory neurons from human organ donors is altered after loss of spinal grey matter. Using a reverse translational approach, we used mouse models to understand the mechanisms underlying these splicing changes. We found that culturing sensory neurons

produced similar alterations in SS4 exclusion, suggesting that these splicing may be regulated by changes in activity, neuronal injury, or synaptic connectivity. While direct membrane depolarization enhanced SS4 exclusion, we found that persistent inflammation induced hypersensitivity rendered splicing unchanged. To model the loss of connectivity observed in human donors, we severed axons of dorsal root ganglia onto spinal neurons, and found that SS4 splicing in mice reflects the changes observed in human sensory neurons one week after loss of synaptic contacts. To test whether these changes in splicing resemble those found during initial development of somatosensory circuits, we examined splicing of embryonic sensory neurons which have not yet formed connections in the spinal cord. We found significant differences in splicing between embryonic and adult mice, suggesting changes in post-transcriptional regulation during development. We are now testing whether these changes in splicing resemble those found in neurons during initial circuit assembly or instead represent a maladaptive response that leads to circuit rewiring during the development of chronic pain.

Abstract: The differentiation of functional cortical neurons from human induced pluripotent stem cells *in vitro* easily lends itself to a serum-free, drug delivery platform advantageous for testing novel chemicals for safety and efficacy in disease treatment. Initially, cortical neuron cultures were characterized morphologically by phase microscopy and immunocytochemistry and functionally by patch-clamp electrophysiology. Specifically, the expression of neuronal markers and neuronal activity increased throughout maturation. On day 0 of maturation, 50 percent of the culture expressed layer V cortical neuron marker ctip2 and neuronal marker beta-III tubulin and displayed spontaneous and repetitive firing through whole-cell patch clamp. By day 28 of maturation, 90 percent of the culture expressed the aforementioned markers and

displayed electrical activity. Subsequently, neurons were cultured on multi-electrode arrays (MEAs) to determine the effects of chemicals on neural circuit physiology for modeling brain disease phenotypes. In this system, we tested $GABA_A$ receptor antagonists and agonists as chemical convulsants or anti-convulsants, respectively. $GABA_A$ receptor antagonist administration enhanced spontaneous activity mimicking an epileptic phenotype, while $GABA_A$ receptor agonist administration quieted spontaneous activity. The versatility of this model lies in its ability to present an array of brain diseases characterized by functional brain deficits. Chemicals affecting receptor binding can be added to either enhance or inhibit neuronal activity. This serum-free, hiPSC cortical neuron model establishes a platform for the evaluation of neuron activity as well as a platform for drug testing in vitro.

Title: Changes in electroencephalogram phase dynamics induced by transcranial magnetic stimulation

Authors: Y. SASAOKA[1], Y. IWAI[1], D. FUTAGI[2], K. KITAJO[3], ***K. KITANO**[1];
[1]Ritsumeikan Univ., Kusatsu, Japan; [2]Grad Sch. Information Sci. and Engin., Ritsumeikan Univ., 1-1-1 Noji-higashi, Kusatsu, Japan; [3]Dept. of Syst. Neurosci., Natl. Inst. for Physiological Sci., Okazaki, Japan

Abstract: Inter-regional interactions of the brain activity obtained by non-invasive recording such as fMRI or EEG are drawing more attention in the whole brain-level studies. In the inter-regional interactions, the phase information of rhythmic activity such as alpha-band oscillations is suggested to play an important role. However, it is generally difficult to see how different brain regions interact thorough the phases in "passively" recorded data because the direct cause to modulate phase relations is not clear. On the other hand, transcranial magnetic stimulation (TMS) enables us to evaluate the causal relation between the controllable direct perturbation and modulated neural activity. In the present study, we investigated how TMS for subjects in the

resting state influenced neural activities in each brain region and the phase interactions between the regions. To this end, we analyzed TMS-EEG data by the model-based approach using coupled phase oscillators as known as Kuramoto model. We assumed that a time-series signal recorded by an EEG electrode was generated by a nonlinear oscillator (presumably a neural population below the electrode) and derived a model to reproduce recorded EEG data by exploring model parameters such as coupling strengths between phase oscillators. The EEG data were obtained by delivering TMS at the visual cortex (Oz electrode) of subjects (n = 4) for real TMS trials (about 50 trials) or sham TMS trials (about 50 trials). Trial variability of derived model parameters were large due to noise inherent in EEG data as is the case for other EEG analyses. Coupling strengths averaged over trials indicated that the averaged coupling strengths in the alpha- and beta-band dynamics were more enhanced during real TMS trials than sham TMS trials. Furthermore, as for changes in coupling strengths before and after TMS, connections between adjacent regions were increased in alpha- and beta-band dynamics whereas those between distant regions were increased in theta-band dynamics. Thus, TMS could affect the phase dynamics between brain regions, which depended on the frequency band and distances between brain regions.

Title: The interbrain EEG synchronization during a joint action reflects the sense of joint agency

Authors: *M. SHIRAISHI, S. SHIMADA;
Meiji Univ., Kawasaki, Japan

Abstract: In a cooperative joint action, people feel the sense of joint agency (e.g., a sense that “we did it”) rather than the sense of self-agency (e.g., a sense that “I did it”). However, the neural correlates of the sense of joint agency have not been fully investigated. In this study, we examined whether the inter-brain synchronization during a joint action reflects the sense of joint agency. Eighteen pairs of healthy right-handed male subjects (aged 21.6 ± 1.3, mean ± SD) participated in the experiment. As a joint action, pairs of participants produced sequence of eight tones, four tones each, at a constant pace by the mouse clicks in the two task (alternating and sequential) conditions. In the alternating task, participants produced tones in alternation with each other. In the sequential task, one participant produced the first four tones and the other produced the last four tones. We defined the role of participants who produced the first tone as

leader and the role of the other as follower. After the joint action, participants rated their feelings of agency from 1 (self-agency) to 9 (joint agency). The brain activities of participant pairs were simultaneously recorded by an EEG system (g.USBamp, g.tec, Austraria) with 14 active electrodes (Fp1, Fp2, F5, Fz, F6, T7, C3, Cz, C4, T8, P5, Pz, P6, Oz) for each participant. The two-way ANOVA (task × role) revealed that participants felt significantly stronger joint agency in the alternating task than in the sequential task ($F(1, 25) = 44.2$, $p < 0.001$). For inter-brain synchronization analyses, we calculated the inter-brain phase synchronization index (PSI). The result showed that the PSI value in theta rhythm (3-8 Hz) between the leader's frontal region (Fz) and the follower's right temporal parietal junction (P6) in the alternating task were marginally greater than that in the sequential task ($t(12) = 1.72$, $p < 0.10$). Moreover, we found a significantly positive correlation between the joint agency score and the PSI value ($r = 0.57$, $p < 0.005$). These results suggest that the functional connectivity in theta rhythm between the leader's frontal lobe and follower's right temporal parietal junction reflects the sense of joint agency.

Title: Low-frequency alpha/beta oscillations: The same side of the same coin?

Authors: *M. ADAMEK[1], P. BRUNNER[1,2], G. SCHALK[1,2,3];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Ctr., New York State Dept. of Hlth., Albany, NY; [2]Dept. of Neurol., Albany Med. Col., Albany, NY; [3]Dept. of Biomed. Sci., State Univ. of New York, Albany, NY

Abstract: Ever since Hans Berger's seminal work on EEG in 1928, thousands of studies have characterized low-frequency brain oscillations by different frequency bands such as alpha and beta. This categorization assumes that the brain generates multiple functionally independent

sinusoidal oscillations. However, recent findings have provided evidence that cortical oscillations are indeed non-sinusoidal and that, consequently, different frequency bands may not be functionally independent. In view of this realization, we aim to replace the conceptual generalization of sinusoidal oscillations and their categorization into defined frequency bands with a physiologically-informed characterization of oscillatory activity.
Working towards this goal, we recorded electrocorticographic (ECoG) signals from the surface of the brain while human subjects performed a hand motor and a passive auditory listening task. To characterize the effects of oscillatory activity in task-related locations, we: 1) established the relationship between low-frequency activity (assessed by power, phase or instantaneous voltage) and population-level activity; 2) distinguished between true oscillations and their harmonics by calculating the power-power and phase-phase correlations across the entire low-frequency spectrum; and 3) recomposed the physiologically-informed oscillatory activity from its frequency components to determine the fraction of the variance of cortical excitability that it explains. Our analysis shows that cortical excitability in auditory and motor cortex is modulated by an oscillation that spans the alpha and theta frequency range (6-10Hz, r^2=0.4, permutation test, Bonf. corrected $p<0.01$). The analysis of harmonic components revealed power-power coupling in 99%, and phase-phase coupling in 77% of all task-related locations (permutation test, Bonf. corrected $p<0.05$). Finally, our results show that the recomposed physiological informed oscillatory activity is a better predictor of cortical excitability than the traditionally-used oscillatory power (45% increase, $p<<0.01$; paired Wilcoxon signed rank test).
We conclude that oscillations in traditional frequency bands (such as alpha and beta) are not independent of each other, but are (at least partially) different measurements from the same non-sinusoidal source. These results encourage further work on replacing frequency-based definitions of oscillatory activity with a functional definition, and suggest careful reinterpretation of past studies on low-frequency oscillatory activity.

Title: Synchronization of millihertz electrophysiological modulation revealed from bilevel spectral analysis of the pediatric EEG

Authors: ***M. E. LOE**[1], S. KHANMOHAMMADI[3], R. MATHER[1], S. TOMKO[4], M. MORRISSEY[4], R. M. GUERRIERO[4], S. CHING[2];

[2]Dept. of Electrical and Systems Engin., [1]Washington Univ. in St. Louis, Saint Louis, MO; [3]Electrical & Systems Engin., Washington Univ. In St. Louis, Saint Louis, MO; [4]Neurol., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: EEG modulation occurs when oscillatory patterns of disparate frequencies interact multiplicatively, often resulting in fast electrophysiological activity being systematically nested in a slow modulatory oscillation. We recently created an analysis pipeline to automatically detect very slow (millihertz) EEG modulation in critically ill young children; we termed this pattern macroperiodic modulating oscillations (MOs). MOs were generally detected in patients with recurrent seizures and status epilepticus (SE), conditions associated with mortality and poor outcomes. We studied the temporal and spatial distribution of these patterns, including their spatial synchronization.

From October 2015 to September 2018, we identified n=36 subjects in pediatric, neonatal, or cardiac intensive care units whose EEGs exhibited slow cycling on density spectral array (DSA). Our pipeline used two levels of spectral analysis to detect millihertz slow EEG modulation: first, a time-series of 5-15Hz band-limited power was extracted for each channel using a sliding window, multi-taper spectral estimation (Fast Fourier Transform). A second time-frequency analysis was performed on these power envelope signals, revealing slow, harmonic processes modulating the 5-15Hz activity, i.e., MOs. Our detection criteria were applied to the second spectrogram: a high power, narrowband signal (occurring in a small, consistent range of very slow frequencies), persisting across multiple consecutive time windows. After assigning each time window a binary categorization (MO present vs. absent) for each channel, we analyzed synchronization at three temporal scales: synchronization of "MO present" epochs, of the modulatory process within "MO present" epochs, and of the fast EEG signal during each modulatory cycle.

MOs were consistently and reliably identified at a frequency between 0.005Hz and 0.009Hz in the second level spectral analysis. In EEGs with MOs present for a large proportion of the time, synchronization of epochs was high. Furthermore, when epochs were synchronized across channels, it was generally at all three levels of synchronization.

MOs are a two-time scale modulatory EEG pattern with a millihertz time-scale that is considerably slower than classical patterns observed in critically ill patients. Our analysis suggests that MOs have a slow, narrowband modulatory effect on faster activity and appear to manifest synchronously across the cortex. Since the MOs pattern was detected in patients with poorer outcomes, this may represent a novel EEG biomarker for impending SE and recalcitrant seizures and may provide insight into mechanisms underlying these events.

Title: Spatio-temporal characterization of TMS-EEG responses to antiepileptic drugs

Authors: *G. DARMANI[1], J. O. NIEMINEN[2,3], U. ZIEMANN[1];
[1]Neurol. and Stroke, Hertie Inst. for Clin. Brain Research, Univ. of Tuebingen, Tuebingen, Germany; [2]Neurol. and Stroke, Hertie Inst. For Clin. Brain Research, Univ. of Tuebingen, Tuebingen, Germany; [3]Neurosci. and Biomed. Engin., Aalto Univ. Sch. of Sci., Espoo, Finland

Abstract: Combination of transcranial magnetic stimulation (TMS) and electroencephalography (EEG) to assess direct effects of central nervous system active drugs on TMS-evoked potentials (TEP) has provided a characterization of several GABAergic and anti-epileptic drugs (AEDs) based on their ability to modulate specific TEP components. Here, we complement these findings by analyzing time–frequency representations (TFR) of neuronal activity and by evaluating the complexity of cortical responses to TMS before and after administration of an AED.
Fifteen healthy males volunteered to a placebo-controlled, double-blind crossover study. TMS, with concurrent high-density EEG, was applied to the left primary motor cortex at an intensity of 100% resting motor threshold of the relaxed abductor pollicis brevis muscle. Single oral doses of the following drugs were studied: carbamazepine (600 mg), a voltage-gated sodium channel (VGSC) blocker, brivaracetam (100 mg), a modulator of GABAergic neurotransmission through binding to the synaptic vesicle protein SV2A, and tiagabine (15 mg), a selective GABA reuptake inhibitor. TFR of TMS-induced oscillations was calculated to assess non-phase-locked oscillatory responses, and the complexity of TEPs was quantified with the perturbational complexity index (PCI).
All drugs reduced significantly early (20–200 ms) beta oscillations mostly over the stimulated sensory–motor cortex; furthermore, only tiagabine decreased the early alpha and theta oscillations as well as late (200–400 ms) theta oscillations. For placebo, no changes were observed. The widespread cortical desynchronization observed in the tiagabine condition was accompanied by significantly reduced PCI values. Overall, our results revealed that AEDs decrease early beta oscillations independent of their modes of action; given previous findings showing that modulators of GABA receptors (alprazolam and baclofen) also reduce early beta activity, we may conclude that both GABAergic inhibition and VGSCs contribute to these TMS-induced oscillations. In addition, the observed reduction of the complexity of the TMS-evoked responses, which so far has been associated to a reduced level of consciousness, with tiagabine seems to relate to wide-spread cortical low-frequency TMS-induced oscillations.

Title: Transcutaneous vagus nerve stimulation in humans induces pupil dilation and modulates EEG brain rhythms

Authors: *O. SHARON[1], F. FAHOUM[3], Y. NIR[1,2];
[1]Physiol. and Pharmacol., [2]Sagol Sch. of Neurosci., Tel-Aviv Univ., Tel-Aviv, Israel; [3]EEG and Epilepsy Unit, Dept. of Neurol., Tel Aviv Sourasky Med. Ctr., Tel-Aviv, Israel

Abstract: Background*:* Vagus nerve stimulation (VNS) is widely used to treat intractable epilepsy and depression. While the long-term therapeutic mechanisms remain unclear, VNS effect may involve stimulation of Locus Coeruleus (LC) via the nucleus of the solitary tract (NTS) that receives afferent vagal inputs. In rats, VNS elevates LC firing and forebrain noradrenaline (NE) levels, and LC lesions suppress VNS therapeutic efficacy. In recent years, non-invasive transcutaneous VNS (tVNS) has been used: electrical stimulation targets the auricular branch of the vagus nerve located at the cymba conchae of the left ear.
Here, we set out to evaluate tVNS effects in healthy volunteers. Given VNS effects on LC-NE in animals, we hypothesized that human tVNS will promote markers of NE including pupil dilation and activation of the EEG. To test tVNS effects beyond tactile stimulation, we compared tVNS to sham stimulation at the earlobe (far from the vagus nerve branch) while recording pupillometry and high-density EEG. Participants were blind to study objectives.
Results: When tVNS was applied in a clinical 30s-ON/30s-OFF protocol during visual fixation (n=23) we observed a trend (p=0.09) for higher pupil dilation upon tVNS (5%±1.8%) compared to sham stimulation. During a closed eyes condition (n=14), tVNS attenuated theta (4-8Hz) power (-13dB±6, p=0.04) and increased alpha (8-12Hz) power (24dB±9, p=0.02) in occipital electrodes compared to sham, likely representing a shift from sleep onset to idle wakefulness rhythms. Significant differences between ON and OFF intervals were lacking, possibly due to carryover effects of the long stimulation.
To better understand phasic effects of tVNS, a second experiment employed shorter 3s-ON/30s-OFF tVNS during visual fixation (n=24). Stimulation intensity was adjusted to a maximal comfortable level for each participant and location separately. Electrical current was slightly higher in sham condition (by 0.62 mA, p=0.03), whereas subjective ratings were not significantly

different ($p>0.05$). However, tVNS led to robust pupil dilation, significantly higher than in sham stimulation (peak = 267%±44 increase from baseline in tVNS vs. 116%±30 increase in sham, $p<0.01$). tVNS-evoked pupil dilation was evident in most individual subjects. We are now assessing the phasic effects of tVNS on EEG activity by quantifying the degree of occipital alpha. The alpha topography is identified in each participant, and the effects of stimulation are compared relative to pre-stimulation baseline.
Conclusion: tVNS affects pupillary and EEG markers of arousal beyond sham stimulation, supporting the notion that it elevates noradrenaline signaling

Abstract: Memory and consciousness are the two manifestations of higher cognitive function that are most closely associated with our self-awareness as individuals. Amnesia (loss of memory) is a major component of general anesthesia (GA) along with loss of consciousness and analgesia. Some patients unexpectedly become aware during surgery and form a traumatic memory. Gamma rhythm of hippocampus plays a crucial role in selecting inputs during memory formation. However, the effect of anesthetics on gamma oscillation has been controversial. In some studies, hippocampal gamma oscillation is preserved or increased under GA, while in others, gamma oscillation attenuated. However, gamma oscillation in hippocampus has not been directly compared between during GA and memory encoding in human. In this study, we calculated power spectrum of hippocampal gamma frequency (32-100 Hz) from the intrahippocampal depth electrode in 9 epilepsy patients (age: 24-55 years) during propofol-induced GA (3~5 ug/ml concentration), resting state, and long-term memory task. Friedman test was performed for intergroup comparisons of gamma power in hippocampus. Gamma power in hippocampus was attenuated during propofol-induced GA compared to those in resting state and

long-term memory task state ($p < 0.01$). Suppression of the hippocampal gamma activity may be the cause of amnesia incurred by general anesthesia.

Title: Level of consciousness is dissociable from cortical complexity and slow oscillations

Authors: ***J. DEAN**[1], D. PAL[2], D. LI[2], M. BRITO[3], A. FRYZEL[2], A. G. HUDETZ[2], G. A. MASHOUR[2];
[1]Dept. of Mol. and Integrative Physiol., [2]Dept. of Anesthesiol., [3]Dept. of Neurosci., Univ. of Michigan, Ann Arbor, MI

Abstract: Measures of complexity, used as a surrogate of information processing in the brain, have reliably indexed level of consciousness, e.g., cortical complexity is high during wakefulness but constrained during anesthetic-induced unconsciousness. We recently demonstrated that reverse dialysis delivery of the cholinergic agonist carbachol into prefrontal cortex of sevoflurane-anesthetized (1.9-2.4%) male SD rats (n=11) produced signs of wakefulness and electroencephalographic (EEG) activation despite continued anesthetic exposure. Delivery of carbachol into posterior parietal cortex (n=11) or noradrenaline into either prefrontal (n=11) or posterior parietal (n=11) cortex in sevoflurane-anesthetized rats (1.9-2.4%) was sufficient to produce EEG activation but failed to produce signs of wakefulness. Thus, we generated a model in which the presence of anesthetic in the brain can be dissociated from level of consciousness. Here, we tested the hypotheses that (1) higher cortical complexity would correlate with wakefulness, and (2) lower cortical complexity and increased slow oscillations (0.5-1.0 Hz) would correlate with general anesthesia. We analyzed temporal Lempel-Ziv Complexity (LZC), which computes the number of unique binary patterns within finite length sequences, within frontal and parietal EEG signals collected before, during, and after sevoflurane and carbachol/noradrenaline infusion into prefrontal and posterior parietal cortices. Similar to prior studies, LZC of the EEG signal in frontal and parietal cortices was reduced from waking during sevoflurane-induced unconsciousness in all cohorts ($p<0.005$). Compared to sevoflurane-induced unconsciousness, both carbachol and noradrenaline-induced EEG activation in frontal and parietal cortices increased LZC to above anesthetized levels, which returned to (frontal EEG signal following carbachol infusion into prefrontal cortex; $p=0.22$) or approached (all other

conditions; $p<0.05$) waking values and continued to increase following cessation of anesthesia. As expected, sevoflurane increased the power of cortical slow oscillations in all cohorts ($p<0.05$). However, there was dissipation of power following administration of carbachol or noradrenaline into both prefrontal and posterior parietal cortices independent of behavioral change ($p>0.05$). Thus, cortical complexity and slow oscillations correlated with changes in EEG activation rather than level of consciousness (i.e., wakefulness). This dissociation between level of consciousness and cortical dynamics prompts a reevaluation of current candidates for the neural correlates of consciousness and anesthesia.

Title: Oscillatory correlates of affect expectation using EEG

Authors: ***E. BENZAQUEN**, T. D. GRIFFITHS, S. KUMAR;
Inst. of Neurosci., Newcastle Univ., Newcastle upon Tyne, United Kingdom

Abstract: Predictive coding (PC) has been highly successful in explaining perceptual processes [1]. Here, we addressed whether a predictive coding account can explain measured neural correlates of predictions and expectation during affective sound processing. We used a classical trace conditioning paradigm with two categories of sounds; highly aversive scraping sounds, and neutral/pleasant water sounds. We manipulated the predictability of the stimuli such that two (certain) cues were always followed by aversive or neutral sounds while a third (uncertain) cue failed to predict the subsequent stimuli. Participants' expectations were recorded on a trial-by-trial basis after the presentation of the cue while 64-channel EEG data were acquired. Time-frequency responses (TFRs) were acquired from 22 normal subjects. Brain activity during the processing of the cue was characterized by a marked beta-band suppression, which was stronger for both ‘certain’ conditions. To further explore if the observed beta suppression corresponded to the degree of expectation for individual subjects, TFRs were averaged over all channels for the complete duration of the cue, and correlated with the reported expectancy scores. A significant correlation indicating greater beta suppression with greater certainty was observed. This relation was further corroborated by correlation between standard deviation of expectancy across trials and beta power; subjects who were more consistent (lower SD) showed

greater beta suppression. To reject the possibility that beta activity reflects a preparation for a motor response, we correlated it with individuals' reaction times, which failed to reach significance. Thus, beta suppression appears to index the certainty of a future outcome or the strength of predictions.
Our data strongly suggest a role of beta band activity in backward predictions consistent with findings from previous predictive coding work.

Title: Differential effects of prestimulus alpha power on perceived stimulus intensity and initial cortex excitation in a somatosensory discrimination task

Authors: *T. STEPHANI[1,2], A. HODAPP[1], A. VILLRINGER[1,3,4], V. V. NIKULIN[1,5];
[1]Dept. of Neurol., Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany; [2]Intl. Max Planck Res. Sch. Leipzig, Leipzig, Germany; [5]Ctr. for Cognition and Decision Making, Natl. Res. Univ. Higher Sch. of Econ., Moscow, Russian Federation

Abstract: Brain responses to identical sensory stimuli vary from moment to moment which has been attributed to instantaneous fluctuations of cortical excitability. Ongoing neuronal oscillations in the alpha band (8-13 Hz) of the human EEG have been suggested to indicate changes of cortical excitability, shaping behavioral performance in paradigms with near-threshold stimulus detection. It remains unclear, however, whether prestimulus alpha power also affects perceived stimulus intensity of supra-threshold stimuli.
To further investigate the relationship of prestimulus alpha power and cortical excitability, we propose to use short-latency somatosensory evoked potentials (SEP). The N20 component of the SEP reflects the first excitatory post-synaptic potentials arriving from the thalamus to the cortex, thus being a direct measurement of cortex excitation when stimulus information enters primary sensory areas.
We measured 64-channel EEG from 32 human participants while they performed a somatosensory discrimination task using electrical median nerve stimuli of two intensities.

Prestimulus alpha band activity was measured over the somatosensory cortex between 200 and 10 ms prior to stimulus onset. Behavioral performance was assessed by sensitivity d' and criterion c derived from Signal Detection Theory.
Higher prestimulus alpha power was associated with lower perceived stimulus intensity (criterion c) but had no effect on the discriminability (sensitivity d'). In contrast, initial cortex excitation reflected in N20 amplitudes did not predict behavioral performance although it was related to prestimulus alpha power and absolute stimulus intensity.
The present results confirm the relationship between prestimulus alpha power and sensory detection criterion, and extend it to perceived stimulus intensity. We conclude, however, that the effect of prestimulus alpha power on behavioral performance is not mediated by changes of initial cortical excitability and may play a role only at later stages of stimulus processing.

Title: Quantitative EEG features during interictal HFO events provide complementary information to HFO rates when identifying pathological tissue

Authors: *S. V. GLISKE, W. C. STACEY;
Neurol. and Biomed. Engin., Univ. of Michigan, Ann Arbor, MI

Abstract: Objective. High frequency oscillations (HFOs) are a promising biomarker of tissue instigating seizures. One challenge to improving the specificity of HFOs is that high frequency oscillations are caused by both pathological and normal processes. Our computational models have suggested quantitative features of the EEG signal during HFO events than can help disambiguate which channels are associated with pathological tissue. The goal of this project is to assess one of these features in a large cohort of human subjects.
Methods. Data were acquired from 29 patients (13 ILAE Class I), each with multiple days of intracranial EEG recording, sampled at over 4 kHz. HFOs were detected using a previously published HFO detector. The intercranial, interictal EEG was band pass filtered within 80-500 Hz, and the skewness of the curvature of on all channels during each HFO event was computed.

Parameters were tuned using 23 subjects, with 6 class I subjects held out as validation data. Fuzzy clustering using non-negative matrix factorization on the distribution of the skewness of the curvature was used to provide a pathological-score for each channel.
Results. Among subjects with ILAE Class I outcomes, an increase of 0.1 in the pathological score increased the odds a channel was in the clinically-identified seizure onset zone by 15% ($p=0.003$, logistic regression, adjusted for HFO rate) and increased the odds a channel was resected by 29% ($p=10^{-15}$, logistic regression, adjusted for HFO rate).
Conclusion. The skew-curve index of intracranial EEG during HFO events provides independent information to HFO rates and can help identify pathological tissue. Further work is needed to optimize prospective, clinical use of this information to identify the epileptogenic zone.
Significance. Complementary information from additional biomarkers can help improve clinical confidence and improve localization of the epileptic focus, potentially improving surgery outcomes.

Title: Sex related differences in cortical EEG, hippocampal LTD and de-depression, following prolonged exposure to surgical levels of isoflurane anesthesia

Authors: *R. TADAVARTY[1], T. MARIAM[1], X. DONG[1], S. LIU[2], T. CHEUNG[2], *P. J. SOJA[1];
[1]Fac. of Pharmaceut. Sci., The Univ. of British Columbia, Vancouver, BC, Canada; [2]Simon Fraser Univ., Burnaby, BC, Canada

Abstract: Exposure to general anesthesia (GA) can not only cause post-operative cognitive dysfunction but also increase the risk of dementia and Alzheimer's disease. Ensuing behavioral cognitive deficits can last up to several months or indefinitely. Surprisingly, female brains resist the manifestation of these deficits; the reason(s) for this discrepancy are not known. Mechanistically, memories are thought to be stored in the brain as representations of synaptic weights with long-term potentiation and long-term depression (LTD) playing a key role in activity dependent up or downscaling synaptic strength, respectively. Reversibility of synaptic strength is necessary for reconsolidation of memories. The cortical EEG signature under surgical anesthesia is primarily comprised of continuous large-amplitude slow wave (0.5-8 Hz) activity

(SWA). Moreover, < 1 Hz oscillations emerge in SWA presumably due to alternating highly active or near silent states of cortical neurons. GA can uncouple such oscillations, disrupt connectivity-patterns and hamper information flow between neural networks, a crucial aspect of mnemonic processing in the brain. We therefore explored whether sex-related differences occur in hippocampal LTD and de-depression, EEG SWA and EEG oscillation dynamics, following prolonged exposure to surgical levels of isoflurane (ISO) anesthesia. Adult male or female SD rats were initially anesthetized in an induction chamber, their trachea intubated and head mounted in a stereotaxic frame. Cortical EEG was recorded using stainless steel screw electrodes positioned in S1 bilaterally. Hippocampal slices were then prepared from either naïve or ISO-exposed (for 5 h) rats. Field excitatory postsynaptic potentials were evoked by stimulating CA3 afferents, and recorded from the apical dendritic layer of CA1 pyramidal neurons. A low-frequency stimulation (1 Hz, 1200 pulses) was used to induce LTD. After following the timecourse of LTD for 30 min, LTD was reversed using a high-frequency tetanic stimulation (4 X 100 Hz, 10 s inter-stimulus interval). Our results indicate that while there is no difference in the timecourse of LTD between male and female rats, LTD could only be reversed in female rats, suggesting a potential lack of cognitive flexibility in male rats following ISO exposure. FFT analyses of EEG SWA revealed sex-related differences in δ and β band relative power. Furthermore, there is a ~ 3 fold increase in the occurrence of Up/Down States in males vs females. Our results disclose for the first time that males and females differ in EEG SWA oscillation dynamics, spectral content and hippocampal synaptic plasticity following exposure to ISO anesthesia.

Title: EEG microstates analysis associated with cognitive thinking

Authors: *R. MAHAJAN[1], T. AZMY[1], C. DEMAREE[1], D. GUPTA[2], F.-S. CHOA[3]; [2]Computer Sci. and Electrical Engin., [1]Univ. of Maryland Baltimore County, Baltimore, MD; [3]UMBC, Baltimore, MD

Abstract: Keywords: Electroencephalography, EEG microstate, Global Field Power (GFP), MicroGFPpeakData
Electroencephalography (EEG) microstates are short duration quasi-stable states of the dynamically changing electrical field topographies recorded via array of EEG electrodes from

the human scalp. EEG microstate analysis offers characterization of the spatio-temporal features of large-scale brain network activity. The aim of the research is to use EEG Microstate Analysis to study brain dynamics when subjects are engaged in performing mathematical calculations. We collected EEG data while three healthy subjects performed a cognitive task of a series of twenty mathematical calculations by each subject. The EEG data recording was performed in a pattern of 10 seconds resting state and 10 seconds mathematical calculations state. We recorded 20 sets of each state for each subject. So totally 400 seconds of EEG data was recorded per subject. In microstate analysis the goal is to segment the recorded EEG time samples into microstate classes. The microstate analysis was performed in Matlab using interactive plug-in of Microstate Analysis Toolbox in EEGLAB. The selected EEG data (MicroGFPpeakData) is segmented into predefined number of microstate prototype topographies by applying the method of K-means clustering to investigate the microstates conveyed by the event-related potential extracted from EEG data during mental cognitive calculations. We studied the clustering algorithm time samples that peaked in the Global Field Power (GFP) time curve, as they are considered to have the "cleanest" representations of their microstate. The number of microstates into which the EEG data to be clustered is set to 4 microstates prototypes. All the prototypes are sorted by Global Explained Variance (GEV). Based on the evaluation of prototype topographies and measures of fit, we selected GEV and CV criterion to identify active number of microstates. We analyzed different measures, including microstate sequences, topographical map, hemispheric lateralization, and duration of microstate, to characterize the dynamics of microstates during metal cognitive tasks. GFP of active microstates is obtained. From GFP active microstates plot it was observed that the activation of right frontal parietal region was stronger according to microstates mode 2. The obtained brain states from EEG microstates will be compared with EEG source information obtained from sLoreta 2D to 3D studies.

Title: Causal evidence for theta-gamma and delta-beta cross frequency coupling in cognitive control

Authors: *J. RIDDLE, A. MCFERREN, F. FROHLICH;
Psychiatry, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Cognitive control is modulated by the number of rules and the level of abstraction of a given task. We used a hierarchical cognitive control paradigm that manipulated taskset in a two by two design: the number of rules, or set-size, and the abstraction of the task (Badre & D'Esposito, 2007). We found that increased set-size increased theta frequency oscillations and theta-gamma phase amplitude coupling (PAC); whereas, an increase in abstraction increased delta and beta oscillations and delta-beta PAC. In order to causally test these correlational findings, we conducted a crossover double-blind placebo-controlled experiment (N=24) that delivered transcranial alternating current stimulation (tACS) to right prefrontal cortex (PFC) with an individualized custom waveform of gamma frequency at the peak of theta phase (Alekseichuk et al., 2016) or beta frequency at the peak of delta phase. TACS was delivered during performance of the cognitive control task and we recorded resting state EEG after each block to quantify the lasting impact of tACS on PAC in the targeted frequencies. The frequency of theta-gamma and delta-beta tACS was individualized for each participant based on their PAC calculated from an initial baseline session. We hypothesized to find a frequency specific modulation of tACS on behavior for the two dimensions of cognitive control. We found that theta-gamma tACS increased accuracy as a function of set-size ($t=2.99$; $p=0.007$) and delta-beta tACS increased reaction time as a function of abstraction ($t=2.31$; $p=0.031$). While we did not find an increase in PAC with tACS in the right PFC, we found that theta-gamma tACS increased theta-gamma PAC in the left PFC ($t=1.72$; $p=0.049$). To capture participant variance in their response to tACS, we ran a brain to behavior correlation analysis and found that the degree to which theta-gamma tACS altered reaction time and theta-gamma PAC as a function of set-size were positively correlated ($r=0.50$; $p=0.014$). In addition, the degree to which delta-beta tACS altered accuracy was predicted by the strength of delta-beta PAC as a function of abstraction during the baseline session ($r=0.38$; $p=0.074$). Altogether, cross frequency coupling is an essential mechanism by which the PFC orchestrates cognitive control and can be systematically targeted with tACS.

Title: Tuning of SOBI recovered ocular artifact components by the direction and distance of directed saccadic eye movement

Authors: *R. SUN[1], C. CHAN[2], J. HSIAO[2], A. C. TANG[3];
[2]Psychology, [3]Lab. of Neurosci. for Educ., [1]The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Much of our understanding of brain functions are based on carefully controlled experimentation carried out in the laboratory context with bulky and expensive imaging modalities. Generalizability of findings made with such constraints cannot be assumed but requires field-friendly brain imaging tools, such as EEG, to enable observation of brain function in more natural context, such as during free eye movement. Yet, ocular artefact in human scalp EEG has been an enduring problem in cognitive neuroscience and biomedical research for nearly a century with a large literature mainly focused on how to remove the ocular artifact from the EEG signals associated with neural activities. Here building upon previous work, we used a hybrid method consists of Second Order Bind Identification (SOBI) for decomposing the EEG into components and a novel Discriminant-index ANd Similarity-index based (DANS) method for automatic identification of the horizontal and vertical ocular components. Going beyond artifact removal, for the first time we show for each individual participant that when correctly extracted and identified, ocular artifact components in the EEG are surprisingly finely tuned by the direction and distance of saccadic eye movement and saccade-related potential (SRPs) amplitude can account for over 90% of variance in the behavioral output of eye movement (saccade coordinates in a short 16 position 32 trial calibration task). Furthermore, we provide the first quantitative individual level determination of the spatial origin of the identified ocular components showing over 95% of variance in the scalp projection accounted for by the physical eye movement. These results show that it is now possible to use EEG alone to extract temporally synchronized neural and eye movement signals.

Title: Cortical inactivity evoked by epileptic seizures is mediated by dysregulation of brainstem arousal circuits: Implications for REM and slow-wave sleep

Authors: *C. ISGOR, A. TYULMENKOVA, S. NICOLAS, A. TERHUNE, M. WARD-MOSES;
Biomed. Sci., Florida Atlantic University, Col. of Med., Boca Raton, FL

Abstract: Sudden unexpected death in epilepsy (SUDEP) is a poorly understood neurological disease. SUDEP may result from postictal suppression of brainstem arousal systems induced by a seizure, eventually leading to irreversible inhibition of cardiorespiratory functions. Epileptic seizures are thought to excite the hypothalamus and lateral septum that send inhibitory projections to the subcortical arousal centers, mainly nucleus pontis oralis (NPO) in the brainstem. The NPO appears to be contral to cerebral activation during the rapid eye movement (REM) sleep. Postictal generalized electroencephalography suppression (PGES) resulting from inhibition of the NPO, may contribute to the risk of cardiorespiratory failure and death. In parallel with inhibition of NPO and associated decline in cortical “wake” signals with seizures, clinical data showed that slow wave sleep (SWS) power is increased in patients with focal epilepsy, positively correlating with instances of seizures in the 3-5 days preceding recordings. SWS reduces the excitability of the brain and slows the cardiorespiratory functions that is reversed by periodic episodes of REM sleep episodes. Therefore it is not far-fetched to think that increase in duration and/or power of SWS particularly associated with, and possibly driven by incidences of seizure even up to ~5 days prior may predict severely long PGES and consequent risk of death in upcoming epileptic seizures. Therefore tracking changes in sleep architecture as a function of seizures, particularly decrease in duration of REM and accompanying increase in SWS duration may be useful markers for SUDEP risk. Our lab uses transgenic mice that overexpresses the brain-derived neurotrophic factor (BDNF) in the forebrain and develop tonic/clonic seizures at ~5 months of age as a model of adult-onset spontaneous epilepsy. The mice show brief motor seizures to cage shaking/tail lifting stimulation at the onset of disease but seizure episodes get more severe with successive seizures as evidenced by longer durations of PGES. Pilot data showed a negative association between PGES length and REM duration in inactive phase. We will confirm this and additionally determine if PGES and SWS are positively associated as the mice progress from mild to severe seizures. Results of this study will discern the viability of using sleep architectural markers in REM sleep, and SWS stages to map out increased severity of seizure-induced loss of consciousness (cortical inhibition) and associated death risk in epileptic subjects.

Title: Fluctuations of hemodynamic global signal are correlated with vigilance states in middle-age and older adults: A simultaneous EEG and fNIRS study

Authors: *Y. CHEN[1], J. ROQUE[2], J. TANG[2], M. A. CRAFT[3], B. W. CARLSON[3], H. YUAN[2]; [1]Univ. Of Oklahoma, Norman, OK; [2]Univ. of Oklahoma, Norman, OK; [3]Univ. of Oklahoma Healthy Sci. Ctr., Oklahoma City, OK

Abstract: Functional near-infrared spectroscopy (fNIRS) allows for the study of neural activity via tracking the absorption of light by oxygen and deoxygenated hemoglobin. Due to its portability and high-resolution measures, fNIRS has been widely deployed in studies of resting state and sleep. Vigilance states, including the level of alertness, appear to play a critical role in interpreting the study findings; with fNIRS global signal components negatively correlated with the level of vigilance. In this study, 19 healthy subjects (clinician verified) were recruited after giving informed consent (middle-age group: 35.5 ± 7.2 years old, rang 28-46 years old, 4 females and 8 males; old group: 55.7± 6.0 years old, rang 50-63 years old, 6 females and 1 male). All subjects were instructed to nap or rest quietly for 45 minutes while lying in a recliner. Recordings were divided into 30-s epochs and scored by a certified expert (B.W.C.) using standard criteria. We further separated the individuals' simultaneous fNIRS and EEG recordings into 30-s epochs and investigated the correlation between fNIRS global signal fluctuation and epoch-level vigilance states which were assessed by EEG measurement. One-sample t-test results show the z-transformed correlation coefficients which derived from all subjects' both HbO and HbR data are significantly different from zero (HbO: $t(17)= -2.88$, $q<0.05$, HbR: $t(17)= -2.96$, $q<0.05$). We ran a two-sample unpaired t-test on middle-age and older groups, there is no significance between them for both HbO and HbR data ($p>0.1$ for both). Our results showed fluctuations of fNIRS global signal were negatively correlated with the corresponding fluctuations of vigilance level, suggesting that the neural sources contribute to fNIRS global signal. However, aging did not show a significant effect on the correlations. Vigilance level can be used to interpret the experimental findings of hemodynamic findings.

Title: Theta power increase in the human visual cortex in response to novelty

Authors: *E. W. TSANG, R. SUN, X. NIU, W. FUNG, A. C. TANG;
Labouratory of Neurosci. for Educ., The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Novelty detection is an evolutionarily significant and ancient function as well as a relatively stable function whose early life status marks for long-term developmental outcomes and predicts a range of adult functions. While various brain regions have been shown to respond to environmental novelty, how different brain regions coordinate in novelty related information processing remains under-explored. Previously (CNS 2018 abstract) using a combination of high-density EEG, second order blind identification (SOBI), and a standard visual oddball task, we provided evidence for a two-stage novelty processing hypothesis which states that two distinct stages of novelty processing exist, one involves early-occurring domain-specific neural activity in the sensory processing areas of the brain and the other involves later-occurring domain-general neural activity involving brain regions beyond the sensory cortices. Here we report further evidence on the timing of novelty-induced theta power increase. Specifically, the latencies of peak theta increase of the SOBI recovered Early visual components (189 ± 26 ms) were statistical significantly shorter than that of the Late P300 component (310 ± 19 ms) [$t(9)= -8.5$, $P< 0.0001$, Cohen's $d_{av}= 1.7$) suggesting that there exists cortical processing areas that are capable of detecting novelty approximately 120 ms earlier than the P300 network. Through source localization using BESA, we further ascertained their visual sensory origin and we found that the scalp projections of these Early components can be well explained by equivalent current dipole models consisting of 1 (N=12) pair or 2 (N=1) pairs of symmetrically placed dipole sources within the occipital lobe (goodness of fits: 94% ± 0.7 %; Talairach coordinates: 26±3; 74±4; 6±4; N=13). Together, these results offer new evidence in direct support for an earlier stage rapid computation of novelty signals by the visual cortex prior to the later stage novelty processing by the well-known P300 network.

Title: Resting-state MEG: A versatile marker of long-term brain adverse effects of leukemia treatments

Authors: *V. OSWALD[1], Y. ZEROUALI[2], D. MEUNIER[3], D. SINNETT[4], S. LIPPE[4], C. LAVERDIÈRE[5], M. KRAJINOVIC[6], K. JERBI[7], P. ROBAEY[2];
[1]Neurosci., Univ. De Montréal, Montréal, QC, Canada; [2]Univ. of Montréal, Montréal, QC, Canada; [3]Aix-Marseille Univ., Marseille, France; [4]Univ. de Montréal, Montréal, QC, Canada; [5]Univ. de Montréal, Montreal, QC, Canada; [6]Univ. de Montreal, Montréal, QC, Canada; [7]Lyon Neurosci. Res. Ctr. - Univ. Lyon I - U1028 - UMR5292, Lyon, France

Abstract: Acute lymphoblastic leukemia (ALL) is the most common cancer type in children. The most common treatment-related neurocognitive impairments are attentional and executive functioning difficulties. The goal of this project is to identify how the neural sources power of the resting-state MEG obtained in the different frequency bands can be used to study the long-term effects of leukemia treatment.We recruited 45 ALL survivors (PA) treated on DFCI-ALL 87-01 to 2005-01 protocols, at least five years post-diagnosis who did not require additional treatments. They were all adults diagnosedbetween 0 and 17 years of age. We also recruited 28 healthy controls (HC). We recorded resting state MEG 5min eyes open and administered the Wechsler Adult Intelligence Scale - 4thedition. Data pre-processing and source reconstruction was performed using Brainstorm. We calculated means Power Spectrum Density for different frequency bands (delta to gamma) and correlated MEG power normalized z-score in each frequency band at the source level with the WAIS-V indices scores. For correlations, we used the function corecoef in MATLAB. Non-parametric cluster mass analyses ($p<0.001$) were used to determine significant correlations.For the power difference between patients and controls, we used t-tests with permutation and correction with FDR ($p<0.01$). For between-group difference in correlations between MEG power and cognitive performance, we used Z-fisher transform function ($p<0.001$).Younger age of diagnostic was related to increased power in alpha and beta bands for bilateral parietal clusters. Higher total corticoid doses received during treatment was related to increased power in alpha and beta bands for bilateral parietal clusters. Higher total dose of methotrexate received during treatment was related to increased power in alpha and beta bands but for frontal and temporal clusters, predominantly in the right hemisphere. In the alpha and beta bands, ALL survivors showed significantly increased power in bilateral frontal and temporal cortex while they showed significant decreased power in bilateral parietal and occipital cortex**.** Working memory scores correlated with alpha and beta bands clusters in the right frontal and parietal regions, and with beta band clusters in the right frontal and left central regions. The former correlations were significantly stronger in survivors, while the latter ones in controls, as compared to the other group.Resting state MEG appears as a reliable and flexible tool to investigate cognitive performance and treatment toxicity. This is the first MEG study of the chemotherapy-related neurotoxicity may be specific to brain regions.

Abstract: Rapid advancements in materials sciences, electronics, and computer technology have led to a revolution in the collection of neurophysiological data. However, these technological innovations have focused almost exclusively on penetrating probes that enhance our ability to collect large numbers of single unit activity. There have been some improvements in surface recording technology as well, but we are in the infancy of understanding the capabilities of these approaches. With advances in microfabrication techniques, we can now sample neural information using hundreds of microscale electrodes which can cover millimeters of the pial surface. These electrodes provide high density sampling over areas on the cortex at lower impedances and smaller contact surface areas than traditional platinum electrodes. Taking advantage of clinically relevant intracranial monitoring performed during surgical brain resections (N=27), we sampled neural activity using a version of these electrodes fabricated from PEDOT:PSS on a parylene substrate. We found that we could observe classifiable events across the data set which varied in size and waveform shape. We confirmed that these signals are unique to brain recordings by comparing tissue recordings to recordings in just saline. Corroborating prior reports, we found waveforms which closely resemble single unit activity across most of the participants (N=23 of 27), some of which were sampled across multiple

electrode contacts. We also found slower events across participants which were modulated by physiological manipulations including epileptiform-inducing medication, cold saline application, and electrical stimulation. These slower events were divided into two types: ones with average rise time constants of 10-15 ms and fall times < 50 ms and others with rise times at 20-50 ms and fall times at 80-100 ms.. The slower event type decreased in frequency with the application of cold saline on the surface of the cortex ($p<0.0001$; N=5) while both event types increased in frequency following local electrical stimulation (N=9). These events traveled across the electrode contacts at ~0.1-0.2 m/sec, the paths spanning a length of 0.200-0.400 mm, suggesting these events may represent axonal action potentials or dendritic calcium spikes. We therefore hypothesize that novel high density, low-impedance electrodes may be able to sample neural dynamics otherwise not possible with other recording methods. We propose further *in vitro* and *in vivo* animal studies may reveal the mechanisms underlying these events.

Abstract: Background:The effects of DBS on non-motor symptoms, such as cognitive function, have been documented. We aimed to investigate whether the preoperative evaluation of neuropsychological function can predict the change in visuospatial function after DBS in patients with Parkinson’s disease. Methods: We included 35 patients with a median age of 60 years (Interquartile range (IQR), 60-68 years) and median disease duration of 11.9 years (IQR, 10.4-15.1) who underwent bilateral STN-DBS. The mean UPDRS-III score was 43.0 ±13.8 / 16.4 ±8.6 (on/off), and the mean L-dopa equivalent dose was 1187 ±326.1 (mean ±standard deviation). Mean MMSE score was 29.1 ±1.5. Cognitive function was evaluated with the

Wechsler Adult Intelligence Scale—Third Edition (WAIS-III) and Rey-Osterrieth Complex Figure Test (ROCFT) preoperatively and one year after the surgery. Block design and matrix reasoning subtests of WAIS-III and ROCFT were categorized as visuospatial function domain. A correlation analysis was performed to investigate the relationship between visuospatial function and preoperative neuropsychological factors. Results:Subthalamic nucleus-DBS significantly improved motor scores, and L-dopa equivalent dosewas also significantly reduced one year after the surgery. The patients' performance on the ROCFT copy test significantly changed after DBS. Factors, such as age, sex, disease duration, or preoperative motor score, were not related to the postoperative change in the ROCFT copy test scores. Decrease in the postoperative ROCFT-copy test scores correlates with the preoperative low score in the block design subtest. Conclusion:The preoperative evaluation of block design subtests might be useful to identify the patients who are susceptible to developing a decline in visuospatial functioning after DBS.

Title: Imaging of human brain using wireless and portable EEG during natural human activities outside of the laboratory

Authors: *A. C. TANG, R. SUN, E. TSANG, G. WONG;
Lab. of Neurosci. for Educ., The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Rapid development in neuroimaging techniques have advanced our understanding of how human brain supports a wide range of human cognitive functions. Yet, much of the research findings are made under a number of well-known experimental paradigms in well-controlled experimental settings. It remains to be explored to what extent the general principles governing the workings of the brain thus discovered can be generalized beyond the confines of the laboratories and how the rich and varying context of the natural and real world will complicate the relatively simple pictures emerged from the highly simplified laboratory environment. Recent development in portable and wireless systems of electroencephalography and advances in blind source separation techniques made it feasible for researchers to explore the possibility of extracting functionally interpretable neuronal source signals from EEG. Building upon our past works on the application of SOBI to MEG and EEG data, in this study, we collected data using a wireless 32 channel systems (Brain Vision Products) during a variety of natural human activities,

previously considered not feasible for making measurement of underlying generators of neural activity using EEG. We include activities that are known to generate ocular, articulation, and body movement artifact, as in the case of (1) reading naturally with free eye movement and aloud; (2) walking around naturally while speaking and during natural head turning; (3) full body physical exercise. We also include activities that involve practicing of being in different mental states, such as different meditation states. Application of SOBI to each set of data of a few minute long resulted in recovery of certain SOBI components similar to those recovered in laboratory settings, indicating some underlying neural networks observable in highly constrained laboratory conditions can also be tracked combining EEG with SOBI in the artifact ridden natural world. More importantly, SOBI components unique to natural activities and certain meditation states were also found and localizable with high values of goodness of fit (Gof).

Title: Metamemory monitoring and control: A high definition transcranial direct current stimulation study

Authors: *C. WILLIAMSON[1], E. CHUA[1,2];
[1]CUNY The Grad. Ctr., New York, NY; [2]Brooklyn Col., Brooklyn, NY

Abstract: Accurately monitoring one's own memory, and adopting strategies to improve memory is crucial in daily life. It is assumed that individuals use the outputs of memory monitoring to strategically control memory, and improve performance. Few studies have tested the relationship between monitoring and control at retrieval, with most studies focusing on monitoring only. Previous research showed that high definitional transcranial direct current stimulation (HD-tDCS) to the left dorsolateral prefrontal cortex (DLPFC) increased monitoring accuracy, using a feeling-of-knowing (FOK) task, in which participants predicted their ability to later recognize the answer to non-recallable items. However, it is unclear if HD-tDCS improvements to metamemory monitoring will lead to strategic control of memory. We tested if metamemory monitoring at retrieval would lead to strategic control of memory and increased memory performance, and the role of the DLPFC in this relationship. In Part 1 of the task, participants assessed if they had ever known the answer to a general knowledge question ("Once knew it" judgment), attempted to recall the answer, and then gave an FOK judgment (i.e., a

metamemory monitoring task). In Part 2, participants chose a subset of un-recallable questions to attempt to recall again with a hint (i.e., a metamemory control task). Participants re-answered their chosen subset of questions, along with a subset chosen by the researcher. Third, participants took a recognition test. Active HD-tDCS was applied to the DLPFC during Part 1, right after Part 1 and during a filler task, or sham HD-tDCS was applied. Preliminary data showed that DLPFC stimulation during Part 1 increased the number of questions given "Once knew it" judgments, suggesting an increased sense of familiarity for the question. FOK ratings did not differ by stimulation, suggesting that stimulation did not increase familiarity for the answer. Participants had higher "Once knew it" and FOK judgments for questions that they chose to re-answer compared to researcher chosen items, showing that familiarity with both the question and answer were factors in choice. This effect did not interact with stimulation type. Strategic control did affect memory performance; participants had greater re-answer recall and recognition for items that they chose compared to researchers chosen items. There was a marginal effect of stimulation type on re-answer recall performance, such that DLPFC stimulation after Part 1 showed greater re-answer recall compared to sham, but this did not extend to recognition. In summary, metamemory monitoring at retrieval allows for strategic control of memory, improving performance.

Title: Scalp and intracranial EEG reveal intermingled surprise and error signals in performance monitoring networks

Authors: *C. W. HOY[1], S. C. STEINER[3], D. KING-STEPHENS[4], K. D. LAXER[4], P. WEBER[4], J. LIN[5], R. T. KNIGHT[2];
[1]Helen Wills Neurosci. Inst., [2]Dept. of Psychology, Univ. of California Berkeley, Berkeley, CA; [3]Univ. of California, Berkeley, Berkeley, CA; [4]California Pacific Med. Ctr., San Francisco, CA; [5]Dept. of Neurol., Univ. of California, Irvine, Irvine, CA

Abstract: Many studies have identified neural responses following negative task feedback in performance monitoring regions such as medial prefrontal cortex (MPFC) using human scalp and non-human primate electrophysiology. Classically, these responses were interpreted as error signals indicating unsuccessful outcomes. However, more recent observations of scalp EEG responses following surprising positive task feedback have inspired an alternative interpretation of these signals as unsigned prediction errors for unexpected outcomes. It is possible that both error and surprise signals occur in different circuits within performance monitoring networks, but previous work has not used task designs that dissociate these hypotheses with sufficient spatiotemporal resolution.

To address this issue, we measured both scalp EEG in normal participants (n = 10) and intracranial EEG (iEEG) in patients undergoing monitoring for epilepsy treatment (n = 4) while they performed an interval timing task. By manipulating the tolerance around the target interval to create easy and hard conditions, we controlled whether positive and negative feedback is expected, thereby dissociating outcome valence and expectancy. EEG data were referenced to ear channels, demeaned, band-pass filtered from 0.1-30 Hz, cleaned with ICA (eye and muscle artifacts), and visually inspected for noisy trials. ERPs were computed after baseline correction for wins vs. losses separately in easy and hard blocks (cluster-based permutations). iEEG data preprocessing included removing epileptic and excessively noisy channels and epochs, bipolar re-referencing, and band-stop filtering line noise. The data were then filtered to 70-150 Hz to isolate high frequency activity (HFA) known to correspond to local population spiking. A sliding window ANOVA with factors for difficulty (easy, hard), outcome (win, loss), and timing (early, late) was computed using HFA averaged over 200 ms windows, sliding by 50 ms steps from feedback onset to feedback offset 1 s later (FDR corrected).

Feedback-locked scalp ERPs revealed enhanced feedback-related negativity at central electrodes for unexpected outcomes regardless of valence, supporting a surprise signal interpretation. However, iEEG HFA in medial prefrontal electrodes shows a mixture of responses, with some sites showing significant main effects for only outcome valence while others showed significant interactions between outcome valence and difficulty (i.e., outcome expectancy, or surprise). Collectively, these results indicate both error and surprise signals may be computed in different circuits within the same performance monitoring regions.

Title: Local perturbations of cortical excitability propagate differentially through large-scale functional networks

Authors: *Z. P. ROSENTHAL, R. RAUT, P. YAN, D. KOKO, A. KRAFT, L. CZERNIEWSKI, B. ACLAND, A. MITRA, L. SNYDER, A. BAUER, A. SNYDER, J. CULVER, M. RAICHLE, J.-M. LEE;

Abstract: Brain networks exhibit coherent spatiotemporal patterns of activity that can be readily observed in electrophysiology, BOLD fMRI, and optical neuroimaging signals. Importantly, the correlation structure of these networks (functional connectivity, or FC) is sensitive to changes due to both focal injury (e.g. stroke, seizure, TBI) and targeted stimulation (e.g. TMS). Here we mechanistically examine how local perturbations are integrated into global FC networks. We test the hypothesis that excitation/inhibition (E/I) balance maintained by parvalbumin interneurons (PV-INs) helps to modulate local connectivity with larger networks. We take advantage of transgenic mouse models to specifically and bidirectionally manipulate PV-IN activity in the left whisker barrel cortex ($S1_W$) using virally-delivered chemogenetic constructs (DREADDs; ↑PV n = 12, ↓PV n = 12, Control n = 11). We then survey how this focal change in $S1_W$ impacts global networks using whole-cortex optical neuroimaging of both calcium dynamics (GCaMP fluorescence) and hemoglobin dynamics (optical intrinsic signal, analogous to BOLD), as well as measuring local field potential (LFP) within $S1_W$. All recordings were conducted in awake animals, to best capture physiological brain dynamics. Strikingly, we show that chemogenetic manipulation of $S1_W$ PV-INs alters local excitability, and that this E/I imbalance propagates differentially through intra- and interhemispheric sensorimotor connections. Changes were statistically verified within and between groups by 2-way ANOVA with multiple comparison testing. We observed significant power spectral density changes locally in $S1_W$ and remotely in the right and left whisker motor cortices ($M1_W$). Network-level changes were further analyzed using event-triggered average wave dynamics across the cortex, as well as FC mapping of long-range connections between homotopic $S1_W$ nodes and between $S1_W$ and $M1_W$. In addition, we reveal that prolonged overexpression of DREADDs in $S1_W$ PV-INs induces plasticity in sensorimotor connectivity, in the absence of the DREADD-activating ligand, CNO. These findings may provide valuable mechanistic context for understanding how brain networks respond to changes in E/I balance induced by focal injury, as well as how these changes may be counteracted with neuromodulatory therapy.

Title: Pharmacological modulation of whole-brain networks of functional connectivity in pre-clinical models

Authors: *H. CRUCES-SOLIS, R. ARBAN, W. NISSEN, B. FERGER;
CNS Dis. Res., Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach an der Riss, Germany

Abstract: The development of novel psychiatric drugs has been slow and particularly challenging. This is partially because, in spite of knowing the molecular mechanisms of action of a given drug, it is harder to assess its effects in multiple circuits across the whole brain. Therefore, it is important to develop tools in pre-clinical models that allow for the assessment of functional connectivity across the whole brain. Here, we combined cFOS whole-brain imaging in mice, as a proxy of neuronal activation, with graph theory to evaluate networks of functional connectivity upon treatment with two compounds with opposite effects on the dopaminergic system: the psychostimulant Modafinil (10, 30, 50 and 100 mg/kg) and the VMAT-2 inhibitor Tetrabenazine (0.25 0.5 1 and 5 mg/kg). Two hours after administration, the brains were prepared for whole-brain cFOS staining. While Modafinil induced a dose-dependent increase in the number of cFOS positive neurons in multiple brain regions across the whole brain, Tetrabenazine affected only a modest fraction of brain regions. To assess functional connectivity, we compute correlations across brain regions to identify regions that co-vary across mice (Wheeler et al 2013). Interestingly, in spite of having different pattern of cFOS activation, Modafinil and Tetrabenazine decreased functional connectivity in the cortex and the hippocampus. Moreover, Modafinil increased average thalamic and hypothalamic functional connectivity, while Tetrabenazine decreased hypothalamic and midbrain functional connectivity. To assess hub reorganization, we used graph theory and computed degree and betweenness. Modafinil induced the pre-limbic cortex, medial habenula and the central amygdala to emerge as new hubs. Remarkably, with Tetrabenazine the pre-limbic cortex, infra-limbic cortex, medial habenula and ventral pallidum displaced the striatum as central hub. Further steps will include testing these neuronal networks with opto- or chemogenetic approaches, followed by the identification of selectively expressed targets in these networks. In conclusion, our approach allows the identification and isolation of novel brain regions that form networks of functional connectivity, and will help to develop and refine novel and more selective therapeutic concepts.

Title: Optical manipulation of parvalbumin and somatostatin inhibitory neurons reveal a differential effect on cortical up-state dynamics

Authors: *J. L. ROMERO-SOSA, H. MOTANIS, *D. V. BUONOMANO;
Dept Neurobio., UCLA, Los Angeles, CA

Abstract: Many computations the brain performs emerge from the neural dynamics generated by recurrently connected neurons within local cortical circuits. One of the most studied forms of locally generated neural dynamics are Up-states, which refer to network-wide patterns of activity that rely on appropriately balanced excitation and inhibition. Here we examine the contribution of parvalbumin (PV) and somatostatin (SST) interneurons to Up-state dynamics in cortical organotypic slices by optical excitation and inhibition.

Consistent with previous work (Neske et al, 2015) whole-cell recordings revealed that the firing rate of PV (18 ± 2.5 Hz) was higher than pyramidal (Pyr; 7 ± 2.2 Hz) neurons. Paired recordings between Pyr and PV, and Pyr and SST neurons revealed strong but not significantly different correlation during Up-states (Pyr-PV:0.72 ± 0.02; Pyr-SST: 0.66 ± 0.21 $p > 0.05$). Of 30 Pyr-PV pairs, 12 exhibited Pyr→PV connections, 8 PV→Pyr connections, and 7 were reciprocally connected—thus reciprocity was present at higher than chance levels. Interestingly, the correlation between Pyr and PV activity during Up states was higher in reciprocally connected pairs (0.67 ± 0.01 vs 0.82 ± 0.008, $p < 10^{-10}$)—suggesting that connected pairs may share common input. To date few connections were observed between Pyr and SST neurons. We observed that Up-state onset occurred earlier (16.9 ± 5.71ms) in PV neurons than Pyr neurons—indicating that events driving Up states may preferentially activate PV neurons. In contrast, Up-state onset of SST and Pyr neurons was not significantly different.

To examine the causal relationship between inhibitory neuron activity and Up-state dynamics, we studied the effects of activation and inactivation of PV and SST neurons. When optical simulation (ChETA) of PV neurons was triggered 250 ms after an Up-state onset the length of Up-states decreased significantly (1.88 ± 0.30 s vs 0.69 ± 0.29 s, $p<0.01$). Although Up-state duration decreased on average when SST was activated it did not reach significance (1.41 ± 0.47 s vs 1.06 ± 0.56 s $p>0.05$). Optical inactivation of PV and SST neurons using halorhodopsin did

not alter in Up-state duration.
These results suggest a differential contribution of PV and SST to Up-states, in which PV neurons exert more powerful control over network dynamics and the ability to turn off Up-states. Furthermore, the finding that PV activation shortened Up-states, but PV inactivation did not alter Up-state duration, suggests that Up-Down transitions do not rely on PV neurons, and support models in which Up-Down transition are produced by synaptic depression of Pyr→Pyr connections.

Title: Loss of KCNQ2 from interneurons leads to augmented NMDA receptor driven neuronal synchrony in the neonatal forebrain

Authors: *B. HOU[1], S. SANTANIELLO[2], A. TZINGOUNIS[1];
[1]Physiol. and Neurobio., [2]Biomed. Engin., Univ. of Connecticut, Storrs, CT

Abstract: KCNQ2 potassium channels are essential for normal brain activity as KCNQ2 dysfunction could lead to severe neurodevelopmental disorders. In the neonatal brain KCNQ2 channels are expressed in GABAergic and glutamatergic neurons, but how KCNQ2 loss-of-function in GABAergic neurons alters neuronal population activity in the neonatal brain is not known. To address this question, we monitored synchronized GABAergic population activity across the forebrain using mesoscale calcium imaging combined with local field potential recordings from the hippocampus. For our study, we used acutely isolated horizontal mouse slices from P4-P6 mice. To increase our signal to noise ratio slices were bathed in 8mM extracellular potassium and maintained at near physiological temperature. Following cell-type specific deletion of KCNQ2 channels from GABAergic neurons, we observed a large increased in synchronized activity in the hippocampal formation and to a lesser extent in the neocortex. In hippocampus, we found that loss of KCNQ2 channels leads to greater frequency of synchronized long-lasting population events (>6s). Mechanistically, these prolonged events were due to increased glutamatergic NMDA receptor transmission as the increased extended activity persisted in the presence of a GABAA receptor blocker, but not in the presence of a NMDA

receptor antagonist. This data suggested that loss of KCNQ2 channels from GABAergic cells leads to augmented glutamatergic transmission in the neonatal forebrain and dampening NMDA receptor activity might be a viable therapeutic target for KCNQ2 encephalopathy.

Title: Coherence states and signal transfer of communicating gamma oscillatory neural networks

Authors: *G. D. DUMONT[1], B. S. GUTKIN[2];
[1]Ecole Normale Superieure, Paris, France; [2]Group For Neural Theory, LNC INSERM U960, Ecole Normale Superieure, Paris, France

Abstract: Macroscopic oscillations of different brain regions show multiple phase relationships that are persistent across time [6]. Such phase locking is believed to be implicated in a number of cognitive functions and is key to the so-called Communication Through Coherence theory for neural information transfer [8]. Multiple cellular level mechanisms influence the network dynamic and structure the macroscopic firing patterns. Key question is to identify the synaptic properties that permit such motifs to arise and how the different coherence states determine the communication between circuits.
We use a semi-analytic approach to investigate the emergence of phase locking within two bidirectionally delayed-coupled spiking circuits with emergent gamma oscillations. Internally the circuits consist of excitatory and inhibitory quadratic integrate-and-fire neurons coupled synaptically in an all-to-all fashion [7]. The circuits can show global pyramidal-interneuron or interneuron gamma rhythms. Using a mean-field approach and an exact reduction method [3,9], we break down each gamma network into a low dimensional nonlinear system. We then derive the macroscopic phase resetting-curves [2,4] that determine how the phase of the global oscillation responds to incoming perturbations.
We then study the emergence of macroscopic coherence states of two weakly synaptically-coupled gamma-networks [1]. We derive a phase equation that links the synaptic mechanisms to the coherence state of the system. We show that the delay is a necessary condition for symmetry breaking, i.e. a non-symmetric phase lag between the macroscopic oscillations. We find that a

whole host of phase-locking relationships exist, depending on the coupling strength and delay, potentially giving an explanation to the experimentally observations [8]. Our analysis further allows us to understand how signal transfer between the gamma circuits may depend on the nature of their mutual coherence states [5].

Title: Human cerebrospinal fluid enhances network function of human organotypic brain slice cultures as revealed by micro-electrode array recordings

Authors: *A. CORNA[1,3], J. WICKHAM[3], N. SCHWARZ[4], T. V. WUTTKE[2], H. KOCH[4], G. ZECK[3];
[1]Ctr. for Ophthalmology, [2]Dept. of Neurosurg., Univ. of Tübingen, Tübingen, Germany; [3]Natural and Med. Sci. Inst. (NMI) at the Univ. of Tübingen, Reutlingen, Germany; [4]Dept. of Neurol. and Epileptology, Hertie-Institute for Clin. Brain Res., Tübingen, Germany

Abstract: *Ex vivo* human tissue from resection surgery represents a unique opportunity to study neural network activity in human cortex and hippocampus. One of the main challenges of this technique is to achieve long term survival of the tissue in culture. Recent studies have proven

that it is possible to overcome this limitation with the use of human cerebrospinal fluid (hCSF) during the culturing steps. The goal of the presented study is to evaluate the effect of hCSF on the functionality of the slices evaluated at cellular and small network level.
Human hippocampal and cortical organotypic slice cultures were prepared from spare access tissue, obtained from patients undergoing epilepsy surgery. The tissue was sliced with a vibratome and cultured as organotypic cultures using hCSF as culturing medium. After 5-17 days *in-vitro* extracellular recordings were performed using two different types of Micro-electrode arrays (MEA): a standard 256 channel MEA and a high-density CMOS-based MEA with 4225 channels.
Spontaneous activity was recorded under three different experimental conditions: first aCSF was used, then hCSF followed by aCSF again. Spontaneous activity recordings proved long term survival of human organotypic slices. The change to hCSF perfusion generated an increased general excitability in almost all the samples recorded. This increase in activity returned to previous levels when aCSF was washed in again. Activity changes were measured in terms of number of active neurons, firing rate, burst and synchronised events. The perfusion with hCSF also caused activation of network regions otherwise silent in aCSF.
The long culture time with sustained viability of the slices allowed the use of viral vector based tools, such as optogenetics. We successfully expressed the light-sensitive ion channel channelrhodopsin under the human synapsin promoter in our cultured slices. We performed simultaneous MEA recordings and light stimulation and successfully demonstrate single cell and network modulation due to optogenetic activation. This approach opens the possibility for dissection of human CNS circuitry.

Title: Inhibitory microcircuit function in the claustrum

Authors: ***M. GRAF**, G. J. AUGUSTINE;
Lee Kong Chian Sch. of Med., Nanyang Technological Univ., Singapore, Singapore

Abstract: The claustrum is highly interconnected with almost all cortical regions and claustro-cortical connections have been well-described. However, almost nothing is known about the local network architecture of the claustrum. We have characterized the inhibitory microcircuitry within the claustrum in acute brain slices. 3 different types of INs - parvalbumin (PV), somatostatin (SST), and vasoactive-intestinal peptide (VIP) – were focally photostimulated via Channelrhodopsin-2 (ChR2), while whole-cell patch recordings were used to measure light-evoked responses in their postsynaptic target cells (N=262). For each postsynaptic neuron recording, 3 network parameters were measured: (1) probability of evoking inhibitory postsynaptic currents (IPSCs); (2) area and location where IPSCs were evoked (input map); and (3) IPSC mean amplitude.
- PV-INs inhibited all neuron types, with a slight bias toward inhibiting PNs. The mean area of PV input maps for PNs was 2.3x larger than for INs. The mean amplitude of light-evoked $GABA_A$-receptor mediated IPSCs was larger in PNs (41.3 $\pm$ 2.5 pA) than in INs (18.4 $\pm$ 1.5 pA).
- SST-IN connection probability was uniformly high across all neuron types; the mean area of SST-IN input maps for PNs was 2.6x larger than for other claustral INs and the largest among all IN connections. The mean amplitude of IPSCs evoked in postsynaptic PNs (32.2 $\pm$ 1.9 pA) was larger than in postsynaptic INs (21.3 $\pm$ 1.3 pA).
- VIP-INs preferentially connected to other claustral INs. As a result, maps of VIP inputs onto PNs were 40% smaller than those onto INs; the mean amplitude of IPSCs were similar for PNs (19 $\pm$ 1.7 pA) and INs (20.3 $\pm$ 1.9 pA). Photostimulation of presynaptic VIP-INs could inhibit AP firing in postsynaptic INs but had little effect in PNs; this differed from PV-INs and SST-INs, which efficiently blocked AP firing in all postsynaptic target cells.
Our results indicate that both PV-INs and SST-INs efficiently inhibit PN activity and, thereby, reduce claustral output. Conversely, VIP-INs can increase PN activity via disynaptic disinhibition, so that VIP-IN activity will increase claustrum output. Thus, local interneurons bidirectionally control claustrum input onto its downstream targets.

Abstract: The locus coeruleus (LC) densely innervates various cortical and subcortical regions, and is the main source of norepinephrine (NE) in the brain. LC hyperactivity is associated with neuropsychiatric disorders such as depression and anxiety, while LC neurodegeneration is observed in Alzheimer's and Parkinson's disease. However, the impact of LC-NE dysfunction and degeneration on its downstream targets remains understudied. The LC has the potential to regulate many brain networks due to its widespread pattern of innervation, and functional magnetic resonance imaging (fMRI) offers a non-invasive approach to studying alterations in these networks. Importantly, fMRI can be combined with pharmacological or genetic manipulations that perturb various systems, providing insight into disease-like states. To investigate the consequences of aberrant NE transmission on brain-wide functional connectivity, adult male wild-type Sprague-Dawley rats were administered vehicle, the selective LC neurotoxin DSP-4 (50 mg/kg, i.p.), or the selective NE reuptake inhibitor atomoxetine (1 mg/kg, i.p.) prior to combined isoflurane-dexmedetomidine anesthesia and structural and functional MRI scans. Preliminary results indicate that perturbations of LC-NE transmission alter brain-wide functional connectivity. Specifically, seed-based analysis indicates consistent decreases in functional connectivity of the medial prefrontal cortex, primary motor cortex, primary somatosensory cortex, and cingulate in animals administered DSP-4 compared to controls. Analysis of functional connectivity in animals administered atomoxetine is ongoing. We are currently leveraging optogenetics during fMRI to selectively drive phasic bursts or tonic LC firing in a rat model of Alzheimer's disease in order to better understand the consequences of LC pathology on functional connectivity in the forebrain.

Title: Synaptic organization of cortico-cortical communication in primate somatosensory cortex

Authors: *M. M. ASHABER[1], L. ZALÁNYI[2], E. PÁLFI[3], I. STUBER[4], T. KOVÁCS[5], R. M. FRIEDMAN[6], A. ROE[7], L. NEGYESSY[8];

Abstract: Synaptic communication is based on two types of axon terminals in hierarchical cortical circuits: small and large, with modulatory and driving roles, respectively. Interestingly, feedforward pathways exert driver-like functions, whereas feedback pathways have modulatory role. However, the synaptic organization subserving the functions of feedforward and feedback pathways is not well understood. The goal of this study was to clarify the existence and functionally relevant structural features of large, driver-like cortico-cortical axon terminals in somatosensory cortical areas 3b and 1. Anterograde tract tracing was used both at the light and electron microscopic levels to reconstruct the 3D morphology of large axon terminals labeled after injections in area 3b and area 1 of the squirrel monkey. At the light microscopic level both small and large boutons were formed by intrinsic, feedforward and feedback pathways. However, large boutons labeled by area 3b injections tended to distribute inter-areally, and in supragranular layers at a higher proportion than those labeled by area 1 injections. Our 3D ultrastructural comparisons showed that surface and volume are highly correlated and provide a powerful tool for classifying cortical endings. Principal component analysis highlighted the significance of the size of mitochondria as a distinguishing feature of bouton type, suggesting that activity shapes the size of boutons. However, the size of the postsynaptic density appeared invariant across the bouton types. Interestingly, perforated postsynaptic density, which signify synaptic plasticity, was associated with a higher degree with the large than to small boutons. Similar to the visual cortex, these findings indicate the existence of driver-like and modulator-like axonal endings in the somatosensory cortex in primates. It is suggested that hierarchically organized large driving-like synapses play a role in the dissemination of tactile information across the intrinsic, feedforward and feedback pathways of area 3b and area 1.

Title: Hemispheric differences in functional interaction between dorsal lateral prefrontal cortex and ipsilateral motor cortex

Authors: *Y. WANG[1], N. CAO[1], J. ZHANG[1], R. CHEN[2];
[1]Sch. of Kinesiology, Shanghai Univ. of Sports, Shanghai, China; [2]Div. of Brain, Imaging and Behaviour – Systems Neurosci., Krembil Brain Inst., Toronto, ON, Canada

Abstract: **Objective**: To test and compare the interactions between the ipsilateral dorsal lateral prefrontal cortex (DLPFC) and the motor cortex (M1) of both hemispheres.**Methods**: Fourteen right-handed subjects participated in the experiment. We used a paired-pulse stimulation technique with two high-power Magstim 200 machines (Magstim). In the control condition, the intensity of test stimulus (TS) was adjusted to evoke a motor-evoked potential (MEP) of 1 mV peak to peak in the relaxed first dorsal interosseous (FDI) muscle using a 50mm figure-of-eight-shaped coil. In the paired-pulse condition, the conditioning stimulus was set at 110% resting motor threshold (RMT) at 5 cm anterior to the FDI hotspot. Interstimulus intervals (ISIs) between CS and TS were 2, 4, 6, 8, 10, 15, 20, 25 and 30 ms. Ten conditions were randomly intermingled: TS alone (MEP) and CS plus TS (conditioned MEP for each nine different ISIs). Twenty responses were collected for the test stimulus alone and 10 responses for conditioned MEPs at each ISI. In half of the participants, left hemisphere was tested first and the other half vice versa.**Results**:The two factor ANOVA showed significant interaction between hemisphere and ISI (F=2.007, p<0.05). Post-hoc analysis revealed significant difference between hemispheres at ISIs of 2 (p<0.05), 10 (p<0.01), 15 (p<0.05) and 20 (p<0.05) ms. There was inhibition when CS was applied 2 ms before TS in the right hemisphere but not in the left hemisphere. There was facilitation at 10, 15 and 20 ms ISI in the left hemisphere and inhibition in the right hemisphere. In the right hemisphere, an inhibitory effect was found at 10 ms compared to the control condition. **Conclusions**:The data suggests that the left DLPFC has a facilitatory influence on motor cortical excitability while the right DLPFC has an inhibitory effect. These effects could be mediated by the superior longitudinal fasciculus between the ipsilateral DLPFC and M1. The hemispheric differences may reflect the different cognitive roles the right and left DLPFC may play in movement tasks.

Title: Three-dimensional *in vitro* neural tissue culture model to investigate network formation

Authors: *Y.-T. L. DINGLE, V. LIAUDANSKAYA, N. VORA, M. BONZANNI, N. ROULEAU, K. C. BERLIND, I. GEORGAKOUDI, T. J. F. NIELAND, D. L. KAPLAN; Biomed. Engin., Tufts Univ., Medford, MA

Abstract: There is a growing need for *in vitro* platforms to study neural circuitry, as impairments in these networks are involved with numerous neurodevelopmental and neurodegenerative disorders. Three-dimensional (3D) *in vitro* neural tissue models provide an improved system to gain insights into neural network formation and dysfunction because they recapitulate the 3D *in vivo* microenvironment and function of the brain more closely than 2D culture. Here we used our unique bioengineering technology to generate a novel 3D brain-like tissue model for investigating neural network development and activity. We fabricated a 3D, biocompatible scaffold composed of porous silk fibroin sponges filled with collagen type I hydrogels. With mouse embryonic (E16) neurons, we used these scaffolds to generate 3D neural tissue models, which resembled the mechanical properties of brain tissue and supported 3D neurite outgrowth and long-term culture stability. Upon culturing the 3D neural tissue model for different times *in vitro*, the formation of mature 3D networks was observed as evidenced by immunofluorescence imaging of Tuj1-positive and MAP2-positive axons and dendrites. Using GCaMP6, a genetically encoded indicator of intracellular calcium (Ca^{2+}) levels, we monitored the activity of the developing neural networks. Employing a custom developed pipeline based on Matlab algorithms, we quantified dynamic changes in the activity of neurons at the single cell level and on the level of the larger 3D networks. Spontaneous but irregular Ca^{2+} transient network-level events were observed at two weeks with varying intervals. At three weeks of culture, network-level Ca^{2+} transients became more frequent with more regular intervals. The increase of network-level events suggested the dynamic maturation process of the 3D neural network, providing a window to investigate potential intrinsic and extrinsic factors that can disrupt this developmental process. To further demonstrate the utility of our 3D neural tissue model to study neural network activity, we treated our 3D brain-like tissues with neurotransmitter receptor antagonists. Treating with GABA receptor antagonists picrotoxin and bicuculline to block inhibitory inputs resulted in increased network-level activity. Treating with AMPA or NMDA receptor antagonist NBQX and AP5 to block excitatory inputs resulted in a reduction of network-level activity. In summary, our 3D bioengineering system presents a powerful tool for investigating neural network structure, function, and defects.

Title: Avalanches in prefrontal cortex of the awake mouse

Authors: *P. A. KELLS, D. PLENZ;
Sect Critical Brain Dynamics, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: The prefrontal cortex (PFC) is crucial for many higher-level cognitive functions such as working memory, rule-based decision making, and goal-directed behavior. It is generally accepted that in order to maintain such high-level function, PFC must communicate with many other cortical areas. Here we address this challenge of communication between cortical areas by identifying cortical dynamics suggested by theory to optimize information transfer between networks. Cortical networks which exhibit population dynamics in the form of neuronal avalanches have been shown to maximize dynamic range and information capacity in local networks while simultaneously maximizing information transmission between distant cortical regions. Our hypothesis is that PFC maintains neuronal avalanches thereby establishing critical brain dynamics which theory and experiments have shown to optimize numerous aspects of information transfer. To test this hypothesis, we transfected adult mice (>P35;C57BL/6) with a nonspecific viral vector to express jGCaMP7s in PFC neurons. A dorsal cranial window was placed to study dorsal anterior cingulate cortex (ACC). In a second set of animals, the dorsal cranial window was combined with a microprism to record from the contralateral prelimbic cortex (PLC). After 2 weeks of recovery, mice were head-fixed on a running wheel and we recorded ongoing population activity in ACC or PLC with 2-photon imaging. Simultaneous recordings of >200 neurons were obtained during quiet resting and free locomotion for periods of 11 min over multiple recording sessions and many days. The arousal state of the animal was tracked using pupillometry. Raw data were motion corrected and ROIs automatically detected using Suite2P (Pachitariu et al. 2016). Spike probabilities were obtained using MLspikes (Deneux et al. 2016). Spike rates were distributed lognormally across animals and periods of increased spiking were typically associated with locomotion (0.2372±0.1734 vs. 0.1832±0.1107 Hz). Animals spent the majority of recordings quietly resting (7.0788±0.1476 min). Ongoing population activity during quiet resting was characterized by intermittent spike clusters. Size and duration of clusters distributed according to power laws with exponents -1.5 and -2 respectively. Despite changes in firing rates between locomotion and rest, size and duration distributions were robust. Our results identify neuronal avalanches as the dominant organization of population activity in PFC in line with expectations for a critical state. We suggest that the maintenance of avalanche dynamics optimizes information transmission between PFC and other brain areas.

Abstract: It has been demonstrated in brain slices that releasing glutamate near the basal dendrites of cortical pyramidal neurons can generate dendritic plateau potentials—long-lasting depolarizations of the dendritic membrane mediated by activation of synaptic NMDA and AMPA receptors and extrasynaptic NMDA receptors. Depending on the location and strength of the glutamate stimulus, as well as on local dendritic morphology and activity, the depolarization from dendritic plateaus can spread into the soma, reducing membrane time constant and bringing the cell closer to the spiking threshold. Using data from voltage-sensitive dye imaging in dendrites and whole-cell patch measurements in somata of prefrontal cortex pyramidal neurons from rat brain slices, we developed a morphologically-detailed cortical pyramidal neuron model with active dendrites that reproduced experimental observations: a threshold for activation of the plateau, saturation of plateau amplitude but increasing plateau duration with increasing glutamate application, depolarization of the soma by approximately 20 mV, and back-propagating action potential amplitude attenuation and time delay. For use in network modeling, this cell model was then simplified morphologically while maintaining overall electrophysiological and plateau behavior. Network simulations demonstrated increased synchrony between cells during induced dendritic plateaus. These results support our hypothesis that dendritic plateaus provide a 200-500 ms time window during which a neuron is particularly excitable. At the network level, this predicts that sets of cells with simultaneous plateaus would provide an activated ensemble of responsive cells with increased firing. Synchronously spiking subsets of these cells would then create an embedded ensemble. This embedded ensemble would demonstrate a temporal code, at the same time as the activated (embedded) ensemble showed rate coding. This line of research may help to understand the implications of dendritic plateaus at the cellular and network level,

and may lead to a better understanding of ensemble synchronization and multimodal cortical information processing.

Title: Large-scale model of human cortex captures LSD-induced connectivity changes via HTR2A-mediated gain modulation

Authors: *J. B. BURT[1], K. H. PRELLER[5], M. DEMIRTAS[2], F. VOLLENWEIDER[6], A. ANTICEVIC[3], J. D. MURRAY[4];

Abstract: Biophysically-based modeling of neural circuit dynamics is a powerful tool for linking molecular and neurophysiological changes to systems-level disturbances in brain function. Neuroimaging and modeling of pharmacological manipulations, which can alter brain physiology while preserving brain structure, provide the ideal framework for probing the causal mechanisms through which molecular perturbations produce large-scale functional disruption. We recently showed experimentally that the neural and subjective effects of the psychoactive drug LSD are primarily mediated by the serotonin-2A receptor (5-HT2AR), yet the spatial topography, cell-type and receptor specificity of these effects remain unclear. Here, we combined structural and pharmacological fMRI (ph-fMRI) with transcriptional data from the Allen Human Brain Atlas to model the neuromodulatory impact of LSD in a large-scale model of human cortex. Gain modulation—a consequence of 5-HT2AR agonism—in the model was

parametrized by regional expression of HTR2A, the gene which codes for the 5-HT2AR. Our model of HTR2A-mediated gain modulation captured the spatial topography of LSD-induced global brain connectivity (GBC) changes, including hyper- and hypo-connectivity of sensory and association areas, respectively. Moreover, our model captured the change in GBC when LSD was administered with vs. without a 5-HT2AR antagonist, implicating the 5-HT2AR specifically. Finally, empirical GBC changes were not as well captured by: models of neurotransmitter-mediated gain modulation at other synaptic receptor sites; null models in which the strength of gain modulation was parametrized by spatial autocorrelation-preserving surrogate maps; or a static linear structural model incorporating diffusion MRI data and the HTR2A map. Thus, our findings collectively link LSD-induced functional alterations to the unique spatial topography and neurophysiological properties of the 5-HT2AR. More generally, our study demonstrates the potential for biophysical modeling, integrated with transcriptomics and ph-fMRI, to causally link molecular manipulations to systems-level disruptions and thereby guide the development of novel therapeutics for psychiatric disorders.

Title: Inference of cortical network connectivity using maximum entropy models

Authors: *S. MAHALLATI[1,2], M. R. POPOVIC[1,3], T. A. VALIANTE[4,2];
[1]Univ. of Toronto, Toronto, ON, Canada; [2]Krembil Res. Inst., Toronto, ON, Canada; [3]Kite, Univ. Hlth. Network, Toronto, ON, Canada; [4]Dept. of Surgery, Div. of Neurosurgery, Univ. of Toronto, Toronto, ON, Canada

Abstract: Microcircuit level investigations of brain networks aim to link cellular measure of activity (ie. spikes) to collective dynamics (ie. brain oscillations). With our current ability to record from thousands of neurons, computational methods to understand collective neuronal activity (ie. as a network) are required. Maximum entropy models (MEM), are statistical models to describe such collective activity[1] where neuronal spiking (spike vs. no spike) is analogous to the spin states (up vs. down) of atoms in a ferromagnetic lattice. ‘Connectivity’ can then be inferred by solving the inverse Ising model for the coupling between neurons, which is a MEM constrained only by pair-wise correlations[2]. There is an ongoing debate on whether pairwise-based models are generalizable to neural systems at various spatial and temporal scales[3,4]. We

thus assessed the reliability of the inverse Ising couplings as a proxy for connectivity to differentiate between different systems or network states. We tested the model on *in silico* inhibitory-excitatory spiking cortical networks using a range of synaptic delays, firing rates, and syncrony levels (ie. different types of collective behavior like oscillations vs. asynchronous firing). In addition, we evaluated the effect of two factors: spike train bin size, and spatial subsampling which affect the synaptic and propagation delays captured by the model, and the practical limits in real recordings respectively. This work thus benchmarks the network characteristics for which a connectivity reconstruction using inverse Ising models are reliable. Title: Computational modeling of cortical transition to slow wave oscillations modulated by K-ATP current

Authors: *B. SETZER[1], M. M. KOWALSKI[2], M. M. MCCARTHY[1], N. J. KOPELL[1]; [2]Dept. of Mathematics and Statistics, [1]Boston Univ., Boston, MA

Abstract: The driving mechanisms of arousal-state transitions from wake to unconsciousness remain unknown. During many types of unconsciousness, networks of neurons in the brain demonstrate periods of high-frequency activity interspersed with periods of quiescence, which gives rise to slow wave oscillations (SWO), a pattern commonly observed in electroencephalogram recordings. Previous in-vitro slice experiments and mathematical simulations implicate the K-ATP current in the generation of SWO. However, it is not known what changes to cortical dynamics could allow for the expression of this slow rhythm. Here, we propose a Hodgkin-Huxley-based biophysical model that builds upon previous work to demonstrate that K-ATP driven SWO may arise as a result of the interaction between neuronal dynamics, ATP-concentration, and altered input strength to either excitatory or inhibitory

neurons. The slow timescale of ATP concentration dynamics enables an awake to SWO transition given only a change in sub-cortical input to excitatory cells from the brainstem or, alternatively, sufficient disinhibition of pyramidal cells via suppression of interneuron activity. These findings make our model generalizable to several states of altered consciousness, including general anesthesia, sleep, and coma, and point to the K-ATP current as an important contender for the source of SWO in these states.

Title: Entrainment of heterogeneous network with excitatory and inhibitory cells

Authors: *J. WEI[1], M. M. MCCARTHY[2], N. J. KOPELL[2];
[1]Physics Dept., [2]Math and Statistics Dept., Boston Univ., Boston, MA

Abstract: Networks of excitatory (E) and inhibitory (I) neurons can produce rhythms and react to input with spectral content in multiple ways. Here we investigate the response of E-I networks to external periodic input in the presence of multiple forms of heterogeneity. Our focus is on understanding which features of the target network and the input allow for a large frequency range of entrainment by the periodic input. The target network consists of single compartment neurons modeled with the spiking currents (Na+, K+, leak) with Hodgkin-Huxley-type conductances. The target network heterogeneity investigated included: network connectivity, coupling strength, applied current to both E and I cells. In addition, we investigated heterogeneity in the inputs including Poisson noise amplitude. We also considered changes in time scales of synapses. Surprisingly, most forms of heterogeneity did not expand the frequency range over which the target was entrained. An exception was heterogeneity in the strength of the AMPA synapse from E to I cells. This allowed the target network to recruit an appropriate number of I cells so that the resulting time-scale of effective inhibition could match the periodic input. In particular, increasing frequency of input lead to few I cells participating in the rhythm. This comes about because a higher frequency of input leads to a faster I-cell rhythm which interacts with the Poisson heterogeneity to the E-cells to suppress some of the latter. With heterogeneity from E to I cells, this smaller amount of excitation picks out only the I-cells most excited by the E cells. The response of the I-cells to a change in local E cells excitability is very

rapid (within one cycle) allowing this mechanism to describe cycle by cycle changes in the balancing of excitation by inhibition as in Atallah et al., 2009. This suggests that there is a relationship between ability to balance excitation with inhibition and ability to entrain to a large range of input frequencies.

Title: Cortical UP DOWN state synchrony drives propofol phase amplitude coupling in slow waves

Authors: *A. E. SOPLATA[1], M. M. MCCARTHY[1], E. A. ROBERTS[1], E. N. BROWN[2], P. L. PURDON[3], N. J. KOPELL[1];
[1]Boston Univ., Boston, MA; [2]MIT, Cambridge, MA; [3]Anesthesia, Critical Care, and Pain Mgmt., Massachusetts Gen. Hosp., Charlestown, MA

Abstract: In adult humans, the level of propofol-induced unconsciousness can be inferred from the type of phase-amplitude coupling (PAC) between slow wave oscillations (SWO, 0.1-1.5 Hz) and alpha oscillations (8-14 Hz) seen on the electroencephalogram (EEG). Low-dose propofol (corresponding to partial responsiveness) shows "trough-max" PAC where alpha power is maximal in the trough of the SWO phase. High-dose propofol (corresponding to complete unresponsiveness) shows "peak-max" PAC where alpha power is maximal in the peak of the SWO phase. How these PAC regimes are related to propofol oscillation interactions and behavioral changes is still unknown. The thalamus, cortex, and their interaction are critical to natural sleep oscillations which have frequencies similar to those of propofol. Therefore, we combined previous thalamic and cortical Hodgkin-Huxley computational models, enabling us to model the EEG signal directly via thalamocortical and intracortical AMPA currents onto pyramidal dendrites. Applying direct propofol effects on the network via increasing GABA-A inhibition and decreasing H-current conductance produced thalamic alpha oscillations, but was insufficient for enabling cortical SWO generation. In contrast, applying indirect propofol effects

via decreasing acetylcholine (ACh) cortical tone enabled cortical SWO generation by decreasing pyramidal K(Na)-current conductance. By combining direct and indirect effects of propofol, we found that cortical SWO UP/DOWN state synchrony could control whether our synaptic EEG model expressed trough-max (low synchrony) or peak-max PAC (high synchrony). Additionally, in the thalamus, trough-max behavior corresponded to persistent thalamic alpha oscillations, while peak-max behavior showed discontinuous thalamic alpha bursting only near cortical UP states. Our simulated EEG model not only exhibits both PAC states, but also corresponded correctly to the relative power differences in alpha and SWO between coupling states seen in experimental data. By analyzing critical factors for these PAC regimes, we have shed light on the mechanisms powering these profound behavioral differences between anesthetic states.

Title: Abnormal cortical excitability in schizophrenia-like mouse models leads to impaired evoked gamma band activity during behavioral task performance

Authors: D. D. AGUILAR[1], L. K. RADZIK[2], R. E. STRECKER[1], *J. M. MCNALLY[1]; [1]VABHS, Harvard Med. Sch., West Roxbury, MA; [2]Stonehill Col., Easton, MA

Abstract: Gamma band (25-80 Hz) oscillations (**GBO**) serve as a fundamental mechanism for the coordination of function across different brain regions and have been strongly linked to cognition. Abnormal GBO, particularly elevated spontaneous GBO and reduced task-evoked GBO, have been linked with all symptom classes of schizophrenia (**Sz**). Thus, investigating GBO may provide insights into novel therapeutic approaches. Cortical GABAergic interneurons which

express parvalbumin (**PV**) are centrally involved in regulating GBO and are impaired in Sz. PV impairment disrupts the balance of excitatory and inhibitory neuron activity (**E/I balance**) in the cortex, which likely impairs GBO. Here, we test this hypothesis using two models that mimic Sz-like cortical PV impairment. First, an optogenetic model utilizing PV-expressing neurons in the basal forebrain (**BF**), a subcortical brain region involved in cortical activation/arousal. Previous work from our group, has shown that stimulation of BF-PV neurons can modulate cortical GBO. Here, we examine how selectively stimulating BF-PV neuron populations effects GBO in response to novel-object investigation. We also use a transgenic model of NMDAR hypofunction, which also plays a role in impaired PV activity, to examine GBO evoked by social investigation.
EEG activity was recorded during task performance in adult mice via skull screw electrodes above the frontal and parietal cortices, referenced to cerebellum. For novel object we used transgenic mice expressing Cre recombinase in PV neurons (n=10). Channelrhodopsin-2 was virally expressed, and optical fibers implanted bilaterally into the BF. Tonic low wattage stimulation (5mW, 2-5 min) of BF PV neurons was used to elicit cortical E/I imbalance and psychosis-like phenotypes. For social investigation, homozygous serine racemase knockout mice (SR KO, n=4) and wild-type (WT, n=3) littermates were used. Online tracking was employed to tag periods of EEG associated with investigation.
Our results demonstrate an impairment in both task performance as well as a significant reduction in evoked low frequency GBO (25-60Hz) response to novel object/mouse investigation in both models. Thus, altered cortical E/I balance may be causally linked to impairments in working memory and the social domains of cognition. Abnormal E/I and GBO are associated with numerous severe neuropsychiatric disorders including schizophrenia, autism, Alzheimer's disease, and Parkinson's disease. Thus, this research provides valuable insight into the pathogenesis of such disorders and lays the groundwork for the development of therapeutic interventions to modulate GBO and improve cognitive function.

Abstract: Huntington's disease (HD) is a fatal, monogenic inherited neurodegenerative disorder, which typically manifests in middle age and is characterized by progressively disordered cognition and movement. HD symptoms are largely due to the profound dysfunction and later degeneration of striatal and cortical neurons. Although less extensive than striatal degeneration, cortical degeneration likely underlies much of the troubling cognitive dysfunction experienced by HD patients. Furthermore, mounting evidence suggests cortical pathology at least partly mediates striatal degeneration by virtue of altered cortex to striatum signalling. Despite this, effects of the mutant huntingtin protein on cortical neuron activity are poorly understood. In particular it is largely unclear if, and how, information processing is altered within the intact HD cortex. We have performed *in vivo* wide-field voltage-sensitive dye imaging (VSDI), in lightly anaesthetized YAC128 HD-model and wildtype (WT) mice, to measure neuronal activity across large swaths of dorsal neocortex. Compared to WT littermates, YAC128 mice showed a more extensive spread of neuronal signals across the cortical surface evoked by limb sensory stimulation. Despite this, spontaneous brain activity revealed reduced functional cortical connectivity in YAC128 mice. Data from pilot *in vivo* recordings, using electrode arrays placed at various cortical areas, is consistent with the above VSD findings. We hypothesize the above cortical activity alterations are mediated by one of the following mechanisms: (1) Deficient feedforward inhibition from cortical interneurons; or (2) Enhanced recurrent excitation due to increased cortical pyramidal neuron expression of extrasynaptic NMDA receptors. *Ex vivo* brain slice patch clamp electrophysiology experiments are currently underway to determine whether YAC128 mice cortical pyramidal neurons show reduced GABA-mediated inhibition or increased extrasynaptic NMDA receptor currents. Ultimately, we hope to clarify details of cortical circuit dysfunction in HD and to identify potential therapeutic drug targets.

Title: A study of the resting state brain network dynamics between different arousal levels of awake mice

Authors: *Z. HAN[1], G. LI[2], Z. LIANG[3];
[1]Inst. of Neurosci., Shanghai, China; [2]Dept. of Biomed. Engin., Peking Univ., Beijing City, China; [3]Inst. of Neuroscience, CAS, Shanghai, China

Abstract: Converging evidence of PET (positron emission tomography) and fMRI (functional magnetic resonance imaging) studies have revealed the existence of default mode network (DMN) in the human and non-human primate brains. DMN exhibits higher metabolic activity during the rest, and lower activity during active tasks. Till now, the neural mechanisms underlying the DMN are still unclear. To solve these questions, techniques of combing brain-wide fMRI and electrophysiological recording will be useful. By combining fMRI and LFP(local field potential) recording methods, previous studies performed on non-human primates showed cross-correlations between the rCBV (cerebral blood volume) signal and LFP γ-band power (Duyn, J. H., et al.,2010). But their results lacked evidence to explain the regional specificity of DMN.
Comparing to non-human primates, rodents are much more accessible for neuroscience research. Based on our previously published work (Han et. al., Neuroimage 2019), we aimed to study the neural mechanisms underlying the DMN in awake mice. In the current study, we developed the simultaneous fMRI and electrocorticogram (ECoG) recording paradigm for awake mice. The ECOG electrodes were specifically designed for a large coverage of the brain (roughly 1/3 of the cortex), and also excellent MRI compatibility (e.g., very low degree of distortion in fMRI images). We collected the BOLD (blood oxygenation level dependent), CBF (cerebral blood flow) and the ECOG signals on awake and resting mice. The ECOG signals were denoised to eliminate the artifacts caused by the fast switching of gradient coils. Based on the ECOG signals recorded from the primary somatosensory area (S1), we categorized the mouse arousal states as alert or drowsy. Our preliminary results indicated different spatiotemporal dynamics of DMN in both ECoG and fMRI signals. Further analysis is being conducted to examine the relationship between ECOG signal dynamics and DMN dynamics.

Title: Causal role of the P25 TMS-evoked potential in modulation of motor cortex excitability: A TMS-EEG study

Authors: *S. AHN[1,2], F. FROHLICH[1,2];
[1]Dept. of Psychiatry, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [2]Carolina Ctr. for Neurostimulation, Chapel Hill, NC

Abstract: Corticospinal excitability measured by motor-evoked potentials (MEPs) is modulated by polarity-dependent transcranial direct current stimulation (tDCS). Specifically, anodal- and cathodal-tDCS applied to the motor cortex (return electrode: supraorbital cortex) increases and decreases the amplitude of MEPs elicited by transcranial magnetic stimulation (TMS), respectively. Yet, it remains unknown how tDCS polarity modulates cortical reactivity and its relationship with corticospinal excitability. The recent development of combined TMS and electroencephalography (EEG) enables us to probe altered brain network dynamics. Here we performed a crossover, double-blind, sham-controlled TMS-EEG study with three tDCS conditions (anodal/cathodal tDCS, and sham) to examine the causal role of cortical reactivity in corticospinal excitability. We recruited 18 healthy right-handed participants (male, 18-35 years old, free of neurological or psychiatric illness) and applied TMS pulses on the hand area of the left precentral gyrus based on individual magnetic resonance imaging (3 Tesla, T1-weighted). We first identified resting motor threshold (RMT) and then applied 100 TMS pulses with 120% intensity relative to RMT over a period of 5 minutes. We collected MEPs and 128-channel EEG data before and after tDCS administration for 10 minutes. We found anodal and cathodal tDCS significantly increased and decreased MEP ratio (post/pre) in "stimulation condition" ($F_{2,28}$=255, p<0.0001) using a linear-mixed effect model with factors "stimulation condition" and "session". This result replicates and confirms previous findings of bidirectional modulation of corticospinal excitability with tDCS. To investigate cortical reactivity in the EEG data, we removed the TMS-induced artifact from -10 to 20ms relative to stimulation onset and calculated the TMS-evoked potential (TEP) components (P25, N45, P60, N100, P180, N280) with respect to the TMS onset. We found that the P25, N45, P60 TEP components are significantly modulated by tDCS. No other TEP components exhibited such modulation by stimulation condition (all p>0.05). Importantly, the modulation of the MEPs and the P25 TEP component by tDCS were correlated for anodal tDCS (r=0.54, p=0.022), cathodal tDCS (r=0.51, p=0.032), but not for sham tDCS (r=-0.15, p=0.54). Together, our findings demonstrate (1) a clear effect of tDCS on corticospinal excitability, (2) the positive cortical reactivity at 25ms (P25) drives the change in corticospinal excitability induced by tDCS. These results provide a strong foundation for future neurophysiology-based examination of tDCS and its effect of motor excitability.

Title: Prediction of peptidergic intracortical modulation networks from single-cell transcriptomic data

Authors: *S. J. SMITH[1], U. SÜMBÜL[1], L. GRAYBUCK[1], F. COLLMAN[1], S. SESHAMANI[1], R. GALA[1], O. GLIKO[1], L. ELABBADY[1], J. A. MILLER[1], T. BAKKEN[1], J. SCHARDT[1], J. ROSSIER[2], Z. YAO[1], E. LEIN[1], H. ZENG[1], B. TASIC[1], M. HAWRYLYCZ[1];

Abstract: Seeking insight into the homeostasis, modulation and plasticity of cortical synaptic networks, we have analyzed single-cell mRNA-Seq data on expression of neuropeptide (NP) signaling genes in large numbers of mouse and human cortical neurons. Our results suggest that virtually all cortical neurons in both mouse and human strongly express genes encoding at least one neuropeptide precursor protein (NPP) and at least one neuropeptide-selective G-protein-coupled receptor (NP-GPCR). It is also evident that most individual cortical neurons express more than one NPP and more than one NP-GPCR. In both species, expressed NPP and NP-GPCR genes are drawn from large palettes (18 to 29 genes), with unique signatures of NPP and NP-GPCR gene expression highly specific to particular transcriptomic neuron types. Intracortical NP signaling is most likely predominantly paracrine, with soluble NP products diffusing locally from NPP-expressing source neurons to numerous nearby neurons, while type-specific NP-GPCR expression determines which individual neurons respond. The sets of NPP and NP-GPCR genes expressed in cortex contain many “cognate” pairs (37 for mouse; 36 for human), where an expressed NP-GPCR is selective for the predicted product of an expressed NPP. NP-GPCRs are known to act via second messengers, including cyclic AMP and calcium ions, to powerfully regulate ion channel and synaptic function. Neuron-type-specific NPP and NP-GPCR gene expression patterns therefore allow for prediction of type-specific intracortical NP signaling networks likely to participate in synaptic network homeostasis, modulation and plasticity. We have generated more than 100 predictions of neuron-type-specific NP signaling networks for two areas of mouse neocortex (primary visual VISp and anterior lateral motor ALM) and two areas of human cortex (primary visual V1 and middle temporal gyrus MTG). Here we’ll present our predictions in the form neuron-type-specific coupling matrices and outline experimental strategies for empirical test of such predictions.

Title: Causal role of the higher-order visual thalamus in cortico-cortical synchronization during sustained attention

Authors: *W. A. HUANG[1,2,3], Z. C. ZHOU[1,2,3], I. STITT[1], S. RADTKE-SCHULLER[1], F. FROHLICH[1,2,3,4,5];
[1]Psychiatry, [2]Neurosci. Curriculum, [3]Carolina Ctr. for Neurostimulation, [4]Cell Biol. and Physiol., [5]Neurol., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Sustained attention, the continuous allocation of processing resources to respond to infrequent but behaviorally relevant stimuli, is impaired in many psychiatric disorders and represents an important aspect of cognitive control. It has been shown that sustained attention is related to top-down signaling from the frontoparietal network as well as thalamo-cortical modulation. However, the causal role of these two circuits - the fronto-parietal network and the posterior visual thalamo-cortical network - in sustained attention remains unknown. Here, we studied this question by combining rhythmic optogenetics and simultaneous recording from four nodes in the frontoparietal and posterior visual thalamo-cortical visual circuit in ferrets. The four nodes are prefrontal cortex (PFC), pulvinar complex (lateral aspect of lateral posterior nucleus, LPl), posterior parietal cortex (PPC), and primary visual cortex (V1). To probe visual sustained attention, we employed a widely used paradigm: the five-choice serial reaction time task, in ferrets, as ferrets have a relatively well-developed higher-order visual thalamus and have a brain size suitable for optogenetics manipulation. In this task, animals need to pay attention to a computer screen during a delay period with random length until a visual stimulus is presented, which the animal touches for reward. We found that in both animals: (1) theta-band functional connectivity (eg. coherence) between LPl, PPC and V1 but not PFC increases during the delay

period before the animal touched the correct stimulus location, (2) theta power/functional connectivity increase is coupled with gamma power/functional connectivity increase and alpha power/functional connectivity decrease in all regions, (3) optogenetic stimulation in LPl in alpha frequency band during delay period increases corresponding functional connectivity between LPl, PPC and V1, but not PFC, (4) alpha-band stimulation increases number of omission trials by 33% (N=2 animals) compared to sham condition and increases reaction time by 0.14s on average (1-way ANOVA, p=0.055, N=136 trials/condition). This alpha stimulation effect is in agreement with human studies that suggest a causal role of alpha oscillation in attentional gating. As a whole, our study provides causal evidence that LPl coordinates cortical functional connectivity of the LPl-PPC-V1 during sustained attention in a frequency specific way, with increasing alpha power in LPl increases omission trials and reaction time. Our work will ultimately provide a circuit-level mechanistic explanation on how a higher-order visual thalamic structure modulates cortical communication.

Title: Optimizing cell encapsulation conditions in ECM-collagen hydrogels to support long-term maintenance of 3D neuronal cultures

Authors: ***D. LAM**[1], H. A. ENRIGHT[1], S. K. G. PETERS[1], J. CADENA[2], M. L. MOYA[2], D. A. SOSCIA[2], J. A. ALVARADO[2], K. S. KULP[1], E. K. WHEELER[2], N. O. FISCHER[1]; [1]Physical and Life Sci. Directorate, [2]Engin. Directorate, Lawrence Livermore Natl. Lab., Livermore, CA

Abstract: The emergence of three-dimensional (3D) cell culture platforms in neural tissue engineering has significantly elevated the complexity of *in vitro* systems. While strategies for tissue engineering have identified a number of biomaterials for cell encapsulation in hydrogels, it will be important to standardize the methodology for neuron encapsulation in 3D and assess their health and function in long-term cultures. In the present study, we investigated the effects of tuning collagen gel to include a heterogenous mixture of ECM called MaxGel, and encapsulated

neurons at three cell concentrations (i.e., $2x10^6$ cells/ml, $4x10^6$ cells/ml, and $1x10^7$ cells/ml). Then, we evaluated the influence of a CO_2 environment during fibrillogenesis on cell health and distribution within the 3D hydrogel at 14 DIV. Our findings demonstrate that increasing the concentration of MaxGel (up to 500 µg/ml) or the initial cell concentration (up to $1x10^7$ cells/ml) did not alter the fibrillogenesis kinetics or the mechanical properties of collagen at a concentration of 1 mg/ml. The distribution of cells within the 3D hydrogel, however, was dependent on the initial cell concentration during encapsulation and the presence of CO_2 during fibrillogenesis of collagen. Uniform distribution of cells was observed in cultures that were initially encapsulated with $2x10^6$ cells/ml and $4x10^6$ cells/ml and in the presence of 5% CO_2 during fibrillogenesis. More heterogeneous cell distributions (i.e. higher cell density at the bottom of the gel relative to the top) occurred when the cell concentration increased to $1x10^7$ cells/ml or in the absence of CO_2 during fibrillogenesis. While the majority of cells encapsulated were viable in the 3D ECM-collagen hydrogel at 14 DIV, a linear relationship between increased cell concentration encapsulated and percentage of cell death was observed. Nevertheless, cells remain viable (assessed by viability staining and calcium imaging) in long term cultures >30 DIV. Furthermore, the ECM-collagen hydrogel was adapted to human primary cells. Collectively, this study demonstrates a framework that systematically evaluates cell viability and the distribution of cells in 3D as a result of tuning the collagen gel with a heterogenous ECM mixture and CO_2 environment, which can have implications on the neurophysiological responses (i.e., electrophysiology and response to drugs) of these 3D neuronal cultures.
This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 through LDRD award 17-SI-002. (LLNL-ABS-771597)

Title: Biophysics of emergence and irreversibility of epileptiform activity in organotypic cultures of mouse cortex following homeostatic adjustment to activity deprivation

Authors: *D. WISE, S. VAN HOOSER, S. NELSON;
Neurosci., Brandeis Univ., Waltham, MA

Abstract: Cells deprived of activity become hyperactive when their activity is restored. This homeostatic adjustment has been linked to spontaneous seizures in vivo following blockade with the sodium channel blocker tetrodotoxin (TTX). This work seeks screen and understand the conditions necessary to induce a dangerous firing paradigm using calcium imaging, synaptic staining and whole cell patch clamp of organotypic slice cultures of mouse cortex. We find that cortex is reliably driven to hyperexcitation upon release from TTX and while slices will recover if deprived for 5 days they will be irreversibly hyperactive if deprived for 10 days. Additionally, preliminary data indicates that the second week of development in mice, concordant to studies on human epileptogenesis and previous work in the rodent, is a vulnerable period for this sort of homeostatic response to activity deprivation. We hope to understand the principles by which homeostatic plasticity might contribute to seizures in humans when neuronal activity is altered by injury or when homeostatic actors in the cell are misapplied.

Title: Eminent increase in EEG gamma oscillation in the Wistar Kyoto rat model of treatment-resistant depression

Authors: *N. UPTON, M. S. DUXON, S. KANTOR;
Transpharmation LTD, London, United Kingdom

Abstract: Introduction: Wistar–Kyoto (WKY) rats exhibit abnormal behavioural, hormonal, neurochemical as well as sleep-wake characteristics that are often associated with depression. Since WKY rats show decreased sensitivity to conventional monoamine-based antidepressant treatment, they are used as a model of treatment-resistant depression (TRD). The N-methyl-D-aspartate-receptor antagonist ketamine has emerged recently as a rapidly acting antidepressant with high efficacy in TRD patients. The aim of this study was to determine whether a subanaesthetic dose of ketamine has differential effects on sleep-wake behaviour and brain oscillations in WKY rats in comparison with Sprague-Dawley (SD) rats.
Methods: 8 SD and 8 WKY adult (200-250 g) male rats were surgically implanted with telemetry transmitters (F40-EET; DSI, USA) for EMG and fronto-parietal EEG recordings. Following post-surgical recovery, baseline sleep-wake behaviour was recorded in the rats for 72 h. Then the rats were treated with a single dose of ketamine (10 mg/kg, s.c.) or its vehicle, and EEG, EMG, locomotor activity and body temperature were recorded for 24 h. Vigilance states were automatically scored using a customized algorithm (SleepSign, Kissei Comtec, Japan).

EEG power spectra were computed for 2 s epochs (FFT routine, Hanning window) between 1-50 Hz.
Results: WKY rats showed about twice as much rapid eye movement (REM) sleep as SD rats during the passive (light) phase of the 24 h cycle. Although ketamine had similar effect on REM sleep amount in both strains, its effect on high-gamma (>40 Hz) EEG oscillations was different in SD and WKY rats. Specifically, ketamine induced an almost twice as high increase in high-gamma EEG power in WKY rats as in SD rats.
Conclusions: Our data suggest that ketamine is more effective in modulating cortical activity in the WKY rat model of depression than in control SD rats. An eminent increase in EEG gamma oscillation after treatment may indicate a therapeutic potential in depression, although this notion needs to be further investigated. Since the sleep and EEG abnormalities in WKY rats largely recapitulate the changes seen in TRD patients, these neurophysiological measures may serve as key translational tools in an effort to discover novel therapeutics against TRD.

Title: Decreased delta oscillations after administration of TSPO ligands Pk11195, Ro5-4864, and FGIN1-27

Authors: *M. I. KHUMNARK[1], R. M. HINES[2], D. J. HINES[2];
[1]Univ. of Las Vegas , Nevada, Las Vegas, NV; [2]Psychology, Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: Network communication in the CNS relies upon multiple neuronal and glial signaling pathways. In addition to chemical transmission between cells, mitochondria are able to directly and indirectly affect cellular communications by either providing energy for vesicular release or though production of neurosteriods respectively. One highly conserved mitochondrial signaling mechanism involves an 18kDa outer mitochondrial membrane protein called translocator protein (TSPO).Originally, the function of TSPO was thought to be as a binding site for benzodiazepines in the periphery, while GABAA (γ-amino butyric acid type A) receptors served as the binding site centrally. It was later discovered that TSPO is implicated in multiple cellular processes, with its role in translocation of cholesterol and steroidogenesis being the most well-known and debated. TSPO has also been implicated in porphyrin transport, cellular response to

stress,inflammation and tumor progression. Although many of these roles have been well defined in the periphery, how TSPO signaling plays a role in the CNS has not been fully clarified. In the present study we assessed the effects of TSPO ligands Pk11195 (antagonist),Ro5-4864(inverse antagonist), and FGIN1-27 (agonist) in adult mice. EEG recordings of the frontal cortex revealed a decreased power in the δ frequency band (0.4Hz - 4Hz) after administration any of the compounds described above. Ro5-4864 and PK11195 had similar levels of suppression of δ, while FGIN 1-27 treated animals had the highest δ suppression. FGIN 1-27 also suppressed the Θ frequency band (4Hz -12.0Hz), while Ro5-4864 and Pk11195 did not. These data suggest that modulation of TSPO causes changes in circuit level signaling.

Title: Pathological mechanisms of DSCR3 mediating APP trafficing in cognitive dysfunction of Down syndrome

Authors: *Q. CUI;
The Inst. for Brain Research, Collaborative In, Wuhan, China

Abstract: Down's syndrome (DS) is one of the most common chromosomal abnormalities. Most patients have cognitive impairment, which seriously affect the quality of life. However, there is no effective treatment and the pathological mechanism is not clear. Therefore, it is of great significance to study the mechanism of DS cognitive impairment. Previous studies showed that Down syndrome critical region protein DSCR3 increased significantly in DS mice brain, and downregulated DSCR3 rescued the cognitive dysfunction phenotype in DS mouse model. It is suggested that the overexpression of DSCR3 may be involved in the occurrence of DS cognitive dysfunction, but the specific mechanism is not clear. Further studies have shown that overexpression of DSCR3 decreased the expression of vesicle transport related protein SNX17 and the content of amyloid precursor protein (APP) on the cell surface. So, we hypothesize that overexpression of DSCR3 induces abnormal APP transport by reducing SNX17 and resulting in cognitive dysfunction of DS. This project will study the role of DSCR3 in cognitive impairment of DS on the cellular and animal level, and elucidate its molecular mechanism, so as to provide new targets for the treatment of DS cognitive dysfunction.

Title: Mossy cells in the rostral and caudal dentate gyrus differ in their patterns of axonal projections

Authors: C. R. HOUSER[1], Z. PENG[1], C. S. HUANG[1], X. WEI[2], *I. MODY[2];

Abstract: Mossy cells (MC) of the dentate gyrus (DG) are a major group of excitatory hilar neurons that are important for regulating activity of DG granule cells. MC are particularly intriguing because of their extensive commissural and longitudinal association connections within the DG. While it generally has been assumed that MC in the rostral and caudal DG have similar patterns of termination in the inner one-third of the dentate molecular layer, this has not been demonstrated directly. We compared the projection patterns of MC in the rostral and caudal DG. Two different transgenic mouse lines that express Cre-recombinase relatively selectively in dentate MC (*Drd2*-Cre and *CalCrl*-Cre mice) were used in this study. The results were similar in the two mouse lines, with MC exhibiting characteristic morphological features and expression of GluA2 throughout the longitudinal extent of the DG. To label MC axons from rostral and caudal regions of the DG differentially in the same mouse, Cre-dependent eYFP and tdTomato were transfected caudally and rostrally respectively. At 3-4 weeks following unilateral labeling of MC in the caudal DG, a dense band of labeled fibers was present in the inner third of the molecular layer and extended bilaterally throughout the rostral-caudal extent of the DG, thus replicating the expected distribution of MC axons. In contrast, following unilateral labeling of MC in the rostral dentate gyrus, a narrower band of fibers was evident and was strongest on the contralateral side. At the level of the transfection, this band was present in the inner molecular layer. However, at progressively more caudal levels, the fibers expanded into the middle molecular layer until, most caudally, the MC axons formed a distinct band in the middle to outer molecular layer and no longer overlapped with the local MC projections of the inner molecular layer. Optogenetic stimulation of these caudal fibers in slices with Cre-dependent expression of ChR2/eYFP or ChIEF/tdTomato in MC demonstrated robust EPSCs, particularly in ipsilateral granule cells, but only sporadic IPSCs. These findings suggest that MC in the rostral and caudal dentate gyrus differ in the distribution of the axonal projections and possibly their function.

Title: Circuit reorganization of hippocampal mossy cell outputs in epilepsy

Authors: *C. R. BUTLER[1], G. L. WESTBROOK[2], E. SCHNELL[3];
[1]Anesthesiol. and Perioperative Med., Oregon Hlth. & Sci. Univ., Portland, OR; [2]Vollum Inst., Portland, OR; [3]Portland VA Med. Ctr., Portland, OR

Abstract: The hippocampal mossy cell, a glutamatergic neuron in the dentate hilus, projects to local GABAergic interneurons and dentate granule cells (DGCs). Mossy cells are lost in neurologic diseases such as epilepsy; however, relatively little is understood about how residual mossy cells drive hippocampal network function. To address this issue, we used a transgenic mouse model, the calcitonin receptor-like receptor Cre mouse (Crlr-Cre), which selectively expresses Cre recombinase in mossy cells. In preliminary studies, we evaluated the specificity of mossy cell labeling in these mice using both Cre-dependent reporter mouse lines and intracerebral Cre-dependent viral injections. We then used optogenetics to functionally characterize mossy cell projections onto DGCs in both healthy controls and in epileptic mice, using the pilocarpine model of temporal lobe epilepsy. In acutely prepared hippocampal slices from healthy mice, mossy cell activation evoked both a direct glutamatergic (AMPAR/NMDAR-mediated) and a di-synaptic GABAergic response in DGCs, consistent with known mossy cell connectivity. In epileptic mice, similar stimulation evoked a significantly reduced direct AMPAR-mediated current, coincident with a dramatic reduction in mossy cell number. However, the amplitudes of di-synaptic GABA-mediated responses were relatively maintained, suggesting network compensation. This observation was not associated with changes in short term plasticity of the direct glutamatergic mossy cell-DGC connection. We are currently working to better characterize whether this maintenance of inhibitory connectivity results from changes at the mossy cell-to GABAergic interneuron connection, or alternatively, a change in interneuron function. Overall, these results suggest that surviving mossy cells preferentially provide feedback

inhibition onto DGCs in epilepsy, which could serve to maintain inhibitory tone following the development of hippocampal hyperexcitability.

Title: Identification of zinc-sensitive metal-regulatory transcription factor 1 positive neurons to study the hippocampal epileptic network activity

Authors: *A. MECONI, S. SCHOCH, A. J. BECKER, K. M. J. VAN LOO;
Dept. of Epileptology, Inst. of Neuropathology, Bonn, Germany

Abstract: The emergence of a hyperexcitable hippocampal network characterizes temporal lobe epilepsy (TLE), the most common focal epilepsy in adults. Previously, we have shown that the metal-regulatory transcription factor 1 (MTF1) can increase the expression of the T-type calcium channel $Ca_v3.2$ after a rise in intracellular Zn^{2+}, resulting in an enlarged density of T-type Ca^{2+}-currents, an augmented propensity for burst discharges, as well as spontaneous seizures. To date, little is known about MTF1-induced signalling cascades and their functional relevance in the development of neuronal microcircuits to generate seizures.
A better understanding of the molecular and functional network recruited by Zn^{2+}-sensitive MTF1-signaling can provide fundamental new insights into key and selective molecular signalling pathways inducing pathological hippocampal microcircuit plasticity. Here, we developed different MTF1-transcriptional units to genetically label MTF1-responsive cells. Analysis of these units in NG108-15 cells and primary neurons led us to the identification of one promising MTF1-transcriptional unit which will be now used to study how the Zn^{2+}-sensitive immediate early gene MTF1 can convert a hippocampal micronetwork hyperexcitable.

Title: The effect of serotonergic neurotransmission and vigilance state on apnea during and after kindled seizures in mice

Authors: *K. G. JOYAL, B. S. PURNELL, G. F. BUCHANAN;
Neurol., Univ. of Iowa, Iowa City, IA

Abstract: Sudden unexpected death in epilepsy (SUDEP) is the leading cause of death in patients with refractory epilepsy. SUDEP is second only to stroke in terms of years of potential life lost to disease. While the exact etiology of SUDEP remains unclear, it is believed apnea is a major precipitant of death. A large body of evidence has implicated serotonin (5-HT) in SUDEP. 5-HT is important in the regulation of breathing and plays a role in regulating seizure threshold and severity. Since seizures can alter 5-HT signaling, we hypothesized that enhancing 5-HT neurotransmission prior to seizure onset would decrease the incidence of ictal and postictal apnea. As SUDEP more often occurs at night, and 5-HT tone is sleep-state dependent, seizures were induced during both wake and sleep. Due to a putative role for the 5-HT_{2A} and 5-HT_{2C} receptors in setting seizure threshold and severity, agonists for these receptors were also utilized. Adult (8-12 weeks) male and female C57BL/6 mice were instrumented for EEG/EMG recording and stereotaxically implanted with a bipolar stimulating/recording electrode into the right amygdala [AP: -1.3; ML: -2.8; DV: -4.7] for amygdala kindling. After recovery from surgery, afterdischarge threshold determination, kindling, and acclimation to the recording apparatus, seizures were induced during wake and non-rapid eye movement (NREM) sleep following treatment with selective 5-HT reuptake inhibitors (SSRI) or 5-HT receptor agonists. We found that the SSRI citalopram (20 mg/kg, *i.p.*) eliminated ictal and postictal apneas that were observed in animals only receiving saline. Another SSRI (fluoxetine, 10 mg/kg, *i.p.*) significantly decreased the incidence of ictal and postictal apnea. Alternatively, there was no decrease in apneas when animals received the 5-HT_{2C} receptor agonist MK-212 (10 mg/kg, *i.p.*) or the 5-HT_{2A} receptor agonist TCB-2 (10 mg/kg *i.p.*). No effect of sleep state was observed. To further investigate this circuit, a series of 5-HT_2 antagonists were administered along with citalopram. These results indicate that increasing endogenous 5-HT before a seizure reduces ictal and postictal apnea. Ongoing work is aimed at better understanding receptor and circuit mechanisms in regulation of post-ictal breathing.

Title: Effects of serotonin replacement on seizure profile in genetically serotonin neuron deficient mice subjected to the pilocarpine model of temporal lobe epilepsy

Authors: *R. LI[1], K. CLAYCOMB[2], M. MATKOVICH[3], G. F. BUCHANAN[3];
[1]Neurol., Univ. of Iowa Carver Col. of Med., Iowa City, IA; [2]Neurol., Yale Sch. of Medicine, Dept. of Neurol., New Haven, CT; [3]Neurol., Univ. of Iowa, Iowa City, IA

Abstract: Approximately 4% of Americans will develop epilepsy in their lifetime. Despite the existence of numerous therapies for epilepsy, about a third of patients remain refractory, which at its worst could threaten their lives. It is notable that seizures are more likely to happen during wakefulness and non-rapid eye movement sleep instead of during rapid eye movement sleep in epilepsy patients and in animal models of epilepsy, suggesting a naturally occurring preventive mechanism that has yet to be fully understood. The neuromodulator serotonin (5-HT) regulates sleep as well as seizures, and its concentration fluctuates in a sleep-dependent manner. Therefore, we hypothesized that genetical elimination of 5-HT neurons in the brain alters the sleep-dependent pattern of seizures and can be partially restored by 5-HT brain infusion. To test our hypothesis, *Lmx1b*$^{f/f/p}$ (n =14) mice of which 5-HT neurons have been genetically deleted and their littermates *Lmx1b*$^{f/f}$ (n =13) mice of both sexes were used in the current study. Mice were injected intraperitoneally with pilocarpine (250-300 mg/kg) 20-30 min after injection of scopolamine methyl nitrate (1 mg/kg). Status epilepticus induced by pilocarpine was stopped by diazepam (1 mg/kg) 60 min later. Mice were then implanted with EEG/EMG headmounts along with a cannula (Brain Infusion Kit 2, Alzet) targeting the lateral ventricle. Osmotic pumps (Model 2002, Alzet) containing either aCSF or 5-HT at different concentrations were switched between each recording session. EEG and EMG were recorded using Sirenia Acquisition (Pinnacle Technology) at a sampling rate of 1000 Hz with a 300-Hz low pass filter and seizures were detected offline using Sirenia Seizure Pro (Pinnacle Technology). Preliminary analyses showed that seizures tended to occur more frequently in *Lmx1b*$^{f/f/p}$ mice with slightly higher duration and a lower coefficient of variance compared with *Lmx1b*$^{f/f}$ mice under aCSF condition. 5-HT at 1 mM was likely to suppress seizures in *Lmx1b*$^{f/f/p}$ mice but not in *Lmx1b*$^{f/f}$ mice. The interaction between vigilant state and seizure frequency, duration, and dynamics will also be examined. The source of 5-HT within the brain is located at the midline raphe nuclei of the

midbrain, pons, and medulla. Future studies will focus on the midbrain raphe nucleus to identify receptor and neuronal circuitry mechanisms of such a phenomenon. Epilepsy patients also have a high prevalence of depression, sleep disorders, and sudden unexpected death. Therefore, understanding the role of serotonin in epilepsy will aid development of new therapies to reduce the burden of epilepsy and its comorbidities.

Title: A heterogeneous thalamic network model that recapitulates oscillations modulated by GABA transporter blockade

Authors: *A. C. LU[1], C. K. LEE[2], B. TRUONG[1], K. S. SILIS[1], J. R. HUGUENARD[2], M. P. BEENHAKKER[1];
[1]Pharmacol., Univ. of Virginia, Charlottesville, VA; [2]Dept Neurol & Neurolog. Sci., Stanford Univ. Sch. Med., Palo Alto, CA

Abstract: Absence seizures are thought to result from 3~5 Hz generalized thalamocortical oscillations. Understanding how such oscillations persist could lead to novel treatments for the most common form of pediatric epilepsy. In acute thalamic slices, bicuculline-induced $GABA_B$ receptor-dependent oscillations were prolonged upon pharmacological blockade of GABA transporters GAT1 or GAT3 individually, but were surprisingly suppressed upon dual blockade of GAT1 and GAT3. Using pharmacological manipulations, distinct temporal profiles of inhibitory post-synaptic currents (IPSCs) from $GABA_B$ receptors of thalamocortical (TC) relay neurons could be recorded for each of 4 pharmacological conditions: (1) control, (2) GAT1 blockade, (3) GAT3 blockade, (4) dual blockade. We propose that the differential effects of GAT blockade on thalamic oscillations could be accounted for by the differential activation of $GABA_B$ receptors in TC neurons. To this end, we developed a biophysical thalamic network model that can recapitulate differences in oscillations when $GABA_B$ activation profiles were varied. We first established 3-compartment single TC neuron models that could recapitulate differences in $GABA_B$ IPSC responses. Using dynamic clamp, voltage responses to each of the 4 $GABA_B$ IPSC conductance profiles, at 3 different levels of maximal amplitude, as well as voltage responses to a current impulse, was recorded for 36 TC neurons. In general, TC neurons had an increase in

low-threshold spike (LTS) probability with GAT1 or GAT3 blockade but a significant decrease with dual blockade. However, there was also high IPSC response heterogeneity among the 36 neurons. By fitting simulated current impulse responses and simulated IPSC responses for each individual cell, we sought to infer geometric and conductance parameters for all 36 neurons. Finally, we incorporated the heterogeneous model TC neurons into an established thalamic network model. A homogeneous network model was sufficient to recapitulate the exacerbation of oscillations with GAT1 or GAT3 blockade and the abolishment of oscillations with dual blockade. Nevertheless, network heterogeneity seemed to be necessary for modelling seizure termination. In summary, we have developed a biophysically-based computational model that recapitulates most effects of GABA transporter antagonists on thalamic oscillations. These results suggest that modulation of GABA transporters is a potential novel treatment for absence epilepsy.

Title: Low glucose modulation of thalamocortical neuron excitability

Authors: *K. A. SALVATI[1,2], A. C. LU[1,3,2], M. L. RITGER[1,3,2], M. P. BEENHAKKER[1]; [1]Pharmacol., [2]Neurosci. Grad. Program, [3]Med. Scientist Training Program, Univ. of Virginia, Charlottesville, VA

Abstract: The link between diet and epilepsy remains unresolved, particularly for epilepsies characterized by spike-and-wave discharges (SWD). Herein, we provide evidence demonstrating that thalamocortical circuits implicated in SWD generation alter activity during acute neuroglycopenia. Using video-EEG, we first demonstrate that low glucose intensifies SWDs in two rodent models [DBA/2J mouse (D) and WAG/Rij rat (W)]. SWDs increase following a 16 hour fast ($p<0.05$, n=12D; 13W animals). Also, seizure exacerbation generally correlates with decreased blood glucose levels ($p<0.05$; $p<0.001$, n=12D; 13W animals). To disambiguate the effects of hypoglycemia and hyperketonemia on SWDs, we monitored seizures following insulin injection, a manipulation that results only in the former. Insulin injection increased SWD occurrence ($p<0.05$, n=11D; $p<0.05$; n=9W). These data suggest that low glucose, not elevated

ketone bodies, modulates SWD occurrence. To support the above stated hypothesis, we directly inhibited glycolysis within somatosensory thalamus using 2-deoxyglucocse (2-DG). SWD count increased during 2-DG infusion ($p<0.05$; n=6W), thus demonstrating that thalamocortical (TC) SWDs are sensitive to glucose metabolism. Next, we performed cell-attached voltage-clamp recordings in acutely prepared thalamic brain slices to determine whether brief exposure to low glucose alters the intrinsic excitability of TC neurons. We observed a significant increase in the number of spikes and mean spike frequency ($p<0.05$; n=12W cells). We hypothesize that changes in TC neuron excitability are attributable to modulation of $GABA_B$ receptor activity in low glucose. Indeed, thalamocortical oscillations in sleep and epilepsy are dependent on $GABA_B$ receptor activity. Previous work demonstrates that p-AMPK interacts with the $GABA_B$ receptor, resulting in a potentiation of $GABA_B$-mediated IPSCs. To establish that this interaction is present in TC neurons, we performed voltage-clamp recordings and added AMPK activators to the internal solution. Baclofen (100μM) was puffed adjacent to the dendrites of the recorded neuron to evoke $GABA_B$-mediated currents. AMPK activators caused an attenuation of $GABA_B$-mediated current run-down ($p < 0.05$; n = 18W cells). Additionally, fasting increased p-AMPK expression in the thalamus, suggesting an increase in p-AMPK likely correlates with an increase in SWDs. Our future *in vitro* and *in vivo* experiments will further elucidate this mechanism. In sum, we demonstrate that glucose modulates thalamocortical excitability and SWDs. Our data support the hypothesis that diet can influence the occurrence of epileptic activity in the brain.

Title: Local synaptic connectivity of subicular pyramidal neurons sorted by multivariate analysis and its impact on population activity

Authors: *M. P. FISKE[1], M. ANSTÖTZ[1], G. MACCAFERRI[2];
[1]Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [2]Dept Physiol, Northwestern Univ., Chicago, IL

Abstract: The subiculum is a key area involved in temporal lobe epilepsy, and its local excitatory circuits have been suggested to be involved in the generation of various forms of epileptiform activity. Although it has now established by many studies that subicular pyramidal

cells exhibit distinct intrinsic excitability, to our knowledge only one study has examined the local connectivity between the distinct types of subicular pyramidal neurons classified as “regular firing” or “bursters” (Böhm et al., 2015). We have re-addressed pyramidal cell diversity with direct patch clamp recordings from subicular slices, classified by a combination of principal component analysis and Gaussian mixture models. Out of n=995 recorded cells, we observed variable proportions of what we term “type 1” and “type 2” cells (51.1% and 48.9%, respectively). When the intercellular relationships were examined, we found functional evidence for both homotypic (type 1 to type 1, n=29 and type 2 to type 2, n=34 synapses) and heterotypic synaptic connectivity (type 1 to type 2, n=25, and type 2 to type 1, n=7 synapses). Overall, the probability of finding a connection was roughly symmetrical for homotypic connections (type 1 to type 1, p=0.046, type 2 to type 2, p=0.052), whereas it was highly asymmetrical in heterotypical connections (type 1 to type 2, p=0.088, type 2 to type 1, p=0.025). The properties of the unitary excitatory postsynaptic potentials were also similar across connections (amplitude 0.54 mV), without obvious differences. In n=6 experiments we verified that uEPSPs were glutamatergic and fully blocked by the AMPA receptor antagonist NBQX (20 μM). When the anatomy of the connected pairs was examined at the light microscopy level, we observed putative contact sites that ranged in numbers between 1 and 9, and appeared consistently biased towards the basal dendrites of the postsynaptic cell (85.3% basal vs 14.7% apical). Lastly, we tested the influence of these local excitatory connections on population activity by recording from pairs of cells in slices surgically isolated from extra-subicular inputs and exposed to gabazine (12.5 μM) and CGP55845 (5 μM). In n=11 recordings, we found that blockade of GABAergic circuits allowed the development of synchronous epileptiform bursts (number of action potentials/burst=29.5, n=27 cells). In conclusion, our data suggest a complex cell type-specific connectivity of intrinsically diverse pyramidal neurons that can sustain, in the absence of GABAergic inhibition, epileptic-like hypersynchronous activity. Title: Dysplastic neurons mediate epileptogenesis in tuberous sclerosis complex

Authors: *L. S. HSIEH[1], L. NGUYEN[1], A. F. BORDEY[2];
[1]Neurosurg., Yale Sch. of Med., New Haven, CT; [2]Dept Neurosurg, Yale Sch. Med., New Haven, CT

Abstract: Disorders caused by mutations in the mTOR pathway genes, exemplified by Tuberous Sclerosis Complex (TSC), lead to mTOR hyperactivity, brain malformations, and life-long epilepsy in the majority of patients. While partially effective, surgical resection of seizure foci or pharmacotherapy with mTOR inhibitors are the only available treatments for epilepsy in TSC. A better understanding of epileptogenic mechanisms in the disease is therefore needed. Two modern hypotheses compete to explain the underlying mechanism of epileptogenesis in TSC. 1) the neuronal hypothesis implicates dysplastic neurons and their abnormal activity as the source of seizure activity. 2) the neuro-glial network hypothesis implicates a pathophysiological network of neuro-glial interplay that occurs outside of cortical tubers. To test whether dysplastic neurons mediates epileptogenesis, we located the seizure focus, measured excitability of dysplastic neurons, and tested the tunability of dysplastic neurons alone to modulate seizure severity in a mouse model of cortical tubers with spontaneous epileptogenesis. We found, after analyzing independent electroencephalographic recordings from each hemisphere that high frequency oscillations (HFOs), which denotes cortical seizure initiation sites, occurs in the tuber containing hemisphere before traversing to the contralateral hemisphere. We also found that dysplastic neurons express more sodium currents, can sustain longer bursts of regenerative firing, and are more depolarized than normal neurons in and outside of cortical tubers as well as in control animals. Furthermore, suppressing activity in the dysplastic neurons alone, with the expression of an exogenous inward-rectifier potassium channel Kir2.1, mitigates seizure activity. Finally, the escalation of neuronal dysplasia severity, i.e. larger cells and greater migration deficits, leads to greater seizure activity. Together these evidences suggest that dysplastic neurons mediate epileptogenesis in TSC.

Title: Sustained network activity prevents development of post-traumatic epilepsy

Authors: *O. C. GONZALEZ[1], S. SOLTANI[2], S. CHAUVETTE[3], G. P. KRISHNAN[1], I. V. TIMOFEEV[4], M. V. BAZHENOV[1];

Abstract: It has long been appreciated that traumatic brain injury is a common cause of acquired epilepsy. Post-traumatic epilepsy (PTE) remains to be a difficult disorder to treat as there can be a prolonged period of time during which epileptogenesis can arise following the initial brain insult. Indeed, it has been reported that epilepsy can develop up to 15 years after the occurrence of the brain trauma. The likelihood of developing epilepsy increases with age at the time of the trauma. Recent *in vivo* studies have shown that older animals were more susceptible to the development of epilepsy following cortical undercut as compared to younger animals. The mechanism that gives rise to PTE remains to be fully understood but may involve mis-regulation of synaptic weights through homeostatic synaptic scaling. In response to brain trauma, there is a reduction of network activity within and near the traumatized brain area. This reduction of activity triggers homeostatic up regulation of synaptic and intrinsic excitability in an attempt to recover normal levels of network activity. If trauma is severe, homeostatic scaling may overcompensate and increase synaptic weights such that the network is primed for transitions to hypersynchronized seizure states. In this new study, we tested the hypothesis that preventing homeostatic up-scaling of synaptic weights following cortical deafferentation could prevent epileptogenesis. Using a detailed biophysical model of the neocortex, we found that a sustained depolarization of the traumatized network was capable of preventing up-scaling of synaptic weights to a pathological state and thereby preventing occurrence of spontaneous recurrent seizures found in the model without depolarization mechanism. In contrast, a sustained hyperpolarization of the traumatized network resulted in increased homeostatic up-scaling, triggering a severe pathological state characterized by the occurrence of frequent spontaneous recurrent seizures. These findings from the computational model are in agreement with *in vivo* experiments in mice where cortical undercut was followed by activation of DREADDs (hM3DGq or hM4DGi) to alter baseline network activity around the undercut area. Together, these results provide evidence for the role of homeostatic synaptic scaling in the development of post-traumatic epilepsy and may provide new insights into novel treatments or preventative measures for trauma-induced epilepsy.

Title: Neuronal chloride loading triggers a cortical spreading depression

Authors: *R. R. PARRISH[1], R. T. JACKSON-TAYLOR[1], J. VOIPIO[3], A. J. TREVELYAN[2]; [1]Newcastle Univ., Newcastle, United Kingdom; [2]Newcastle Univ., Newcastle Upon Tyne, United Kingdom; [3]Univ. of Helsinki, Helsinki, Finland

Abstract: Cortical spreading depressions (CSDs) are characterized by a wave of neuronal and glial depolarization that results in a loss of neuronal membrane resistance. Generally, this leads to neuronal silencing that lasts for minutes following a CSD as this migrates through the brain at rates of around 4 mm per minute. These events occur in the brain following injury and are associated with migraines and seizures in experimental conditions. While we have a general understanding of the mechanisms contributing to the spread of CSDs, very little is known about the underlying cellular triggers. Experimentally, CSDs can be induced through an increase in extracellular K^+, electrical stimulation, and, more recently, with Channelrhodopsin to activate neurons. Importantly, the mechanism thought to be a key trigger to the induction of the CSDs in these manipulations is a pathological elevation in extracellular K^+. Using the optogenetic chloride-pump Halorhodopsin, we demonstrate that loading chloride into neurons can reliably trigger a CSD in acute slices (prepared from both male and female mice expressing Halorhodopsin either under the EMX or CaMKII promoter; CSDs arose ~33% of the time following a 90 sec activation of Halorhodopsin from 60 slices). Remarkably, these CSDs start before any increase in extracellular K^+, monitored using an ion-selective microelectrode. Notably, we do not see the same effect following activation of the proton-pump Archaerhodopsin, which achieves similar levels of neuronal hyperpolarisation (n = 12). In addition, Halorhodopsin can trigger CSDs in the presence of TTX, glutamate and GABA receptor blockers, and during blockade of the potassium chloride cotransporter KCC2. This leads us to hypothesise that the chloride-loading effect of Halorhodopsin is the critical trigger. These data suggest a dynamic role of chloride in the induction of CSDs, and we are actively investigating secondary consequences of this increased neuronal chloride. A complete understanding of the critical ionic and cellular triggers of a CSD could have enormous therapeutic benefits for various neurological disorders.

Title: Concurrent infraslow and high frequency recordings of pathological brain activity using arrays of graphene transistors in awake mice

Authors: *R. C. WYKES[1], E. MASVIDAL[2], T. M. SMITH[1], A. BONACCINI[3], X. ILLA[4], J. GARRIDO[3], A. GUIMERA-BRUNET[2];

Abstract: DC shifts and infraslow activity (ISA), frequencies < 0.1 Hz, are associated with pathological brain states including cortical spreading depression (CSD) and seizures. Recording ISA with microelectrodes is hampered by current electrode materials and technology due to limitations resulting from high electrode impedance and voltage drift. Few studies have attempted to investigate CSD or the involvement of ISA in seizure initiation and propagation in awake brain. A major limiting factor has been the absence of experimental tools that allow concurrent recordings of both ISA and high frequency activity associated with seizures. Graphene transistor arrays (gSGFETs) have demonstrated full-band recording capabilities due to the direct signal coupling on the transistor and from the electrochemical inertness of graphene (Masvidal-Codina, E et al Nature Materials, 2019). We report the ability of epicortical and flexible intracortical gSGFETs arrays for studying two types of pathological brain activities, CSD and seizures, in awake head-fixed mice. To study CSD we virally transduced cortical neurons in the motor cortex (M1/M2) of adult male c57bl/6J mice with channelrodopsin-2. An epidural 16 channel transistor array (1.6 x 1.6mm) was placed over somatosensory cortex. Continuous blue light stimulation (5-20s, 12mW), administered through the skull, induced in a wave of depolarisation propagating across the cortex at a speed of ~4 mm/min. With non-invasive and reproducible properties, optogenetic induction of CSD is highly suited for evaluating pharmacological agents capable of reducing CSD propagation. Chemoconvulsants (Picrotoxin 10 mM and 4-AP 50 mM) induced epileptiform activity and seizures and electrographic recordings made using either epidural or penetrating depth gSGFETs. DC shifts were frequently observed just before, at onset, or during seizures. Around 20% of seizures were followed by a post-ictal CSD. Additionally gSGFETs recorded cortical high frequency oscillations (HFO) ~200-300Hz. These novel devices permit recording concurrently ictal baseline shifts and HFOs, markers identified as useful in localising seizure onset zones. They may also aid in preclinical investigations examining the link between post-ictal CSD and sudden unexplained death in epilepsy (SUDEP).

Title: *In vivo* approaches to study seizure generation and epileptogenesis in SCN1A knock-in mouse models

Authors: J. C. BAHR, M. HARRER, U. B. S. HEDRICH, H. KOCH, H. LERCHE;
Hertie Inst. for Clin. Brain Res., Tuebingen, Germany

Abstract: Genetic epilepsies show a large variability in their clinical features, even if the same mutation segregates within a single family. One well-studied epilepsy gene is *SCN1A* which encodes the voltage-dependent sodium channel Nav 1.1, which is mainly expressed in GABAergic interneurons in the whole central nervous system (CNS). Mutations in this gene can cause the Dravet syndrome (DS), a pharmaco-resistant severe developmental and epileptic encephalopathy (DEE) with febrile seizures starting during early childhood, a high seizure frequency and a delayed development. Additionally, mutations in *SCN1A* cause the milder generalized epilepsy with febrile seizures plus (GEFS+). The most frequently detected genetic causes of these syndromes are loss-of-function (LOF) mutations in the *SCN1A* gene. Recent publications including from our own group, suggest that LOF is leading to epilepsy due to hypoexcitability of inhibitory neurons. Here, we tried to unravel the consequences of two known *SCN1A* mutations, one causing the mild GEFS+ and the other one the severe DS, on the network function *in vivo* using a knock-in mouse model for GEFS+ (Hedrich et al., 2014) as well as a conditional LOF knock-in mouse line expressing a DS-causing mutation in the presence of Cre. By using these mouse models, we were able to study (i) the appearance of thermally-induced generalized seizures by using ultra-flexible surface grids with high recording resolution and (ii) the critical time window and brain region for the development of specific phenotypes by injecting a *Cre*-carrying virus at a specific time point during development into particular brain regions for locally restricted expression of the mutation. Our results thus gain insight into the spreading of temperature-induced generalized seizures as well as underlying mechanisms during epileptogenesis. To experimentally elicit the beginning of febrile seizures in these mice, we tested different temperature ramps to heat up the surrounding of the animals. We did not find any differences in the velocity of the temperature increase, only in the maximum temperature needed to elicit the beginning of a febrile seizure. Since generalized seizures appear to start in all parts of the brain simultaneously and have no identifiable onset, we are currently working on the identification of the origin of the experimentally induced febrile seizures with the GEFS+ mouse strain. This study will help to shed light on the mechanisms underlying ictogenesis and cortical spreading depression to identify new treatment options for the affected patients.

Title: Seizure genesis broad spectrum dynamics in rodent epilepsy models

Authors: *D. E. EHRENS[1], F. ASSAF[2], N. J. COWAN[3], S. V. SARMA[4], Y. SCHILLER[5]; [1]Johns Hopkins Sch. of Med., Baltimore, MD; [2]Fac. of Med., Technion Israel Inst. of Technol., Haifa, Israel; [3]Dept. of Mechanical Engin., [4]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [5]Technion Med. Sch., Haifa, Israel

Abstract: A third of epilepsy patients are pharmacologically intractable and must consider invasive alternatives such as resective surgery and neural electrical stimulation. Current stimulation strategies attempt to suppress seizures once they have initiated, but none aim to prevent the seizure from initiating altogether. For this, reliable detection of a neurophysiological state leading to seizure initiation (preictal state) is needed in order to apply the proper electrical stimulation waveform and drive the epileptic network away from entering a seizure state. Using two different electrographical seizure models in rodents (4-AP, Kainic Acid), LFP and MUA activity was recorded to characterize the progression in neural activity leading to seizure onset in the spectral domain. Spectral analysis was performed on a broad power spectrum (4-1000 Hz) divided into 15 different bands. Showing increased activity in frequencies above 500 Hz before seizure onset. Singular values from correlation matrices were computed to track the degree of correlation as the seizure onset approached. Results indicate a progressively increasing correlation between higher frequency bands (>500 Hz) preceding seizure initiation that drops at seizure onset. This results demonstrate that correlation in the high frequencies can be used by closed-loop systems for detection of a preictal state and prevention of seizure genesis.

Title: All or nothing change in network excitability immediately before the transition into an ictal event

Authors: R. GRAHAM, L. ALBERIO, R. PARRISH, ***A. J. TREVELYAN**;
Newcastle Univ., Newcastle upon Tyne, United Kingdom

Abstract: *Understanding the nature of epileptic state transitions remains a major goal for epilepsy research. Simple in vitro models offer unique experimental opportunities for exploring these issues.* Bathing brain slices in $0Mg^{2+}$ artificial cerebrospinal fluid (aCSF) induces an evolving pattern of epileptiform activity, including short interictal bursts of activity, and sustained discharges that replicate many features of tonic-clonic seizures in vivo. Removing Mg^{2+} ions from the bath provides a rapid enhancement of glutamatergic excitatory synaptic effects, and yet the evolution of epileptic activity occurs over a far slower time frame. These network changes therefore, cannot be ascribed simply to the NMDA effect, but rather, involve dynamic reorganisation of the network. We used an optogenetic approach, using cell-class specific expression of Channelrhodopsin to selectively stimulate one of three different subclasses of neurons, namely pyramidal cells, and parvalbumin-positive (PV+) and somatostatin-positive (SOM+) interneurons. We then monitored progressive changes in the postsynaptic effect downstream of the activated neuronal population, and related that to the network excitability. Brief optogenetic activation (10ms flashes, delivered at <0.1Hz, close to the recording location through an optic fibre connected to an LED. The postsynaptic effects of pyramidal activation was monitored using parallel extracellular electrodes in layers 2/3 of neocortex, and stratum radiatum of CA1 in hippocampus. Postsynaptic interneuronal efficacy was monitored by voltage clamp recordings of pyramidal cells downstream of activated interneurons. We found clear changes in all three synaptic pathways associated with the evolving activity. Critically, we demonstrate a sudden, irreversible transformation of the excitatory post-synaptic potential minutes before the onset of an ictal event in the local tissue. This provides a key insight into a sudden, all-or-nothing transformation in network excitability, that is a key stage in ictogenesis. *Funded by Newcastle University PhD program and MRC (MR/R005427/1)*

Title: Corticocortical evoked potentials reveal epileptogenic network and locate epileptogenic zone

Authors: *K. SUN[1], L. WANG[2], W. WANG[1];
[1]Sch. of Syst. Science,Beijing Normal Univ., Beijing, China; [2]Inst. of Psychology, Chinese Acad. of Sci., Beijing, China

Abstract: It is gradually recognized that epilepsy is a neural network disease involving both epileptogenic brain areas and normal brain areas. Despite many approaches based on time series analysis of seizure signals, the network structure and mechanisms underlying the process of seizure propagation is elusive. Here study epileptogenic networks based on cortico-cortical evoked potentials (CCEP) that capture direct electrical responses among Intracranial electrodes and map an incentive-response neural network. Our purpose is to reveal the relationship between CCEP and epileptogenic propagation networks, and explore the potential function of CCEP on locating seizure zone. Specifically, we recorded seizure signals and construct CCEP networks of 12 patients by stereotactic-EEG. We found (i) when exclusively stimulating epileptogenic zone, the responses of epileptogenic zone have significantly higher amplitudes and root-mean-square (RMS) than those in outside zones, i.e., propagation zone and non-involved zone; (ii) when stimulating all electrodes in different zones, the overall responses of epileptogenic zone have significantly higher amplitudes and RMS than the other two zones. The finding (i) and (ii) can help to recover epileptogenic networks and locate epileptogenic zone, respectively. Our findings have potential to support better diagnosis and treatment of epilepsy.

Title: Functional mapping of frontal motor seizures

Authors: *A. BRODOVSKAYA[1], S. SHIONO[1], J. WILLIAMSON[1], J. KAPUR[2];
[1]Neurol., Univ. of Virginia, Charlottesville, VA; [2]Dept Neurol., Univ. Virginai Hlth. Sci. Ctr., Charlottesvle, VA

Abstract: Motor seizures are dangerous because they increase the risk of injury and sudden unexpected death in epilepsy (SUDEP). However, circuits that underlie these seizures have not been fully described.
We used TRAP (Targeted Recombination in Active Populations) technology that utilizes the promoter region of immediate early genes (IEGs) to drive the expression of tamoxifen-dependent $CreER^{T2}$, so that only neurons that express IEGs are labeled with tdTomato. To initiate frontal motor seizures, we implanted 1.7 mg of cobalt wire in the secondary motor cortex of TRAP mice. For track tracing, we injected AAV9-GFP virus two weeks prior to Co insertion. For temporal resolution of the seizure spread, we recorded local field potentials (LFP) with microelectrodes.
We hypothesized that seizure spread follows the anatomical connections from the focus. Seizures spread rapidly to the contralateral premotor cortex, faster than ipsilateral somatosensory cortex (5 sec delay, 0-10.5 sec, n=8, $p<0.001$). Callosal pyramidal neurons were activated during seizures as demonstrated by colocalization of GFP and tdTomato in the corpus callosum and layer 2/3 pyramidal neurons. To characterize spread from motor to somatosensory cortex, we quantified tdTomato expression using cortical layer markers (n=6). Focal seizures consistently engaged layer 2/3 of posterior somatosensory cortex (100%, 50-100%, p=0.002) but not layer 5/6 (71.4%, 0-85.7%, p=0.002). Posterior layer 5/6 was engaged later than 2/3 during generalized seizures (5 sec delay, 0-10.5 sec, n=8, $p<0.001$). Premotor onset seizures also traveled through striatum, globus pallidus, and substantia nigra reticulata as indicated by the tdTomato expression and LFP recordings. Electrophysiological recordings also indicate that seizure spread to the contralateral cortex was faster than to contralateral thalamus.
Our results delineate a more complex neuronal network activated by motor seizures than previously proposed thalamocortical circuit.

Title: Evoked assay of neural circuit function with microelectrode array (MEA) technology and *in vitro* cell culture models

Authors: *D. C. MILLARD, A. M. NICOLINI, C. A. ARROWOOD, **H. B. HAYES**, S. A. CHVATAL;
Axion Biosystems, Atlanta, GA

Abstract: Microelectrode arrays (MEAs) monitor and manipulate cultured cell activity *in vitro*, providing insight into neuronal network interactions to inform "disease-in-a-dish" models, stem cell characterization, toxicology screening, and drug safety and development. Recently-developed multiwell MEA systems enable high-throughput assessment of functional endpoints at greatly reduced time and cost. Activity, Synchrony, and Oscillation endpoints quantify the functional behavior of neurons, synapses, and networks. However, spontaneous neural network activity may vary across wells within a plate or across model systems. Here, we describe an evoked assay of neural circuit function, providing complementary information to spontaneous endpoints, using pairs of stimuli with varying interstimulus interval via electrical or optogenetic stimulation. The paired stimulation quantified the balance of excitation and inhibition in the network, by comparing the response to a second stimulus relative to the first as a function of the interstimulus interval. Measures of evoked neural response for single and paired stimulation protocols were used to quantify changes in activity induced by pharmacological manipulation with 12 compounds, including proconvulstants, anti-epileptic drugs, and negative controls. These findings demonstrate the potential of evoked assays to characterize neural circuit function *in vitro* for applications in safety pharmacology, toxicology, stem cell model development and validation, and "disease-in-a-dish" models.

Tübingen, Tübingen, Germany; [4]Cell Biol. of Neurolog. Dis., German Ctr. for Neurodegenerative Dis. (DZNE), Tübingen, Germany

Abstract: Investigation of pathophysiological mechanisms of human CNS disease, such as epilepsy or neurodegenerative disorders, mostly relies on studies based on human post mortem or biopsy/surgery tissue and on studies using animal models, cell culture or heterologous expression systems. However, it frequently remains elusive whether such data can be translated to the human brain. Development of strategies relying on live human CNS tissue could offer a promising step toward bridging this gap. We present the development of a model system based on human organotypic cortical slice cultures derived from spare access tissue of epilepsy surgery. Extensive studies were performed to quantify the stability of function and morphology of human pyramidal neurons within human cortical slice cultures. Proof-of-concept experiments involving viral transduction demonstrate the feasibility of genetic manipulation of human neurons within cultures. Our data reveal sustained cortical neuronal survival up to several weeks, both on single neuron and on network level, including maintenance of action potential generation, synaptic connectivity and presence of tonic and phasic network activity. Biocytin fillings and virus driven overexpression of GFP were applied toward high-resolution 3D morphological assessment of human pyramidal neurons demonstrating robust preservation of characteristic complex neuronal cytoarchitecture. Comparative analysis of both approaches validates genetic labeling as an efficient tool toward detailed morphological studies of relatively large quantities of adult human neurons per tissue sample, providing a valuable alternative to classic single cell biocytin fillings. Combinations of the described model system with state-of-the-art technology including viral transduction of human neurons, high-resolution confocal and two-photon microscopy together with electrophysiological approaches are applied toward the goal of validating data from non human model systems and to translate such data to the human brain. The focus of interest of ongoing and future studies includes investigation of plasticity mechanisms of human neurons, the impact of epilepsy-causing mutations on the excitability of human neurons and neuronal networks as well as dissection of human cortical circuitry.

Genet., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Objective Approximately 1% of the world population suffers from epilepsy, a neurological disorder characterized by repeated seizures. The degree and symptoms of the disease differ significantly among patients, resulting in the need for further characterization of the specific patient-centered epileptic pathophysiology. Recent advances in tissue engineering enable the development and use of genetically modified cerebral organoids as a unique platform for investigating these patient-specific analogues. Point mutations and deletions in the WW domain-containing oxidoreductase (WWOX) gene result in one such analogue, associated with severe neurological disorders and epilepsy in both rodents and humans. By exploring the phenotypic electrophysiological changes in WWOX-deficient organoids, this research sheds light onto the WWOX-related epileptic encephalopathy (WOREE) and other epilepsy disorders.
Methods Cerebral organoids were generated using both hEPC and iPSC lines, matured to 70-80 days, and prepared for electrophysiological recordings. Organoids were sliced into 300-micron thick slices and incubated in artificial cerebrospinal fluid at 37 degrees. A recording electrode was inserted into various layers of the organoid structure to record local field potentials (LFPs). A stimulating electrode was used to assess excitatory responses, while 4-aminopyridine (4-AP) was added to the incubating media to enhance spontaneous-epileptiform currents.
Results Early results from both WWOX-KO (generated by CRISPR/CAS9) and control organoids show evoked and spontaneous extracellular activity, with WWOX-KO being more active than control. Both WWOX-KO and control organoids showed increased slow wave activity upon application of 4-AP. Several metrics of excitability, including spectral power and frequency of seizure-like events were evaluated and contrasted between all groups of organoids, highlighting WWOX-dependent changes in both spontaneous and chemically-evoked

excitability.
Significance Acute recordings of LFPs from cerebral organoids validate their electrical connectivity and viability for assaying their physiological function. Observed differences in the electrophysiological activity of organoids with WWOX deletions present a unique opportunity to study the developmental effects of WWOX on epileptogenesis. We are now developing an organoid-based high-throughput drug screening platform for assessing various putative treatments of epilepsy syndromes in personalized, patient-derived cerebral tissue to target intractable epilepsy.

Abstract: The mammalian brain is complex, with multiple cell types performing a variety of diverse functions, but exactly how the brain is affected with aging remains largely unknown. Here we performed a single-cell transcriptomic analysis of young and old mouse brains. We provide a comprehensive dataset of aging-related genes, pathways and ligand-receptor interactions in nearly all brain cell types. Our analysis identified gene signatures that vary in a coordinated manner across cell types and gene sets that are regulated in a cell type specific manner, even at times in opposite directions. Thus, our data reveal that aging, rather than

inducing a universal program, drives a distinct transcriptional course in each cell population. These data provide an important resource for the aging community and highlight key molecular processes, including ribosome biogenesis, underlying aging. We believe that this large-scale dataset will facilitate additional discoveries directed towards understanding and modifying the aging process.

Abstract: Aging of the brain is a cause of cognitive decline and the major risk factor for neurodegenerative diseases, such as Alzheimer's disease. Epigenetic noise has been highly implicated in both aging *per se* and cognitive impairment. In order to delineate the role of epigenetics in brain aging, we are investigating three mouse models, ICE, NICE, and NASA, to evaluate age-related cognitive decline due to different DNA damage responses, as compared to normally aged C57/B6J wild-type mice. The novel ICE mouse has whole-body inducible changes in the epigenome, whereas the NICE mouse has neuronal-specific inducible changes in the epigenome, with both ICE and NICE models using the homing endonuclease I-*Ppo*I to induce tissue- and time-specific non-mutagenic, site-specific double-strand DNA breaks. The NASA mouse has been irradiated with 30 cGy over a sequential exposure to 6 different beams to

mimic the deep-space cosmic radiation damage that astronauts are exposed to during spaceflight. Using a battery of physiological and cognitive tests, our results thus far demonstrate that 15 month-old ICE and NICE mice show cognitive impairments similar to that found in 24 month-old C57 mice. Specifically, Barnes maze results demonstrate that ICE and NICE mice under-perform with regards to memory recall, compared to age-matched Cre controls, and more closely resemble memory deficits in aged C57 animals. In the elevated plus maze, both ICE and NICE mice spent more time in and actively sought out the open arms suggesting a decrease in thigmotaxis and anxiety. Open-field testing in ICE and NICE mice showed an increase in time spent in the center of the arena, a finding confirmed also in aged C57 mice. Interestingly, although no major impairments in spatial working memory were detected with the Y-maze in ICE mice, NICE mice did present with deficits similar to that found in aged C57 mice. Additionally, using frailty index testing, we found that ICE, but not NICE mice, present with advanced aging phenotypes more akin to those found in aged C57 mice. Immunohistochemical studies thus far indicate a change in gliosis with an increase in activated microglia, but no increase in neurodegeneration in ICE and NICE mice. Preliminary studies using the NASA mice suggest an increase in aging phenotypes as well as changes in thigmotaxic behavior that mirror ICE, NICE, and aged C57 mice. Ongoing studies aim to elucidate how different types of DNA damage can elicit chromatin remodeling and neuronal functional changes, which may identify treatment strategies for age-related diseases and disorders of the brain.

Abstract: Human DNA-methylation data have been used to develop highly accurate biomarkers of aging ("epigenetic clocks"). Recent studies demonstrate that epigenetic clocks for mice (Mus

Musculus) can be developed. Epigenetic clock studies in mice have revealed that epigenetic aging can be slowed by gold standard anti-aging interventions such as calorie restriction and growth hormone receptor knock-outs. Here we present a novel epigenetic clock based on over 600 mouse tissue samples from across the entire lifespan (3 weeks old to 30 months old). Methylation levels were assessed using a highly robust Infinium array platform: 38k probes from the HorvathMammalMethyl40 chip. The resulting pan tissue mouse clock stands out in terms of its high reproducibility across different data sets and mouse strains. Moreover, we begin to correlate the DNA methylation changes to transcriptomic changes in a specific brain region (i.e. the striatum). Huntington's disease (HD) has been found to be associated with epigenetic age acceleration in human brain samples. It is not yet known whether epigenetic age acceleration can also be observed in tissues from mouse models of Huntington's disease. We apply our new mammalian epigenetic clock to address the question whether HD accelerates epigenetic aging in different tissues (striatum, cortex, liver, blood, cerebellum) of the Q175 knock-in model of HD. We compared age- and sex-matched HD mice to wildtype controls and observed that HD is associated with significant age acceleration in mouse cerebellum (p=0.002), striatum (p=0.016), and liver (p=0.01). In summary, our study demonstrates that Huntington disease is associated with accelerated epigenetic age acceleration in mice.

Abstract: In the past century, life expectancy has increased dramatically, and we do not yet understand how this may impact the brain, including at the level of gene expression. Aging is the main risk factor for neurodegenerative disease, yet the molecular underpinnings of resiliency and decline are unknown. Epigenetic mechanisms may play important roles in the aging brain. Histone deacetylases (HDACs) are epigenetic enzymes that regulate gene expression via chromatin modification. Preclinical and postmortem studies have demonstrated HDAC- related alterations with age in brain regions relevant for cognition and neurodegeneration, however, until now, nothing has been known about HDAC levels in the living human brain across the lifespan. Using [^{11}C]Martinostat, for positron emission tomography (PET) to measure HDACs in the living human brain, we observed an increase in [^{11}C]Martinostat uptake in healthy individuals with age. The increase localized to white matter (*n*=41, age 18-79; 20 females, 21 males; voxel-wise analysis correlating standard uptake value normalized to whole brain mean with age, controlling for sex and brain volume; $P_{FWE} < 0.05$; Gilbert and Zurcher et al., in submission). [^{11}C]Martinostat uptake negatively correlated with white matter microstructure measured by general fractional anisotropy, derived from simultaneously acquired diffusion imaging (Spearman's r= -0.37, *P*= 0.018). HDAC expression also localized to specific white matter tracts negatively correlated with social cognition in a subset of individuals assessed with the Mayer-Salovey-Caruso Emotional Intelligence Test (MSCEIT) (*n*= 23, age:23-79,12 females, 11 males, $P_{cluster} < 0.05$) Using imaging findings to guide biochemical analyses, we identified increases in HDAC1 and HDAC2 protein levels as drivers of the increase in [^{11}C]Martinostat uptake in older compared to younger donor periventricular white matter (*n*= 9 each group, mean ages 85±8 and 18±1 years; sex matched; three replicates; two-tailed unpaired *t*-test, false discovery rate (FDR) corrected for multiple comparisons; HDAC1: *P*= 0.022 and P_{FDR}= 0.031, HDAC2: *P*= 0.018 and P_{FDR}= 0.29). HDACs 1 and 2 are critical for oligodendrocyte differentiation and in rodents become dysregulated with age, resulting in failed re-myelination. We initiated a program to identify cell-types related to increased HDACs and will ultimately measure age-associated transcriptional change. Our work suggests that HDACs may become altered across the lifespan in relation to decreased white matter structural integrity. These data carry implications for neurodegenerative disease and will help further stratify HDACs as therapeutic targets.

Title: Recurrent herpes simplex virus type 1 infection modulates aging-related epigenetic markers in mouse brains

Authors: *G. NAPOLETANI[1], M. E. MARCOCCI[1], V. PROTTO[2], A. T. PALAMARA[1,3], G. DE CHIARA[2];

Abstract: Aging is one of the major risk factors for Alzheimer's disease (AD). At the brain level, this process is characterized by a slow, time-dependent change of multiple physiological functions and cognitive decline. Genome instability, together with changes in gene expression, driven by epigenetic imbalance, are the main features of neuronal senescence. Recent data from our group showed that recurrent Herpes Simplex Virus 1 (HSV-1) infection in mice induces an accumulation of AD hallmarks, including amyloid-β and tau hyperphosphorylation, paralleled by irreversible cognitive deficits. In this scenario, we hypothesized that recurrent HSV-1 infection may also accelerate the normal brain aging, by affecting epigenetic mechanisms. To verify this hypothesis, we evaluated the levels of specific aging hallmarks, such as histone 3 deacetylation (i.e., at H3K56), in mouse experimental models of acute and recurrent virus infection. We also analysed the expression of two key epigenetic regulators, such as Sin3/HDAC1 complex, and the histone chaperone HIRA, both involved also in the regulation of HSV-1 life-cycle and viral-host interaction. To these aims, entorhinal cortex homogenates from HSV-1- and Mock-infected BALB/c female mice were analysed in western blot for H3K56 acetylation, and HIRA and

Sin3/HDAC1 expression. A group of mice was analysed 4 days post primary infection (dpi), whereas the others were subjected to multiple thermal stress (TSs) every 6 weeks, to induce repeated virus reactivations. 5 mice for group were sacrificed after the 3rd and the 7th TS. A group of 4 mice were sacrificed just before the 7th TS (during latent infection). The virus presence in the brain was assessed by molecular analysis of viral gene/protein expression as well as by virological methods. We found that TS-induced virus replication caused in mouse brain a significant decrease in H3K56 acetylation ($p<0,05$ post-3TS; $p<0,01$ post-7TS) as compared to those observed in Mock-infected mice, suggesting that the infection impairs the histone acetylation process. Accordingly, we found a significant increase in Sin3/HDAC1 protein expression levels with respect to matched Mock-infected mice, starting from 4 dpi ($p<0,05$). A similar increase was observed following 7 TSs ($p<0,05$). Notably, these effects, together with a significant increase in HIRA protein levels, were found also in those mice sacrificed before the 7th TS, indicating that epigenetic imbalance may persist over time. Overall these data strongly suggest that recurrent HSV-1 infection enhances cellular epigenetic aging and may widely affect the epigenetic landscape in mice.

Title: Exceptionally long-lived proteins as pillars of mitochondrial architecture in mammalian brains

Authors: *E. BOMBA-WARCZAK, J. N. SAVAS;
Northwestern Univ., Chicago, IL

Abstract: Aging is a major risk factor for a host of diseases, including cancer, cardiovascular disorders, and neurodegenerative diseases. Currently available data suggests that an accumulation of mitochondrial damage together with an age-dependent decline in protein degradation activities are likely to play a key role in aging. In fact, mitochondrial dysfunction represents a point of convergence for a number of adult-onset neurological disorders. Yet, the precise mechanism behind mitochondrial contribution to the pathology of these conditions remains unknown. In our previous research, we identified proteins with exceptionally long life

spans that we termed extremely long-lived proteins, or ELLPs. Due to their persistence, ELLPs likely accumulate damage and are thus a potential point of vulnerability in an organism's fight against aging. This is especially vital for post-mitotic cells, such as neurons, which cannot dilute the macromolecular damage through cell division. Interestingly, we found that a small fraction of the brain mitochondrial proteome lasts the entire lifetime of a mouse. We propose to investigate the role that these newly identified mitochondrial ELLPs (mito-ELLPs) play in the processes of aging in the brain. We will characterize the mitochondrial long-lived proteome by integrating metabolic stable isotope pulse-chase labeling, advanced proteomic analysis, live cell fluorescent imaging, and *in vivo* mouse aging experiments. This research provides a rare opportunity to obtain a previously inaccessible understanding of mitochondrial contribution to the process of aging and the mechanisms causing age-related neurological disorders. Insights from this research could lead to novel targets for potential therapeutic interventions for a myriad of age-related disorders.

Title: Extracellular vesicles in the adult murine brain: When heterogeneity reveals a different neuropathological potential

Authors: *P. D'ACUNZO[1,2], T. HARGASH[1], C. N. GOULBOURNE[1], M. PAWLIK[1], R. PEREZ-GONZALEZ[1,2,5], E. LEVY[1,2,3,4];

Langone Hlth., New York, NY; [5]Dept. of Neurol., Hosp. de la Santa Creu i Sant Pau, Ctr. for Networked Biomed. Res. on Neurodegenerative Dis. (CIBERNED), Barcelona, Spain

Abstract: Extracellular vesicles (EVs) are nanoscale-sized vesicles that are released by cells and are thought to be key factors in intercellular communication. Historically, two main EVs subtypes have been characterized: microvesicles, which bud directly from the plasma membrane, and exosomes, which have an endosomal origin and are released upon fusion of the late endosomes/multivesicular bodies with the plasma membrane. More recently, it was postulated that different subsets of microvesicles and exosomes might exist. We hypothesized that these subpopulations carry different cargos and likely have specialized functions, giving new

perspective into cell-to-cell communication both in physiology and pathology of the brain. However, the lack of valuable methods and markers to diversify these subtypes impinged on their characterization.
Herein, we describe a new high-resolution, density-based method to fractionate the small EVs isolated from 12-month-old murine brains. Combining cryogenic electron microscopy, morphometric properties, and biochemical markers, we provide an extensive characterization of eight different EVs fractions. While microvesicles appear electron-lucent, bare polarized membrane micro-domains and are preferentially restricted to low-density fractions, exosomes show electron-dense granularity and are mostly found in average-to-high density sections. We demonstrate that at least two different exosome subclasses are present in the murine brain and that they differ in their content of the full-length amyloid precursor protein and of its neurotoxic metabolites implicated in Alzheimer's disease pathology. These data suggest the existence of brain exosomal-subtypes with different neuropathological roles. We also demonstrate for the first time the presence of a previously unidentified high-density EVs subset bearing no known microvesicles or exosomes markers.
In summary, here we show an extensive characterization of the murine brain EVs subpopulations and provide evidence that different exosome subgroups have specialized roles *in vivo*. We also show that cryogenic electron microscopy is a valuable (yet not fully explored) method to shed light on EVs heterogeneity.

Title: Arc content in blood circulating extracellular vesicles as a biomarker of memory-related plasticity in a rat model of aging

Authors: P. MORENO-CASTILLA, E. L. RIVERA, L. M. WANGLER, J. M. LONG, *P. R. RAPP;
Neurocognitive Aging Section, NIH, Natl. Inst. on Aging, Baltimore, MD

Abstract: The activity-regulated cytoskeleton-associated protein (Arc) is an essential coordinator of synaptic plasticity important for cognition that has a highly dynamic expression in

the brain. Arc expression in brain peaks rapidly at sites of local synaptic activity and is cleared in a short time course. Interestingly, we previously found that aged rats with spatial memory impairment have increased basal Arc protein levels in hippocampus and fail to induce Arc expression following behavioral training. These findings point to dysregulation of Arc protein homeostasis as a potentially important contributor to age-related cognitive decline. Other studies have revealed that Arc protein and mRNA are intercellularly transferred by self-assembling into capsid-like structures that are released from neurons in extracellular vesicles (EVs). Brain-produced EVs readily cross the blood brain barrier, and accordingly we hypothesized that blood circulating Arc-EVs might be coupled to the Arc synthesis and turnover in active neuronal circuits and thus predict memory dysfunction in aging. To test this hypothesis, we used an established model of cognitive aging in which aged Long-Evans rats are categorized as impaired (AI) or unimpaired (AU) relative to young, based on their spatial learning and memory capacities. Plasma EVs were isolated under basal conditions and after memory-induced activation of relevant neural networks using a task in which animals distinguished a novel odor from a familiar one, after a short (30 min) or a long delay (24 h). Young rats with good memory showed increased levels of Arc-EVs after the 90 min long-term memory test compared to baseline, but not after the short-term memory test. We also found increased basal levels of Arc-EVs in aged rats with memory impairment, together with a loss of the memory-dependent increase in Arc-EVs observed in young rats. Our results suggest that the activation of neural circuits can be detected in plasma Arc-EVs and serve as a peripheral biomarker of memory dysfunction in aging.

Title: Age-dependent expression of neurodegeneration-causing antimicrobial peptides

Authors: *L. E[1], N. PUJOL[3], D. YAN[2];
[1]Duke Univ., Durham, NC; [2]Duke Univ., Chapel Hill, NC; [3]Ctr. d'Immunologie de Marseille-Luminy, CIML, Aix Marseille Univ., Marseille, France

Abstract: Antimicrobial peptides (AMPs) are part of the innate immune defense mechanism in response to infections. Recent studies have suggested a link between AMPs and neurodegenerative diseases, such as Alzheimer's disease. Previously, using *C. elegans* as a model we revealed a causative role of an epidermially-expressed AMP, neuropeptide-like protein 29 (NLP-29), in triggering aging-associated neurodegeneration, by binding its specific receptor on neighboring neurons to transduce autophagy-mediated degeneration signals. We also discover that NLP-29 expression level significantly increases with age in wild-type animals. Finding the mechanisms underlying this age-dependent increase will therefore be crucial in identifying the root causes of aging-associated neurodegeneration mediated by AMPs. Here, we show that in *C. elegans* the age-dependent expression of NLP-29/AMP requires the DCAR-1/GPCR - TIR-1/SARM - PMK-1/p38 MAPK innate immune signaling, partially sharing the same pathway in response to infections. In addition, NIPI-3, whose mammalian homolog Tribbles has been implicated in Parkinson's disease, plays a critical role in the upstream regulation of TIR-1 - PMK-1 signaling and subsequent production of NLP-29 during aging. Epidermis-specific overexpression of NIPI-3 can induce an early-onset degeneration of epidermis-neighboring neurons by overproducing NL-29. Interestingly, NIPI-3 expression level also significantly increases with age in wild-type animals. Surprisingly, the DAF-2/IGF-1R - DAF-16/FOXO1/2/4 classic aging signaling is not involved in regulating the age-dependent expression of NLP-29 or NIPI-3. DAPK-1/death-associated protein kinase 1 is a negative regulator of NLP-29 expression via interaction with TIR-1 - PMK-1 signaling. We find that in wild-type animals the ratio of NIPI-3 and DAPK-1 expression levels strongly and positively correlates with NLP-29 expression level during aging. Moreover, epidermal overexpression of DAPK-1 provides neuroprotective effects by substantially delaying the onset of aging-associated neurodegeneration. Our data suggest that the aging-associated imbalance of non-neuronal immune signaling networks functions as a trigger for AMP-mediated neurodegeneration, and provide exciting insights for the root causes of aging-related neurodegenerative diseases.

Title: Contribution of chaperone-mediated autophagy malfunctioning to aging and neurodegeneration

Authors: *M. BOURDENX[1], J. A. RODRIGUEZ[1], H. R. MONDAY[2], I. TASSET[1], A. DIAZ[1], P. E. CASTILLO[3], A. CUERVO[1];

[1]Developmental and Mol. Biol., [2]Neurosci., Albert Einstein Col. of Med., Bronx, NY; [3]Albert Einstein Coll Med., Bronx, NY

Abstract: Neuronal protein quality control decreases with age increasing the risk of neurodegenerative diseases. The contribution of different types of autophagy in the clearance of toxic neurodegeneration-related proteins is well documented. We are interested in the dual interplay of a selective form of autophagy, chaperone-mediated autophagy (CMA), with neurodegeneration-related proteins. Previous results have shown a direct toxic effect of these proteins on CMA. In addition, during physiological aging, lysosomal levels of LAMP-2A, the rate limiting component for CMA, decrease, leading to a slower activity of the pathway. However, the contribution that reduced neuronal CMA with age may have in the progression of neurodegenerative diseases remains unknown. In this work we have investigated: (i) first, if LAMP-2A knockout in neurons induces changes in neuronal proteostasis similar to those observed in aging, thus accelerating disease progression in a neurodegeneration disease context; (ii) second, if maintaining LAMP-2A levels throughout life-span slows down the progression of age-related neuronal impairments. Using a combination of mouse lines with knock-out or knock-in of LAMP-2A specifically in neurons, we have found that blockage of neuronal CMA induces behavioral impairments, alterations of neuronal physiology, changes in the neuronal proteome and protein aggregation reminiscent of brain aging. Conversely, maintaining LAMP-2A levels throughout life reduces age-associated behavioral impairments and protects neurons from age-related dysfunction. We are currently investigating the molecular mechanisms underlying the deleterious effect of CMA deficiency as well as the beneficial effect upon restoration of neuronal CMA activity in old mice.

Title: Vimentin protects neural stem cells from a loss of proteostasis

Authors: *C. S. MORROW, T. J. PORTER, C. XU, K. AKO-ASARE, H. H. HEO, D. L. MOORE;
Univ. of Wisconsin - Madison, Madison, WI

Abstract: Maintaining proteostasis, the balance between the synthesis and degradation of protein, is essential for neural stem cell (NSC) function and is lost with aging, leading to stem cell dysfunction. In many cell types, the intermediate filament vimentin reacts to a loss of proteostasis by becoming upregulated and collapsing to form cages around aggregated proteins residing in the nuclear bay in a structure called the aggresome. Despite knowledge of vimentin's presence at the aggresome for over twenty years, vimentin's role at the aggresome remains unclear. We used CRISPR/Cas9 to generate mouse NSCs that have vimentin tagged with the fluorophore mNeon or vimentin knocked out (KO). Vimentin-mNeon NSCs confirm that NSCs form aggresomes surrounded by vimentin cages. Vimentin KO NSCs are able to make aggresomes, but demonstrate a reduced capacity to recover from a loss of proteostasis. Taken together, our data suggests that vimentin is critical for proper aggresome function and suggests a critical role for vimentin in protecting NSCs during aging.

Title: Effects of reducing eEF2 phosphorylation via eEF2K deletion on cognitive impairments in aged mice

Authors: *S. GOSRANI[1], H. JESTER[1], X. ZHOU[2], T. MA[2];
[1]Neurosci., [2]Intrnl. Medicine, Geriatrics and Gerontology, Wake Forest Sch. of Med., Winston Salem, NC

Abstract: The normal aging process is commonly associated with a decline in learning and memory function. Currently, a treatment to alleviate such cognitive deficits does not exist. As the aging population increases, there is a growing need to develop novel therapies for cognitive

decline. It has been established that *de novo* protein synthesis is an integral process in long-term memory formation and synaptic plasticity. Eukaryotic elongation factor 2 (eEF2) is a crucial modulator of mRNA translation, mediating the translocation step of elongation. eEF2 is tightly regulated by its only known kinase, eEF2 kinase (eEF2K), and phosphorylation of eEF2 (by eEF2K) inhibits its activity, hindering *de novo* protein synthesis. We have previously shown that knockdown of eEF2K in mouse models of Alzheimer's disease (AD) alleviates AD-associated cognitive deficits. Here, we seek to determine whether cognitive deficits in aged mice (19-22 months old) can be improved by genetically deleting eEF2K (eEF2K KO) and thus reducing eEF2 phosphorylation. Multiple behavioral tasks were applied to evaluate cognition including hidden platform Morris water maze (MWM) and novel object recognition (NOR). We found that performance of eEF2K KO mice in these cognitive tasks was not significantly different from that of WT littermates. Additionally, deletion of eEF2K did not alter *de novo* protein synthesis in the hippocampus, as assessed by SUnSET assay. Collectively, these results provide preliminary evidence that removal of eEF2K does not improve cognitive deficits or *de novo* protein synthesis in aged mice.

Title: Temporal reduction in proteasome activity results in irreversible protein aggregation in *Drosophila melanogaster*

Authors: *T. SCHMIDT-GLENEWINKEL[1], C.-H. YEH[1], V. VERNACE[2], M. JANSEN[1], J. GAO[1], M. FIGUEREIDO-PEREIRA[1];
[1]Biol. Sci., Hunter Col. and Grad. Ctr. of CUNY, New York, NY; [2]Hlth. and Natural Sci. Dept., Goodwin Col., East Hartford, CT

Abstract: The ubiquitin-proteasome system and autophagy have an important role in the control of protein turnover in eukaryotic cells. In a previous study, we have investigated proteasome activity and ATP levels as part of an aging study in Drosophila melanogaster. We found a sharp

decline in both genders of about 50% ATP levels as well as a sharp decrease in the 26S proteasome activity in 43-47 day old flies (Vernace et al., 2007). We have now extended our studies to investigate if a brief temporal decline in proteasome activity results in an accumulation of ubiquitinated proteins. We used an RNAi directed against the dbeta5 subunit of the proteasome in a binary system in which RNAi expression was controlled by an RU486 inducible Act5 promoter. This way proteasome activity could be tuned to any level at any stage of the development. Exposure of flies for 5 days (0-5 days post eclosion) to 200umoles of RU486 resulted in a 23% decrease in proteasome activity and an increase of polyubiquitinated proteins by 74%. Proteasome activity was then allowed to recover in the absence of RU486 and returned to control levels. However, ubiquitinated proteins, accumulating during the temporal disruption of proteasome activity, continue to accumulate after restoration of proteasome activity and are not removed when proteasome activity is restored to control levels. This clearly indicates that ubiquitinated proteins are in a state not accessible for degradation by the proteasome. Immunocytochemistry using an anti–Fk1 antibody against polyubiquitin shows widespread aggregates in the CNS of Drosophila melanogaster after temporary inhibition of proteasome activity. Future experiments using different RU486 inducible promoters will allow us to investigate the effect of reduced proteasome activity at different stages of development and in different models of neurological diseases in Drosophila melanogaster.

Title: Exploring the role of the endoplasmic reticulum unfolded protein response in *C. elegans* neurons

Authors: *N. P. OZBEY[1], S. IMANIKIA[1], C. KRUEGER[2], M. SHENG[1], M. CASANUEVA[2], R. C. TAYLOR[1];
[1]MRC LMB, Cambridge, United Kingdom; [2]Babraham Inst., Cambridge, United Kingdom

Abstract: The nervous system of *C. elegans* plays a role in the orchestration of systemic stress responses. One of these stress responses, the unfolded protein response of the endoplasmic reticulum (UPR^{ER}), is activated to re-establish proteostasis upon the detection of ER stress; overexpression of active, spliced XBP-1 (XBP-1s), a transcription factor that acts downstream of

the UPR^{ER} kinase/endoribonuclease IRE-1, in the nervous system of *C. elegans* increases the lifespan and healthspan of worms through UPR^{ER} induction in the intestine. To investigate XBP-1s-dependent changes in the nervous system of these animals, we conducted tissue-specific RNA-Seq in neurons. This approach allowed us to characterise differentially regulated neuronal and synaptic components, which may mediate changes to the nervous system that cause the release of inter-tissue UPR^{ER}-activating signals. We also employed a candidate approach based on our previous finding that neurotransmitter secretion is required for cell non-autonomous UPR^{ER} activation, and identified positive and negative regulators of intestinal UPR^{ER} activation. We find that the neuronal circuitry required to activate the UPR^{ER} within the intestine can also generate behavioural phenotypes following neuronal XBP-1s overexpression. This suggests that inter-tissue UPR^{ER} activation, increased longevity and healthspan can be coordinately regulated with stress-responsive behaviour by the activation of this transcription factor in the nervous system. We are further investigating this circuitry to better understand the mechanistic links between the regulation of behaviour and longevity by neuronal XBP-1s activation.

Title: Inhibition of Thioredoxin interacting protein ameliorates age associated neuroinflammation and memory decline

Authors: *S. ISMAEL[1], L. LI[2], A. YOO[2], F. WAJIDUNNISA[2], M. KHAN[3], T. ISHRAT[2]; [1]Anat. and Neurobio., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN; [2]Anat. and Neurobio., [3]Neurol., Univ. of Tennessee Hlth. science Ctr., Memphis, TN

Abstract: Inflamm-aging is an independent risk factor for several age associated neurological diseases including Alzheimer's disease (AD), dementia, stroke and neurodegeneration. Accumulating evidence showed that thioredoxin-interacting protein (TXNIP), an endogenous negative regulator of thioredoxin (TRX, a cellular redox regulator) is known to contribute to the progression of age-associated neorodegeneration. However, the contribution TXNIP in mediating age associated neuroinflammation and cognitive impairment through NOD-like receptor protein (NLRP3)-inflammasome axis remain unclear. In the present study, we have determined influence of temporal and gender specific difference in TXNIP-NLRP3 activation in

C57BL/6 mouse brain of different age group (2 , 12 and 18months) using western blot and immunostaining analysis. To evaluate the role of TXNIP on neuroinflammation, 18 months old C57BL/6 mice were treated with verapamil (1mg/kg/day) in drinking water for one month and. The animals were tested for cognitive function by novel object recognition and Morris water maze. The results demonstrated that there was an age dependent increase in the protein expression of TXNIP-NLRP3 inflammasome components in male and female mouse brain with reciprocal down regulation of TRX. In addition, the age and sex-dependent increase in TXNIP immunoreactivity was also observed in cortex and hippocampus of mouse brain and is localized in the neurons. Moreover, inhibition of TXNIP with a non-selective inhibitor, verapamil significantly attenuated NLRP3 inflammasome activation, oxidative stress and improved cognitive function in aged mice without affecting blood pressure. Supportingly, genetic deletion of TXNIP attenuated neuro inflammation in older animals. Together, these findings shed light on the mechanistic and molecular basis for age-associated changes in the brain. This suggests that these targets might contribute to the higher prevalence and severity of AD in the elderly and other age-related dementias.

Title: Hippocampal bradykinin B1 receptors blockade mitigates spatial learning and memory deficits in middle-aged rats

Authors: R. M. BITENCOURT[1], A. C. GUERRA DE SOUZA[1], ***M. A. BICCA**[1], F. A. PAMPLONA[2], N. DE MELLO[1], G. F. PASSOS[3], R. MEDEIROS[1], R. N. TAKASHI[1], J. B. CALIXTO[1], R. D. S. PREDIGER[1];

Abstract: A variety of studies have demonstrated abnormal bradykinin receptors expression in Alzheimer's disease (AD) brains from humans and animal models, as well as that targeting bradykinin receptors is an efficient strategy to counteract the cognitive and memory impairment associated with aging and AD. Being the hippocampus critical for cognition, abnormalities in this brain region are linked to memory decline. Yet, the impact of bradykinin signaling on hippocampal function remains poorly understood. Here, we aimed to investigate the role of hippocampal bradykinin receptors B1R and B2R on the cognitive function of twelve month-old rats (middle-aged) in comparison to 3 month-old rats (mature-adult). We used male Wistar rats divided in three cohorts for behavioral (n = 8-10 animals/group), neurochemical (n = 5 animals/group) and immunohistochemical (n = 4 animals/group) studies. Rats were kept in collective cages (2-3 animals/cage) and distributed randomly in between groups. All efforts were made to minimize the number of animals used and their suffering. All procedures performed complied with university IACUC and NIH guidelines. Middle-aged rats exhibited impaired ability to acquire and retrieve spatial information, evaluated using the Morris water maze task. Furthermore, a single intra-hippocampal injection of the selective B1R antagonist des-Arg9-[Leu8]-bradykinin (DALBK, 3 nmol), but not the selective B2R antagonist D-Arg-[Hyp3,Thi5,D-Tic7,Oic8]-BK (Hoe 140, 3 nmol), reversed spatial learning and memory deficits in these animals. Interestingly, the cognitive function of mature-adult rats was not affected by any of the drugs, suggesting absence of nootropic properties. Western blot and immunohistochemistry analysis revealed an up-regulation of B1R expression in the hippocampal

CA1 sub-region and pre-frontal cortex of middle-aged rats, whereas no changes in B2R expression were observed. Our findings provide new evidence that inappropriate hippocampal B1R expression and activation exert a critical role on the cognitive and memory function of middle-aged rats.

Title: Perirhinal cortex projection neurons to the dentate gyrus mediate novel object recognition in both young and aged mice

Authors: *S. KOSMIDIS[1], L. R. HARVEY[2], E. R. KANDEL[1];
[1]Neurosci., [2]Columbia Univ., New York, NY

Abstract: Normal aging is often accompanied by mild memory loss, which affects the quality of life and potentially progresses to severe deficits into the dentate gyrus and Alzheimer's-like phenotypes. We have previously found that direct administration of Osteocalcin (OCN), a bone-derived-hormone, in the dentate gyrus (DG) of young and aged mice can enhance discrimination memory for Novel object Recognition (NOR) by increasing the expression of RbAp48 protein. We used rAAV2 viruses to identify the neuronal circuitry mediating NOR in association with the DG. We find that the ventral perirhinal cortex, a region involved in object recognition in humans, and the entorhinal cortex, both project to the DG. In addition, we examine whether activity-dependent inhibition of RbAp48 protein in the perirhinal cortex and DG can affect object recognition preference in young animals. Further, we show that opto-genetic stimulation of cfos-positive neurons of the DG after a NOR task can restore NOR preference. We also demonstrate restoration of NOR memory in Aged animals upon injection of OCN in the perirhinal cortex. Collectively, our studies identify a DG-perirhinal cortex neuronal circuit as a mediator of NOR discrimination memory and shows that this specific circuit deteriorates with Aging.

Title: Modulation of calcium dysregulation in aged F344 rats by FK506 and FK520

Authors: *J. C. GANT[1], O. THIBAULT[3], N. M. PORTER[2], E. M. BLALOCK[4], P. W. LANDFIELD[2];
[2]Pharmacol. and Nutritional Sci., [1]Univ. of Kentucky, Lexington, KY; [3]Dept. of Pharmacol. and Nutritional Sci., Univ. Kentucky Med. Ctr., Lexington, KY; [4]Dept Pharmacol, Univ. Kentucky Coll Med., Lexington, KY

Abstract: Normal aging results in a decline of cognitive performance. During this process there is a progressive alteration in the function of principal neurons within the limbic system. We have shown that FK506 binding protein 1b (FKBP1b/FKBP12.6) expression is also influenced by age. A decline in the FKBP1b protein occurs simultaneously with the decline in cognition and we have shown that increasing FKBP1b protein *in vivo* by genetic therapy can reverse age-related cognitive impairment as well as age- and learning-related neuronal biomarkers in the hippocampus. However, the mechanistic processes underlying their effect are less clear. Here, we tested for such *ex vivo* effects. For the current experiments we used FK506 (tacrolimus) and FK520 (ascomycin; an analog of FK506) in young and aged slices to determine their effect on these biomarkers. Hippocampal slices were prepared from 20 mo and 5 mo old F344 rats and maintained in a holding chamber containing artificial cerebral spinal fluid. FK506 or FK520 was added to the wells of the incubation chamber (final concentration of 5μM) for at least 2 hours before electrophysiological measures were obtained. Neither FK506 nor FK520 influenced passive membrane properties of CA1 pyramidal neurons. However, both compounds reduced the amplitude and duration of the slow afterhyperpolarizion in aged slices, but had no effect in young. In a second set of experiments aged and young rats received bilateral injections of AAV expressing GCaMP6s (a calcium sensitive fluorescent protein) and remained in the vivarium for at least 4 weeks before slices were prepared. Again the slices were maintained in the incubation chamber and treated with FK506 or FK520 for 2 hours before imaging. We are currently examining the multi-photon data to determine Fk506 and FK520's effect on calcium transients. These results demonstrate that FK506 and FK520 might be useful compounds for treating memory dysfunction associated with aging through its interaction with calcium-induced calcium release in the CA1 region of the hippocampus.

Title: DNMT1 deletion prevents age-related loss of cortical interneurons

Authors: C. BAYER[1], D. PENSOLD[1], A. HAHN[2], L. BERMUDEZ[2], T. PIELER[3], T. LINGNER[4], G. SALINAS-RIESTER[4], L. BLÜMEL[2], A. URBACH[5], *G. ZIMMER-BENSCH[1]; [1]RWTH Aachen Univ., Aachen, Germany; [2]Univ. Hosp. Jena, Jena, Germany; [3]Ctr. for Nanoscale Microscopy and Mol. Physiol. of the Brain, Göttingen, Germany; [4]Transcriptome and Genome Analysis Lab., Göttingen, Germany; [5]Dept. of Neurol., Jena Univ. Hosp., Jena, Germany

Abstract: The cerebral cortex, the seat of higher cognitive functions, is composed of two main neuronal subtypes: the excitatory principal neurons and the inhibitory gamma-amminobutyric (GABA)-positive interneurons. Although GABAergic interneurons make up only 20% of the overall neuronal population, their inhibitory action is elementary for proper cortical function. Interestingly, different studies reported a selective vulnerability of inhibitory interneurons towards aging in different mammalian species. The aging phenotype, characterized by declined cognitive, motoric and sensory skills, represents a result of complex interactions between genetic, epigenetic and environmental factors. Epigenetic gene regulation by DNA methylation, executed by DNA-methyltransferases (DNMTs), and histone modifications emerge to be critical for the maintenance of neuronal health and function throughout the entire lifespan. As we found that DNMT1 affects cortical interneuron survival during development (Pensold et al. 2017), we next asked for a potential implication of DNMT1 in the long-term survival regulation of cortical interneurons in the aging brain. To this end, we analyzed a transgenic knockout mouse model in which *Dnmt1* was specifically deleted in PV-positive interneurons. We found an amelioration of the age-related interneuron loss in motoric and visual cortical areas in *Dnmt1* depleted mice, which was accompanied by improved motor performances of aged knockout mice compared to equal aged wild-types. Together, we provide evidence for DNMT1 being implicated in the age-associated vulnerability of inhibitory cortical interneurons.

Title: SIRT1 is negatively regulated by CHFR to maintain neuronal integrity

Authors: ***M. KIM**[1], J. SEO[2], J. SEOL[2];
[1]Korea Brain Res. Inst., Daegu, Korea, Republic of; [2]Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: SIRT1 is a nicotinamide adenine dinucleotide (NAD+)-dependent protein deacetylase that controls brain development, aging, and neurodegenerative disease. SIRT1 is known to regulate neurite length through its deacetylase activity and control apoptosis by suppressing p53. In addition, SIRT1 is phosphorylated upon oxidative stress and subsequently down-regulated. However, it still remains elusive how SIRT1 stability and activity are controlled. Here, we have demonstrated that CHFR functions as an E3 Ub-ligase of SIRT1, responsible for its proteasomal degradation under oxidative stress conditions. CHFR interacts with and destabilizes SIRT1 by ubiquitylation and subsequent proteolysis. Such CHFR-mediated SIRT1 inhibition leads to the increase of p53 acetylation and its target gene transcription. CHFR facilitates SIRT1 destabilization and prominent apoptotic cell death upon oxidative stress. Meanwhile, JNK inhibitor prevents SIRT1 phosphorylation, leading to elevated SIRT1 protein levels even in the presence of H_2O_2. Taken together, our results indicate that CHFR plays a crucial role in maintaining neuronal integrity during neuronal stress response by controlling the stability and function of SIRT1.

Title: High-temperature-processed green tea potentiates neuronal differentiation by enhancing the levels of epimerized catechins that inhibit DNA methyltransferase1

Authors: *H.-S. KIM, A. KIM, S.-Y. CHO, W.-S. PARK;
AMOREPACIFIC R&D Unit, Yongin-Si, Korea, Republic of

Abstract: Alterations in neurogenesis appear to be a common hallmark in different neurodegenerative diseases including Parkinson's disease (PD), Alzheimer's disease (AD), and Huntington's disease (HD). For neurogenesis, neuronal stem cells undergo appropriate neuronal differentiation and differentiates into neurons. DNA methylation plays a central role in epigenetic regulation of neuronal differentiation. Green tea catechins, especially (-)-epigallocatechin (EGCG), have been reported to modulate gene expression by targeting DNA methyltransferases. EGCG can be epimerized during the processing of tea into (-)-gallocatechin gallate (GCG), which is present in tiny amounts in fresh tea leaves. However, the regulatory effect of GCG on DNA methylation is not delineated. In the present study, we characterized the effect of GCG and high-temperature-processed green tea extract (HTP_GTE), which contained about 6 fold increased GCG than fresh green tea leaves extract by heat-induced epimerization of EGCG, on DNA methylation catalyzed by DNA methyltransferase1 (DNMT1) and neuronal differentiation. Remarkably, GCG exhibited a higher inhibitory effect on DNMT1 than its corresponding epimer (EGCG). HTP_GTE also efficiently inhibited DNMT1 *in vitro*. In addition, to induce neuronal differentiation, simultaneous treatment of HTP_GTE and retinoic acid in the neuroblastoma cell line, SH-SY5Y, downregulated DNMT1 and induced DNA hypomethylation at *Synaptophysin* promoter. HTP_GTE also increased in the mRNA expression of synaptophysin, which is neuronal differentiation marker. These results suggest that HTP-GTE could facilitate neuronal differentiation by regulating DNA methylation level.

Title: Bioinformatics strategy to advance the interpretation of Alzheimer's disease GWAS discoveries

Authors: *O. CHIBA-FALEK[1], D. SPRAGUE[2], M. LUTZ[2];
[1]Duke Med., Duke University, NC; [2]Duke Univ., Durham, NC

Abstract: Late-onset Alzheimer's disease (LOAD) is a genetically heterogenous disease. Genome wide association studies (GWAS) and whole genome/exome sequencing (WGS/WES) discovered about 40 LOAD-associated SNPs, navigating the genetic research of LOAD to specific regions in the genome. While the target genes have been inferred by proximity to the most significantly associated SNPs, the actual causal genes are yet to be identified. Thus, there is an unmet need for post-GWAS research that applies a multifaceted strategy combining *in silico, in vitro* and *in vivo* approaches to identify and validate the precise causal gene/s within the associated loci. We propose a bioinformatic strategy built on the hypothesis that dysregulation of gene expression mediated by genetic and epigenetic mechanisms contributes, at least in part, to LOAD pathogenesis. We defined LOAD-GWAS regions by the associated SNP±0.5Mb and extended the loci boundaries such that they are not within a gene. We developed a bioinformatics pipeline that utilizes the hippocampus-specific chromatin state segmentation track available from the Roadmap Epigenomics Project to map active enhancers and data on hippocampus specific frequencies of chromatin interaction using the virtual 4C software to visualize interactions between active enhancers and gene promoters. We augment our pipeline with biomedical and functional information from publications. We applied the bioinformatics strategy using three ~1Mb LOAD-GWAS loci known by the proximate genes: *BIN1*, *PICALM*, *CELF1*. These loci contain 10-24 genes, an average of 106 active enhancers and 80 CTCF sites. We integrated the active enhancers from the chromatin state segmentation track with the enhancer-promoter interactions from 4C data and identified all genes corresponding to the promoters that interact with the active enhancer positioned the closest to the LOAD-GWAS-SNP. This strategy generated a shorter list of prioritized candidate LOAD genes, ranging from 5-14 per locus. In conclusion, we suggest that the interpretation of LOAD-GWAS discoveries requires the integration of brain-specific functional genomic and epigenomic datasets and information related to regulatory activity, rather than inference based on proximity to the GWAS-SNPs. We

demonstrated that our bioinformatics pipeline is feasible to identify the highest priority LOAD candidate genes and to guide post-GWAS laboratory experiments to investigate causality.

Title: Reproducible bioinformatic tools for analysis of AMP-AD RNA-seq data

Authors: *W. L. POEHLMAN, J. A. EDDY, K. S. MONTGOMERY, K. DANG, T. THYER, M. A. PETERS, S. K. SIEBERTS, L. OMBERG, A. K. GREENWOOD, L. M. MANGRAVITE, B. A. LOGSDON, T. M. PERUMAL;
Sage Bionetworks, Seattle, WA

Abstract: Background:
The systemic failure to develop successful treatments for Alzheimer's disease (AD) is in part driven by an incomplete understanding of underlying heterogeneous biological processes such as gene expression patterns. To help address this challenge in the context of RNA-seq analysis, we develop reproducible bioinformatic tools for reprocessing 2114 RNA-seq samples from postmortem brain tissue. These samples are derived from three AMP-AD studies (ROSMAP, Mayo RNASeq, and MSBB), and are available through the AMP-AD Knowledge portal (ampadportal.org). To perform a comprehensive meta-analysis between these studies, it is necessary to standardize the processing of these datasets such that software tools, versions, and parameters are consistent across samples. The development of an automated workflow that allows processing of RNA-seq datasets will benefit the research community by enabling reproducible execution in diverse computing environments, and re-use of tools for new RNA-seq studies.
Methods:
We implement an RNA-seq processing pipeline in common workflow language (CWL). This workflow begins with BAM alignment files that were previously generated using diverse

software tools across research groups. Following conversion to fastq, reads are re-aligned to the hg19 human reference genome using the STAR read aligner and gene counts are quantified. We demonstrate execution of this workflow in a batch computing environment on Amazon Web Services (AWS). The Toil workflow engine is utilized to direct execution of tasks in the workflow.
Results:
We demonstrate that our workflow is scalable to thousands of samples. The results of this study is available through the AMP-AD Knowledge Portal in the rnaSeqReprocessing study: https://www.synapse.org/#!Synapse:syn9702085. We provide documentation on configuring and executing the workflow in github: https://github.com/Sage-Bionetworks/amp-workflows, and provide further resources for CWL workflow execution: https://www.synapse.org/#!Synapse:syn17872025.
Conclusions:
The development of a reproducible RNA-seq reprocessing workflow provides a valuable resource for the research community. By enabling consistent software execution, users can perform similar RNA-seq experiments without implementing new pipelines. Furthermore, as new datasets are produced, they can be processed in a standardized manner that allows for cross-study comparisons. While we have demonstrated execution of this workflow in the cloud, users may also run this workflow on local HPC systems. As these infrastructures evolve, our CWL workflow will remain a stable resource for processing RNA-seq datasets.

Title: Agora: A platform for exploration of Alzheimer’s disease evidence

Authors: *A. K. GREENWOOD, K. DAILY, J. GOCKLEY, T. PERUMAL, K. WOO, S. SIEBERTS, D. ALUTHGAMAGE, S. SIMON, R. DEMBOGURSKI, T. THYER, M. PETERS, K. DO, B. HOFF, M. DOERR, J. WOODBURN, L. OMBERG, B. A. LOGSDON, L. M. MANGRAVITE;
Sage Bionetworks, Seattle, WA

Abstract: Previous clinical trials for Alzheimer's disease (AD) have failed to identify successful disease modifying therapies. This is due, in part, to a primary focus on a small number of targets and therapeutic hypotheses. One way to de-risk the drug development process is for the research community to collectively share and evaluate evidence in support of new AD targets during early stages of research. To this end, we developed the Agora platform (https://agora.ampadportal.org), which provides open access to molecular evidence derived from a variety of analytical approaches. Agora currently supports two main functions. First, users can evaluate their own hypotheses about the molecular basis for AD by viewing multi-omics analyses relating genes and proteins to AD. These results are visualized through interactive explorers designed to support non-bioinformaticians in the interpretation of multi-omic analytical results. Second, users can explore hypotheses being considered by other researchers in the field by viewing a list of new AD targets developed from molecular assessments of human samples. The initial list of nominated targets was provided by the Accelerating Medicines Partnership in AD (AMP-AD) research consortia who derived their nominations based on systems biology analyses of human multi-omic data. To support the selection of candidate targets for further validation and/or drug discovery, Agora also presents information about the druggability of these targets. In summary, we have built a platform to empower the AD research community to contribute and unite around promising target hypotheses.

Title: RNA splicing dysfunction exacerbates the progression of Alzheimer's disease

Authors: *X. HAN[1], P.-C. CHEN[2], J. YUN[1], J. PENG[3];
[1]St Jude Children's Res. Hosp., Memphis, TN; [2]Structural Biol. and Developmental Neurobio., St Jude Children Res. Hosp., Memphis, TN; [3]Structural Biol., St. Jude Children's Res. Hosp., Memphis, TN

Abstract: Alzheimer’s disease (AD), the most common form of dementia, is a chronic neurodegenerative disease. AD leads to memory loss and bodily function disorders, but its causative mechanisms are not fully elucidated. Besides Aβ and tau aggregation, the insoluble proteomics data from our group have identified, an early, tangle-like pathology of U1 small nuclear ribonucleoprotein complex (snRNP), including U1-70K and its *N*-terminal cleavage product (N40K), in sporadic and familial cases. N40K has a dominant effect to down-regulate full-length U1-70K. The mouse model with neuronal expression of N40K (N40K Tg), can recapitulate AD-associated events, such as neuronal loss, memory loss and RNA splicing dysfunction. We also characterized an inducible N40K transgenic mouse model (iTg), in which N40K expression is controlled by tetracycline-controlled transactivator (tTA). ITg displays AD-related phenotypes, like neurodegeneration and memory loss which are similar to the phenotypes observed in N40K Tg. The two mouse models prove that RNA splicing dysfunction are crucial in AD development. As RNA splicing dysfunction and Aβ aggregation are two important pathologies in AD cases, I tested that if these two pathologies play a synergistic role in AD development by crossing N40K Tg mice with 5xFAD to get a new double transgenic mice (dTg) mouse model. It was observed that the performances of dTg were worse than 5xFAD and N40K Tg only in Morris Water Maze and Novel Object Recognition. These studies imply that splicing dysfunction and Aβ aggregation play a synergistic effect on AD progression. These studies represent RNA splicing dysfunction as a novel target for potential pharmaceutical treatment.

Title: Translational study of biomarkers and potential drug targets for Alzheimer's disease

Authors: *X. WANG, T. XU, X. ZHANG, W. YU, Y. SUN, X. RONG;
Inst. Materia Med., Beijing, China

Abstract: Alzheimer’s disease (AD) is a common neurodegenerative disease among elderly people. So far the pathogenesis of AD is still not clear. Therefore, the diagnosis of the disease at early stage and therapeutic evaluation are needed urgently. To solve these issues, we tried to find AD biomarkers by screening the protein changed in the brain of APP/PS1 transgenic mice using 2DE proteomics and further validated by Elisa and western blot. About 30 differentially expressed proteins were found. Next step, we detected the expression of these differential proteins in AD patient serums. In our study, 68 serums from AD patients were collected and 6 proteins were validated in these patient serums. Then we verified these proteins in four AD

animal models. In brain tissues in different animal models: APP/PS1 transgenic mice, mouse model of Aβ intracerebral ventricular injection, SAMP8 mice and the older rats (>20 months), we found that some proteins expressed in the same way as they expressed in AD serums. These differential proteins included VDAC1, ITI-H4 subunits, Apo-L1, Apo-M and so on. What is interesting is that some of these differential proteins could be recovered when the animals were treated with anti-AD drugs.
Conclusion: About 30 differentially expressed proteins were detected in proteomics and 6 of them were validated in both AD patient serums and the brain tissues of AD animal models. They might be recovered by anti-AD agents. Therefore, these proteins might be used for AD diagnosis and also for new drug evaluation.

Title: Neural stem cell-derived exosomes promote synaptic resilience to amyloid beta and tau oligomers through modulation of neuroinflammatory tone via specific miRNAs

Authors: *O. ZOLOCHEVSKA[1], E. BISHOP[2], W. ZHANG[2], B. TUMURBAATAR[2], M.-A. MICCI[3], G. TAGLIALATELA[4];
[1]Neurol., [2]Univ. of Texas Med. Br., Galveston, TX; [3]Dept. of Anesthesiol., The Univ. of Texas Med. Br. At Galvesto, Galveston, TX; [4]Neurol., Univ. of Texas Med. Br. Dept. of Neurol., Galveston, TX

Abstract: Alzheimer's Disease (AD) is the most common form of dementia typically characterized by synaptic loss at early stages, presence and accumulation of aggregated forms of amyloidogenic proteins, and neuronal loss at later stages of the disease. Aging is the greatest risk factor for the disease development, suggesting that the accumulation of different pathological events leads to increased synaptic vulnerability. Therefore, a potential approach for development of a successful therapy against AD is to promote synaptic health and resilience to various pathologic events. We have previously reported that exosomes secreted by hippocampal neural stem cells (NSCs), and not mature neurons (MN), act via specific miRNAs to provide synaptic protection against Aβ and tau oligomers. Delivery of these NSC-specific miRNAs (17, 322, 485)

intracerebroventricularly (ICV) to wild-type mice resulted in preserved long-term potentiation (LTP) during an Aβ and tau oligomer challenge protocol. Moreover, we observed reduced Aβ and tau oligomer binding to synaptosomes isolated from mice treated with these miRNAs or NSC-exosomes. Here we aimed to determine the mechanism of action of NSC-derived exosomes and their bioactive miRNA cargoes in comparison to MN-derived exosomes using transcriptomics and proteomics approaches. Male and female wild-type mice were injected ICV with NSC- or MN-derived exosomes, or a combination of the three selected miRNA cargoes (17, 322, 485). Synaptic fractions were prepared twenty-four hours after the ICV injections and either total RNA or protein were isolated. Transcriptomics and proteomics analysis were performed using Ingenuity Pathway Analysis, PANTHER and Reactome. The transcriptomics analysis identified upregulation of several inflammatory pathways, including TNF, NFκB and IL-8. At the protein level, oxidative phosphorylation, NFAT and PKA pathways were upregulated after treatments with miRNAs and NSC-derived exosomes, while MN-exosomes inhibited those signaling pathways. Remarkably, overall inhibition of cellular signaling was observed only after treatment with MN-derived exosomes. Collectively these data suggest that specific miRNA cargoes enriched in NSC-derived exosomes stimulate the neuroinflammatory tone which plays an important role in synaptic plasticity, thus promoting synaptic resilience to Aβ and tau oligomers.

Title: Behavioral and psychological symptoms of dementia (BPSD) in Alzheimer’s disease: Antemortem clinical assessment and postmortem RNA-sequencing analysis

Authors: *R. KESZYCKI[1], D. FISHER[1], D. BENNETT[2], R. WILSON[2], H. DONG[1]; [1]Psychiatry, Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [2]Rush Alzheimer's Dis. Ctr., Chicago, IL

Abstract: By 2050, the global number of patients with dementia is expected to rise to 115.4 million people of which 60-80% will carry a diagnosis of Alzheimer’s disease (AD) specifically. The vast majority of these individuals will experience behavioral and psychological symptoms of dementia (BPSD). Thus, BPSD represents a critical worldwide healthcare issue. It has long been

contended that BPSD should be categorized into domains based commonly co-occurring symptoms that potentially have common underlying etiologies and represent effective treatment targets. The purpose of this study was to choose AD patients who were either highly affected or unaffected-to-mildly-affected on particular BPSD domains. Based on previous research findings, we hypothesized that patients' symptoms would cluster into: affective symptoms (depression and anxiety), apathy, hyperactivity (irritability, disinhibition, aggression, and aberrant motor behavior), and psychosis (delusions and hallucinations). We performed factor analysis on 660 antemortem behavioral interviews with dementia patients, revealing four factors that were similar to, yet different from, those we had hypothesized. In accordance with our hypothesis, we obtained apathy and affective domains. Regarding psychosis, delusions did not load well onto any of our factors, and aberrant motor behavior loaded strongest with hallucinations. Aggressive symptoms, including impulsive aggression, constituted our last factor. We obtained severity scores for all patients on these four domains who had an AD diagnosis and a behavioral interview within two years before death (n = 100). Within a particular domain, we designated those in the top 70% as "cases" and those in the bottom 30% as "controls." We selected 55 patients using these cutoffs and gender counter-balancing across all domains' cases and controls. In the near future, we plan to perform RNA sequencing analysis on several postmortem brain regions from these additional patients. Previously, we conducted preliminary RNA-sequencing analysis on 17 patients' post-mortem anterior cingulate tissues according to the four domains we had hypothesized. This analysis revealed 57 differentially expressed genes for the affective domain, 44 for the hyperactivity domain, 34 for the psychosis domain, and 20 for the apathy domain. We propose that we will find differentially expressed genes across our adjusted BPSD domains and additional brain regions as well. Future research should consider how epigenetic and interventions upregulating or downregulating these domain-related genes may be helpful in developing treatment strategies.

Title: Integrative network analysis identifies microglial-specific key drivers for phagosome and abeta-clearance in Alzheimer's disease

Authors: *R. CHANG;
Univ. of Arizona, Tucson, AZ

Abstract: Late-Onset Alzheimer's Disease (LOAD) results from a complex pathological process influenced by genetic variation, aging and environment factors. Genetic susceptibility factors indicate that myeloid cells such as microglia play a significant role in the onset of LOAD. Here, we developed a computational systems biology approach to construct probabilistic causal and predictive network models of genetic regulatory programs of microglial cells under LOAD diagnosis by integrating two independent brain transcriptome and genome-wide genotype datasets from the ROSMAP and Mayo Clinic studies in AMP-AD consortium. From this network model, we identified and replicated novel microglial-specific master regulators predicted to modulate network states associated with LOAD. We not only experimentally validated three master regulators (FCER1G, HCK and LAPTM5) associated with phagocytosis, a process associated with LOAD, that in turn causally links phagocytosis to Abeta burden, and revealed the causal relations among the three, but also we validated the molecular impact these master regulators have on modulating downstream genomic targets by perturbing them in primary human microglia-like cells (MDMi). Thus, we propose three new master regulator genes that emerged from our network analyses as robust candidates for further evaluation in LOAD therapeutic development efforts.

Title: A potential role for miRNAs in hippocampal maturation, sex-differences, and disease pathology as revealed by an analysis of the 5XFAD mouse model of Alzheimer's disease

Authors: *R. S. NOWAKOWSKI[1], J. L. BUNDY[2], C. M. VIED[1];
[1]FSU Col. of Med., Tallahassee, FL; [2]Duke Univ., Durham, NC

Abstract: Like many neurological disorders, Alzheimer's disease has a sex-biased epidemiological profile, affecting approximately twice as many women as men. We investigated

the changes in miRNA levels females and males using the 5XFAD genetic mouse model of Alzheimer's disease. The 5XFAD mouse genome contains two co-inserted mutated human transgenes (*APP* and *PSEN1*) associated with familial Alzheimer's disease. 5XFAD mice on the C57BL/6J background develop histopathological features of Alzheimer's disease, such as Aβ42 positive plaques, as early as four months of age. We profiled the miRNAome and the transcriptome of the mouse hippocampus in male and female mice during early stages of disease development (one, two, and four months of age). Our analysis reveals 231 miRNAs that are differentially expressed as a function of age (218 miRNAs), disease status (6 miRNAs) or sex (8 miRNAs). The overlap among the 3 patterns is small (see upper Venn diagram) with only 2 miRNAs differentially expressed by age and disease status and 1 miRNA differentially expressed by both age and sex. To gain insight into the possible role of the differentially expressed miRNAs we downloaded their putative targets from mirdb.org. The total target numbers are large: age (15,521 targets), disease status (1,874 targets) and sex (6,090 targets). The overlap among the 3 patterns, in contrast to the miRNA overlap, is considerable (see lower Venn diagram). The intersection of all 3 sets of targets (i.e., by age, disease status and sex) has 972 targets which from their gene ontology (mousemine.org) is rich in genes involved in CNS and neuron functions and in diseases related to mental illness. Overall, this analysis points to miRNAs as occupying a gene regulatory niche that could potentially mediate many changes in CNS function in normal maturation, sex-related functions and disease pathology.

Title: Mutant presenilin 1 dysregulates exosome cargo derived from human induced pluripotent stem cell (iPSC) neurons, revealed by proteomics analyses

Authors: *A. JONES[1], Q. LIU[1], S. PODVIN[1], C. LIETZ[1], C. MOSIER[1], T. IKEZU[2], R. RISSMAN[1], S. YUAN[1], V. HOOK[1];
[1]UCSD, La Jolla, CA; [2]Pharmacol. and Neurol., Boston Univ. Sch. of Med., Boston, MA

Abstract: Exosomes, extracellular vesicles, have been found to participate in Alzheimer's disease (AD) propagation of neuropathology. Prior studies show that plasma neurally-derived exosomes (NDEs) from AD patients, when injected into mouse brain, result in AD-like pathogenesis demonstrated by accumulation of tau aggregates (Winston et al., 2016). These findings suggest that dysregulation of the proteome cargo of NDEs may occur in AD, and raise the question of whether gene mutations of familial AD (FAD) can alter the proteome cargo of exosomes during its biogenesis in human neuronal cells. For this reason, we conducted proteomics analyses of exosomes generated by patient-derived iPSC neurons containing the presenilin 1 (PS1) A246E mutation, compared to those from control iPSC neurons. Exosomes isolated from the media of these neurons were subjected to high throughput proteomics mass spectrometry and bioinformatics analyses, resulting in the identification of over 1,000 proteins. Proteins were categorized as (a) present only in mutant PS1 exosomes (111 proteins), (b) present only in control exosomes (276 proteins), and (c) present in both mutant PS1 and control exosomes (757 proteins). For the large group of proteins shared in mutant PS1 and control exosomes, quantitation revealed distinct patterns of down-regulated and up-regulated proteins in the mutant PS1 exosomes compared to controls, with significance values of $p < 0.05$. Gene ontology and STRING analysis provided insight into the biological functions of the exosome proteomes, which implicated involvement of vesicle transport and protein localization, exocytosis, and disruption of cellular signaling networks. With respect to tau, western blots showed that the mutant PS1 exosome displayed elevated levels of total tau; these exosomes also contain phospho-tau (Ser396), known to be present in NDEs from plasma of AD patients (Winston et al., 2016). These findings demonstrate that the PS1 A246E FAD mutation dysregulates exosome cargo, via exosome biogenesis, in human patient-derived iPSC neurons.

Title: Exosome protein cargos and dynamics in Alzheimer's disease

Authors: *D. GRAYKOWSKI[1], Y.-Z. WANG[1], J. N. SAVAS[2];
[1]Neurol., [2]Northwestern Univ., Chicago, IL

Abstract: Exosomes are nanosized (50-100 nm in diameter) extracellular vesicles that are a vehicle for cellular communication and waste removal in mammals. In the central nervous system, exosomes are secreted by neurons, astrocytes, microglia, and oligodendrocytes. We are interested in testing the hypothesis that exosomes secreted by neurons play essential roles in synaptic plasticity events while concurrently contributing to the spreading of pathology in disease states including Alzheimer's disease (AD). AD is characterized by the amyloid-beta (Aβ) plaques and neurofibrillary tangles (NFT) pathological hallmarks. Interestingly, exosomes may contribute to the seeding or the prion-like aspects of Aβ or tau in AD models. Thus, exosomes potentially exacerbate AD pathology. However, precisely how exosomes and their protein cargo are perturbed in the context of AD is not well understood. We hypothesize that in the context of different levels of AD pathology in both mouse models and actual AD in humans, the presence of Aβ plaques and NFT's will alter exosome cargo and dynamics. In preliminary experiments, we isolated exosomes from the brains of three lines of 6 months old APP knock-in mouse models: NL, NL-F, and NL-G-F, and analyzed the purified exosomes with tandem mass spectrometry-(MS) based proteomics. We identified several known exosome proteins including CD81, Alix, APP, and Aβ. We look to expand upon these preliminary findings by first verifying the MS results by western blotting and negative staining electron microscopy. Next, we will perform multiplexed-TMT MS experiments on the different lines of APP knock-in mice at 3, 6, 9, and 12-month time points in appreciation of the timeline of increased Aβ levels, synapse loss, and plaque formation. Additionally, we look to investigate exosomes and their respected proteomes in the context of mutant tau via a widely investigated tauopathy model mouse, P301S. The workflow will follow a similar design; optimization of exosome purification from the brain, verification (using immunohistochemistry), and quantitative analysis via multiplexed TMT MS. Lastly, to get a more complete illustration of exosomes in the context of actual AD pathology, exosomes isolated from human AD brain will be analyzed. This part of the study will follow the same biochemical workflow: exosome purification, verification with western blot for the exosome markers Tsg101 and CD63, and multiplexed TMT MS analysis. Taken all together, we

expect this research will begin to clarify the relationship between excitatory synaptic transmission and exosome-based communication in the context of AD-like pathology.

Title: Studying hierarchical connectome modularity structure in healthy aging versus Alzheimer's disease patients

Authors: *Z. D. MORRISSEY[1], L. ZHAN[2], O. A. AJILORE[1], O. LAZAROV[3], A. D. LEOW[1]; [1]Psychiatry, Univ. of Illinois at Chicago, Chicago, IL; [2]Electrical and Computer Engin., Univ. of Pittsburgh, Pittsburgh, PA; [3]Dept Anat & Cell Biol, Univ. Illinois, Chicago, Chicago, IL

Abstract: In connectomics, modules are a fundamental network component that offers insight into network organization. Neurodegenerative disorders notably disrupt connectivity between brain regions, leading to a breakdown in neuronal communication and modular network architecture. In Alzheimer’s disease (AD), evidence suggests that impairment in key brain networks including the default mode network (DMN) are implicated in AD cognitive decline. To that end, we applied graph theory and the path-length associated community estimation (PLACE) algorithm to study the hierarchical community structure properties of AD patients using DTI data from the Alzheimer’s Disease Neuroimaging Initiative (51 healthy aging subjects (mean age = 69.7), 112 MCI patients (mean age = 71.7), and 39 AD patients (mean age = 75.6)). Using a top-down approach, we found that modularity similarity between healthy-AD notably decreased with further bifurcations; at just 8 communities (Fig. 1A), 18% of nodes were differentially assigned compared to healthy aging controls in areas involved in the DMN, working memory, self-awareness, and language/visual processing (Fig. 1B). In addition, network analyses indicate statistically significant differences between healthy aging and AD subjects in characteristic path length (p &lt 0.005) as well as network diameter (p &lt 0.005), indicating that AD structural networks exhibit less efficient network architecture. Node-specific analyses for betweenness centrality, a measure of network integration, likewise indicate the largest group-wise mean differences (healthy-AD) in the posterior cingulate cortex, thalamus, pallidum, hippocampus, and precuneous, suggesting that DMN regions are heavily compromised at the network level (B-H FDR q &lt 0.2). Together, these results suggest that hierarchical community

structure is compromised in AD networks and offer further insight into how AD pathology affects the network level of the brain.

Title: Elucidating retrotransposon dysregulation in Alzheimer's disease mouse model

Authors: *J. AW, D. LEUNG;
The Hong Kong Univ. of Sci. and Technol., Hong Kong, Hong Kong

Abstract: Transposable elements are mobile stretches of DNA that are ubiquitous in the eukaryotic genome, the largest component of which are retrotransposons. These elements mobilize via RNA intermediates in a "copy and paste" mechanism. Due to their deleterious effects on the genome, most retrotransposons are silenced through mutations, truncations, inversions, deletions and epigenetic mechanisms. However, there is evidence of such sequences being adapted for use in specific cell types. The neuronal gene *Arc*, a master regulator of synaptic plasticity, is derived from retrotransposon Gag proteins. Moreover, retrotransposons possess cis-regulatory functions. For example, the transcription of the mouse neuronal apoptosis inhibitory protein (*Naip*) gene initiates from an ORR1E LTR-derived promoter. Recently, retrotransposon dysregulation has been shown to occur in Alzheimer's disease, but the mechanisms that lead to the dysregulation are yet unclear. In this study, we aim to elucidate the role of these elements in the mouse brains. Using state-of-the-art techniques, we profile transcription and epigenetic marks from four brain regions in the Alzheimer's disease mouse model R1.40 and wildtype (WT) mice. Our data show that retrotransposons are upregulated in the R1.40 mice, especially in the hippocampus. Interestingly, we also find retrotransposon expression in the WT, hinting at a potential inherent role for retrotransposons in the brain.

Title: Functional screening of miR126 targets in *in vitro* and *in vivo* AD models

Authors: H. NOH[1], ***S. SONG**[1], K. C. SONNTAG[2], H. SEO[1];
[1]Hanyang Univ., Seoul, Korea, Republic of; [2]McLean Hospital, Harvard Med. Sch., Belmont, MA

Abstract: Alzheimer's disease (AD) is chronic neurodegenerative disease caused by loss of neurons and synapses in several brain regions including entorhinal cortex and hippocampus. Alteration of the expression of micro RNA (miRNA), a small non-coding RNA, has been studied for pathological process of several neurodegenerative diseases, as it functions in RNA silencing and post-transcriptional regulation of gene expression. One of the miRNAs, miR126 has been reported as a novel pathological marker of various neurodegenerative diseases such as Parkinson's disease (PD) and AD, but its pathophysiological targets are poorly understood. In this study, we predicted several genes as potential targets of miR126, using network topologic analysis. To determine transcriptomic changes, we screened the targets of miR126 using next generation sequencing (NGS) analysis in cholinergic neurons after Lenti-miR126 overexpression under AD-like pathological environment induced by amyloid beta 42 (Aβ-42). The selected genes from this screening analysis were functionally evaluated in *in vitro* AD cell model. The function of various target genes of miR126 in this study can reveal the pathophysiological mechanisms and potential therapeutic approaches in AD.

Title: Estimation of late-onset Alzheimer's disease progression from post-mortem RNA-seq samples

Authors: S. MUKHERJEE[1], C. PREUSS[2], A. K. GREENWOOD[3], S. JAYADEV[4], G. A. GARDEN[4], G. CARTER[2], L. MANGRAVITE[3], ***B. LOGSDON**[3];

Abstract: Background: We infer disease progression for Alzheimer's disease (AD) using RNA-Seq data from post-mortem brain samples from the Accelerating Medicine Partnership - Alzheimer's disease (AMP-AD) consortia with a manifold learning method. We test that the estimate of disease progression is concordant with neuropathological and clinical measures of disease and we identify the genetic basis of disease progression based on our estimates of relative disease progression.
Methods: We use a manifold learning approach to learn a tree structured subspace from the RNA-Seq data from the AMP-AD studies. This low-dimensional subspace defines an ordering of samples along the tree - treated as degree of disease progression - based on the similarity in the RNA-Seq profiles. We test for association between the estimated measure of progression and neuropathological, clinical, and cellular measures of disease severity. To identify progression specific pathways, we perform a differential expression analysis on inferred disease progression tree branches and we perform a genome-wide association study to identify loci associated with our quantitative measure of disease severity.
Results: We show that this estimate of disease progression is concordant with neuropathological ($p<10^{-4}$), clinical ($p<10^{-5}$), and cellular measures of disease ($p<10^{-16}$). Our GWAS analysis identifies suggestive associations in ADAMTS14, IL7, and MAN2B1 ($p<10^{-5}$) and associations in APOE, BIN1, and PTPRD ($p<10^{-5}$) which have been previously associated with AD or AD endophenotypes. We also identify a potentially 'resilient' subset of patients whom may be compensating for prodromal AD associated pathophysiology via activation of protein trafficking, splicing, negative regulation of apoptosis, and prevention of amyloid cleavage.
Conclusions: We develop a novel approach to identify pathways associated with Alzheimer's disease progression and stage patients given the molecular signature of their disease.

Title: Chronic gamma entrainment induces a persistent neuroprotective state in mouse model of neurodegeneration

Authors: C. ADAIKKAN, A. MARCO, ***K. ABDELAAL**, L.-H. TSAI;
Picower Inst. for Learning and Memory, MIT, Cambridge, MA

Abstract: Neurodegenerative diseases, such as Alzheimer's disease, are characterized by devastating degeneration of brain and cognitive functions. We have recently demonstrated that chronic non-invasive Gamma ENtrainment Using Sensory Stimuli (GENUS) preserves neuronal and synaptic density, limits ventricle expansion, and improves spatial learning and memory in Tau P301S and CK-p25 mouse models of neurodegeneration. Moreover, neuron and microglia specific RNA-sequencing suggest a gene expression shift toward a globally neuroprotective state with reduced neuroinflammation, enhanced synaptic integrity, upregulation of neuroprotective factors, and reduced DNA damage following GENUS. While our findings represented an exciting potential of GENUS for neuroprotection during and up to 24-hour post-GENUS regimen, the long-term extent of the observed neuroprotective phenotypes following chronic GENUS has not yet been determined. In the present study, we subjected CK-p25 mice to 1 hour daily GENUS (40 Hz flicker) for 42 days, sacrificed at 7 to 15 days post-GENUS, and then analyzed for extent of detectable neuroprotection. Preliminary analyses revealed that the neuroprotective effects persist for several days after the termination of chronic GENUS. To further examine the molecular mechanism of persistent neuroprotective state induced by GENUS, we assessed epigenetic and gene expression alterations using neuron specific ATAC- and RNA-sequencing, that revealed an increase in chromatin accessibility and upregulation of genes related to synaptic function and vesicle trafficking. By combining pharmacology and GENUS, we are currently establishing the causal role of GENUS induced gene expression alterations to neuroprotection and cognitive processes.

Title: Amyloid associated epigenomic signatures at promoters of late and early onset Alzheimer's risk genes in human hippocampal oligodendrocytes

Authors: *E. RAMAMURTHY[1], G. WELCH[2], J. CHENG[2], Y. YUAN[1], L. GUNSALUS[1], L.-H. TSAI[2], A. R. PFENNING[1];
[1]Computat. Biol. Dept., Carnegie Mellon Univ., Pittsburgh, PA; [2]The Picower Inst. for Learning and Memory, MIT, Cambridge, MA

Abstract: Mounting evidence is pointing towards a role for enhancer and promoter regulatory elements in influencing Alzheimer's disease predisposition and progression through their activity in different cell types. Therefore, to better understand cell type-specific epigenomic mechanisms involved in AD, we isolated major brain cell classes (neurons, microglia and other glia) using fluorescent activated nuclei sorting (FANS) from two brain regions: the dorsolateral prefrontal cortex (dlPFC) and the hippocampus of postmortem human brain samples. On each sorted fraction, we performed ChIP-seq of H3K27ac, a histone mark associated with active enhancers and promoters. Then, using peak calling methods and by aggregating information across multiple subjects, we constructed an atlas of H3K27ac peaks enriched in the three cell classes. We compared this atlas with a well powered genome wide association study (GWAS) and report that H3K27ac peaks enriched in microglia have a strong preference for colocalization with AD associated GWAS variants (permutation test adjusted p=9e-06) relative to H3K27ac peaks enriched in neurons and oligodendrocytes. These results support previous observations that microglial and/or myeloid cell gene regulation influences predisposition towards AD.
In parallel, we similarly profiled the cell type-specific epigenomes of postmortem brains of subjects with pathology indicative of late onset Alzheimer's disease (LOAD). Then, for samples of each sex, brain region and cell type, we compared differences in levels of H3K27ac between subjects with and without amyloid pathology. Our analysis revealed a strong epigenomic signature associated with amyloid load in the human hippocampus that is enriched for promoters of several genes associated with both late and early onset Alzheimer's disease risk including APP, PSEN1, PSEN2, BACE1, BIN1, PICALM, ADAM10, ADAMTS4, SORL1, FERMT2 and TARDBP (TDP-43). Further, ontological annotation enrichment analysis for genes associated with these peaks revealed processes associated with myelination, amyloid processing and genes differentially expressed upon treatment of monocytes with anti-TREM1 and LPS. We further show that this signature displays a stronger trend in female subjects compared to male subjects. Our study is the first to report genome-wide maps of H3K27ac in different brain cell types. In addition, our analysis reveals an epigenomic module in oligodendrocytes that is likely disrupted in both early and late onset Alzheimer's disease. This opens up the opportunity to target these specific genomic locations in oligodendrocytes for potential therapeutics.

Title: Gray and white matter neurovascular ceruplasmin expression in Alzheimer's disease

Authors: *K. HARGIS-STAGGS[1], E. S. JOHNSON[2], P. NELSON[3], E. M. BLALOCK[4];
[1]Pharmacol. and Nutritional Sci., [2]Dept. of Pharmacol. and Nutritional Sci., [3]Univ. of Kentucky, Lexington, KY; [4]Dept Pharmacol, Univ. Kentucky Coll Med., Lexington, KY

Abstract: Alzheimer’s disease (AD) is a debilitating and chronic disease targeting the ever-increasing aging population, yet effective therapeutics remain elusive. The majority of AD cases (~90-95%) are sporadic AD (sAD) and a variety of modifiable and unmodifiable risk factors contribute to the development of the disease. For example, aging and being female (~2/3 AD cases) are two key unmodifiable risk factors for sAD, though, it is unclear how this translates into an increased risk. Here, our lab identified a panel of 85 genes that changed with age, worsened with AD, and exacerbated in female sAD subjects. Among these genes, ceruloplasmin (CP) showed robust expression changes in age that were worsened in AD, and exacerbated in females. CP is strongly expressed in neurovascular units (NVUs), especially in white matter. Therefore, we hypothesized that white matter NVUs from the Brodmann area 9 (BA9) region of the frontal cortex will show greater CP expression in sAD females than males. To test this, we used transcriptional profiling of laser-capture microdissected gray and white matter NVUs from FFPE sections in male and female aged control and AD subjects.

Abstract: Aggregation of hyperphosphorylated tau in neurofibrillary tangles (NFTs) is closely linked to neuronal death, early memory loss, and the progression of cognitive deficit in Alzheimer's diseases (AD). Although pathological tau appears to contribute to disease progression via axonal transport defects, synapse dysfunction, and neuroinflammation, our understanding of the cellular and molecular alterations associated with tau aggregation in the brain of AD patients is limited. Here, we developed procedures for high-throughput isolation of individual somas with NFTs from frozen human brain and profiled the transcriptomes of cells with or without NFTs from the prefrontal cortex of AD patients and age-matched controls. By comparing the transcriptomes of single neurons with NFTs to those of neighboring NFT-free neurons, we provide unbiased and precise identification of the cell types exhibiting aggregates. Our data support the previously recognized selective vulnerability of excitatory neurons and further identify the aggregate-prone or resistant subtypes. Differential gene expression analysis between cells with or without NFTs within each cell subtype and across the different cell subtypes identified commonly altered and cell type-specific genes and pathways associated with tau aggregation. Our data provide a framework for improved disease modeling and an unprecedented resource for identifying new biomarkers and targetable molecules and pathways in human AD.

Abstract: Epigenetic control of enhancers alters neuron functions and may be involved in Alzheimer's disease (AD). Here, we identify enhancers in neurons contributing to AD by comprehensive fine-mapping of DNA methylation at enhancers, genome-wide. We examine 1.2 million CpG and CpH sites in enhancers in prefrontal cortex neurons of individuals with no/mild, moderate, and severe AD pathology (n = 101). We identify 1,224 differentially methylated enhancer regions; most of which are hypomethylated at CpH sites in AD neurons. CpH methylation losses occur in normal aging neurons, but are accelerated in AD. Integration of epigenetic and transcriptomic data demonstrates a pro-apoptotic reactivation of the cell cycle in post-mitotic AD neurons. Furthermore, AD neurons have a large cluster of significantly hypomethylated enhancers in the DSCAML1 gene that targets BACE1. Hypomethylation of these enhancers in AD is associated with an upregulation of BACE1 transcripts and an increase in amyloid plaques, neurofibrillary tangles, and cognitive decline.

Title: Cell-type specific, mechanistic and directional transcriptional regulatory networks in the brain

Authors: *C. C. FUNK[1], P. SHANNON[1], D. GIBBS[1], N. RAPPAPORT[1], M. ALLEN[2], M. CARRASQUILLO[2], N. ERTEKIN-TANER[2], T. E. GOLDE[3], I. SHMULEVICH[1], L. HOOD[1], N. PRICE[1];

Abstract: Single cell RNA-seq is rapidly redefining our understanding of cell types in the brain. Limited in the number of genes detected per cell, single cell RNA-seq is too sparse for creating transcriptional regulatory networks (TRNs), which require quantitative expression for all transcription factors and target genes. Bulk tissue RNA-seq provides appropriate coverage of genes for TRNs, but is not cell-type specific. Using single cell RNA-seq from the Allen Brain Atlas, we have redistributed read counts in the AMP-AD bulk RNA-seq for cell-types of the brain, building cell-type specific TRNs. These TRNs represent a directional and mechanistic list of putative transcription factors for nearly all expressed genes in the brain.
We reprocessed all ENCODE brain DHS using Wellington and HINT to identify transcription factor binding sites. We assembled motifs from multiple databases, totaling 1,530 motifs mapping to 1,515 transcription factors. We developed and utilized Transcriptional Regulatory Network Analysis (TReNA), as an R Bioconductor package. Regulatory regions were defined by GeneHancer. TReNA utilizes multiple machine learning techniques to prioritize transcription factors for each target gene. Single cell RNA-seq data from the Allen Brain Atlas was used to define cell types, for redistributing the reads from bulk RNA-seq.
Our TRNs contain a prioritized list of putative transcription factor regulators for all genes in a cell-type specific manner. This information, combined with the footprints (and their genomic locations) allows us to integrate genetic information from GWAS or eQTL analysis to generate testable hypotheses around the functional annotation of variants. These cell-type specific TRNs can be used to identify key transcription factors enriched in gene lists identified in independent perturbation experiments of comparable cell types. We have identified multiple microglia-enriched transcription factors that regulate many differentially and co-expressed genes in AD. These resulting models can be applied to other datasets that generate lists of differentially or co-expressed genes, including single cell RNA-seq data, as well as provide testable hypotheses for non-coding variants of interest. We are actively engaged in testing several hypotheses through experimental means and have made these TRNs publicly available.

Abstract: Despite many advances, the pathogenesis of Alzheimer's disease (AD) and the commonest cause of dementia in the elderly remains incompletely understood. Recently, epigenetic modifications have been shown to play a potential role in neurodegeneration, but the specific involvement of epigenetic signatures landscaped by heterochromatin has not been studied in AD.Herein,we discovered that H3K9me3-mediated heterochromatin condensation is elevated in the cortex of sporadic AD postmortem brains. In order to identify which epigenomes are modulated by heterochromatin, we performed H3K9me3-chromatin immunoprecipitation (ChIP)-sequencing and mRNA-sequencing on postmortem brains from normal subjects and AD patients. The integrated analyses of genome-wide ChIP- and mRNA-sequencing data identified epigenomes that were highly occupied by H3K9me3 and inversely correlated with their mRNA expression levels in AD. Biological network analysis further revealed H3K9me3-landscaped epigenomes to be mainly involved in synaptic transmission, neuronal differentiation, and cell motility. Together, our data shows that the abnormal heterochromatin remodeling by H3K9me3 leads to down regulation of synaptic function-related genes, suggesting that the epigenetic alteration by H3K9me3 is associated with the synaptic pathology of AD.

Title: The synthetic amyloid bata oligomers induce pathological features associated with Alzheimer’s disease in nonhuman primates

Authors: F. YUE[1], S. FENG[2], T. ZHANG[2], C. YUE[2], ***N. JING**[2];
[1]Dept. of Neurobio., Beijing Inst. of Geriatrics, Xuanwu Hosp. of Capital Med. Univ., Beijing, China; [2]State Key Lab. of Cell Biol., Shanghai Inst. of Biochem. and Cell Biology, Chinese Acad. of Sci., Shanghai, China

Abstract: As an insidious and slowly progressive neurodegenerative disorder, Alzheimer's disease (AD) uniquely develops in humans but no other species. Thus, it has been difficult to replicate the progression and typical pathological features of AD in various animal models. The non-human primates share the closest similarities with human and are naturally attractive in modeling AD. However, it still remains largely unclear whether the pathological progress of AD can be reproduced in non-human primates. In this study, synthetic Aβ oligomers (AβOs) were intracerebrally delivered into the cerebral parenchyma of adult cynomolgus monkeys (*Maccaca fascicularis*). As short as 7 months later, massive Aβ plaques globally developed in the cynomolgus brain as in AD patients. More strikingly, intraneuronal neurofibrillary tangles formed in multiple brain regions and were reminiscent of those in AD patients. AβO-induced monkeys also displayed activated astrocytes and microglia surrounding Aβ plaques and the neuroinflammation was triggered in cynomolgus brain. The degenerative neural cells that closely associated with Aβ plaques were detected in temporal cortex of AβO-induced cynomolgus monkeys. Finally, we confirmed that delivering AβOs into parenchyma but not lateral ventricle induced multiple AD-like features in cynomolgus monkeys. Together, cynomolgus monkeys rapidly developed the early pathological features of AD upon synthetic AβOs infusion, suggesting that the AβO-induced cynomolgus monkey might be a promising research model for uncovering the early pathogenetic events of AD.

Abstract: Alzheimer’s disease (AD) is characterized by amyloid plaques, neurofibrillary tangles, and synaptic and neuronal loss. Recently, a rare autosomal dominant coding mutation, T835M, was discovered in the Un-coordinated 5c (*UNC5C*) netrin receptor gene that segregated with late-onset AD (LOAD). T835M alters a conserved amino acid in the hinge region of the UNC5C death domain, suggesting the mutation may increase apoptosis. Indeed, in primary hippocampal neurons, overexpression of UNC5C T835M increased cell death in response to neurotoxic stimuli including beta-amyloid (Aβ). These results suggest a mechanism by which UNC5C T835M may confer increased risk of LOAD, however the effects of this mutation in an AD animal model have not yet been explored. We hypothesize that the T835M mutation predisposes to LOAD by exacerbating neuronal death, as observed in the 5XFAD brain, via increased sensitivity to Aβ-induced neurotoxicity and UNC5C death domain activation. Toward this end, we generated a mouse knock-in (KI) model of Unc5c T835M and crossed it with the 5XFAD mouse model of amyloid pathology and neuron loss. Our preliminary results show that homozygous KI mice are very similar to WT littermate controls in terms of the histology, protein and RNA expression or in cell death. However, proteomics analysis of KI and wildtype mice brains showed upregulation of apoptotic proteins and down-regulation of neuronal proteins. We are further investigating mechanisms of cell death and distal phenotypes in 5XFAD; Unc5c T835M KI mice by biochemical, cellular, and unbiased proteomics approaches. Although neuron loss is a cardinal feature of AD, the molecular mechanism of cell death in AD is still unclear. We expect our results to provide valuable insight into the role of UNC5C T835M mutation in Aβ-associated cell death, and thereby identify novel therapeutic targets to prevent neuron loss in AD.

Ctr., New York, NY; [7]Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Down syndrome (DS) is a genetic disorder caused by triplication of chromosome 21. By middle-age DS individuals develop Alzheimer's disease (AD) neuropathology including amyloid-β plaques and neurofibrillary tangles, abnormal early endosomes, and degeneration of cholinergic basal forebrain neurons. The trisomic Ts65Dn mouse model of DS/AD recapitulates several key aspects of DS and AD pathology, including cognitive dysfunction, loss of basal forebrain cholinergic neurons (BFCNs), and dysregulation of the endosomal-lysosomal system. We hypothesize that BFCN degeneration stems from deficient neurotrophic support, a biproduct of aberrant septohippocampal endosomal transport. An inexpensive treatment modality, maternal choline supplementation (MCS) attenuates overexpression of genes underlying endosomal defects, indicating MCS may improve endosomal transport. We previously demonstrated that reproducible quantification of endosomal pathology is achievable via z-stack reconstruction using the 3D modeling program Imaris (Bitplane). Results indicate that 11 month old (MO) Ts65Dn mice had significantly increased Rab5-immunoreactive early endosomes per BFCN compared to disomic (2N) littermates when these offspring were fed a normal choline diet. MCS administered during the perinatal period decreased the average number of early endosomes per BFCN in both Ts65Dn and 2N mice, irrespective of genotype and endosomal pathology. To explore the extent to which early choline delivery can affect endosomal phenotype and BFCN survival, we compared Ts65Dn mice at two time-points: 3-4 MO (pre-BFCN degeneration) and 10-12 MO (post-BFCN degeneration). BFCNs were dual labeled with antibodies directed against Rab5 and choline acetyltransferase (ChAT): an early endosome marker and a cholinergic marker, respectively. Quantitative analysis of endosomal compartments was performed using Imaris 9.1 software. Unbiased neuronal counts and density measurements, as well as morphometric analysis of BFCN size, were achieved utilizing specialized macros in ImageJ. Preliminary results reveal no significant differences between Ts65Dn and 2N littermates at 3-4 MO. Comparison of early endosome quantification between young and aged cohorts indicates that the average number of Rab5-positive endosomes per BFCN increases with age regardless of genotype. MCS treatment *in utero* lessens the magnitude of this increase in both Ts65Dn and 2N offspring at 11 MO, suggesting that early-life MCS treatment may confer long-lasting neuroprotective benefits on vulnerable neuronal populations. One mechanism of action may be through the rescue of endosomal pathology.

Title: RNA-sequencing (RNA-seq) of medial septal nucleus basal forebrain cholinergic neurons (BFCNs) within the Ts65Dn mouse model of Down syndrome (DS) and Alzheimer's disease (AD) identifies dysregulated transcriptional pathways

Authors: *M. J. ALLDRED[1,3], S. H. LEE[2], S. C. PENIKALAPATI[1], T. LHAKHANG[4], A. HEGUY[4], S. D. GINSBERG[1,3,5,6];

Abstract: Basal forebrain cholinergic neuron (BFCN) loss is a hallmark of individuals with Down syndrome (DS) and Alzheimer's disease (AD). DS subjects also experience hippocampal CA1 pyramidal neuron degeneration and synaptic loss. Further, they develop AD pathology including neurofibrillary tangles and amyloid plaques by the third decade of life. The septohippocampal pathway, including BFCNs which project to CA1 pyramidal neurons exhibit selective vulnerability in both DS and AD patients during disease progression. Current therapeutics have been unsuccessful in slowing disease progression, likely due to the complex pathological interactions and dysregulated pathways that are still poorly understood. The Ts65Dn mouse model recapitulates both the cognitive and morphological deficits of DS and AD, including BFCN degeneration. We utilize this trisomic mouse model to further understand the mechanistic pathways that underlie BFCN degeneration. We performed high-throughput, single population RNA sequencing (RNA-seq) to assess expression level changes in BFCNs from the medial septal nucleus (MSN) in the Ts65Dn mouse and in normal disomic (2N) littermates. Expression profiles from MSN BFCNs were generated by laser capture microdissection (LCM) to isolate ~500 choline acetyltransferase-immunoreactive neurons in adult Ts65Dn and 2N littermates. This procedure enabled quantitative analysis of mRNAs and noncoding RNAs to help understand mechanism(s) underlying neurodegeneration, and link these expression level changes to established pathological hallmarks and cognitive decline for therapeutic development

in human DS and AD. RNA-seq library preparation was performed on isolated RNA species to determine the viability RNA-seq from individual neuronal cell types for downstream transcriptional analysis. Results indicated unique transcriptomic profiles for MSN BFCNs from Ts65Dn and 2N littermates at ~6 months of age. We further analyzed the resulting differences utilizing Ingenuity Pathway Analysis to link the changes seen in gene expression profiles to canonical pathways, along with dysregulated disease networks and aberrant physiological functions. Preliminary results indicate pathological changes in specific genes within a multitude of pathways, including RNA expression and molecular transport. Validation strategies include qPCR from LCM-Nissl stained neurons and protein assays from regional tissue dissections. The resultant expression profiles are posited to provide key information leading to mechanistic understanding of selective vulnerability within the septohippocampal circuit in models of DS and AD for therapeutic intervention.

Title: RNA-sequencing (RNA-seq) of distinct deep and superficial hippocampal CA1 pyramidal neuron populations in a mouse model of Down syndrome (DS) and Alzheimer’s disease (AD)

Authors: *S. D. GINSBERG[1,4,5,6], S. C. PENIKALAPATI[1], H. M. CHAO[1,4], S. H. LEE[2], A. HEGUY[7], E. PETKOVA[3,8], M. J. ALLDRED[1,4];

Abstract: People with Down syndrome (DS) have intellectual disability (ID) and develop hallmark Alzheimer’s disease (AD) pathology during midlife. There are several circuits underlying memory and executive function in the DS and AD brain that are particularly

vulnerable, most notably synaptic and neurodegeneration of the interconnected basal forebrain cholinergic system and the hippocampus. A fundamental lack of knowledge exists as to the etiology and mechanisms of disease progression within the septohippocampal circuit in DS, AD, and relevant models. Studies by Masurkar et al. (2017) demonstrate murine CA1 pyramidal neurons have two distinct sublayers along the radial axis, deep and superficial neurons, that also differ along the transverse axis with regard to innervation and function. While this mediolateral innervation pattern is postulated to have an effect on spatial and non-spatial learning and memory, there is a current lack of knowledge linking gene and encoded protein expression to the learning and memory behaviors thought to be associated with these subregions. Herein, we combined laser capture microdissection of these individual CA1 pyramidal neuron populations (deep and superficial; approximately 500 Nissl-stained neurons per assay) with RNA-sequencing (RNA-seq) to determine differences in gene expression levels that may underlie spatial and non-spatial memory associated with proper CA1 structure and function. Gene expression profiles were accrued from a trisomic mouse model of DS and AD, Ts[Rb(12.17^{16})]2Cje (Ts2), which presents phenotypic and pathological features similar to the Ts65Dn mouse model as well as the human condition including synaptic loss and degeneration of basal forebrain cholinergic neurons. Importantly, trisomic mice have deficits in spatial and non-spatial learning and memory linked to the septohippocampal pathway and CA1 pyramidal neurons. Preliminary RNA-seq results indicate that deep and superficial CA1 neurons represent distinct CA1 pyramidal neuron populations with differential expression profiles. We are determining whether they also have significantly different noncoding RNA (ncRNA) profiles. Preliminary profiling results support the hypothesis that both deep and superficial CA1 pyramidal neurons have dysregulated gene expression in Ts2 mice, and we have undertaken pathway analysis to see which individual genes as well as mechanistic pathways are specifically impacted. Understanding expression profiles of distinct cell populations involved in learning and memory may translate into novel treatment options for DS and could possibly lead to novel treatments for cognitive decline in AD.

Title: First identification of ITM2B partners in human retina

Authors: *J. WOHLSCHLEGEL[1], M. ARGENTINI[1], T. LÉGER[2], C. CONDROYER[1], C. ZEITZ[1], I. AUDO[1];

Abstract: ITM2B is a type II ubiquitous protein which role remains unclear. *ITM2B* mutations have been associated with different disorders: mutations leading to longer mutant proteins have been reported in two distinct Alzheimer-like autosomal dominant disorders with early-onset progressive dementia, cerebellar ataxia, spasticity associated and variable degree of deafness, early onset-cataract and vascular retinal abnormalities. Both disorders share neurological features including severe cerebral amyloid angiopathy, non-neuritic plaques, and fibrillary tangles as in Alzheimer Disease. Our group reported a missense mutation in *ITM2B* underlying an unusual retinal dystrophy with no dementia. This finding would suggest a specific role of ITM2B in the retina. A new alternative transcript leading to exon 1 skipping and resulting in a shorter protein was recently reported. The identification and characterization of retinal transcripts for ITM2B as well as the corresponding proteins and protein partners would bring new insights to the cellular functions of ITM2B in the retina. Using RT-PCR, we demonstrated the presence of at least two transcripts for *ITM2B* in human retina leading to a 266- and 210-amino acid (aa) proteins. We then performed ITM2B immunoprecipitation followed by quantitative proteomic analysis on normal human retina using two distinct antibodies: one (sc-374362, Santa Cruz), reacting against the 266-aa isoform whereas the other (PA531441, Thermofisher) recognizing both the 266- and 210-aa isoforms of ITM2B. Two pools of ITM2B protein partners were identified for each antibody and compared using ClueGo plugging for functional annotation. Besides common protein partners, specific protein partners for the 210-aa isoform were identified suggesting a role in mitochondrial homeostasis. To our knowledge, this is the first report of ITM2B interactome in human retina. Our findings support a unique and specific role for the newly identified *ITM2B* protein isoform. Further disease modeling using retinal organoids derived from patients will allow to investigate how the corresponding mutant isoforms impact on protein interactions and will bring new insights in the molecular mechanisms associated with ITM2B-related retinal disease.

Title: Noise-induced hearing loss accelerates cognitive decline in a mouse model of Alzheimer's disease

Authors: S. COCCO[1], F. PACIELLO[2], M. RINAUDO[1], G. CONFORTO[1], D. TROIANI[1], A. R. FETONI[2,3], M. V. PODDA[1,3], G. PALUDETTI[2,3], *C. GRASSI[1,3];

Abstract: Chronic exposure to noise induces hearing loss due to cochlear damage within the organ of Corti. Noise-induced peripheral damage also up-spreads to auditory cortex, causing both functional (i.e., reduced basal synaptic transmission) and structural (i.e., reduced spine density in layer 2/3 pyramidal neurons) alterations (Paciello et al., 2018). Epidemiological evidence suggests that hearing loss might affect cognitive functions. Here we investigated the effects of noise exposure on memory performances in a mouse model of Alzheimer's disease (AD) to evaluate if hearing loss accelerates cognitive decline in AD. Transgenic mice developing a time-dependent AD-like phenotype (i.e., male 3×Tg-AD) were exposed to noise (100 dB, 60 min/day for 10 days) at 2 months of age and they were studied at 3, 6 and 9 months. Auditory brainstem response (ABR) recordings were used to evaluate auditory function. To investigate basal synaptic transmission, electrophysiological recordings were performed at layer 2/3 horizontal connections of auditory cortex brain slices. Novel object recognition (NOR) and open field (OF) tests were performed to evaluate recognition memory and locomotor activity, respectively. Noise exposure induced a significant auditory threshold elevation in 3×Tg-AD mice at each time point studied thus worsening age-related hearing loss. In particular, noise exposure caused a threshold shift of about 35, 15 and 15 dB at middle-high frequencies (12-32 kHz) in 3×Tg-AD mice of 3, 6 and 9 months compared to age-matched controls ($P=0.0002$, $P=0.0004$ and $P=0.006$, respectively). At electrophysiological level, basal synaptic transmission at layer 2/3 horizontal connections was impaired in 3×Tg-AD mice exposed to noise compared to controls ($P<0.001$ at 3 months, $P<0.001$ at 6 months, $P=0.01$ at 9 months). At the behavioral level, cognitive decline was clearly manifested in male 3×Tg-AD mice at 9 months of age, as revealed by NOR tests assessing short-term (NOR STM: $P=0.04$, 9-month-old vs. 6-month-old 3×Tg-AD mice) and long-term memory (NOR LTM: $P=0.03$, 9-month-old vs. 6-month-old 3×Tg-AD mice). Of note, noise-induced hearing loss anticipated cognitive deficits inducing memory alterations at 6 months of age (NOR STM: $P<0.001$; NOR LTM: $P=0.01$). No changes of locomotor activity were observed in noise-exposed 3×Tg-AD mice compared to controls at any studied ages ($P>0.05$). Our findings provide novel evidence that hearing loss may accelerate cognitive decline in Alzheimer's disease and pave the way to further studies investigating the cross-talk between auditory cortex and brain areas directly involved in cognitive functions.

Title: Amyloid precursor protein and Aβ in the ear and auditory system - Assessment of possible mechanistic relationships between hearing loss and cognitive decline in Alzheimer's disease

Authors: *C. M. YUEDE[1], D. F. WOZNIAK[1], K. K. OHLEMILLER[2], M. E. WARCHOL[2], M. A. RUTHERFORD[2], J. R. CIRRITO[3];

Abstract: Many studies demonstrate a relationship between hearing loss and Alzheimer's disease (AD), in which the degree of hearing loss predicts the rate of cognitive decline (Lin et al., 2013, Hardy et al., 2016). Gates and colleagues (2002) reported that central auditory processing dysfunction may precede the onset of clinical dementia and can be detected many years before the diagnosis of AD. Whether these changes in hearing function occur because of a common underlying pathology or speed up the progression of AD due to the loss of sensory input remains unknown. Basic research into the mechanisms driving the link between hearing loss and AD are needed to provide a better understanding of this relationship. We hypothesize that increased soluble Aβ in the central auditory system drives auditory processing deficits that are detectable before the onset of cognitive impairments. Using the APP/PS1 mouse model of AD and their wildtype littermates (WT), we stained for APP/Aβ in the cochlea, focusing on the afferent synapses between sensory hair cells and auditory nerve fibers. We measured acoustic startle response and prepulse inhibition (PPI) of the acoustic startle response in a group of APP/PS1 and WT mice prior to the development of cognitive deficits, to identify any changes in behaviors involving auditory processing. Soluble and insoluble Aβ levels were measured in the brain and correlated with measures of startle response and PPI. We found an exaggerated startle response in APP/PS1 mice compared to WT littermates, and a significant correlation between soluble Aβ levels in the brain and deficits in PPI. Soluble Aβ could impact central auditory function/processing which could lead to deficits in cognitive function. Understanding factors driving the link between hearing loss and AD may shed light on AD pathology and progressive functional deficits. In addition, hearing diagnostics could be an early behavioral biomarker of emerging AD and may be useful low-cost, clinical screening tools for identifying patients that may benefit from preventative therapies before the appearance of overt cognitive symptoms.

Title: Intrahippocampal administration of amyloid beta 42 diminishes catecholaminergic axons and disrupts spatial contextual memory

Authors: *L. LANDA NAVARRO, C. VELÁZQUEZ DELGADO, F. BERMÚDEZ RATTONI;
Neurociencias cognitivas, UNAM IFC, Ciudad de México, Mexico

Abstract: Alzheimer’s disease (AD) is the most prevalent type of dementia in the elderly. Its major characteristics are amyloid-beta (Aβ) aggregates, neurofibrillary tangles of hyperphosphorylated tau, synaptic failure and neuritic dystrophy that lead to cognitive impairment and memory loss.
It has been reported that increased Aβ deposition or its exogenous administration reduces catecholaminergic neurotransmission, impairs recognition memory and converts long-term potentiation in long- term depression in the cerebral cortex and dorsal hippocampus. Recent evidence from our laboratory has shown that Aβ pathologic alterations, in a transgenic mouse model for AD, coincide with catecholaminergic neurotransmission disruption and recognition memory impairment. Moreover, recently we have shown data that links catecholaminergic input into the hippocampus with the encoding of novel contextual information. In this paper, we aim to evaluate the effects of exogenous Aβ administration on long-term spatial and contextual memory evocation and the induced changes in the catecholaminergic system.
Methods: In a Morris Water Maze (MWM) task, we measured the number of crosses with one-way ANOVA Fisher LSD. Also, in a location memory task (OLM) we measured the preference of a novel object location with a two tailed Student's t test. To evaluate the length of tyrosine hydroxylase (TH +) and microtubule-associated protein 2 (MAP2), stereology analyses were evaluated using two-way Fisher LSD ANOVA.
We found that the intrahipocampal administration of Aβ after memory acquisition and before evocation impairs spatial memory ($F_{4,39} = 6,256$, $P = 0.0005$), codification of novel contextual information ($t_9 = 1.446$, $p = 1.822$) and decreases TH + axons after 24 h, but not after five days ($F_{2.21} = 10.58$, $P = 0.0007$). While no differences were found when analyzing the MAP2 +

axons (F2,8 = 1,351, P = 0.3123).
Catecholaminergic neurotransmission and spatial memory evocation are disrupted by intrahippocampal Aβ administration. These findings suggest the importance of the catecholaminergic system in AD that is relevant for the development of new therapeutic targets.

Title: Divergent roles of astrocytic versus neuronal glutamate transporter EAAT2 deficiency on cognition and overlap with aging and Alzheimer's molecular signatures

Authors: A. SHARMA[1], S. KAZIM[1], C. LARSON[2], A. RAMAKRISHNAN[1], J. GRAY[2], B. MCEWEN[2], P. ROSENBERG[3], L. SHEN[1], *A. C. PEREIRA[1];
[1]Icahn Sch. of Med., New York, NY; [2]The Rockefeller Univ., New York, NY; [3]Boston Children's Hosp., Boston, MA

Abstract: EAAT2 is the major glutamate transporter in the brain expressed predominantly in astrocytes and at low levels in neurons and axonal terminals. EAAT2 expression is reduced in aging and sporadic AD patients' brains. EAAT2's role in cognitive aging and its associated mechanisms remain largely unknown. Conditional deletion of astrocytic EAAT2 with GFAP-CreERT2 and neuronal EAAT2 with Syn-Cre mouse lines in aging mice results in spatial reference learning and long-term memory deficits. Astrocytic, but not neuronal EAAT2 deletion, leads to early deficits in short-term memory and learning. Transcriptomic analysis of hippocampus from astrocytic EAAT2 deficiency demonstrates dysfunction of immune pathways, which negatively correlate with hippocampus dependent cognitive behavior in mice. Astrocytic, not neuronal EAAT2 deficiency in the hippocampus also has overlapping transcriptomic signature with human aging and Alzheimer's disease.

Title: A novel epigenetic mechanism for synaptic and cognitive deficits in Alzheimer's disease

Authors: *J. B. WILLIAMS, Q. CAO, W. WANG, Z. YAN;
Physiol. and Biophysics, Univ. At Buffalo Jacobs Sch. of Med. and Biomed. Sci., Buffalo, NY

Abstract: Cognitive deficits associated with Alzheimer's disease (AD) have been linked to synaptic dysregulation in the prefrontal cortex (PFC), a brain region involved in 'executive' functions, including working memory and decision making, however, the exact mechanisms remain to be elucidated. We hypothesize that the alteration of transcription of genes regulating synaptic functions in AD could be due to abnormal epigenetic changes in PFC. Consistent with it, we have found the significantly elevated histone 3 lysine 4 trimethylation (H3K4me3) and its catalyzing enzyme Smyd3 in PFC from AD human postmortem tissues and P301S Tau transgenic mouse model of AD. Behavioral assays indicated that systemic administration of the Smdy3 inhibitor, BCI-121, rescued spatial memory and novel object recognition memory deficits in P301S Tau mice. The Smdy3 inhibitor also restored the level of synaptic AMPA and NMDA receptors in PFC of P301S Tau mice. Using chromatin immunoprecipitation sequencing (ChIPseq), we discovered that in PFC of P301S Tau mice, there was the significantly increased enrichment of H3K4me3 at the promoter region of Fbxo2, an E3 ubiquitin ligase controlling the degradation of NMDA receptor subunits, which was associated with the higher level of Fbxo2 mRNA revealed by qPCR assays. These data suggest that the elevated H3K4me3 methyltransferase Smyd3 in AD induces the upregulation of the E3 ligase Fbxo2 in PFC, leading to the increased degradation of NMDARs and cognitive deficits. By targeting the epigenetic factor Smyd3, it provides a novel strategy to restore synaptic function and cognitive behaviors in AD.

Title: Progressive deterioration of cellular and network dynamics in hippocampus of the novel Alzheimer's mouse model App^{NL-G-F}

Authors: *L. ARROYO GARCÍA, Sr, Y. ANDRADE-TALAVERA, H. BALLEZA-TAPIA, A. G. ISLA, P. NILSSON, A. FISAHN;
Neurogeriatrics, Karolinska Institutet, Stockholm, Sweden

Abstract: Alzheimer's Disease (AD) is one of the most devastating neurodegenerative diseases, characterized by neuronal loss and decrease in cognitive capabilities. The exact cause of AD is still unknown, but the disease involves the misfolding and aggregation of amyloid-β peptide (Aβ). Previously, different mouse models attempted to mimic AD pathology by overexpressing the Aβ precursor protein (APP). This approach generates unwanted side effects in the animals due to the high unphysiological APP levels that interfere with data analysis. Recently, a new APP knock-in mouse model (App^{NL-G-F}) has been generated that shows an aggressively increase of Aβ42 and Aβ42/Aβ40 ratio without APP overexpression and avoids the unwanted side effects of APP overexpression models. These mice develop Aβ plaques from two months of age and cognitive impairment at six months of age.
The aim of this project is to use the App^{NL-G-F} mouse model to investigate the cellular mechanisms responsible for aberrant network oscillations in the gamma-frequency band (30-80Hz) and the neuronal dysfunction that has been observed in AD patients. We used 2-, 4- and 6-months old App^{NL-G-F} and wild type (WT) mice to evaluate their capacity to generate gamma oscillations, to characterize the electrophysiological state (neuronal E_m, EPSCs, IPSCs) of fast spiking interneurons (FSP) and pyramidal cells (PC) in the hippocampal CA3 region and to evaluate the action potential synchronization of these neuronal classes during gamma oscillations. Our results show gamma oscillation-impairment in the App^{NL-G-F} mice at 2-months old, and a progressive further deterioration at 4- and 6-months of age. Also, we found alterations in FSP and PC action potential synchronization across the different ages. Together, these results confirm previous acute Aβ studies and provide further evidence for the network and cellular mechanism responsible for the neuronal dysfunction and gamma oscillation disruption in AD. In upcoming work, we will use the App^{NL-G-F} model for evaluation of novel treatment approaches.

Title: Changes in dentate gyrus granule cell spontaneous excitatory postsynaptic potentials and evoked responses to perforant path stimulation evaluated at 2 months of age in the Tg2576 mouse model of Alzheimer's disease neuropathology

Authors: *D. ALCANTARA-GONZALEZ, E. CHARTAMPILA, H. SCHARFMAN;
Ctr. for Dementia Res., Nathan S. Kline Inst. For Psychiatric Res., Orangeburg, NY

Abstract: Increasing evidence suggests that Alzheimer's disease begins earlier than the age when there is classic neuropathology, i.e., amyloid-β plaques and neurofibrillary tangles. In animal models, we previously showed abnormalities as early as 5 weeks of age (Kam et al., 2017). The abnormalities occurred in two mouse models where the precursor to amyloid-β is mutated and overexpressed (Tg2576, APP23). The EEG showed interictal spikes in sleep that increased with age. The spikes were recorded using electrodes over the cortex and hippocampus, and the data suggested emergence in hippocampus, especially in a mouse model of Down's syndrome (Ts65n). To determine changes that might be responsible for interictal spikes, recordings were made in hippocampal slices. Using extracellular recording, the dentate gyrus showed differences between Tg2576 mice and controls (WT). Granule cell (GC) layer recordings showed a larger evoked population spike without a change in the evoked field EPSP in response to electrical stimulation of the major glutamatergic input, the perforant path. GCs were then patched from mice that were 2-2.5 months of age. Spontaneous EPSPs (sEPSPs) showed an increased frequency in Tg2576 mice relative to WT (1.29 ± 0.10 events/s, n=16 vs 2.2 ± 0.18, n=21, respectively; p=0.0003). There was a small but significant decrease in sEPSP amplitude (0.49 ± 0.03 vs 0.43 ± 0.03 mV, respectively; p=0.046). To clarify if the changes in excitatory events could be related to altered intrinsic excitability, intrinsic properties were studied. GCs from Tg2576 mice showed a more hyperpolarized resting membrane potential (RMP; -76.30 ± 1.97 mV, n=22 vs -71.32 ± 1.70, n=19; p=0.034), reduced input resistance (226.1 ± 17.6 vs 271.6 ± 16.4 MΩ; p=0.032), and the time constant was reduced (23.9 ± 1.5 vs 29.9 ± 1.7/sec, p=0.006). The action potential at threshold (evoked by direct current injection from RMP) exhibited an increased time to peak (1.31 ± 0.08 vs 1.08 ± 0.10 ms; p=0.034) and a reduction in the maximum rate of rise (224.3 ± 16.9 vs 283.9 ± 23.3 μV/ms; p=0.021). These data suggest that the changes in sEPSPs are accompanied by altered intrinsic properties. Many intrinsic properties showed decreased excitability. Therefore, the increased frequency of sEPSPs in Tg2576 mice is unlikely

to be a result of changes in intrinsic properties. However, the small decrease in sEPSP amplitudes could be related to the changed intrinsic properties. Together the results suggest several alterations in dentate gyrus GCs in a very early stage of life of the Tg2576 mouse model, supporting the view that many changes occur long before plaque deposition.

Title: MRI histopathology correlations of amyloid related imaging abnormalities (ARIA) in post mortem human brain samples

Authors: *A. SCHERLEK[1], D. BOCHE[2], J. A. R. NICOLL[2], B. J. BACSKAI[1], A. J. VAN DER KOUWE[1], S. M. GREENBERG[1], M. P. FROSCH[1], S. J. VAN VELUW[1];
[1]Massachusetts Gen. Hosp., Boston, MA; [2]Univ. of Southampton, Southampton, United Kingdom

Abstract: Amyloid-Related Imaging Abnormalities (ARIA) are MRI-defined adverse events frequently observed in the context of anti-Aβ immunotherapy trials in patients with Alzheimer's disease (AD). ARIA-H include cerebral microbleeds (CMBs) and cortical superficial siderosis (cSS) and ARIA-E vasogenic edema. The underlying histopathology and mechanisms of ARIA remain unknown, although coexisting Cerebral Amyloid Angiopathy (CAA) seems to be a risk factor. We used *ex vivo* MRI in *post mortem* human brain samples from patients that underwent anti-Aβ immunotherapy during life to determine presence and underlying histopathology of ARIA. Cases were selected from the long-term follow-up study of patients who enrolled in the first clinical trial of active Aβ immunization for AD (AN1792; Elan Pharmaceuticals Inc) and consented to brain donation. 13 cases with available formalin-fixed brain slabs were selected: 11 immunized and 2 placebo. One coronal slab from the occipital lobe per case was imaged on a 7T MRI scanner. The protocol included a T2-weighted (voxel size 300 μm^3) and a T2*-weighted gradient echo sequence (voxel size 200 μm^3). Each scan was screened for possible ARIA-E and ARIA-H. Representative samples were cut in serial sections and stained with Hematoxylin & Eosin (H&E), Perl's Prussian blue (for iron), and Von Kossa (for calcifications). The cases were on average 80 ± 9 years old at time of death and mean survival time after first immunization was

110 ± 52 months [range 20-184]. There was evidence of plaque removal in 10/11 (91%) of the immunized cases, as previously reported. On MRI, evidence of possible ARIA-E was observed in 5/11 (45%) immunized cases, appearing as diffuse T2-hyperintensities in the cortex or white matter. No evidence of possible ARIA-E was observed in placebo cases. Histopathology of areas with ARIA-E showed tissue loss and vacuolization on H&E-stained sections, without iron accumulation. Evidence of possible ARIA-H was observed on MRI in 5/11 (45%) immunized cases, appearing as either focal or disseminated cSS. No CMBs were observed on MRI in any of the cases. Histopathology of areas with cSS showed iron-positive vessels and neurons that also stained positive for calcium. Some degree of iron and calcifications was also observed in placebo cases. These preliminary observations suggest presence of ARIA in *post mortem* brain samples of patients that underwent anti-Aβ immunotherapy during life. The pathological findings confirm edema and old bleeding events as the substrate of ARIA-E and ARIA-H. Ongoing work is aimed at increasing the number of control cases to determine the specificity of these findings as well as assessing CAA severity in areas with ARIA.

Title: Noradrenergic denervation-supersensitivity in the TgF344-AD rat driven by β-adrenergic receptors

Authors: *A. GOODMAN, L. L. MCMAHON;
Cell Developmental and Integrative Biol., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: The locus coeruleus (LC) is the sole source of norepinephrine (NE) for most of the brain and maintains everything from cognitive abilities to mood and even normal sleep-wake cycles. Despite the importance of the LC in maintaining a wide-range of cognition/behavior, it is exceedingly understudied in the context of neurodegenerative diseases. In Alzheimer’s disease (AD) the deposition of hyperphosphorylated tau (pTau) first occurs in the LC, and its degradation is correlated with the transition into amnestic mild cognitive impairment. Selective ablation of the LC in animal models of AD cause exacerbation of pathology and

synaptic/cognitive symptoms. Furthermore, degeneration of the noradrenergic (NA) system causes an upregulation of most adrenergic receptors (ARs) leading to a supersensitivity to agonist receptor activation. The novel TgF344-AD rat (containing the APPSwe and PSEN1DeltaE9 mutations driven by a mouse prion promoter) is one of the most comprehensive models of human AD and the first rodent model to display endogenous pTau accumulation in the LC. Previous studies in our lab in the TgF344-AD rat found deficits in basal synaptic transmission at medial perforant path (MPP) to dentate granule cell (DGC) synapses and pathologically increased long-term potentiation (LTP) as early as 6-months of age. In new studies we found that NA fiber density in the dentate gyrus is reduced by an average of 37% (p=0.03) as early as 6-months (and similar amounts in other hippocampal subfields), but in extracellular dendritic field potential recordings at MPP-DGC synapses in acute slices, synaptic potentiation induced by NE [40μM] or the β-AR agonist isoproterenol (ISO) [1μM] is unchanged between Tg and non-Tg littermates. However, by 9-months, [1μM] ISO induces heightened potentiation that is longer lasting ($p<0.01$) in the Tg rats, suggesting increased sensitivity of β-ARs that is masked with higher concentrations of ISO [10μM]. Furthermore, Tg rat slices have a faster time to reach peak reaction to the application of NE which is abolished with the addition of the β-AR antagonist propranolol [10μM]. Collectively these results are consistent with a heightened function of β-ARs following NA denervation of the hippocampus.

Title: Investigating the roles of Papez circuit in health and Alzheimer’s disease

Authors: *W.-C. HUANG[1], L. LIU[1], H. MATHYS[1], Z. PENG[1], F. GAO[1], L.-H. TSAI[1,2]; [1]The Picower Inst. for Learning and Memory, Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA; [2]Broad Inst. of MIT and Harvard, Cambridge, MA

Abstract: Loss of memory and cognition are core symptoms of Alzheimer’s disease (AD), but the neural circuits underlying these deficits remain poorly understood. Interrogating disrupted neural circuits in AD might reveal neurobiological substrates leading to cognitive decline and identify potential targets for therapeutic intervention. Accumulating evidence indicates that impaired memory in early AD reflects much wider neurodegeneration in an extended memory network (i.e. Papez circuit). As a subcortical hub of the Papez circuit, the mammillary body

(MB) receives inputs from the hippocampus, and outputs to the anterior thalamus, which projects back to the neocortex and the hippocampus. Several autopsy studies have reported amyloid deposition, neurofibrillary tangles, reduction of dendritic arbors, and neuronal loss in the MB of AD individuals. Moreover, lesions in the MB result in anterograde amnesia and memory deficits in humans and animal models. However, the mechanisms by which the activity of MB circuits regulates memory and whether impairment of these circuits contributes to the progression of memory decline in AD remain elusive. Here, we use molecular, cellular, and electrophysiological approaches to investigate MB circuits at multiple levels in wildtype and AD model mice. Our findings identify a previously undefined memory retrieval circuit composed of anatomically, genetically, and functionally distinct neuronal subtypes, and highlight the role of this circuit as a critical inflection point in the progression of memory decline in Alzheimer's disease.

Title: Retromer repletion with AAV9-VPS35 restores endosomal function in the mouse hippocampus

Authors: *Y. H. QURESHI[1], D. E. BERMAN[1], R. L. KLEIN[2], V. M. PATEL[1], S. SIMOES[1], S. KANNAN[1], R. COX[3], S. D. WAKSAL[4], B. STEVENS[5], G. A. PETSKO[6], S. A. SMALL[1]; [1]Columbia Univ., New York, NY; [2]Dept. Pharmacol., LSUHSC, Shreveport, LA; [3]Cornell Univ., New York, NY; [4]Meira GTX, New York, NY; [5]Harvard Med. Sch. Neurobio., Boston Children's Hosp., Boston, MA; [6]Harvard Univ., Boston, MA

Abstract: Retromer has emerged as a master conductor of endosomal trafficking, and VPS35 and other retromer-related proteins are found to be deficient in late-onset Alzheimer's disease (AD). Depleting VPS35 in neurons impairs retromer function, affecting for example the trafficking of the amyloid-precursor protein (APP) and the glutamate receptor GluA1. Whether VPS35 repletion, after chronic in vivo depletion, can rescue these impairments remains unknown. Here we set out to address this question by using a viral vector approach for VPS35

repletion. First, we completed a series of studies using neuronal cultures in order to optimize AAV9-VPS35 delivery, and to understand how exogenous VPS35 expression affects its endogenous levels as well as its binding to other retromer proteins. Next, we completed a series of studies in wildtype mice to determine the optimum protocol for in vivo delivery of AAV9-VPS35 to the hippocampus. In wildtype mice/neurons a pattern consistent with autoregulation was observed, whereby the higher the levels of exogenous VPS35 expressed, the lower the levels of endogenous VPS35 were detected. Co-immunoprecipitation studies were performed to establish that exogenous VPS35 binds endogenous retromer core proteins. We relied on information from WT mice studies to deliver optimal dose of AAV9-VPS35 to the hippocampus of mice genetically engineered to have chronic, neuronal-selective, VPS35 depletion. VPS35 repletion in the hippocampus was found to normalize APP cleavage and to restore glutamate receptor levels. Unexpectedly, chronic VPS35 depletion in neurons caused glial activation, similar to the pattern observed in AD, which was also partially normalized by VPS35 repletion. Taken together, these studies strengthen the mechanistic link between retromer and AD, and have therapeutic implications.

Title: Cleavage of neural cell adhesion molecules by BACE1 is spatio-temporally regulated *in vivo*

Authors: *W. KIM[1], S. LOMOIO[1], C. BANEVICIUS[2], H. WATANABE[2], G. TESCO[1]; [1]Neurosci., Tufts Univ. Sch. of Med., Boston, MA; [2]Tufts Univ., Boston, MA

Abstract: β-site amyloid precursor protein cleaving enzyme 1 (BACE1) cleaves amyloid precursor protein (APP) to initiate the generation of amyloid beta peptides (Aβ). Studies strongly suggest that Aβ is associated with synaptic dysfunction and neuronal loss in Alzheimer's disease (AD). Thus, BACE1 is considered a prime therapeutic drug target for lowering Aβ levels in the AD brain. However, very recently, two clinical trials using two different BACE1 inhibitors in patients with prodromal or preclinical AD were halted due to the worsening of cognitive functions, most likely owing to mechanism-based side effects.
In addition to APP, several neuronal proteins, including the neural cell adhesion molecule L1-like protein (CHL1) have been identified as BACE1 substrates and validated *in vivo*. We report here, for the first time, that neural cell adhesion molecule 1 and 2 (NCAM1 and NCAM2, respectively) are BACE1 substrates*in vivo*. Neural cell adhesion molecules have been shown to regulate formation, maturation, and maintenance of synapses. Since synaptic loss is one of the earliest signs of AD, the relationship between NCAMs and AD has been studied intensively. Interestingly, reduced synaptic NCAM1 and NCAM2 levels were reported in AD brains. BACE1-mediated processing of NCAM1, NCAM2 and CHL1 was analyzed in the olfactory bulb and hippocampus of wild type mice and BACE1-/- mice at three different ages (postnatal day 10 (P10), 4 and 12 months). NCAM2 was cleaved in the olfactory bulb of wild type but not BACE1-/- mice at all ages analyzed. Instead, NCAM1 was processed by BACE1 in olfactory bulb at 4 and 12 months of age but not at P10 in wild type mice. Moreover, CHL1 was processed by BACE1 in olfactory bulb at P10 and 4 months of age but not at 12 months of age in olfactory bulb. In the hippocampus, NCAM1 and NCAM2 BACE1-mediated processing was detected only in synaptosomes but not in total homogenates. In contrast, CHL1 processing was clearly detected in both hippocampal homogenates and synaptosomes.
We also found that NCAM2 but not NCAM1 is sequentially cleaved by BACE1 and γ-secretase*in vitro*. Next, we identified and validated the BACE1 cleavage site of NCAM1 and NCAM2 by mass spectrometry and site-directed mutagenesis.
Taken together, our data demonstrates that the regulation of BACE1-mediated processing of neural cell adhesion molecules (CHL1, NCAM1, and NCAM2) depends on the regions of brain, age, and subcellular localization *in vivo*, suggesting that BACE1 may play important roles in physiological functions by regulating the proteolysis of substrates spatio-temporally.

Title: Converging cellular signaling pathways driving early synaptic pathology in AD

Authors: S. MUSTALY[1], S. SCHRANK[1], J. MCDAID[1], R. A. MARR[1], ***G. E. STUTZMANN**[2];
[1]Neurosci., RFUMS/Chicago Med. Sch., North Chicago, IL; [2]Ctr. for Neurodegenerative Dis. and Therapeut., Rosalind Franklin Univ. /Chicago Med. Sch., North Chicago, IL

Abstract: To date, the cellular mechanisms that directly lead to memory deficits in AD have remained elusive, likely due to insufficient understanding of the basic pathogenic mechanisms that arise early in the disease process. Memory encoding is initiated at the synapse; thus it makes sense functionally that synaptic defects are most highly correlated with memory loss in AD. While aberrant protein aggregations are an attractive target for therapeutic development, their association with cognitive functions and to synaptic properties are not clear. To better identify key cellular mechanisms that drive later memory encoding deficits, we and others are looking to upstream signaling abnormalities that directly couple to synaptic structure and function and occur prior to amyloid and tau pathology. Here, using a combination of patch clamp and field potential electrophysiology, live-cell fluorescent imaging of intracellular signaling and organelle functioning, hippocampal neural network imaging, electron microscopy, and immunoassays, we asked what the functional relationships are among key organelles responsible for protein handling, calcium regulation, and cellular metabolism that can regulate synaptic activity. Our goal was to identify the extent to which dysfunction in one organelle may impact functions in others, thus linking ER calcium and misfolded protein handling, lysosomal-mediated degradation and autophagy clearance, and mitochondrial bioenergetics with synaptic function and vesicle release properties. Using mouse models of AD, human neurons derived from AD patients using direct reprogramming methods, and cellular model systems, we demonstrate that the core later stage features of AD, such as soluble and insoluble amyloid species, phosphorylated tau, and synaptic loss can be linked to altered organelle functionality, particularly those that require acidic compartments and strong ionic gradients. The earlier cellular defects include altered lysosomal pH properties, defective autophagosome clearance, mitochondrial impairments, and neurotransmitter vesicle loss. Further upstream, we identify that intracellular calcium dyshomeostasis originating from ER stores is underlying the respective impairments through a variety of organelle-specific mechanisms, and this is observed in mouse and human neurons expressing AD genotypes. Thus, through stabilizing intracellular calcium release from ER stores, lysosomal-mediated clearance of autophagosomes and the aberrant protein products within are cleared, mitochondrial function is restored, and synaptic structure and memory-encoding properties are normalized.

Title: Glutamatergic neurotransmission and cognition in health, disease, aging, and intervention: Evidence from mouse models

Authors: *E. R. HASCUP[1], C. A. FINDLEY[1], N. ESPERANT-HILAIRE[1], J. BRITZ[2], L. SIME[1], S. MCFADDEN[1], E. LOKAITIS[1], Y. FANG[1], S. TISCHKAU[2], H. A. BOGER[4], A. BARTKE[3], K. N. HASCUP[1];
[1]Neurology, Neurosci. Institute, Ctr. for Alzheimer's Dis., [2]Pharmacol., [3]Intrnl. Med., Southern Illinois Univ. Sch. of Med., Springfield, IL; [4]Neurosciences, Med. Univ. of South Carolina Dept. of Neurosciences, Charleston, SC

Abstract: It is well established that hippocampal glutamatergic neurotransmission is required for learning and memory. Here, we present data on glutamatergic neurotransmission and cognition from mouse models of normal aging (C57BL/6), successful aging (growth hormone receptor knock out; GHR-KO), metabolic disease (high-fat diet), and Alzheimer's disease (AD; AβPP/PS1 and $APP^{NL-F/NL-F}$). Mice underwent cognitive evaluation using the Morris water maze (MWM) spatial learning and memory task followed by *in vivo* electrochemistry to assess glutamatergic neurotransmission independently in the dentate gyrus, CA1, and CA3 subregions of the hippocampus. Regardless of mouse model, we observed that tighter hippocampal glutamatergic signaling led to better performance on MWM memory recall, while elevated basal glutamate was often associated with impaired cognition. Furthermore, when glutamatergic signaling was restored through pharmaceutical intervention with Riluzole, an approved drug for the treatment of amyotrophic lateral sclerosis, cognitive performance was similar to that measured in control mice. Additionally, postmortem brain tissue analysis (mRNA and protein levels, immunohistochemistry, and measures of cellular senescence) revealed potential mechanisms underlying these observed changes in neurotransmission. These mechanisms may

serve as early biomarkers and therapeutic targets for restoring glutamate signaling and improving patient outcome by delaying or stopping cognitive decline.

Title: Hyperglutamatergic signaling throughout disease progression in Alzheimer's mouse models

Authors: *K. N. HASCUP, E. R. HASCUP;
Neurosci. Institute, Neurology, Ctr. for Alzheimer's Dis. and Related Disorders, Southern Illinois Univ. Sch. of Med., Springfield, IL

Abstract: Alzheimer’s disease (AD) is characterized by severe impairment in new learning and memory, progressive dementia, cerebral atrophy, and eventual death. Increased soluble β-amyloid $(A\beta)_{42}$ is the earliest detectable biomarker and contributes to the neurotoxicity associated with AD progression. We have demonstrated that soluble $A\beta_{42}$ elicits hippocampal glutamate release through a presynaptic α7nAChR mechanism. As soluble $A\beta_{42}$ accumulates during AD progression, this causes a concomitant hyperglutamatergic environment that is hypothesized to underlie the cognitive and functional decline. We measured basal and stimulus-evoked glutamate release in the dentate (DG), CA3, and CA1 of male AβPP/PS1 and $APP^{NL\text{-}F/NL\text{-}F}$ mouse models of cerebral amyloidosis. At 2-3 months of age, prior to cognitive decline, elevated stimulus-evoked glutamate release was observed in the CA1 of AβPP/PS1 (9.1 ± 1.1 µM, n=12; $p<0.001$) and $APP^{NL\text{-}F/NL\text{-}F}$ (5.4 ± 0.4 µM, n=4; $p<0.01$) mice compared to age-matched C57BL/6 (2.9 ± 0.3 µM, n=10) control mice. By 12-15 months of age, hippocampal hyperglutamatergic signaling became more pronounced in AβPP/PS1 mice when cognitive deficits are observed. This phenotype was reproducible across multiple cohorts of 12-15 month old AβPP/PS1 mice used as controls for various intervention strategies including dietary, 0.9%

saline injection, and 1% sucrose water treatments. Averaging glutamate dynamics across these cohorts, AβPP/PS1 mice had significantly elevated basal glutamate compared to age- and treatment-matched C57BL/6 mice in the DG (1.3 ± 0.1 µM, n=41 vs 0.8 ± 0.1 µM, n=45; $p<0.01$), CA3 (1.4 ± 0.1 µM, n=41 vs 0.8 ± 0.1 µM, n=46; $p<0.0001$), and CA1 (1.7 ± 0.1 µM, n=41 vs 0.9 ± 0.1 µM, n=46; $p<0.0001$). Similarly, average stimulus-evoked glutamate release was elevated in the same cohorts of AβPP/PS1 mice compared to age- and treatment-matched C57BL/6 mice in the DG (9.3 ± 1.0 µM, n=40 vs 4.1 ± 0.4 µM, n=46; $p<0.0001$), CA3 (7.9 ± 0.8 µM, n=40 vs 5.5 ± 0.5 µM, n=46; $p<0.01$), and CA1 (8.0 ± 0.6 µM, n=41 vs 3.3 ± 0.3 µM, n=45; $p<0.0001$). This hyperglutamatergic signaling is a result of elevated vesicular glutamate transporter 1 density in 12-15 month old AβPP/PS1 compared to age-matched C57BL/6 mice in the DG (0.9 ± 0.1, n=6 vs 0.7 ± 0.1, n=13; $p=0.2$), CA3 (0.7 ± 0.1, n=7 vs 0.5 ± 0.1, n=11; $p<0.01$), and CA1 (0.9 ± 0.1, n=7 vs 0.5 ± 0.1, n=13; $p<0.001$). These data support a role of $A\beta_{42}$ mediated hyperglutamatergic signaling throughout disease progression in mouse models of cerebral amyloidosis that is consistently observed across multiple cohorts of intervention control groups. This elevated glutamatergic signaling may serve as an early biomarker or therapeutic strategy for AD.

Title: Loss of Presenilin function in inhibitory neurons causes impairments of memory, synaptic plasticity and age-dependent neurodegeneration

Authors: *J. KANG, S. LEE, J. SHEN;
Neurol., Brigham & Women's Hospital, Harvard Med. Sch., Boston, MA

Abstract: Mutations in the *Presenilin* (*PSEN1* and *PSEN2*) genes are the major genetic cause of Alzheimer’s disease (AD). Inactivation of Presenilin (PS) in excitatory neurons of the postnatal mouse forebrain results in memory and synaptic impairment as well as age-dependent neurodegeneration. Although the function of interneurons and the oscillatory network activities they regulate are altered in AD, the role of PS in inhibitory neurons is unknown. Here we generated inhibitory neuron-specific *PS* conditional double knockout (IN-*PS* cDKO) mice, in which PS is selectively inactivated by Cre recombinase expressed under the control of the Gad2 promoter. Western analysis confirmed reduction of PS1 in the cerebral cortex and the striatum, in

which ~95% of neurons are GABAergic medium spiny neurons. Interestingly, IN-*PS* cDKO mice exhibit earlier mortality relative to littermate controls. Moreover, IN-*PS* cDKO mice at 2 months of age show spatial learning and memory deficits in the Morris water maze, as indicated by significant increases of latency during training and reduced quadrant occupancy in post-training probe trials. Furthermore, paired-pulse facilitation, frequency facilitation, and long-term potentiation are enhanced in the Schaffer collateral pathway of IN-*PS* cDKO mice at 2 months of age. Importantly, we found age-dependent neurodegeneration in IN-*PS* cDKO mice, similar to excitatory neuron-specific *PS* cDKO mice. The number of inhibitory neurons is reduced in the cerebral cortex and the striatum of IN-*PS* cDKO mice at the age of 9 months but is unchanged at 3 months, relative to littermate controls. Consistent with these findings, the number of apoptotic cells labeled by active caspase-3 immunoreactivity and the TUNEL assay is increased in the cerebral cortex and the striatum of IN-*PS* cDKO mice at the age of 9 months. Neurodegeneration in IN-*PS* cDKO mice is also accompanied with gliosis as shown by elevated GFAP and Iba1 immunoreactivity. These findings demonstrate essential roles of PS in synaptic plasticity, learning and memory, and neuronal survival in adult interneurons.

Title: Modeling sporadic Alzheimer’s disease in mice through miR-34a targeted polygenic suppression

Authors: ***S. N. SARKAR**[1], E. B. ENGLER-CHIURAZZI[1], J. Z. CAVENDISH[2], J. M. POVROZNIK[1], A. RUSSELL[2], D. D. QUINTANA[2], P. MATHERS[2], J. W. SIMPKINS[2]; [1]Physiol. and Pharmacol., [2]West Virginia Univ., Morgantown, WV

Abstract: Autosomal dominant Alzheimer disease (AD) is caused by rare mutations in one of three specific genes namely APP, PS1, and PS2. This contrasts with idiopathic, sporadic AD (sAD), which has a more polygenetic risk profile and represents more than 95% of cases. Polygenic risk factors and reduced expression of many genes in sAD impedes the path to

progress in generating a useful mouse model and success for identifying novel target(s) for disease-modifying therapies. Previously we sought to identify expression of selected microRNAs in AD brains that maximizes the number of target genes possibly involved in cognitive function. We have found that miR-34a in human AD patient's brains and primary neurons repressed proteins related to synaptic plasticity and energy metabolism. Furthermore, our bioinformatic analysis of many of the miR-34a targeted genes were predicted to be similarly down regulated as found in the differentially expressed genes in AD and control human patients from Gene expression Omnibus (GEO) database. These genes were analyzed for functional and pathway enrichment analysis of Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) to elucidate the pathological polygenic mechanisms of sAD in mice.To this end, we have generated conditionally miR-34a overexpressing mice (TetR-TetO-miR-34a-Transgenic mice) and investigated functional consequences of polygenic suppression of miR-34a target genes by identifying shared behavioral and molecular signatures characteristics of sAD in human. Doxycycline-treated mice of either sex exhibited profound behavioral impairment compared to untreated groups with only 1-2 months of over-expression of miR-34a. Cognitive impairment of individual mice in T- and Y-maze tasks correlated with elevated miR-34a expression in many parts of the brain including the hippocampus and prefrontal cortex, regions which are known to be involved in this task and implicated dysfunction in sAD. Immunocytochemistry of brain sections from mice show high amyloid β and phosphorylated tau-specific staining in the hippocampus and cortex. Analysis of protein samples from these mice revealed that miR-34a targets specific genes involved in structural and functional synaptic plasticity, amyloid precursor protein (APP) metabolism, phosphorylation-dephosphorylation of tau, faster spike transmission in inhibitory neurons, and functional hyperemia. Thus, our results suggest that the polygenetic dysfunction caused by miR-34a may be involved in initiation and or progression of sAD and disclose miR-34a as a potential therapeutic target.

Title: ATase1 is the preferential target to rescue the proteotoxicity associated with Alzheimer's disease

Authors: *L. PUGLIELLI, M. J. RIGBY, V. BANDUSEELA, G. KAUR, R. SULLIVAN, A. LAKKARAJU;
Univ. of Wisconsin Madison, Madison, WI

Abstract: Nε-lysine acetylation in the lumen of the endoplasmic reticulum (ER) has emerged as a novel mechanism for the regulation of protein homeostasis by regulating the selection of correctly folded glycoproteins and the autophagy-mediated disposal of unfolded/misfolded protein aggregates. Acetyltransferase 1 (ATase1/NAT8B) and acetyltransferase 2 (ATase2/NAT8) are ER-resident enzymes responsible for Nε-lysine acetylation; pharmacologic inhibition of both ATase1 and ATase2 results in activation of reticulophagy (ER-specific autophagy), enhanced clearance of protein aggregates within the secretory pathway, and rescue of Alzheimer's disease (AD)-like neurotoxicity in the mouse. The physiologic and pathologic differences between ATase1 and ATase2 remain uncharacterized, which prevents more targeted therapeutic approaches. To elucidate these differences, we used a combination of structure-biochemistry approaches to dissect the enzymatic properties of the two transferases. We also generated ATase1$^{-/-}$ and ATase2$^{-/-}$ mice. The results show that ATase1 (but not ATase2) can be allosterically activated, thus enabling this transferase to couple the induction of reticulophagy to the levels of acetyl-CoA within the ER in real-time. Consistently, ATase1$^{-/-}$ (but not ATase2$^{-/-}$) mice displayed increased activation of reticulophagy, thus suggesting improved proteostatic functions. Importantly, neither ATase1$^{-/-}$ nor ATase2$^{-/-}$ mice developed a significant phenotype. To determine the specific translational potential of ATase1 and ATase2 inhibition in AD, we crossed ATase1$^{-/-}$ and ATase2$^{-/-}$ mice with APP$_{swe}$/PSEN1dE9 mice. The results show that genetic disruption of ATase1 (but not ATase2) improved the lifespan of APP$_{swe}$/PSEN1dE9 mice. Biochemical and pathologic examination of APP/PS1;ATase1$^{-/-}$ and APP/PS1;ATase2$^{-/-}$ mice is currently underway. In conclusion, our results demonstrate that ATase1 is the preferred target to improve the proteostatic functions of the secretory pathway and rescue associated proteotoxic disease states.

Title: A transient physiological role for amyloid beta oligomers during CNS development

Authors: *W. L. KLEIN[1,2], N. RAO[1], M. BICCA[1], E. HO[1], H. XIA[1], E. CLINE[1], S. BARTLEY[1], K. L. VIOLA[1], F. G. DE MELLO[3,4];

Abstract: Toxic amyloid beta oligomers (AβOs) accumulate in Alzheimer's brain and cerebrospinal fluid (CSF). The hypothesis that these toxic AβOs instigate neural damage leading to dementia was first proposed in 1998 based on discoveries that fibril-free synthetic preparations of AβOs rapidly inhibit long-term potentiation and ultimately cause selective nerve cell death, preventable by knockout of the *fyn* gene (MP Lambert et al 1998 PNAS). The AβO hypothesis has been widely investigated since that time (reviewed in E Cline et al 2018 JAD). Detectable by conformation-sensitive antibodies, AβOs manifest in human brain and CSF in an Alzheimer's disease (AD)-dependent manner and in frequently used transgenic models of familial AD. Experimentally, synthetic and AD brain-derived AβOs instigate cognitive dysfunction and major features of AD pathology such as tau hyperphosphorylation, synapse elimination, and selective nerve cell death. In this study, we have investigated whether AβOs might be present in the central nervous system (CNS) during neural development, which also manifests synapse elimination, selective nerve cell death, and transiently abundant hyperphosphorylated tau (pSer396). Our experiments used embryonic chick, chosen because its Aβ42 sequence is the same as humans. Western blots with AβO-selective antibodies and mass spectrometry confirmed the presence of AβOs in embryonic chick retina. The sodium dodecyl sulfate-stable core of the naturally-occurring embryonic AβOs comprises 9mers and 10mers, which are smaller than the type 2 AβOs prominent in AD brain. Abundance and distribution of AβOs were developmentally regulated in a pattern that was approximately coincident with tau phosphorylation at Ser396. A transient role for AβOs in CNS development may be one of the reasons evolution has conserved a peptide that manifests such deleterious gain-of-function properties in the aging brain. Studies of transient AβOs in the developing retina offer new opportunities for investigating a physiological regulation that is disrupted in AD and perhaps in diseases of the eye such as glaucoma, macular degeneration, and diabetic retinopathy. This study is funded by NIH research grant R21 AG060203

Title: Potential roles of APP-cleaved products in an animal model of temporal lobe epilepsy

Authors: *S. KAR, A. KODAM, D. OURDEV, M. MAULIK, A. SCHMAUS, A. DAHAL, Y. WANG;
Med., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Temporal lobe epilepsy (TLE) is the most common form of epilepsy that originates from the hippocampus and then propagates to other limbic areas such as the amygdala and entorhinal cortex. The main pathological feature associated with TLE is hippocampal sclerosis, which is characterized by atrophy, induration, gliosis, synaptic reorganization and loss of neurons in CA1, CA3 and dentate hilar regions. Some animal models, *albeit* do not exactly match the complex etiologies identified in humans, are found to recapitulate most of the pathological features observed in TLE. There is evidence that systemic administration of kainic acid (KA) can cause seizures in the CA3 region of the hippocampus that can lead to loss of neurons and astrogliosis characteristic of TLE. Our results show that injection of KA along with seizures, gliosis and loss of hippocampal neurons, can increase the level/processing of amyloid precursor protein (APP), resulting in the enhanced production of amyloid beta (Aβ)-related peptides - which play critical roles in Alzheimer’s disease (AD) pathology. The changes in APP levels/processing were evident primarily in activated astrocytes, implying a role for astrocytic Aβ-related peptides in KA-induced toxicity. Accordingly, we showed that treating rat cultured astrocytes and human U-373 astrocytoma with KA can lead to increased levels of APP and its cleaved products by selectively activating kainate receptor. Additionally, we revealed that KA reduces neuronal viability more in neuronal/astrocyte co-cultures than in pure neuronal culture, and this is attenuated by precluding Aβ production. Collectively, these results indicate that increased production/secretion of Aβ-related peptides from activated astrocytes can contribute to seizure/ neurotoxicity in KA-treated rats. Since KA administration can lead to neuropathological changes resembling TLE, it is likely that APP/Aβ peptides derived from astrocytes may have a role in TLE pathogenesis.

Title: Proteomic analysis of lamellar bodies in Lrrk2 knockout mice

Authors: *M. ARAKI, S. TAKATORI, G. ITO, T. TOMITA;
Pharmaceut. Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: Parkinson disease (PD) is one of the most common neurodegenerative disorders. PD is characterized by the loss of dopaminergic neurons and formation of Lewy bodies in the substantia nigra. It has been shown that mutations in leucine-rich repeat kinase 2 (LRRK2) cause familial PD (FPD). As FPD mutant LRRK2 exhibits an increased kinase activity, LRRK2 kinase inhibitors are expected to be useful for treatment of PD. Therefore, several brain penetrable LRRK2 inhibitors have been developed. Although these inhibitors effectively suppress the LRRK2 kinase activity in the brain, morphological abnormalities in peripheral tissues were observed in rodents as well as non-human primates treated with these compounds. Especially, in the lung, the number and size of lamellar bodies in alveolar epithelial type 2 cells were significantly increased. Lamellar body is a lysosome-related organelle that stores pulmonary surfactants required for maintaining a low surface tension of alveoli. Given the importance of lamellar bodies in the physiological function of lung, it is possible that the disruption of lamellar body homeostasis upon inhibition of LRRK2 impairs the lung function. To reveal the molecular mechanism of the lamellar body hypertrophy, we undertook a proteomic analysis on the lamellar bodies isolated from mouse lungs. We confirmed that the area and number of lamellar bodies in *Lrrk2* knockout (KO) mice (Tong et al., PNAS 2010) were dramatically increased to those in wild-type (WT) mice. Next, we isolated the lamellar bodies from these mice using sucrose gradient centrifugation and compared the protein abundance by a label-free quantitative proteomic analysis. Approximately 1500 proteins were identified from these lamellar body fractions. We found more than two-fold increase in the levels of 103 proteins in the *Lrrk2* KO lamellar bodies. A gene ontology enrichment analysis of these proteins revealed a significant enrichment for proteins associated with small GTPase signal transduction and cellular vesicle transport including Rab proteins. These results suggested that the intracellular vesicular transport was changed in the lungs of *Lrrk2* KO mice, which potentially lead to the lamellar body hypertrophy.

Abstract: Synucleinopathies are neurodegenerative disorders characterized by abnormal a-synuclein deposition and neuroinflammation. Neuronal-released a-synuclein have been shown to induce neurotoxic microglial responses through Toll-like receptor 2 (TLR2), resulting in the production of pro-inflammatory responses. However, the molecular mechanism is poorly understood. Here, we elucidate a critical role for Leucine-rich repeat kinase 2 (LRRK2), in the activation of microglia by a-synuclein. Microglial exposure to a-synuclein was found to significantly enhance LRRK2 kinase activity. While genetical and pharmacological inhibition of LRRK2 affected the expression of only TNFa and IL-6, overall a-synuclein-mediated microglial neurotoxicity was diminished. LRRK2 also phosphorylates and induces nucleus translocation of the immune transcription factor, nuclear factor of activated T-cells, cytoplasmic 2 (NFATc2). We also identified accumulations of NFATc2 in the brains of synucleinopathy patients and mouse models. Therefore, we propose the modulation of LRRK2 and its downstream signaling mediator NFATc2 as a novel therapeutic strategy for synucleinopathies.

Abstract: Mutations in LRRK2 are the most common cause of dominantly inherited Parkinson's disease. LRRK2 is a multi-domain protein with both GTPase and kinase activities that has been shown to affect various cellular processes including membrane trafficking, axonal transport and protein homeostasis. A main cellular pathway to remove aggregated ubiquitinated proteins is aggrephagy: the cytosolic class IIb histone deacetylase HDAC6 recognizes ubiquitinated misfolded proteins and recruits them to the molecular motor cytoplasmic dynein which transports them to the perinuclear region where they are trapped in aggresomes that are subsequently removed by macroautophagy. We show that LRRK2 regulates HDAC6-dependent aggresome formation. LRRK2 directly interacted with the HDAC6 deacetylase domains via its Roc domain and phosphorylated HDAC6 on serine-22. Serine-22 phosphorylation of HDAC6 enhanced its interaction with cytoplasmic dynein and stimulated recruitment of ubiquitinated proteins to aggresomes. Knockdown or knockout of LRRK2 impaired HDAC6-mediated aggresome formation. Parkinson's disease mutant LRRK2 G2019S showed reduced interaction with HDAC6 and did not support aggresome formation to the same extend as wild type LRRK2. This was recapitulated in LRRK2 G2019S patient-derived iAstrocytes that showed an aggresome formation defect. In conclusion our data reveal HDAC6 as a target of LRRK2 and suggest that deregulation of HDAC6-mediated aggresome formation and aggrephagy could contribute to the pathology of Parkinson's disease.

Title: ATP13A2 functionally interacts with LRRK2 in Parkinson's disease models

Authors: *M. ERB[1], A. PODHAJSKA[2], J. KORDICH[1], N. LEVINE[1], D. J. MOORE[1]; [1]Van Andel Res. Inst., Grand Rapids, MI; [2]Brain Mind Inst., Swiss Federal Inst. of Technol. (EPFL), Lausanne, Switzerland

Abstract: Parkinson's disease (PD) is a progressive neurodegenerative movement disorder that results from the death of substantia nigra dopaminergic neurons. Although most cases of PD have no known cause, mutations in over 15 genes cause heritable PD with a surprising number involved in intracellular trafficking pathways. For example, mutations in *leucine-rich repeat kinase 2* (*LRRK2*) cause autosomal dominant late-onset PD, and loss-of-function mutations in *ATP13A2 (PARK9)* cause autosomal recessive early-onset parkinsonism. Recent studies suggest that *ATP13A2* genetic variants may reduce the age-of-disease-onset in *LRRK2*-linked PD subjects. Using synthetic genetic array screens in *Saccharomyces cerevisiae*, we find that deletion of *YPK9*, the yeast ortholog of *ATP13A2*, enhances human LRRK2-induced toxicity. To determine whether LRRK2 and ATP13A2 converge in a common PD pathway, we first tested if these proteins interact in HEK-293T cells or rat primary cortical neurons. Using co-immunoprecipitation assays, we find that FLAG-tagged LRRK2 robustly interacts with V5-tagged ATP13A2 with a minimal impact of PD-linked LRRK2 or ATP13A2 mutations on this interaction. Confocal microscopy further reveals the partial co-localization of FLAG-LRRK2 and GFP-ATP13A2 on vesicular structures in cortical neurons. Using Phos-tag assays, WT or mutant LRRK2 expression fails to induce ATP13A2 phosphorylation in cells. Oppositely, WT or mutant ATP13A2 expression has no effect on cellular LRRK2 phosphorylation (S910, S935, S1292) or substrate phosphorylation (Rab10). Next, we assessed the role of ATP13A2 in a model of mutant LRRK2-induced neuronal toxicity in primary cortical cultures. We find that wild-type ATP13A2 (but not an ATPase-inactive D513N variant) attenuates the impaired neurite outgrowth induced by G2019S LRRK2. Interestingly, LRRK2 has been shown to modulate

lysosome size, number and acidity, and ATP13A2 expression, in cultured primary astrocytes. We are currently developing models to evaluate whether ATP13A2 overexpression in astrocytes can rescue the impaired lysosomal morphology and function induced by mutant LRRK2. Similar studies are being conducted in an established Ad5-mediated gene transfer rat model of PD where G2019S LRRK2 expression induces robust nigral dopaminergic neurodegeneration. We are evaluating whether lentiviral-mediated expression of ATP13A2 is protective in this LRRK2 model, and whether ATP13A2 knockout mice exhibit enhanced G2019S LRRK2-induced neurotoxicity. We hope to define a novel PD pathway linking LRRK2 and ATP13A2, and to establish ATP13A2 as a promising therapeutic target for disease-modification in PD.

Title: Leveraging LRRK2 biology to develop therapeutic opportunities for Parkinson's disease

Authors: C. CHEN[1], M. CLUTTER[2], L. PARISIADOU[1];
[1]Dept. of Pharmacol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [2]High Throughput Analysis Lab., Northwestern Univ., Chicago, IL

Abstract: Leucine rich repeat kinase 2 (LRRK2) has been linked to both familial and the most common non genetic form of Parkinson's disease (PD) and it represents one of the most promising therapeutic targets for PD. Specifically, targeting LRRK2 kinase activity has generated a great amount of interest followed by the development of several LRRK2 kinase inhibitors. Although this remains a priority therapeutic approach, a number of safety liability concerns of the developed inhibitors in peripheral tissues highlights the importance of alternative therapeutic approaches that take into account aspects of LRRK2 biology particular in the neuronal population specifically susceptible to PD. High throughput screening of cellular phenotypes could enable the discovery of new targets that modulate mutant LRRK2 function in an unbiased manner. Our previous studies were among the first to demonstrate that one of the most consistent cellular phenotype that reflect mutant LRRK2 activity is a decrease in neurite outgrowth and neuronal complexity. Here, we employed a cell based imaging assay using primary dopaminergic neurons of mutant LRRK2 mice by measuring neuron outgrowth

amenable to large scale screening. A library of translational compounds was used for screening and those compounds that increased the neuronal complexity of mutant LRRK2 with no significant change in wild-type were set to reflect modification of mutant LRRK2 function. Overall in the present study, we successfully established a platform for the identification of compounds that reverse mutant LRRK2 activity using neuronal populations with maximum disease relevance. The identified top hit compounds represent novel LRRK2 targeted agents in a precise disease relevant context and the present study opens up several opportunities to pursue preclinical development of the identified compounds.

Title: A novel protective role for N-acylphosphatidylethanolamine phospholipase D in 6-OHDA-induced neurodegeneration

Authors: *F. PALESE[1,2], S. PONTIS[2], N. REALINI[2], D. PIOMELLI[1];
[1]Anat. and Neurobio., Univ. of California Irvine, Irvine, CA; [2]Drug Discovery and Develop. (D3) Dept., Italian Inst. of Technol., Genoa, Italy

Abstract: N-acylphosphatidylethanolamine phospholipase D (NAPE-PLD) is a zinc hydrolase that catalyzes the cleavage of membrane NAPEs into fatty-acid ethanolamides (FAEs), a family of lipid mediators with diverse important biological activities. Biophysical experiments suggest that, in addition to their role as FAE precursors, NAPEs may also serve autonomous structural and signaling functions, such as stimulation of membrane fusion, consolidation of lipid raft structure and stabilization of the lipid bilayer. It is largely known that NAPEs are produced in the brain following several injurious stimuli, however, the functional significance of this accrual is still not clear. In the present study, we used a well established model of Parkinson's disease, administering the dopaminergic neurotoxin 6-hydroxydopamine (6-OHDA) in the striatum of mice. We report that injections of 6-OHDA cause increase in NAPE and FAE levels *in situ*, which precedes neuronal cell death. Striatal NAPE, but not FAE accumulation is enhanced in mice lacking NAPE-PLD, which also display a substantial reduction in 6-OHDA-induced neurotoxicity, as assessed by measuring survival of substantia nigra dopamine neurons, integrity of striatal dopaminergic fibers, and striatal dopamine metabolite content. Moreover, reduced neuronal damage in NAPE-PLD-/- mice is accompanied by a significant attenuation of the motor response evoked by the dopaminergic agonist apomorphine. Consistent with these results, we find that 6-OHDA incubation stimulates NAPE and FAE formation in cultures of human

catecholaminergic SH-SY5Y cells and that siRNA-mediated NAPE-PLD silencing augments NAPE, but not FAE levels in these cells. NAPE-PLD silencing also protects the cells from 6-OHDA-induced reactive oxygen species production, caspase-3 activation, and death. Simultaneously, we looked at naïve NAPE-PLD-/- mice and NAPE-PLD-silenced cells, to determine whether NAPEs may influence the membrane association of LRRK2, a multifunctional protein involved in Parkinson's disease. NAPE-PLD deletion and the consequent accumulation of non-metabolized NAPEs are accompanied by a remarkable shift of LRRK2 protein from the membrane to the cytosol and a reduction in total LRRK2 content in mice brain and neuronal cell culture. Conversely, exposure of intact SH-SY5Y cells to an exogenous PLD lowers NAPE levels and enhances LRRK2 association with membranes. These findings point to a previously unrecognized role for NAPE-PLD in the regulation of dopamine neuron survival, which might be linked to the ability of this enzyme to control LRRK2 localization by regulating membrane NAPE levels.

Title: LRRK2 kinase inhibitor mitigates rotenone-induced cellular senescence in dopaminergic neurons

Authors: *D.-H. HO, I. SON, W. SEOL;
InAm Neurosci. Res. Ctr., Gunpo, Korea, Republic of

Abstract: Leucine-rich repeat kinase 2 (LRRK2) is one of the pathogenic factors for Parkinson's disease (PD). Our previous study demonstrated that LRRK2-mediate p53 phosphorylation increased the induction of p21 and neuronal toxicity. The activated p53-p21 pathway is involved in the cellular senescence. In a previous study, rotenone promoted cellular senescence. The cellular senescence is responsible for the defect of proteolytic pathways in cells. Rotenone-induced LRRK2 kinase activity is reported as a mediator of neuronal death by oxidative stress. Thus, we hypothesized that rotenone-mediated LRRK2 kinase activation would induce senescence in dopaminergic neuron via the induction of p21 following the phosphorylation of p53, thereby deteriorating the aggregation of α-synuclein (αSyn). We treated rotenone with or without GSK2578215A (GSK-KI), an LRRK2 kinase inhibitor, into differentiated SH-SY5Y cells for 48hr. Cell lysates were analyzed by Western blot assay and Cathepsin D (CTSD) activity assay. In addition, we co-treated SH-SY5Y cells with αSyn fibril under the same condition as above and cell lysates were subjected to Western blot analysis. Rotenone promoted

the cellular senescent markers, which are represented by the decrease in phosphorylated Rb and the increase in β-galactosidase levels, and changes of these senescent markers were rescued by the administration of LRRK2 kinase inhibitor. CTSD activities were also changed along with rotenone-induced LRRK2 kinase activity or co-treatment of GSK-KI. The accumulation of αSyn fibril was accelerated by rotenone treatment along with the increase in p62 level and LC3BII/I ratio, but the administration of GSK-KI rescued αSyn accumulation. In reprogrammed human dopaminergic neurons, similar results were found in the treatment of rotenone with or without MLi-2 LRRK2 kinase inhibitor. And the ectopic expression of G2019S LRRK2 mutant in differentiated SH-SY5Y and reprogrammed human dopaminergic neurons from G2019 LRRK2 human PD patient fibroblast also showed the increase of cellular senescence markers. These results suggest that LRRK2 kinase activity would promote the cellular senescence; aggravating accumulation of αSyn via dysfunction of lysosomal clearance.

Abstract: As the greatest known genetic contributor to Parkinson's disease (PD), the *leucine-rich repeat kinase 2* (LRRK2) gene and protein are targets of interest for Parkinson's disease research and therapeutic development. Unfortunately, critical research tools for understanding the function and role of LRRK2 in disease pathogenesis are lacking. To address this gap, The Michael J. Fox Foundation (MJFF) has taken an active role in designing, validating, and distributing various tools and models that can be used to investigate LRRK2-related mechanisms of PD neurodegeneration or strategies to prevent, slow, or halt disease progression. Here we summarize MJFF-led efforts to develop and characterize a variety of LRRK2-related tools. One such tool is a set of viral vectors that can be used to overexpress wild-type and various mutant forms of LRRK2 *in vivo* to understand the role of this protein in disease biology, pathways

related to PD, and test therapeutic interventions aimed at reducing LRRK2-related pathology. Characterization data for these viral vectors in the rat brain will be presented, including information on the expression profile and resulting neurodegeneration. In addition, we will be presenting data on a new mouse model that overexpresses Rab29 protein—a protein that increases LRRK2 kinase activity and acts as a substrate for LRRK2 kinase activity. We will provide data on the protein and mRNA expression levels, as well as data demonstrating the effects on LRRK2 kinase activity. Finally, we will include information on how to access these important tools and models. Ultimately, MJFF's investment in providing the research community with robust, well-characterized tools and models will speed research towards a cure for PD by enabling research, de-risking investment in PD research, and increasing reproducibility by providing the tools to researchers across labs.

Title: Collapsin response mediator protein (CRMP)-2 is pathological target in LRRK2 R1441G Parkinson's disease model

Authors: *J. SONG, J. JEON, T. KIM, H. SEO;
Hanyang Univ., Seoul, Korea, Republic of

Abstract: Parkinson's disease (PD) is one of the most prevalent chronic neurodegenerative disorders. PD is caused by progressive degeneration of dopaminergic neurons in the substantia nigra. Mutation in leucine-rich repeat kinase (LRRK2) is frequently found in familial and sporadic PD and LRRK2 Roc domain R1441G mutation has been previously studied to explain dopaminergic cell death. In this study, we determined differentially phosphorylated proteins in LRRK2 R1441G transgenic mice using phospho-proteomics technology, and found that several cytoskeletal proteins are involved as phosphorylated targets including collapsin response mediator protein (CRMP)-2. CRMPs have been reported as crucial regulator of microtubule dynamics during neurite/axonal growth. Phosphorylation level of CRMP-2 was increased in LRRK2 R1441G transgenic mice compared to normal mice. When GW5074 was administered to inhibit LRRK2 activity, the level of phosphorylation of CRMP-2 was down-regulated *in vivo* and

in vitro PD models. GW5074 also improved neurite outgrowth of primary cultured cells and improved motor deficits in LRRK2 R1441G mice. These results suggest that cytoskeletal proteins are pathologically targeted in LRRK2 R1441G Parkinson's disease model and the phosphorylation of specific cytoskeletal protein can explain the mechanism of dysfunctional cytoskeletal transport in PD.

Title: Increased sleep spindle density in LRRK2 G2019S mice

Authors: *E. J. MONROE[1], L. M. CROWN[4], M. J. BARTLETT[5], J.-P. WIEGAND[2], A. J. EBY[2], T. FALK[6], S. L. COWEN[3];

Abstract: The G2019S mutation of the leucine-rich repeat kinase 2 (LRRK2) gene is the most common genetic cause of Parkinson's disease (PD). Sleep disorders are a common complaint of early PD patients, suggesting a tie between neuronal networks that regulate sleep and those involved in PD. Sleep spindles are thalamo-cortical oscillations involved in memory consolidation during sleep, and they are generated via GABAergic and glutamatergic neurotransmission. Because previous studies have shown increased glutamatergic activity in neurons of LRRK2 G2019S mice, we hypothesized that sleep spindle activity would be enhanced in LRRK2 G2019S knock-in mice. To test this, we recorded electrocorticographic (ECoG) activity from 7-10 mo. old male mice (n=24 wild-type and n=28 LRRK2 G2019S) before and after they performed either a rotarod-based motor-enrichment task or spent one hour in an unenriched polycarbonate box. While we found that expressing the G2019S mutation did not alter physiological features of the sleep spindles themselves (oscillatory frequency, power, or duration), we did observe that LRRK2 animals showed a significantly higher sleep spindle density (spindles per minute of sleep) compared to wild type animals (2-sample t-test, p=0.04). This supports our hypothesis that increased spindle density represents hyperactivity of cortico-thalamic networks. Additionally, in wild-type animals spindle density in post-task sleep was no different between motor enrichment and unenriched days, suggesting that either the task was not

enriching enough to engage consolidation processes or that the un-enriching task was still sufficiently novel to induce memory consolidation. In contrast, the LRRK2 animals showed greater spindle density following the unenriched experience than following the motor task (paired t-test, $p<0.001$). The increase in spindle density following the unenriched experience was also significantly greater than for wild type animals (2-sample t-test, $p=0.014$), suggesting that spindle density increases in LRRK2 animals as sleep progresses. Finally, to determine if these effects were a direct result of excessive LRRK2 kinase activity, we administered MLi-2 (Merck Pharmaceuticals, 60mg/kg in-diet), a LRRK2 kinase inhibitor, in the second week of experiments (n=12 LRRK2, n=14 wild type), and we found no effect of the drug on spindle density or spindle features in either LRRK2 or wild type animals. In sum, the observed increase in sleep spindle density may indicate excessive excitatory activity in LRRK2 cortical neurons. Such excitation could stress cortico-striatal-thalamic loops involved in motor function and contribute to PD.

Title: Neuroprotective effects of lifespan-extending pathways in a G2019S LRRK2 model of Parkinson's disease

Authors: *M. SENCHUK[1], J. VAN RAAMSDONK[2], D. MOORE[1];
[1]Van Andel Res. Inst., Grand Rapids, MI; [2]Harvard, Cambridge, MA

Abstract: Increased age is the primary risk factor associated with the development of Parkinson's disease (PD). Genetic mutations associated with familial PD (i.e. *SNCA*, *LRRK2*) are generally well-tolerated until advanced age, suggesting an interplay between PD pathogenesis and normal age-associated cellular decline. Conserved pathways regulating aging have been defined in *C.elegans*, including the insulin/IGF pathway, dietary restriction, proteostasis, mitochondrial dynamics and reactive oxygen species. Previous studies have established that modulation of the insulin/IGF pathway is neuroprotective in *C.elegans* and *Drosophila* models of PD, while compounds inducing lifespan extension including metformin, resveratrol, and rapamycin have been found to be beneficial in cell and animal models of disease. In this study,

we sought to determine whether chronological age can be uncoupled from neurodegeneration to further understand how age-related decline leads to neuronal loss. We employed a *C.elegans* model of PD expressing human G2019S LRRK2 specifically in dopaminergic neurons, combined with genetic deletion or tissue-specific gene silencing of key lifespan-regulating genes, including ife-2/EIF4E (protein translation), eat-2 (caloric restriction), nuo-6 (mitochondrial dynamics/Complex I) osm-/che (osmotic sensing), gpl-1 (germline ablation) and daf-2/age-1 (insulin signaling). The studied aimed to examine the correlation between lifespan extension and rescue of dopaminergic degeneration, and moreover, to identify pathways impacting LRRK2-mediated phenotypes. Our data demonstrate that PD-related phenotypes can be disassociated from aging *per se*, as not all lifespan-extending mutants can rescue G2019S LRRK2-induced neurodegeneration. Targeting specific age-related pathways (age-1, daf-2, nuo-6) provides the most robust rescue of G2019S LRRK2-induced neurodegeneration, suggesting that these pathways may contain druggable targets for PD. The deletion of age-1 and daf-2 genes were most effective at providing neuroprotection against LRRK2, and accordingly we are currently conducting rescue experiments with pan-neuronal or dopaminergic-specific AGE-1 and DAF-2 transgenes to determine the cell autonomous effects of these lifespan signaling pathways. Similarly, the role of transcriptional regulator daf-16 (FOXO) and cellular energy homeostasis effector aak-1/2 (AMPK) downstream of daf-2/age-1 and metformin pathways, respectively, are being assessed. Our study demonstrates that targeting specific age-related pathways can be neuroprotective in a G2019S LRRK2 animal model of PD.

Title: The G2019S LRRK2 mutation affects the oxidative stress and neurodegenerative response in a novel dual-hit *in vitro* co-culture of Parkinson's disease

Authors: *T. J. CHARLTON[1], B. M. FENNER[2], Z. DWYER[1], W. WILLMORE[1], S. HAYLEY[1];
[1]Neurosci., Carleton Univ., Ottawa, ON, Canada; [2]Neurosci., Kings Col., Wilkes-Barre, PA

Abstract: The majority of cases of Parkinson’s disease (PD) are idiopathic, with much emphasis recently being placed on a potential causative role for environmental chemical and immune agents. In any case, microglial-driven neuroinflammatory processes are clearly somehow involved in disease genesis and/or development. The inflammatory protein, LRRK2, has been implicated as both a familial and a vulnerability factor in PD and interestingly, is found in high

levels in the immune cells and is known to affect the release of oxidative free radicals. We were interested in assessing the role of LRRK2 in isolated neurons and microglial cells. To this end, primary microglia and dopaminergic cells from wild type mice and LRRK2 G20192 knock-in mice were assessed using a double-hit model of PD. Specifically, microglial were separately pre-treated with LPS and neurons pre-treated with glutamate and then co-cultured together. We found that the release of reactive oxygen species as well as mitochondrial specific superoxides were particularly increased in the G2019S knockin mice. Further, RT-qPCR analyses revealed increased expression of proinflammatory cytokines and the WAVE2 protein in wild type but less so in LRRK2 mutants, which is important in the phagocytic response of microglia. These data are consistent with a role for LRRK2 in PD inflammatory pathology and also suggest a novel dual-hit *in vitro* model that could be used as testing platform for potential therapeutics.

Title: Towards the development of a marmoset model of Parkinson's disease based on the spreading of human alpha-synuclein pre-formed fibrils

Authors: *C. KWAN[1,2], D. BÉDARD[1], M. KANG[2], S. G. NUARA[2], J. C. GOURDON[2], A. MATHIEU[3], C. L. TARDIF[1], G. MASSARWEH[1], T. M. DURCAN[1], A. HAMADJIDA[1], E. A. FON[1], P. ROSA-NETO[2], S. FREY[4], P. HUOT[1];

Abstract: The protein alpha-synuclein is widely disseminated within the brain of patients with advanced Parkinson's disease (PD) and there is increasing evidence suggesting that this abnormal dissemination and accumulation of alpha-synuclein may be neuro-toxic. Therefore, drugs interfering with alpha-synuclein propagation might perhaps slow PD progression. A key step in the development of such drugs is the development of animal models of PD that recapitulate this feature of the disease. Here, we present preliminary results of a pilot experiment conducted in a male common marmoset which was injected with alpha-synuclein pre-formed fibrils (PFFs) in the putamen. The co-ordinates of the putamen were determined after acquisition

of brain magnetic resonance imaging (MRI) and computed tomography (CT) scans. Baseline striatal dopaminergic innervation was determined by performing positron emission tomography (PET) scan to the vesicular monoaminergic transporter 2 ($VMAT_2$) with [^{11}C]-dihydrotetrabenazine (DTBZ). Endotoxin-free recombinant human alpha-synuclein PFFs were synthesised and injected in the left putamen of a marmoset using a neuro-navigational approach with the Brainsight® software. PET scans with [^{11}C]-DTBZ were obtained 1- and 2-months post-surgery. Two months after intra-putaminal alpha-synuclein PFFs injection, there was a noticeable reduction of binding to the VMAT2 within the striatum. Post-mortem experiments to characterise the extent of dopaminergic lesion within the striatum and the substantia nigra, as well as the extent of alpha-synuclein spreading are on-going and the results will be presented at the conference. These preliminary results suggest that the injection of human alpha-synuclein PFFs in the putamen of the common marmoset might lead to dopaminergic denervation. This represents an exciting first step in the creation of a marmoset model of PD based on the propagation of alpha-synuclein.

Title: Early sociability and social memory impairment in A53T mouse model of Parkinson's disease are ameliorated by chemogenetic modulation of orexin neuron activity

Authors: *M. STANOJLOVIC[1], **J. PALLAIS**[1], A. VIJAYAKUMAR[1], C. M. KOTZ[2]; [1]Univ. of Minnesota, Minneapolis, MN; [2]Integrative Biol. and Physiol., Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: Parkinson's disease (PD) is a multi-layered progressive neurodegenerative disease. Signature motor system impairments are accompanied by a variety of other symptoms such as mood, sleep, metabolic and cognitive disorders. Interestingly, social cognition impairments can be observed from the earliest stages of the disease, prior to the onset of the motor symptoms. In this study we investigated age-related reductions in sociability and social memory in the A53T

mouse model of PD. Since inflammation and astrogliosis are an integral part of PD pathology and impair proper neuronal function, we examined astrogliosis and inflammation markers and parvalbumin expression in medial pre-frontal cortex (mPFC), part of the brain responsible for social cognition regulation. Finally, we used DREADDs (Designer Receptors Exclusively Activated by Designer Drugs) for stimulation/inhibition of orexin neuronal activity to modulate sociability and social memory in A53T mice. We observed that social cognition impairment in A53T mice is accompanied by an increase in astrogliosis and inflammation markers and loss of parvalbumin neurons and inhibitory pre-synaptic terminals in mPFC. Moreover, DREADD induced activation of orexin neurons restores social cognition in the A53T mice model of PD.

Title: Osmotin mitigates susceptibility of alpha-synuclein and mptp induced neuropathology and dopaminergic neuronal death via the AMPK activation

Authors: *M.-G. JO, M.-H. JO, M. IKRAM, M.-W. KIM, M.-O. KIM;
Div. of Applied Life Sci. (BK 21), Col. of Natural Sci., Gyeongsang Natl. Univ., Jinju, Korea, Republic of

Abstract: Parkinson's disease (PD) is the age-associated neurodegenerative disorder. It is clinically characterized by tremor, bradykinesia, muscle rigidity and postural instability. The accumulation of pathological a-synuclein as a major component of Lewy bodies is considered as a neuropathological characterization in PD. AMPK is a master regulator believed to play a critical role in the control of energy homeostasis and survival of neurons. Osmotin, an adiponectin homolog, induces the phosphorylation of AMPK which is a downstream marker of adiponectin receptor 1 and exhibits therapeutic effects on PD models. Osmotin mitigated neurological impairment in transgenic mice overexpressing neuron specific enolase (NSE)-controlled human alpha-synuclein. It also attenuated dopaminergic neuronal cell death in the SNpc region and enhanced dendritic complexity and spine density in the hippocampal region of the PD models. Osmotin not only reduced α-synuclein expression but also enhances cell survival and synaptic neurotransmission through enhanced dopamine synthesis. Taken together, our study

suggests that osmotin exerts a potential role as a therapeutic agent against α-synuclein induced neuropathy via activation of AMPK and its associated downstream signaling proteins.

Title: Alpha synucleinopathy associated cabl activation causes p53 dependent autophagy impairment

Authors: *R. KARIM[1], E. E. LIAO[2], M. K. LEE[2];
[2]Neurosci., [1]Univ. of Minnesota, Minneapolis, MN

Abstract: Studies link c-Abl activation with the accumulation of pathogenic α-synuclein (αS) and neurodegeneration in Parkinson's disease (PD). Currently, c-Abl, a tyrosine kinase activated by cellular stress, is thought to promote αS pathology by either directly phosphorylating αS or by causing autophagy deficits. We show that the pathologic effects of c-Abl in PD might also involve activation of p53, as c-Abl activation in a transgenic mouse model of α-synucleinopathy (TgA53T) and human PD cases is associated with increased p53 activation. Significantly, active p53 in TgA53T neurons accumulates in the cytosol, which may lead to inhibition of autophagy. Thus, we hypothesized that c-Abl-dependent p53 activation contributes to autophagy impairment in α-synucleinopathy. In support of the hypothesis, we show that c-Abl activation is sufficient to inhibit autophagy in p53-dependent manner and inhibition of either c-Abl, using nilotinib, or p53, using pifithrin-α, was sufficient to increase autophagic flux in neuronal cells. Moreover, nilotinib and pifithrin-α upregulated the phosphorylation of AMP-activated kinase (AMPK) which was accompanied by pS555-ULK1 activation and conversely down-regulated mTORC1 signal molecule ribosomal S6 and translation repressor protein 4EBP1. These results show that c-Abl inhibition induces autophagy-lysosomal process via regulation of p53, which in turn inhibit mTORC1 by ULK1 activation. Finally, we show that pharmacological attenuation of c-Abl activity in the TgA53T model reduces activation of p53, stimulates autophagy, decreases accumulation αS pathology, and delays disease onset. Collectively, our data show that c-Abl

activation by α-synucleinopathy causes p53 dependent autophagy deficits and both c-Abl and p53 represent therapeutic target for PD.

Title: Oligodendrocyte dysfunction in Parkinson's disease: A study case

Authors: *C. AZEVEDO, G. TEKU, M. CHUMARINA, M. VIHINEN, L. ROYBON; Exptl. Med. Sci., Lund Univ., Lund, Sweden

Abstract: Oligodendrocytes, which are produced during the development and postnatally, are responsible for myelinating axons in the central nervous system. During differentiation, oligodendrocytes undergo morphological changes and express specific markers depending on the state of differentiation. Developing oligodendrocytes are characterized by co-expression of transcription factors SOX10, OLIG2 and NKX2.2. Oligodendrocyte progenitor cells (OPCs) are the first cell type of the oligodendrocyte lineage and express PDGFR-alpha. The transition of OPCs to immature/non-myelinating oligodendrocytes is marked by the modification of cell-surface sulfatide, which is recognized as O4 antigen. Mature-myelinating oligodendrocytes express myelin basic protein (MBP), which is involved in the myelination of axons. An important challenge in disease modeling using stem cells is to produce enough oligodendrocytes to be able to reveal disease mechanisms. Also, recent evidence suggests that oligodendrocytes may play an important role in neurodegenerative diseases. Scaling up the production of oligodendrocytes is therefore of paramount importance for modeling neurodegenerative diseases and study possible disease-related mechanisms. Here, we report a new protocol for generating oligodendrocytes from human pluripotent stem cells, yielding up to 60% of O4-positive oligodendrocyte lineage cells measured by fluorescent activated cell sorting (FACS). Interestingly, oligodendrocytes carrying the A53T variation in the SNCA gene encoding for alpha-synuclein exhibited delayed maturation from OPCs to MBP-positive oligodendrocytes when compared to control cells. Gene expression studies of FACS-purified O4-positive oligodendrocytes supported this evidence: we observed upregulation of OPCs-related transcripts and downregulation of myelin/mature oligodendrocyte-related transcripts in SNCA A53T

variants compared to control. The scaled-up production of oligodendrocytes from diseased pluripotent stem cells should allow further identification of altered cellular networks, potentially revealing oligodendrocytes as novel targets for therapeutic intervention in Parkinson's disease.

Title: The propagation of alpha-synuclein in the central nervous system and other organ systems in the Parkinson's disease rat model

Authors: *L.-Y. CHEUNG[1], Y.-J. CHEN[1], C.-T. WANG[1,2,3,4];
[1]Inst. of Mol. and Cell. Biol., [2]Dept. of Life Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan; [4]Genome and Systems Biol. Program, Natl. Taiwan Univ. and Academia Sinica, Taipei, Taiwan

Abstract: Parkinson's disease (PD) is the second most common movement disorder, owing to degenerative loss of dopamine (DA) neurons in the substantia nigra pars compacta (SNc) of midbrain. Recent studies showed that the main hallmark of PD is the Lewy body pathology, resulting from aggregation of α-synuclein. The assembly of toxic, oligomeric species of α-synuclein can be further spread out to other brain regions upon PD progression. Moreover, in the past decade, constipation has been found as one of the most common symptoms of PD. Treating the gastrointestinal (GI) complaints appeared to alleviate the movement-related problems associated with PD. In 2003, Heiko Braak proposed that PD may originate in the gut rather than the brain, as evidenced by that Lewy bodies appeared in both brain and GI system in post-mortem samples of PD patients. However, it remains unclear what is the relationship between PD progression and the propagation of α-synuclein aggregates in the gut-brain axis. To answer this question, we examined whether the human pathogenic α-synuclein mutant may propagate from the SNc to the gut or other peripheral organs in a rat model mimicking sporadic PD during adulthood. In this PD model, male Sprague-Dawley rats (~250 g, 2 week-old) were deeply anesthetized for stereotaxic surgery. The 2 μL solution containing DNA plasmids (5 μg/μL) was microinjected into SNc to deliver genes expressing the human pathogenic α-synuclein mutant. Five electric pulses were delivered by homemade platinum electrodes via ear bars, with duration

of 50 msec, intervals of 950 msec, and electric field strength of 133 V/cm. After 3-4 months following *in vivo* electroporation, the motor function and dopamine neuronal loss in the PD rats were examined by gait analysis and immunostaining of the DA neuronal marker, respectively. Furthermore, the PD rats were sacrificed to verify α-synuclein aggregates in the SNc by immunostaining the phosphorylated Ser129 (pS129) of α-synuclein (the pS129 immunoreactivity as the hallmark of α-synuclein aggregates). Finally, by using Western analysis, we found that the tissues from the gut and epididymis fat also presented the pS129 immunoreactivity. These results suggest that the human pathogenic α-synuclein mutant can be propagated from the rat brain to other peripheral organs during the early stage of PD progression.

Abstract: Analysis of human pathology led Braak to postulate that α-synuclein (α-syn) pathology could spread from the gut to brain, via the vagus nerve. Here, we test this postulate by assessing α-synucleinopathy in the brain in a novel gut-to-brain α-syn transmission mouse model, where pathological α-syn preformed fibrils were injected into the duodenal and pyloric muscularis layer. Spread of pathologic α-syn in brain, as assessed by phosphorylation of serine 129 of α-syn, was observed first in the dorsal motor nucleus, then in caudal portions of the

hindbrain including the locus coeruleus, and much later in basolateral amygdala, dorsal raphe nucleus, and the substantia nigra pars compacta. Moreover, loss of dopaminergic neurons, motor and non-motor symptoms were observed in a similar temporal manner. Truncal vagotomy and α-syn deficiency prevented the gut-to-brain spread of α-synucleinopathy and associated neurodegeneration and behavioral deficits. This study supports the Braak hypothesis in the etiology of idiopathic PD.

Title: Poly(ADP-ribose) bound α-synuclein fibrils display different binding properties of PET tracers

Authors: ***Z. LENGYEL**[1], L. PUENTES[2], J. J. FERRIE[3], J. PETERSSON[3], R. H. MACH[1]; [1]Dept. of Radiology, [2]Dept. of Systems Pharmacol. and Translational Therapeut., [3]Dept. of Chem., Univ. of Pennsylvania, Philadelphia, PA

Abstract: α-synuclein (α-syn) is an intrinsically disordered protein that is localized at the presynaptic nerve terminals in the central nervous system. Aggregation of this protein results in insoluble Lewy bodies and Lewy neurites, that is the major hallmark feature in Parkinson's disease (PD). Traditionally, patients are diagnosed with PD upon the clinical presentation of motor disturbances, however early diagnosis is problematic since these features may also appear in patients with Parkinsonian syndromes. Due to the advances of positron emission tomography (PET) imaging of amyloid β (Aβ) plaques and tau-based pathology in Alzheimer's (AD) patients, there have been interests in developing PET radiotracers to map aggregated α-syn in PD patients to improve early stage clinical diagnosis of this disease. However, since Aβ and tau have both been found in post-mortem tissue of PD and AD patients, developing a selective α-syn ligand has been extremely challenging. A greater understanding of protein interactions and binding sites for small molecules in α-syn fibrils is important to guide the design of PET radiotracers.

Recently, it was shown that poly(adenosine 5'-diphosphate-ribose) polymerase-1 (PARP-1) modulates α-syn fibril formation in mouse and that α-syn fibrils can, in turn, activate PARP-1 and increase PAR levels. We hypothesize that this PAR/α-syn interaction changes not only the biophysical properties of the fibrils, but also the binding properties of PET radiotracers. Using various biochemical techniques, we characterized α-syn fibrils formed in the presence of PAR and showed that PAR accelerates α-syn fibril formation *in vitro* and increases fibril stability. We also conducted radioligand saturation binding assay using various radiotracers that bind to different sites in α-syn fibrils. Interestingly, the radiotracer that binds closer to the N-terminus of the protein displayed a significantly different binding curve and dissociation constant in α-synuclein fibrils compared to α-synuclein+PAR fibrils. This study suggests that PAR either blocks the binding sites near the N-terminus or alters the structure of α-synuclein fibrils, thus altering the binding of radiotracer. These findings will aid the development of PET imaging agents and also drugs targeting α-synuclein.

Title: Modulation of lipid metabolism alters alpha-synuclein based aggregation and toxicity in Parkinson's disease

Authors: *J. W. NICHOLATOS, L. A. HRDLICKA, L. DANG, J. GROOT, X. HRONOWSKI, W. D. HIRST, A. WEIHOFEN;
Biogen, Cambridge, MA

Abstract: α-Synuclein is the major component of the hallmark aggregates (Lewy bodies) found in Parkinson's disease (PD) patients. The interaction of α-Synuclein with lipid membranes is emerging as a critical feature in its normal function and its propensity for aggregation and toxicity, which is hypothesized to drive PD pathophysiology. Indeed, familial Parkinson's mutations, such as E46K, have been shown to alter α-Synuclein lipid membrane interactions. We are investigating the relationship between α-Synuclein and lipid metabolism using the 3K α-Synuclein model, which harbors E46K and two additional lysine mutations in KTKEGV motifs. The 3K α-Synuclein model is more prone to aggregation and cytotoxicity than E46K alone, making it useful to study synuclein pathology. Transcriptional profiling of primary neuronal cultures transduced with 3K α-Synuclein showed enrichment in genes related to lipid biosynthetic processes as significantly altered, this included Stearoyl-CoA desaturase (SCD).

Modulation of SCD, and other identified genes pharmacologically and/or by siRNA, altered 3K α-Synuclein based aggregation and cytotoxicity. Additionally, mass spectrometry of neuroblastoma cells expressing 3K α-Synuclein revealed changes in lipid metabolites, supporting a connection between lipid metabolism and α-Synuclein pathology. Our data suggest that modulation of lipid metabolism can alter α-Synuclein based pathology and may be a viable strategy for novel Parkinson's therapeutics.

Abstract: While the mechanism underlying Parkinson's disease (PD) pathology has not yet been elucidated, recent evidence suggests misfolded α-synuclein (αSyn) may propagate in a prion-like manner. Using an αSyn mouse model of PD, with a known locus of pathology, we examined network patterns of αSyn-induced magnetic resonance imaging derived brain atrophy. Intracerebral inoculation of the pathological form of αSyn (preformed fibrils; PFF) or phosphate buffered saline (PBS) was performed on M83 αSynA53T transgenic mice (n=8 mice/group; 4 males and 4 females) in the right dorsal neostriatum. At 90 days post-injection (the onset of symptomatology), the mice were sacrificed and imaged ex-vivo (Bruker 7T; T1-weighted images; 70 μm3 voxels). αSyn PFF-induced brain atrophy networks were examined using orthogonal projective non negative matrix factorization (NMF). Brain atrophy was assessed using deformation-based morphometry, to measure nonlinear differences between the groups. NMF of the relative jacobians at each voxel for each subject gives two matrices describing voxel-wise and subject-wise component weightings. The spatial pattern of voxel scores for each component was plotted onto the mouse brain. Group differences of subject weights, describing how each subject loads onto each atrophy network, were assessed using a general linear model,

with sex modelled as a covariate.
Significant group differences among component weightings were found for two NMF components (p<0.05), revealing two significant patterns of αSyn PFF-induced pathology. Component 4 revealed a striatal-nigral-hypothalamic pattern, while Component 2 revealed a midbrain-pons-medulla pattern (Fig. 1).
The inoculation of αSyn PFF in the striatum give rise to widespread network patterns of PFF-induced brain morphological changes, particularly involving regions that project to, or receive input from the injection site. These results are in accordance with PD studies in which show prominent αSyn pathology in the neurons of these structures, as well as functional impairment of these structures in patients with PD.

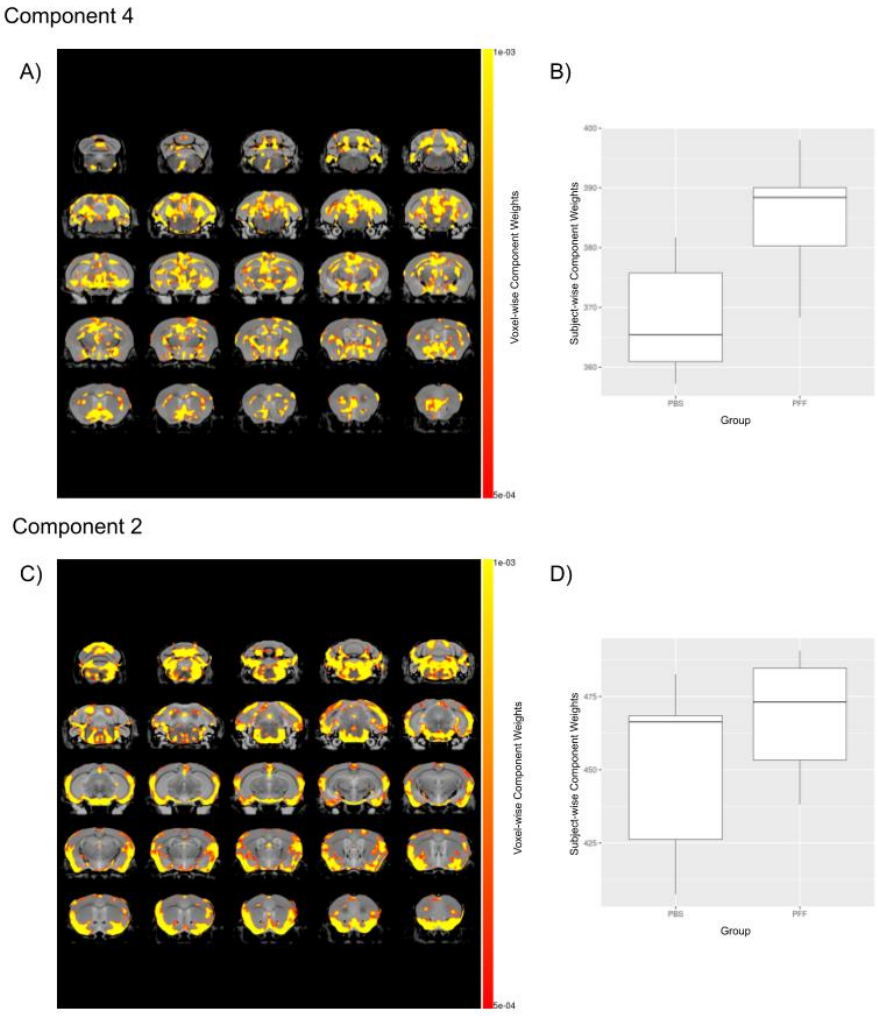

Figure 1. NMF decomposition of voxel-based deformation in M83 αSynA53T transgenic mice. Significance for αSyn PFF-induced network level pathology assessed using a general linear model. B&D. Group differences of NMF component weightings, which describe how each subject loads onto the identified atrophy pattern, were assessed using a general linear model and covarying for sex. A&C. The spatial pattern of voxel scores for two significant components (Component 4 [A] and 2 [C]) plotted onto the mouse brain, depicting networks of voxels sharing a similar variance pattern. A. Component 4 revealed a striatal-nigral-hypothalamic pattern. C. Component 2 revealed a midbrain-pons-medulla pattern.

Abstract: Abnormal alpha synuclein (α-syn; SNCA) is one of the components within Lewy body characterized by Parkinson's disease (PD). A53T mutant α-syn induces mitochondrial autophagy and macroauthophagy leading to cell death. Cerebral dopamine neurotrophic factor (CDNF), endoplasmic reticular (ER)-resident protein, is a promising therapeutic target treating PD and inhibits ER stress-induced apoptosis pathway. Here we report that CDNF endogenously produced in astrocytes regulates autophagy pathway in A53T-α-syn-lesioned rat PD model, resulting in improvement of amphetamine-induced rotational asymmetry and increased survival of dopamine neurons in the substantia nigra. The present study is the first description determining function of CDNF in A53T-α-syn-lesioned genetic animal model of PD and might give great insight treating familiar PD therapy.

Abstract: Parkinson disease (PD) pathology is predominated by aberrant forms of alpha-synuclein protein (aSyn), observable in detergent-insoluble biochemical extractions and phosphorylated at serine 129 (pS129). Transmission of pathological aSyn is thought to occur during PD progression. Supporting this hypothesis, animal models that incorporate intracranial administration of recombinant sonicated aSyn fibrils (aSyn PFFs) result in the formation and spread of synuclein pathology to anatomically interconnected brain regions such as the cortex, amygdala, striatum and substantia nigra. In this work, we describe the phenotypes of a transgenic mouse model (homozygous, heterozygous and wildtype littermates; male mice) expressing human A30P synuclein under the control of the Thy-1 promoter. The A30P mutation of synuclein is a known genetic cause for a familial form of PD. We observe human A30P synuclein protein robustly overexpressed throughout the brain in this mouse; interestingly, pS129 synuclein is observed in only a restricted set of brain structures. Using traditional 2D histology as well as 3D histology (LifeCanvas Technologies), we further investigated the interplay of synuclein pathology, Iba1 and dopamine levels in this mouse model of PD. In A30P mice, aSyn PFF injection resulted in a morphological conversion of endogenous pS129 signal into Lewy neurite-like structures, an indication of synuclein pathology. In addition, administration of aSyn PFF into A30P resulted in marked elevation of Iba-1 staining, indicating a role for activated microglia. aSyn PFF administration into both WT and A30P animals led to reductions in dopamine containing fibers, suggesting neurodegeneration. Although the PFF-induced pSer129 signal in A30P mice was greatly enhanced in comparison to the WT mice, TH reductions in both the WT and A30P animals were comparable over multiple timepoints. Furthermore, when examined at 90 days post-PFF injections, the loss of TH reduction increased as the signal of pSer129 decreased. Additional studies demonstrated that doubling the initial dose of PFF, while directly impacting the amount of pSer129 that was induced, had only minor, if any, impacts on the level of TH depletion that was observed. Having a deeper understanding of the temporal and spatial progression of different PD-related endpoints and their relationships to each other will enable better interpretations of how therapeutic agents can alter PD disease progression.

Title: 14-3-3theta reduces behavioral deficits and alpha-synuclein inclusions in the alpha-synuclein fibril model

Authors: *T. A. Y. YACOUBIAN[1], R. N. UNDERWOOD[2], M. GANNON[3], S. CHANDRA[2], A. KLOP[3], A. PATHAK[3];
[1]Univ. Alabama Birmingham, Birmingham, AL; [2]Neurol., [3]Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Alpha-synuclein (αsyn) plays a critical role in Parkinson's disease (PD). Research points to a prion-like mode for αsyn toxicity: αsyn is released as aggregated species that cause further aggregation and toxicity in neighboring cells. We have studied the role of 14-3-3 proteins in regulating αsyn propagation. 14-3-3s are chaperone-like proteins that reduce protein aggregation, regulate protein secretion, and promote cell survival. We have previously demonstrated the protective effects of 14-3-3s on αsyn propagation and toxicity in the *in vitro* fibril model. Here we have expanded our studies to test the effect of 14-3-3s on αsyn propagation in an αsyn *in vivo* protofibril (PFF) model. To test whether 14-3-3θ blocks αsyn inclusion formation in the PFF model, we injected transgenic cortical 14-3-3θ overexpressing (OE) mice and wild type littermate controls with PFFs in the striatum at 8 weeks and performed behavioral analysis at 3- and 6-months post injection followed by immunohistochemical evaluation of αsyn pathology and cell death. PFF-injection induced a deficit in wildtype mice in the cortically-dependent social dominance test which was rescued by 14-3-3θ OE at 6 months. At 3 months, αsyn inclusion counts were reduced by ~50% in the cortex of 14-3-3θ mice compared to wildtype mice injected with PFFs. No differences in αsyn inclusion counts were observed in the substantia nigra, where 14-3-3θ is not overexpressed in this transgenic mouse line. At 6 months, αsyn inclusion counts in wildtype mice was dramatically reduced in the cortex, presumably due to loss of neurons. However, αsyn inclusion counts in 14-3-3θ mice at 6 months was comparable to that seen at 3 months. These data suggest that 14-3-3θ slows inclusion formation and delays neurodegeneration. We are currently analyzing neuronal counts in these groups.
We have also investigated the impact of 14-3-3 inhibition in the in vivo PFF model. Difopein is a pan 14-3-3 peptide inhibitor that we have previously shown to increase αsyn propagation *in*

vitro. Difopein-expressing PFF-injected mice showed increased social dominance deficits at both 3 and 6 months post injection in comparison to wildtype PFF-injected mice. We are currently examining αsyn inclusion counts and neuronal loss in these mice. We conclude that 14-3-3θ regulates αsyn propagation and may serve as a target for therapeutic intervention in Parkinson's disease.

Title: Could an anti-inflammatory mediator be the culprit in Parkinson's disease?

Authors: *J. DELA CRUZ;
InTouch BioSolutions LLC, Moreno Valley, CA

Abstract: The etiology of Parkinson's disease (PD) is not known. We uncovered a pathway that we propose explains the events that result in aggregation of alpha-synuclein (a-syn) and subsequent neurodegeneration in synucleinopathy. Alpha-MSH is a 13 amino acid peptide that functions in pigmentation and energy homeostasis. It is an anti-inflammatory mediator produced by activated microglial cells and regulates inflammation in the brain. Alpha-MSH is implicated in synuclein disease and is elevated in cerebrospinal fluid of patients with PD and Multiple System Atrophy (MSA). PD patients administered with the peptide exacerbated symptoms. In contrast, pharmacologic reduction of alpha-MSH resulted in improved symptoms. Using a human pigmented cell line (MNT-1) as a model of neuromelanin-containing neurons, we observed induction of synuclein pathology after incubation with alpha-MSH. The peptide triggered aggregation of a-syn and impaired autophagy, which was measured by a decrease in melanin. With autophagy impaired, the cells failed to adjust to declining levels of glucose in culture and continued a rate of metabolism that deprived nutrients to vulnerable cells that died by apoptosis. Synuclein pathology in PD also show evidence of impaired cellular autophagy, diminished neuromelanin and display Lewy bodies (LB) composed of aggregated a-syn. In addition, neurons that contain LBs appear normal, while surrounding cells have degenerated and died by apoptosis. The receptor for alpha-MSH is expressed by nigral dopaminergic neurons. We tested whether exogenous alpha-MSH was sufficient to initiate synuclein disease *in vivo*. Mice administered intranasal alpha-MSH exhibited progressive decline in gait, a prevalent condition seen in patients with PD. Moreover, we observed LB-like aggregate of alpha-synuclein in the substantia nigra. Injury or infection in the brain induces inflammation and activation of

microglial cells. During resolution, microglial cells produce alpha-MSH to reduce inflammation. Our observations suggest synuclein pathology is initiated when bystander cells are exposed to elevated levels of alpha-MSH. Aggregation of a-syn is induced and autophagy is impaired. Furthermore, cells fail to slow metabolism under low nutrient conditions, depriving neighboring cells of vital nutrients. As vulnerable cells die, another round of inflammatory response is initiated leading to chronic cell loss that manifest in a synucleinopathy. Our current goal is to confirm the central role of alpha-MSH in synuclein disease in non-human primates, to design novel therapeutic strategies against PD, MSA and Dementia with LB, that target alpha-MSH and related pathways.

Title: Rab27b regulates alpha synuclein release, toxicity and clearance

Authors: *R. N. UNDERWOOD, B. WANG, T. YACOUBIAN;
Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Alpha synuclein (αsyn) is the primary component of proteinaceous aggregates termed Lewy Bodies that pathologically define Parkinson's Disease (PD). αSyn is hypothesized to spread through the brain in a prion-like fashion by misfolded protein forming a template for aggregation of endogenous αsyn. The release and uptake of αsyn from cell to cell are essential processes for this prion-like spread. αSyn does not have a signal peptide for classical secretion and is thought to be released through non-classical secretion mechanisms regulated by a family of proteins called Rab GTPases. Rab27b is one of several GTPases essential to the endosomal-lysosomal pathway and is necessary for the proper localization of endosomal compartments. We have developed an *in vitro* doxycycline-inducible αsyn model in M17 neuroblastoma cells (termed ISYN cells). Induction of αsyn expression by doxycycline in ISYN cells causes a corresponding increase in the release of αsyn into the conditioned media (CM). When transferred to separately-cultured primary neurons, thisαsyn-enriched CM is toxic to these neurons. We found that upon αsyn induction Rab27b protein expression increased by ~2 fold in the ISYN

cells. Similarly we observed a ~2 fold increase in Rab27b expression in the postmortem human brain lysates from PD patients compared to healthy controls. To examine the impact of Rab27b dependent pathways on αsyn release and toxicity, we knocked down Rab27b expression by lentiviral transfection of shRNA. shRNA knockdown of Rab27b decreased αsyn release into the CM by ~40%. Surprisingly, despite the reduction in αsyn release, CM from induced ISYN cells in which RAB27b was knocked down cells induced greater toxicity in separately cultured SH-SY5Y cells compared to control; this toxicity is ablated by αsyn immunodepletion. We hypothesized that this paradoxical increase in toxicity but decreased paracrine release may be due to changes in the autophagic pathway with Rab27b KD leading to decreased clearance of misfolded αsyn species. Rab27b KD leads to increased formation of endogenous LC3 positive puncta. In addition, Rab27b KD leads to decreased LC3 turnover with bafilomycin treatment, indicating a defect in autophagic flux. These data indicate a potential role for Rab27b in the release, toxicity and clearance of αsyn and ultimately in PD pathogenesis.

Title: Cytosolic trapping of a mitochondrial heat shock protein is an early pathological event in synucleinopathies

Authors: *T. F. OUTEIRO, E. M. SZEGO;
Exptl. Neurodegeneration, Univ. Med. Ctr. Goettingen, Goettingen, Germany

Abstract: Alpha-synuclein (aSyn) accumulates in intracellular inclusions that are associated with synaptic and mitochondrial dysfunctions in Parkinson's disease (PD) and other synucleinopathies, but the precise underlying mechanisms are still elusive. Here, we identified the 10 kDa heat shock protein (HSP10) as a key mediator of aSyn-induced mitochondrial impairment in striatal synaptosomes. We found an age-associated increase in the cytosolic levels of HSP10 in transgenic mice expressing human aSyn, alongside with a concomitant decrease in the mitochondrial levels of the protein. This resulted in a reduction in the levels of superoxide dismutase 2, a client protein of the HSP10/HSP60 mitochondrial folding complex that handles mitochondrial reactive oxidative species, and in synaptosomal spare respiratory capacity, confirming functional impairments. Importantly, overexpression of HSP10 ameliorated aSyn-associated mitochondrial dysfunctions and delayed aSyn pathology both *in vitro* and *in vivo*. Altogether, our data indicate that increased levels of aSyn induce mitochondrial deficits, including decreased ATP production on demand, reduce mitochondrial membrane potential and

decrease efficient handling of reactive oxygen species, at least partially by sequestering HSP10 in the cytosol and preventing it from acting in mitochondria. Importantly, these mitochondrial alterations manifested first at presynaptic terminals and, at later stages, induced energy deficits and increased ROS production, which in turn slowed down the synaptic machinery, further contributing to aSyn pathology. Our study provides novel mechanistic insight into synucleinopathies and opens new avenues for addressing underlying cellular pathologies.

Title: Synonymous single nucleotide polymorphism alters SNCA mRNA and protein homeostasis *in vitro*

Authors: *K. M. VON HERRMANN[1], K. W. HORN[2], L. A. SALAS[1], F. L. ANDERSON[1], B. C. CHRISTENSEN[1], M. C. HAVRDA[1];
[1]Geisel Sch. of Med. at Dartmouth, Hanover, NH; [2]Dartmouth Col., Hanover, NH

Abstract: Synonymous single nucleotide polymorphisms (sSNPs) scattered throughout the genome are capable of dramatically altering mRNA processing and/or protein translation. sSNPs have been reported to eliminate mRNA splice sites, disrupt mRNA secondary structure, alter mRNA stability, or impact codon optimality, resulting in changes at the mRNA and protein level. Considering the importance of mRNA and protein homeostasis in the context of neurodegenerative disease, we investigated the impact of synonymous SNPs on alpha-synuclein protein *in vitro*. *SNCA* codes for the 140 amino acid, intrinsically disordered alpha-synuclein protein comprised of three main regions, the amphipathic helical N terminus, the hydrophobic central region, and the acidic disordered C terminus. Under normal conditions alpha-synuclein is involved in synaptic vesicle transport, while under pathological conditions including Parkinson's disease, the protein aggregates into various oligomers, protofibrils, and fibrils and can be eventually sequestered into Lewy body inclusions and Lewy neurites. Alpha synuclein oligomers and protofibrils are cytotoxic, and emerging data indicate that pathogenic fibrils can be transmitted from cell-to-cell, propagating the pathology. The influence of synonymous SNPs on alpha-synuclein aggregation is not clearly understood. Many sSNPs identified by GWAS are deemed "likely benign" and remain uncharacterized. Experimental interrogation of synonymous

genetic variants in genes involved in proteinopathy like *SNCA* are important to determine if this class of genetic variation impacts the development of disease. We selected five of the many *SNCA* sSNPs and utilized site-directed mutagenesis and transfection to produce multiple independent polyclonal HEK293 cell lines carrying sSNP sequences. To characterize the impact of the sSNPs on mRNA and protein *in vitro* we then conducted real-time PCR and immunoblotting, as well as immunoprecipitation and solubility assays. Expression of *SNCA* harboring the sSNP rs76642636 resulted in significantly lower *SNCA* mRNA and monomeric alpha-synuclein protein levels, contrasted with an increase in high molecular weight alpha-synuclein protein species. These findings were replicated in differentiated SH-SY5Y cells and primary cortical neurons. Ongoing studies suggest that despite encoding the same amino acid, synonymous SNPs have the capacity to significantly alter the protein lifecycle with the potential to influence protein homeostasis and function in the context of proteinopathies like Parkinson's disease.

Abstract: The neuropathological hallmarks of Parkinson's disease (PD) are loss of dopaminergic (DA) neurons in the substantia nigra (SN) and formation of intraneuronal protein inclusions termed Lewy bodies, composed mainly of α-synuclein (α-syn) protein. Abnormally accumulating α-syn leads to progressive DA neuronal loss, motionless and dementia. This late stage is preceded by a variety of early signs including emotional, autonomic and memory symptoms. More recently, much attention is also directed toward the eye, as it has been shown that α-syn accumulation in the retina and visual acuity defects are early markers of synucleinopathy (Ortuño-Lizarán et al., 2018).

We have recently reported that adeno-associated viral vector -mediated overexpression of α-syn (AAV- α-syn) in the midbrain of adult mice induces highly selective striatal-dependent motor learning-induced metaplasticity deficit (Giordano et al., 2018). This early stage is followed by progressive loss of nigral DA neurons and spreading of α-syn in other brain regions, associated to bradykinesia, increased anxiety and endophenotypes of psychosis recapitulating early stages of dementia with Lewy Bodies. In this study, using the same experimental approach, we explored the synaptic and behavioral effects of α-syn overexpression in different brain regions, including the retina. We show that α-syn leads to a time-dependent degeneration of dopamine amacrine cells in the retina, impaired visual acuity and altered contrast-light sensitivity evaluated with an electroretinogram (ERG). The visual and ERG impairments are rescued by systemic administration of L-DOPA.
Our study provides the first experimental evidence showing that α-syn exerts harmful effects on DA neurons in the retina leading to impaired vision sensitive to L-DOPA treatment. These findings have high translational relevance as the eye is gaining momentum for studying neurodegenerative disorders due to its easy accessibility (London et al., 2013). Indeed, it represents an ideal model organ for both an early identification of protein aggregates and for testing novel therapeutic approaches.

Med., Univ. Pennsylvania, Philadelphia, PA; [7]Inst. of Biotechnology, Univ. of Helsinki, Helsinki, Finland

Abstract: Robust and reliable counting and analysis of p129S-alpha-synuclein-positive (alpha-synuclein phosphorylated at S129) inclusions of Lewy bodies (LBs) and Lewy neurites (LNs) is a necessity in Parkinson's disease research as these inclusions are characteristic features in the brains of both sporadic and familial forms of Parkinson's disease patients. Current analysis of LBs and LNs is performed using either stereology, which is time-consuming and prone to interobserver variation or using automated image analysis methods which are limited by their ability to recognize LBs and LNs in the brain sections reliably. In contrast, deep convolutional neural networks (CNN) algorithms provide high performance pattern recognition making them an ideal solution for automated analysis of LBs and LNs. Intra-striatal injection of preformed alpha-synuclein fibrils was used to induce alpha-synuclein pathology in the mouse brain. Paraffin sections from brains were stained with a p129S-alpha-synuclein antibody and counterstained with hematoxylin. Digital whole-slide images of brain sections were acquired with a digital slide scanner at 0.22 µm/pixel resolution and uploaded to Aiforia® cloud platform for supervised CNN training. CNN algorithms were trained in Aiforia® to detect intracellular LBs and LNs automatically in digitalized images. The algorithm measured the length, width, area, and location for individual LNs and LBs. The combination of cloud-computing and CNN-based detection of p129S-alpha-synuclein immunoreactivity enables quantitative and reproducible high-throughput analysis of LNs and LBs in the mouse brain. The algorithm can be trained to detect LBs and LNsin any sample regardless of tissue or species, provided they can be stained with p129S and hematoxylin. This enables a variety of Lewy pathologies to be examined yielding length, area, and width distribution curves from large brain regions.

Abstract: Tauopathy is a group of neurodegenerative diseases characterized by hyperphosphorylation, misfolding and aggregation of Tau protein, as well as behavioral deficits and neuronal loss. Here, we developed a novel tau Tg mouse model which overexpresses 5-fold all six isoforms of the WT human tau (GEM1) and a tetracycline responsive, Camk2a-activated transgene carrying a human Tandem Repeat Tau (TRT) sequence at lower expression levels (GEM2). The TRT sequence serves as a tau aggregation primer accelerating the tau pathology without having to use known tau mutations like eg P301L, etc. Indeed, expression of TRT in HEK293 cells results in formation of soluble, hyperphosphorylated, high molecular weight tau oligomers. Brains were collected from WT controls, GEM1, and GEM2 mice, as well as from the GEM1 and GEM2 composite mouse (GEM3), at various ages, for biochemical and histological evaluation. Despite the high overexpression of WT human tau, GEM1 showed only a modest increase in tau hyperphosphorylation in sagittal sections stained for the tau phospho (Ser202, Thr205) specific antibody AT8, a marker for pathologically phosphorylated tau. In contrast, the GEM2 and GEM3 transgenic mice showed a dramatic increase in tau hyperphosphorylation. Similar results were obtained with staining of hippocampus and cortex for AT180 antibody, which recognizes hyperphosphorylated Thr231, and for PHF1 antibody, which recognizes tau phosphorylated at Ser396/404. Behaviorally, 20-month old GEM3 mice showed moderately increased locomotor activity, but normal performance in the rotarod assay, compared to WT controls. In the Morris Water Maze, GEM3 mice showed equivalent performance to age-matched WT mice in a 5-day cued learning task, but impaired learning a hidden platform task. GEM3 mice also exhibited spatial learning deficits in three probe tests (e.g., Day 10 probe test: Percent of time spent in island quadrant; WT: 51.5 ± 6.4; GEM3: 31.7 ± 3.8; $P<0.01$) and analysis of swim patterns indicated search strategies reflective of impaired learning. In summary, this novel tau transgenic mouse model recapitulates key aspects of Alzheimer's Disease-like symptoms including tau hyperphosphorylation and learning and memory impairments.

Title: Detection of alpha-synuclein aggregates in the brain of two different mouse strains of tauopathy model, rTg4510 and PS19

Authors: *Y. TAKAICHI[1], T. WASHINUMA[1], H. INOUE[1], Y. ANO[2], J. K. CHAMBERS[1], K. UCHIDA[1], A. TAKASHIMA[3], H. NAKAYAMA[1];

Abstract: *Introduction:* The accumulation of specific phosphorylated protein aggregates in the brain is a hallmark of neurodegenerative disorders. Specifically, hyperphosphorylated tau (hp-tau) accumulates in tauopathies and phosphorylated α-synuclein (p-αSyn) accumulates in α-synucleinopathies. Co-deposition of different pathological proteins is common in the brains of patients with neurodegenerative diseases. In this study, we examined the hp-tau-dependent p-αSyn aggregation in the brain of two strains of the tauopathy model mouse. *Methods:* Two strains of the tauopathy model mouse, rTg4510 mice that overexpress human P301L mutant tau, and PS19 mice that overexpress human P301S mutant tau were used. As controls, the background strains, FVB/N-C57BL/6J and C57BL/6J mice were examined, respectively. The rTg4510 and PS19 mice were euthanized at 10 and 13 months of age, respectively, and the brains were collected. The deposition of hp-tau and p-αSyn in the brain of these mice were examined by immunohistochemistry. *Results:* Human hp-tau and mouse p-αSyn aggregates were detected within the same neuronal cells mainly in the cerebral cortex of rTg4510 mice and the cerebral cortex and brain stem of PS19 mice. In rTg4510 mice, numerous p-αSyn-positive grains, occasionally p-αSyn-positive spherical Lewy body (LB)-like inclusions, and minute and uniform neuronal granules were observed. On the contrary, in PS19 mice, in addition to p-αSyn-positive spherical LB-like inclusions, and minute and uniform neuronal granules in the cerebral cortex, many p-αSyn-positive dense, uniform aggregates and p-αSyn-positive spherical LB-like inclusions were detected in the brain stem. Semi-quantitative analysis revealed a significant regional correlation between hp-tau and p-αSyn accumulations. After proteinase K-treatment, αSyn-positive aggregates were detected in the cerebral cortex of rTg4510 mice, but not in PS19 mice. *Conclusion:* The present results indicate that endogenous mouse αSyn is phosphorylated and accumulates in neurons with hp-tau aggregation, and suggest that the overexpression of human P301L and P301S mutant tau may enhance endogenous αSyn phosphorylation and

aggregation. Therefore, kinases and phosphatases which control the phosphorylation process of both tau and αSyn may be involved in the mechanism of the co-deposition. The morphological variations of p-αSyn aggregates and different proteinase K-resistance of αSyn aggregates between the two tauopathy mice may imply the direct interaction of tau and αSyn proteins. This synergic effect of tau and αSyn accumulations may exacerbate the brain pathology.

Title: Transmissibility of SOD1 prion strains between mice expressing different mutant human SOD1s

Authors: *E. EKHTIARI BIDHENDI[1], P. ANDERSEN[2], S. MARKLUND[1], T. BRÄNNSTRÖM[1];
[1]Dept. of Med. Biosci., [2]Dept. of Pharmacol. and Clin. Neurosci., Umea Univ., Umeå, Sweden

Abstract: *Background.* Two structurally different human (h) SOD1 aggregate strains, A and B, can arise in CNS of transgenic (Tg) mice expressing hSOD1 variants (Bergh et al. 2015). When inoculated into spinal cords of Tg mice both strains transmit exponentially growing templated hSOD1 aggregation and premature paralysis (Bidhendi et al. 2016, 2018).
It is known from the prion protein field that there are species barriers for prion transmission and that mutations/polymorphisms in a given species can determine susceptibility to prion transmission. Here we investigate if such transmission barriers exist for hSOD1 aggregate/prion strains when prepared from, and inoculated into Tg mouse expressing different hSOD1 variants.
Methods. hSOD1 A and B seeds were prepared from mouse spinal cords by ultracentrifugation

through a density gradient (Bidhendi et al. 2016). Seeds were microinoculated into lumbar spinal cord of adult recipient Tg mice.
Results. We have shown that A-prions prepared from hSOD1^{G85R}, hSOD1^{G127X} Tg mice and B-prions from hSOD1^{D90A} mice efficiently seed aggregation and motor neuron disease in hSOD1^{G85R} mice (Bidhendi et al. 2016, 2018).
We have also found that strain A seeds from hSOD1^{G85R} mice efficiently seed aggregation and disease in both hemi and homozygous hSOD1^{D90A} mice. Likewise strain B seeds from hSOD1^{D90A} mice transmit disease to hemi and homozygous hSOD1^{D90A} mice. A second passage strain B seed from hSOD1^{G85R} mice transmitted disease to hSOD1^{G85R} mice, but without any enhanced efficiency compared with such seeds from hSOD1^{D90A} mice. Finally, strain A-like seeds from hSOD1^{G127X} mice efficiently transmitted disease to both hemi and homozygous hSOD1^{G127X} mice (unpublished data).
However, strain A seeds from hSOD1^{G93A} Tg mice did transmit strain A aggregation and disease to hSOD1^{G85R} mice, but apparently with low efficiency. The lifespans of recipient mice were longer than expected from the dose of hSOD1^{G93A} aggregates that was inoculated. Finally, strain A seeds prepared from paralytic hSOD1^{WT} mice (Graffmo et al. 2013) have so far failed to transmit disease to hSOD1^{G85R} mice.
Conclusions. Our experience suggests that hSOD1 A and B prions on different hSOD1 mutation backgrounds in most cases freely transmit disease to Tg mice expressing other mutant hSOD1s. However, strain A seeds on hSOD1^{G93A} background apparently showed reduced efficiency in hSOD1^{G85R} mice, and we have so far failed to transmit ALS with strain A seeds from hSOD1^{WT} Tg mice.

Abstract: Tauopathies consist of a group of neurodegenerative diseases characterized by intracellular protein aggregates formed by abnormal accumulation of microtubule-associated protein tau. Tau aggregates are often diagnosed as neurofibrillary tangles in postmortem tauopathy brain tissues and correlates closely to brain atrophy and memory deficits. Clinical phenotypes of tauopathies manifest as cognitive impairment and behavioral disturbance. Tau remains a central target for drug discovery, but currently there are no effective treatments that treat disease. Our previous work revealed a unique interaction between tau biology and arginine metabolism. G protein coupled receptor (GPCR) family C, group 6 member A (GPRC6A) was a putative L-arginine extracellular sensor and recently linked to mechanistic target of rapamycin complex 1 (mTORC1) pathway *in vitro*. Our preliminary work suggests hyper-mTORC1 signaling in both human Alzheimer's disease patient brains and animal models of tauopathy. We aim to decrease GPRC6A signaling, which is predicted to inhibit mTORC1 signaling, promote tau degradation, and mitigate cognitive impairment in a mouse model of tauopathy. We used recombinant adeno-associated virus (rAAV) encoding shRNA specific to mouse GPRC6A or scrambled shRNA control. The rAAV constructs were bilaterally delivered into anterior/ entorhinal cortex and hippocampus of tau P301S (PS19) mice and non-transgenic littermates at the age of 6 months. After four months' viral incubation, we measured a series of mouse behavioral tests associated with tau neuropathology. The shRNA rAAV successfully downregulated mouse GPRC6A expression both *in vitro* and *in vivo*. Long-term *in vivo* downregulation of GPRC6A significantly changed tau P301S mouse behaviors, including improved spatial working memory measured in radial arm water maze (RAWM) and enhanced fear associated recall in fear conditioning (FC) measurement. In summary, this is the first evidence to show that central nervous system GPRC6A repression *in vivo* can partially rescue components of the tau phenotype. Further biochemistry and immunohistochemistry analysis of key proteins involved in mTORC1 signaling and different aspects of the tau phenotypes are warranted to validate the effects of GPRC6A repression. Therapeutics that modulate GPRC6A activity may potentially provide new treatments to improve cognition and mitigate tauopathies in human patients.

Title: Progress towards the first preclinical model of progressive supranuclear palsy

Authors: *G. S. KING, K. M. VEROS, S. D. CLARK;
Pharmacol. and Toxicology, Univ. At Buffalo- SUNY, Buffalo, NY

Abstract: The brainstem structure pedunculopontine tegmentum (PPTg) has become a focus in the study of Parkinsonisms, such as Progressive Supranuclear Palsy (PSP). Pathologically, PSP shows an extensive loss of PPTg cholinergic neurons, as well as aggregates of the microtubule stabilizing protein tau, which are greatest in areas innervated by the PPTg. PSP symptomology includes deficits in acoustic startle reflex (ASR), motor function and coordination, and working memory. Currently, there are no pharmacotherapies available for PSP patients and drug discovery is hindered by the lack of an adequate preclinical model. Previously, selective cholinergic PPTg lesions in rats induced PSP-like symptomology and pathology including motor deficits, a significantly reduced ASR, substantia nigra (SN) dopaminergic loss, and enlarged lateral ventricles. However, lesioned rats showed no evidence of pathological tau. Building upon previous efforts, we hypothesize that the loss of PPTg cholinergic neurons, coupled with deposition of tau in areas seen in PSP, will mimic PSP symptomology and pathology.
Male and female ChAT-Cre Long Evans rats were injected in the PPTg with a virally mediated (adeno associated virus) tau contruct or GFP construct as a control. Following surgery, rats were tested in a battery of behavioral paradigms: ASR, marble burying, locomotor activity, horizontal ladder, hindlimb clasping, and an operant task. As early as four weeks post-surgery rats exhibited significant PSP-like motor deficits, which did not diminish over the duration of 20 weeks. Cognitively, operant testing revealed an intact working memory, but gave insight to other potential deficits also analogous to PSP.
While histology is still in progress, preliminary results confirm a significant loss of PPTg cholinergic neurons as well as a trend towards loss of dopaminergic SN neurons. Presence of phosphorylated tau is also evident, further indicating PSP-like pathology. To determine the progression of pathology, brains will be analyzed for presence of various forms of pathological tau as well as ventricle width. Thus far, both behavior and histology results suggest the induction of tau in the cholinergic PPTg may be an adequate animal model for PSP, and could be used in drug discovery efforts.

Title: The anti-tau antibody HJ8.5 reduces tau seeding and aggregation *in vitro* and *in vivo*

Authors: *L. E. RUETER[1], A. STRIEBINGER[2], S. BARGHORN[2], H.-Y. WU[3], J. BREWER[3], C. HAMILTON[4], R. CHANG[4], T. DELLOVADE[4], K. SCHLEGEL[2], M. MEZLER[2], F. LE PRIEULT[2], K. KAYGISIZ[2], K. DIRY[2], D. CLAUSZNITZER[2];
[1]Abbvie, North Chicago, IL; [2]AbbVie, Ludwigshafen, Germany; [3]AbbVie, Worcester, MA; [4]AbbVie, Cambridge, MA

Abstract: Emerging evidence suggests the progression of tau pathology in neurodegenerative diseases such as Alzheimer's disease (AD) and progressive supranuclear palsy (PSP) is due, at least in part, to the trans-neuronal propagation of misfolded tau capable of templating tau aggregation in neurons that take up the pathological "seed". Anti-tau antibodies have been proposed as a potential therapeutic intervention based on the theory that they will bind to seeding competent tau in extracellular space and reduce subsequent downstream neuronal seeding and intracellular tau aggregation. HJ8.5 is an anti-tau antibody that binds the N terminal of tau. Using ELISAs, it was demonstrated that HJ8.5 bound to tau in soluble and insoluble fractions isolated from AD and mouse tau transgenic brains as well as to monomeric and paired helical filament (PHF) recombinant tau. In functional *in vitro* assays, HJ8.5 decreased tau aggregation induced by the application of seeding competent tau to biosensor cells expressing a tau repeat domain containing the P301S mutation. The antibody reduced tau aggregation induced by total AD brain lysate, by sarkosyl insoluble tau from AD brain lysate and by sonicated recombinant PHF tau. HJ8.5 was also tested in an *in vivo* seeding model. In the model, AD brain lysate was injected into the hippocampus of young, pre-pathology rTg4510 transgenic mice expressing human tau with the P301L mutation. Three weeks after injection, brains were analyzed for the presence of aggregated tau in the ipsilateral hippocampus using AT100 immunohistochemistry. Dosing mice with HJ8.5 prior to the injection of AD brain lysate led to a dose dependent reduction in AT100 immunoreactivity in the hippocampus. The level of target engagement required to reduce AD brain lysate-induced tau aggregation in the rTg4510 *in vivo* seeding model was calculated by determining the degree of reduction of unbound tau in the CSF seen at efficacious brain concentrations. Reductions in *in vivo* tau aggregation induced by HJ8.5 were correlated with the level of target engagement in the CSF. These data support the seeding and propagation theory of

tau pathology progression and suggest antibodies such as HJ8.5 are capable of reducing pathological tau-induced seeding.

Title: Microbiome manipulation modifies tau-mediated neurodegeneration in *Drosophila melanogaster*

Authors: H. KOHL, V. HYDE, *K. M. LOHR;
Biol., Washington and Jefferson Col., Washington, PA

Abstract: The deposition of the microtubule-associated protein tau is a hallmark pathology of the family of neurodegenerative diseases known as tauopathies, including Alzheimer's disease, frontotemporal dementia, and chronic traumatic encephalopathy. Despite progress in the study of tau-mediated neurodegeneration, the field has shown that most tauopathy cases do not have a single genetic cause. Instead, genetic contributions may interact with peripheral or environmental factors to contribute to disease. Recently, the gut microbiome has emerged as a potential modifier of brain function in human, rodent, and invertebrate models via changes to neurotransmitter levels and systemic inflammation. We show that Drosophila expressing human tau in neurons have a progressive deficit in fecal deposition compared to control flies. Further, tau-expressing flies grown with a limited microbiome using an axenic preparation show enhanced neurodegenerative outcomes, as shown by locomotor activity deficits and increased brain vacuole formation. 16S rDNA analysis was also used to define the typical microbiome composition in tau and control flies at multiple time points. Taken together, these data suggest that tau-expressing flies have an innate deficit in gut function and that manipulation of the gut microbiome is capable of altering neuronal health in this Drosophila model of human tau expression.

Title: Electrophysiological and behavioral properties in the striatum of the K3 transgenic mouse

Authors: *M. MO[1], M. E. JÖNSSON[2], M. A. MATHEWS[1], D. JOHNSTONE[1], T. T. FURLONG[2], B. W. BALLEINE[2], L. M. ITTNER[2], A. J. CAMP[1];
[1]Physiol., Univ. of Sydney, Sydney, Australia; [2]NeuRA, Sydney, Australia

Abstract: *Objective*: Validated animal models of neurodegenerative disease are required to understand disease mechanisms. In order to validate animal models, it is necessary to understand the impact on individual neurons in affected brain regions. Here we assessed the electrophysiological properties of striatal neurons, and behavioral measures in a transgenic model of Picks disease (the K3 mouse) compared with *wildtype* mice.
Methods: All experiments were approved by the Animal Ethics Committee of the University of Sydney. The electrophysiological discharge properties (n = 66) and synaptic input properties (n = 5) of mouse striatal neurons were characterized in two experimental groups; *wildtype* mice (n= 38), and K3 transgenic mice (n= 28), all on the C57BL/6 background. For behavioral studies, twenty-one mice were used, comprised of both *wildtypes* (n=10) and K3 mice (n=11). Electrophysiological recordings were made from coronal slices (200 μm) distributed evenly across the entire striatum in whole-cell current-clamp and voltage-clamp mode at room temperature. Voltage-clamp recordings to interrogate synaptic input profile were carried out under pharmacological blockade using known excitatory and inhibitory receptor blockers. For behavioral procedures an outcome devaluation test was used to quantify the formation of habitual behavior.
Results: The proportion of striatal neuron discharge profiles in *wildtype* mice was significantly altered when compared with the K3 transgenic group (p= 0.006). In general, this alteration was characterized by a shift towards burst firing discharge profiles in the K3 transgenic mice. Furthermore, the K3 transgenic mice showed significantly higher subthreshold excitatory postsynaptic potentials activity at rest (p= 0.03). The passive membrane properties including input impedance and capacitance of striatal neurons were not significantly different between both mouse groups. The synaptic input profile of striatal neurons is predominantly excitatory in nature. Results of the outcome devaluation test indicated a reduced ability for K3 mice to form habits relative to *wildtype* mice, and thus behaved in a goal-directed manner, suggestive of impairments in the dorsal striatum.
Conclusion: Neurons in the striatum of K3 transgenic mice display a hyper-excitable state, which may contribute to reduced habit formation when compared with *wildtype* mice.

Title: Neuropsychiatric symptoms in mouse models of AD and bvFTD

Authors: *E. S. E. DREESEN, L. ROBINSON, V. MELIS, P.-H. MOREAU, C. HARRINGTON, C. M. WISCHIK, G. RIEDEL;
Univ. of Aberdeen, Aberdeen, United Kingdom

Abstract: For Alzheimer's disease (AD) and other forms of dementia a lot is known about cognitive symptoms and their neurobiological basis. However, more recently studies have focused on the importance of different neuropsychiatric symptoms (NPS) discriminating between the different types of dementia. Possible recurring NPS in AD are psychosis, depression, anxiety and apathy, while patients with the behavioural variant of frontotemporal dementia (bvFTD) exhibit e.g. increased impulsivity, disinhibition, hyperphagia and apathy. These symptoms have a critical impact on the quality of life of both patients and caregivers and a considerable economic impact. To study NPS, their neurobiological basis as well as their presence and influence on disease progression, preclinical trials should be done in mouse models. The **research objective** of this exploratory study was to assess NPS in two tau transgenic mouse models described in Melis *et al.* (2015). Briefly, L1 overexpresses a truncated repeat domain of the tau fragment to model AD while L66 overexpresses full-length tau with two pathogenic point mutations (P301S and G335D) to represent bvFTD. Focus lay on behavioural tests for anxiety, depression, inhibition and motor impairment as well as cognition.
Methods: Experiments were performed with female mice, aged 3 and 6 months and compared to NMRI controls. Experiments were carried out in accordance with the European Communities Council Directive (63/2010/EU) and a project license with local ethical approval under the UK Animals (Scientific Procedures) Act (1986). Sample sizes were based on power calculations and all experiments were performed blind and counterbalanced. Behavioural tests done: elevated plus maze, open field, light-dark box, forced swim test, sucrose preference test, pre-pulse inhibition (PPI), delay discounting, Y-maze and Barnes maze.
Results: A hyperactive, anxiolytic phenotype with impaired PPI, spatial reference and working memory was found in L1 animals. L66 mice presented with neophobia as well as impaired PPI and working memory. No evidence of a depressive phenotype was found in either model.
Conclusions: It appears that our tau-based models display NPS together with cognitive impairments. The type of NPS found in L1 and L66 mice is in accordance with predictions for

human patients with AD and bvFTD, respectively, and provides an excellent non-clinical test bed for the development of new drug therapies. It is paramount to include tests for NPS as they can have a major influence on behaviour seen in cognitive tests. Furthermore, these tests are well suited to discriminate the different types of dementia when establishing new models.

Title: Behavioral characterization of sensorimotor, neuropsychiatric, and cognitive function in transgenic mice overexpressing human tau

Authors: I. SAFI, Y. AL-RHAYYEL, D. E. HERMAN, L. LIN, S. M. FLEMING, *C. M. DENGLER-CRISH;
Pharmaceut. Sci., Northeast Ohio Med. Univ., Rootstown, OH

Abstract: Tauopathies are a group of diseases characterized by abnormal tau phosphorylation and accumulation in neurons in the brain. Tau pathology is associated with neurodegeneration and a wide spectrum of behavioral symptoms. Alzheimer's disease, progressive supranuclear palsy (PSP), and chronic traumatic encephalopathy are all tauopathies. Common behavioral symptoms include neuropsychiatric conditions such as depression, anxiety and cognitive dysfunction. Sensorimotor function can also be affected as is evident in PSP. Currently, there are few symptomatic treatments and no disease-modifying therapies for tauopathies. This is due, in part, to a lack of understanding of the timecourse and progression of behavioral alterations in these diseases. Thus, a tauopathy model that develops a broad spectrum of behavioral anomalies would be optimal in preclinical trials testing potential therapeutics. In this study, we sought to characterize sensorimotor, neuropsychiatric, and cognitive function in mice that selectively overexpress all human tau isoforms (hTau). Male and female C57Bl/6 (n=9), Tau knockout (Tau -/-; n=8), and hTau (n=9) mice were tested on a battery of behavioral assays to determine the effect of hTau on sensorimotor, neuropsychiatric, and cognitive behaviors. At 13-15 months of

age, male and female hTau mice showed sensorimotor deficits compared to control that differed depending on the test. Males displayed decreases in hindlimb stepping, stride length, and locomotor activity, while female hTau mice reared significantly less than control in the activity tests. Female hTau mice were more affected in the neuropsychiatric tests compared to control and males. Latency to approach in novelty suppressed feeding was increased in hTau females compared to control and they drank less sucrose solution in the sucrose preference test of anhedonia. Cognitive function was also more affected in female hTau than males. Female hTau mice showed reduced investigation and impaired discrimination in an object recognition test. These results show overexpression of human tau leads to impairments in multiple aspects of behavior particularly in female mice. These data will help inform preclinical testing of novel therapeutics and facilitate translation to human tauopathies.

Title: Age-dependent and region-specific miRNAs deregulation in the hTau mouse model of tauopathy

Authors: *E. LAURETTI, D. PRATICO;
Lewis Katz Sch. of Med. at Temple Univ., Philadelphia, PA

Abstract: Tauopathies are a class of neurodegenerative disorders characterized by accumulation of abnormally phosphorylated tau in association with progressive loss of memory and cognitive functions. Despite intensive research the mechanisms responsible for tau pathology is still unknow. Small non-coding RNAs, microRNAs (miRNAs), are post-transcriptional regulators involved in the modulation of cellular processes including tau metabolism. Analysis of the expression profile of miRNAs in the brain of tauopathy patients has identified several miRNAs that are dysregulated, however, it is unclear whether those alterations are secondary contributing factors to the pathogenesis of these disorders. To tackle this question, we characterize the miRNAs expression profile in distinct brain regions and in different stages of the pathological phenotype in the hTau mouse model of human tauopathy with the goal of correlating them to the onset and progression of the pathological changes. Thus, we analyzed miRNAs expression levels in the cortex and hippocampus of hTau and wild type mice utilizing the Mouse Neurological Development & Disease miScript miRNA PCR Array and results were further confirmed by qPCR (n=6/8 per group) looking at three different age-time points (3, 6 and 12 months). Next, to

explore whether these changes correlate with the age- and region-specific development of tau neuropathology, we performed behavioral tests to assess learning and memory and also looked at synaptic dysfunction, tau metabolism and neuroinflammation in wild-type and hTau mice at the time points and in the brain regions of interest. Notably, we found six miRNAs (miR132-3p, miR22-3p, miR298-5p, miR489-3p, miR455-5p and miR146a-5p) upregulated in the hippocampus of hTau mice at 12 months of age, and among them miR132-3p, miR22-3p and miR-146a-5p were already upregulated at 6 months before the development of memory and cognitive impairment and tau pathology. No changes instead, were observed in the cortex of the same animals. In conclusion, our data show differential expression of specific miRNAs at both presymptomatic and symptomatic stages of tauopathy in the hippocampus of hTau mice and suggest that these miRNAs might be part of the pathological process and/or contribute to the disease progression by targeting crucial key signaling pathways.

Title: Two axes of CHCHD10^{S59L} dominant toxicity: TDP-43 and PINK1

Authors: *N. KIM, Y.-J. CHOE, M. BAEK;
Pharm. Practice and Pharmaceut. Sci., Univ. of Minnesota, Duluth, MN

Abstract: Mutations in coiled-coil-helix-coiled-coil-helix-domain containing 10 (CHCHD10) have been identified as a genetic cause of amyotrophic lateral sclerosis and frontotemporal dementia. However, the disease-causing mechanism and the nature of mutations have not been fully understood. In this study, we generated a *Drosophila* model to study the function of CHCHD10 and disease-causing mechanisms. Mutant dCHCHD10^{S59L} expression caused dominant toxicity in Drosophila eyes, motor neurons and muscles as well as HeLa cells while other mutants (R15L, P34S, G58R, and G66V) showed various effects in *Drosophila* and Hela cells. With the dCHCHD10^{S59L} *Drosophila* model, we found that CHCHD10^{S59L} is a dominant gain-of-toxicity mutant forming protein aggregates in mitochondria. Expression of CHCHD10^{S59L} affects TDP-43 solubility and mitochondrial translocation. In addition, the PINK1/Parkin pathway is activated by dCHCHD10^{S59L}. Blocking TDP-43 mitochondrial

translocation peptide inhibitors mitigated CHCHD10^{S59L}-induced mitochondrial fragmentation. Surprisingly, co-expression of CHCHD10^{WT} reduced insoluble TDP-43 and mitochondrial translocation. On the other hand, RNAi-mediated reduction of PINK1 and Parkin expression significantly rescued abnormal phenotypes in *Drosophila* tissues and HeLa cells. Furthermore, treatment of newly developed peptide inhibitors of PINK1 reversed CHCHD10^{S59L}-induced mitochondrial phenotypes in HeLa cells. With our *Drosophila* model, we found two downstream substrates of PINK1, mitofusin, and mitofillin, are involved in the toxicity-generating process. Recently developed mitofusin2 agonists also restored mitochondrial functions disrupted in HeLa cells and *Drosophila* models for dCHCHD10^{S59L} and C9orf72. Our data suggest that mitochondrial translocation of TDP43 and chronic activation of the PINK1-mediated pathways by CHCHD10^{S59L} generates dominant toxicity in our model systems and suggest TDP43 mitochondrial translocation and the PINK1-mediated pathways as potential therapeutic targets for mutant CHCHD10-induced degenerative diseases and other related diseases.

Title: Perturbed atlastin-1 results in axonal and synaptic defects in human cortical neurons

Authors: *Y. MOU[1], Y. DONG[3], S. MUKTE[1], S.-C. ZHANG[4], X.-J. LI[2];
[2]Dept. of Biomed. Sci., [1]Univ. of Illinois, Rockford, IL; [3]Waisman Ctr., Univ. of Wisconsin - Madison, Madison, WI; [4]Waisman Ctr., Univ. Of Wisconsin - Madison, Madison, WI

Abstract: Hereditary spastic paraplegias (HSPs) are a heterogeneous group of neurogenetic disorders characterized by axonal degeneration of cortical motor neurons (MNs), a group of large projection neurons (PNs). Why axonal defects occur specifically in cortical PNs and how synaptic connections between cortical PNs and their targets are affected in HSPs remain largely unknown. SPG3A, the most common early-onset form of HSP, is caused by mutations in the *ATL-1* gene that encodes atlastin-1. We have previously modeled axonal degeneration of SPG3A using patient-specific iPSCs. Here, to further dissect the role of atlastin-1, we first knocked in an *ATL-1* mutation (*ATL*161 line, p.A161P) using CRIPSR-cas9 mediated homologous recombination, which generated both heterozygous and homozygous SPG3A isogenic human pluripotent stem cell (hPSC) lines (c. G>C). The mutation of *ATL-1* (p.A161P) induced axonal defects, including decreased axonal outgrowth, increased axonal swellings and impaired axonal

synaptophysin transport in cortical PNs. Interestingly, heterozygous mutation results in axonal defects at a comparable level to homozygous mutations. This is coinciding that SPG3A is autosomal-dominant and suggests that a critical levels of atlastin is needed to maintain normal axonal function. Next, we seek to determine the synaptic defects in HSP by establishing a co-culture model for SPG3A. We generated the channel rhodopsin 2 (ChR2)-EYFP expressing hPSC lines. The SPG3A and control hPSC lines were differentiated into cortical PNs (ChR2+), which were then co-cultured with their target cells, spinal MNs derived from their corresponding regular hPSC (without ChR2). After the immunostaining, we observed a dramatic decrease in the numbers of the Synapsin+/EYFP+/PSD95+ synaptic clusters in the SPG3A co-cultures comparing to control coculture of cortical PNs and spinal MNs. Furthermore, the electrophysiological analysis revealed that the frequency of spontaneous excitatory postsynaptic currents (sEPSCs) recorded in SPG3A spinal MNs decreased significantly comparing to control coculture group after the activation of ChR2-expressing cortical PNs using blue light stimulation, indicating the impaired functional synaptic connections between co-cultured cortical PNs and spinal MNs in SPG3A cell model. Taken together, our data reveal that perturbed atlastin-1 induced disease-specific axonal defects and the impaired synaptic connections between cortical PNs and spinal MNs in a SPG3A co-culture model, which will serve as a unique system to study the pathogenic mechanism and explore the treatment for HSPs.

Title: Abnormal interaction between p97/VCP and a concealed UBX domain in adjacent missense alleles (A988V and T994I) of the Menkes disease copper transporter ATP7A cause an isolated distal motor neuropathy resembling Charcot-Marie-Tooth disease type 2 (CMT2)

Authors: *L. YI[1], K. MATHEWS[2], S. G. KALER[3];
[1]NICHD/NIH, Bethesda, MD; [2]Univ. of Iowa Stead Family Children`s Hosp., Iowa City, IA; [3]NICHD, Bethesda, MD

Abstract: The copper transporter ATP7A is an eight-transmembrane protein critical for normal copper homeostasis. Mutations in ATP7A lead to severe infantile-onset Menkes disease (MNK), milder Occipital Horn Syndrome (OHS) or an isolated adult-onset distal motor neuropathy. The missense mutations A988V, T994I, and P1386S cause distal motor neuropathy without copper metabolism abnormalities, as documented in three unrelated families with clinical phenotypes similar to Charcot-Marie-Tooth disease, type 2 (CMT2). P1386S causes unstable insertion of the

eighth transmembrane segment, preventing proper position of the carboxyl-terminal tail, and disturbs the normal physical interactions of ATP7A with adaptor protein complexes 1 and 2 (AP-1, AP-2). ATP7A-P1386S leads to abnormal axonal localization in transfected NSC-34 motor neurons, and alters calcium signaling following glutamate stimulation. The ATP7A-related distal motor neuropathy caused by the two other ATP7A missense mutations, A988V and T994I, both within the 6th transmembrane segment, involves abnormal interactions with p97/VCP, a hexameric AAA ATPase that has a diversity of biological functions. Our immunoprecipitation studies revealed that both ATP7A-A988V and ATP7A-T994I physically interact with p97/VCP, whereas wild type ATP7A and ATP7A-P1386S do not. We identified a concealed UBX domain in the third lumenal loop between the fifth and the sixth transmembrane domains of ATP7A that interacts with the N-terminal domain of p97/VCP. Since inherited mutations in p97/VCP itself may cause motor neuron degeneration phenotypes including CMT2, hereditary spastic paraplegia, and ALS, the isolated motor neuron disease associated with these unique ATP7A missense mutations may provide insight and opportunity to dissect the mechanism(s) of p97/VCP-mediated motor neuron degeneration of varied molecular basis.

Title: NEK1 loss-of-function in iPSC-derived motor neurons causes ALS-related phenotypes

Authors: *R. P. MAYERS[1], E. L. DALEY[1], L. TELLEZ[1], J. E. LANDERS[2], E. KISKINIS[1]; [1]Neurol., Northwestern Univ., Chicago, IL; [2]Neurol., Univ. of Massachussetts Med. Sch., Worcester, MA

Abstract: Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disease characterized by the degeneration of motor neurons (MNs), leading to eventual paralysis and death; at present, no effective therapy exists. Three independent exome sequencing studies reported a significant enrichment of heterozygous loss of function mutations in the NIMA-related kinase 1 (NEK1) gene in ALS patients that may account for up to 3% of all ALS cases. NEK1 is a cell cycle kinase involved in the DNA damage response, ciliogenesis, and apoptosis. Here, we modeled NEK1-associated ALS using patient-derived motor neurons and siRNA-mediated knockdown in control motor neurons. We observed ALS-related phenotypes, including

a redistribution of TDP-43 from the nucleus to the cytoplasm and higher levels of DNA damage. This study provides support for a key role of NEK1 in ALS-related motor neuron dysfunction.

Med., Tulane Univ. Sch. of Med., New Orleans, LA

Abstract: EWSR1 (Ewing Sarcoma breakpoint region 1/EWS RNA binding protein 1), a multifunctional protein, was found to be associated with amyotrophic lateral sclerosis (ALS). However, the EWSR1-dependent pathological mechanism in CNS and ALS has not been fully investigated yet. We found that the immunoreactivity of EWSR1 was significantly decreased in oligodendrocytes in the spinal cord of ALS patients and ALS transgenic [mutant SOD1 (G93A)] mice. Demyelination-associated axonal pathology was observed in the spinal cord of ALS patients and SOD1 (G93A) mice. In addition, the levels of PLP, MBP and OLIG2 were significantly down regulated in the ventral horn of G93A mouse spinal cord. To determine the Ewsr1 deficiency-associated gene expression signatures, we performed whole RNA-sequencing from the spinal cords of wild type (WT) and *Ewsr1*KO mice. We found that myelination and axon ensheathment-related genes including *Plp1, Mbp,* and *Utg8a*were markedly down regulated in *Ewsr1*KO mice. EWSR1 modulated the transcription of *Plp1*through the EWSR1-binding element in the 5'-UTR region. Moreover, knockdown of *ewsr1*in G93A zebrafish exacerbated impaired oligodendrocyte maturation and poor motor neuron myelination. Our data indicate that

EWSR1 plays a *bona fide* role in oligodendrocyte activity and its deficiency impairs oligodendrocyte-derived gene expression, leading to the axonal damage of motor neurons in ALS. Together, our study indicates that EWSR1 dysfunction is a molecular marker of ALS pathology and a potential therapeutic target for restoration of oligodendrocyte function.

Abstract: Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disorder characterized by the progressive loss of motor neurons, producing muscle weakness, paralysis and death. A large number of genes are implicated in familiar and sporadic cases, like so in the spectrum associated with Frontotemporal Dementia (FTD), among which, there are *FUS* and *GRN*. *FUS* (16p11.2) codes for a nuclear protein involved in the biogenesis, regulation and transport of RNA. The *GRN* (17q21.31) has cell regulation, proliferation and differentiation functions. We identify gene variants in *FUS* in Mexican patients with ALS and evaluate variants in GRN in patients with ALS-FTD. We studied 157 patients who met The Escorial clinical criteria of ALS. Prior informed consent, a peripheral blood sample was taken for genomic DNA extraction. Exons 5,6,14 and 15 of the *FUS* gene were amplified by PCR and analyzed by Sanger type sequencing. In addition, in 11 patients with a history of probable FTD, the *GRN* gene was analyzed. We find in *FUS*, the pathological mutation p. P525L in an individual with brachial juvenile presentation in sporadic case. As well as 5 variants of uncertain significance; p.Y239C; p.G488G C> T; intronic variant c.524_21T> C; two in 3'UTR c. * 48G> A and c. * 41G> A. In *GRN*, 2 variants were identified: p.D591V; c. * 78C> T in 3`UTR in a homozygous and heterozygous manner.

The evaluation of these variants in *FUS* and *GRN* confirm the presence of the DFT-ELA spectrum. Interestingly, the p.P525L mutation of *FUS* affects the C-terminal domain of nuclear localization signaling, rich in glycine, critical for protein aggregation, with an early onset presentation corresponding to the ELA6 phenotype. The variants were presented in sporadic cases. In addition, in 36% of cases DFT-ELA were associated with mutations in the *GRN* gene, highlighting the variant in 3`UTR c. * 78C> T in homozygous state as a risk factor.

Title: ALS-linked FUS induces nuclear pore defects in patient-derived motor neurons

Authors: *Y.-C. LIN, M. S. KUMAR, D. GRUNWALD, D. A. BOSCO;
Umass Med. Sch., Worcester, MA

Abstract: FUS is an DNA/RNA binding protein that shuttles between the nucleus and cytoplasm and is actively involved in nucleocytoplasmic transport (NCT). Mutations in FUS cause amyotrophic lateral sclerosis (ALS), a fatal and incurable motor neuron disorder. Compromised NCT has recently emerged as a pathogenic mechanism underlying ALS and other neurodegenerative diseases. Here, we uncovered nuclear pore defects, including reduced nuclear membrane occupancy and abnormal clustering of pores, in motor neurons derived from human induced pluripotent stem cells (iPSCs) harboring an ALS-linked FUS mutation. Further, the Ran gradient was significantly altered in these neurons. As Ran is a master NCT regulator, these results are consistent with disrupted NCT in ALS-FUS. Importantly, these NCT-related defects were rescued by genetically correcting the *FUS* mutation in iPSCs. To gain insight into how expression of mutant FUS causes nuclear pore defects, we probed for potential interactions between FUS and a class of low complexity nucleoporin proteins called Nups. The major function of Nups is to maintain a functional and dynamic NCT. We detected an interaction between FUS and Nups via co-immunoprocipitation in different cellular models. Further, interactions between FUS and Nup were detected *in situ* within human neurons through a proximity ligation assay, which reported a significantly higher signal for mutant FUS and Nups

within the cytoplasm. This observation may account for the reduced occupancy of pore proteins at the nuclear membrane within the patient line, and is consistent with the pathological accumulation of NCT-related proteins within post-mortem ALS tissues. Intriguingly, both FUS and Nup proteins are known to undergo liquid-liquid phase separation (LLPS). Liquid-like properties allow proteins to rapidly concentrate and disassemble under various conditions. Indeed, we found that recombinant Nup62 and FUS proteins co-localize within liquid droplets *in vitro*, implicating aberrant LLPS of these proteins in the nuclear pore defects observed in human neurons. Collectively, these findings implicate aberrant Nup interactions in the pathogenic mechanism of ALS-FUS, and support the premise that the NCT pathway is a viable therapeutic target for neurodegenerative disorders.

Title: Accumulation of cytoplasmic Nup62 initiates TDP43 aggregate formation

Authors: *A. GLEIXNER[1], J. GALE[2], J. R. MANN[3], K. E. COPLEY[4], J. C. MAUNA[6], C. J. DONNELLY[5];
[2]Sch. of Med., [3]Neurobio., [4]Neurosci., [5]Dept. of Neurobio., [1]Univ. of Pittsburgh, Pittsburgh, PA; [6]Neurobio., Univ. of Pittsburgh Dept. of Neurobio., Pittsburgh, PA

Abstract: ALS and FTD are fatal, neurodegenerative diseases that both present with cytoplasmic mislocalization and aggregation of TAR DNA-binding protein 43 (TDP43). TDP43 is an RNA and DNA binding protein that is predominantly located in the nucleus of healthy cells. However, in ALS and FTD, TDP43 is redistributed to the cytoplasm where it forms insoluble aggregates and these are pathologically hyperphosphorylated, ubiquitinated, and p62-positive. Several genetic mutations in the TDP43 gene have even been linked to familial ALS and FTD cases. TDP43 mutations have also been shown to cause neurotoxicity. In TDP43 *Drosophila* models, neurotoxicity was reduced by mutating the phenylalanine-glycine (FG) domain of nucleoporin 50. The concentrated region of FG repeats in FG nucleoporins creates an area of hydrophobicity. A similar phenomenon is observed in the low complexity domain of TDP43. Therefore, we sought to examine whether FG nucleoporins are associated with TDP43 aggregate formation. We

hypothesized that these characteristics may favor interactions between FG nucleoporins and TDP43 that eventually yield insoluble TDP43 aggregates. Our studies revealed that the cytoplasmic accumulation of the FG nucleoporin Nup62 colocalizes with TDP43. These TDP43 aggregates are insoluble and mimic hallmark pathology typically observed in neurodegenerative diseases. Further characterization of the mechanism by which Nup62 seeds TDP43 aggregation may lend insight into the mechanism driving TDP43-aggregate formation in ALS and FTD.

Hospi, Charlestown, MA; [7]Pediatrics, Harvard Med. School/MGH, Charlestown, MA

Abstract: Previous studies have demonstrated that mitochondrial dysfunction is a pathogenic mechanism in ALS. Abnormal mitochondrial structure, alteration in mitochondrial protein transport and trafficking, and deficits in electron transport by complexes I-IV have been described in cellular and animal models of ALS as well as in patients. Importantly, these alterations lead to energy imbalance, oxidative stress, apoptosis, and impaired calcium signaling. Impairments in mitochondrial function have been described in the SOD1, wild-type and mutant TDP43 mice and a recent study demonstrated that oxidative stress and DNA damage were increased in iPSC-derived *C9ORF72* motor neurons in an age-dependent manner. Our genetic studies have unveiled a novel genetic variant in the WW domain-containing oxidoreductase (WWOX) gene in 4,366 ALS samples from Project MinE which is completely absent in gnomAD. WWOX is involved in a number of critical cellular functions one of which is to decrease oxidative stress by interacting with mitochondria. Therefore, we hypothesized that mutations in WWOX may lead to oxidative stress in ALS. We have begun to address this hypothesis by measuring alterations in mitochondrial function in post-mortem samples from

ALS patients. Our results indicated that WWOX protein levels are significantly decreased in post-mortem ALS motor cortex, supporting our hypothesis. In addition, there was a significant decrease in mitochondrial proteins involved in the electron transport chain (SDHB, UQCRC2, ATP5A, COXII, NDUFB8) and the citric acid cycle (SDHB) in *C9ORF72* ALS motor cortex compared to control. Furthermore, there is a significant decrease in peroxiredoxin 5 (PRDX5), an antioxidant enzyme targeted to the mitochondria during inflammation, in ALS patient plasma, suggesting that PRDX5 may be a novel biomarker for ALS. Together, these findings suggest that mutations in WWOX may lead to mitochondrial dysfunction and oxidative stress in ALS, specifically in patients with *C9ORF72* mutations.

Title: C9orf72 arginine-containing dipeptide repeat proteins disrupt nuclear import

Authors: *L. R. HAYES[1], K. BOWEN[1], L. DUAN[1], P. KALAB[3], J. D. ROTHSTEIN[2]; [2]Brain Sci. Inst., [1]Johns Hopkins Univ., Baltimore, MD; [3]Johns Hopkins Whiting Sch. of Engin., Baltimore, MD

Abstract: Disruption of nuclear transport is increasingly recognized as an important pathophysiologic mechanism in neurodegenerative disease, including C9orf72-mediated amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). Dipeptide repeat proteins (DPRs) produced by translation of the C9orf72 G4C2 hexanucleotide repeat expansion have been implicated in nuclear transport disruption, but the precise mechanism remains unclear. Here, we adapted the permeabilized cell nuclear import assay for primary cortical neurons, and tested the effect of each of the five C9orf72 DPRs (poly-GP, poly-GA, poly-GR, poly-PR, and poly-PA). We found dose-dependent inhibition of nuclear import by poly-GR and poly-PR. Both triggered visible aggregate formation in the assay, and mass spectrometry analysis of the aggregates confirmed sequestration of numerous RNA processing proteins, low complexity domain-containing proteins, and proteins involved in nucleocytoplasmic transport, including karyopherins, Ran cycle proteins, and some nucleoporins. These protein-protein interactions

were validated by Western blot, FRET, and bead halo studies, which confirmed the high affinity of poly-GR and poly-PR for importin β. Consistent with these data, we observed loss of importin β from the nuclear membrane in postmortem motor cortex and spinal cord from C9orf72-ALS/FTD patients. High concentrations of total cellular RNA reduced DPR-induced aggregation and rescued nuclear import. In summary, poly-PR and poly-GR inhibit nuclear import in an *in vitro* assay, via a mechanism involving disruption of importins and aberrant nucleoporin interactions. RNA-based approaches may offer a method for blocking these interactions and restoring nuclear import.

Title: Ubiquilin-2 efficiently lowers levels of common disease proteins, including the ALS-linked protein TDP-43

Authors: *J. WELDAY[1], *J. E. GERSON[2], S. S. PISTORIUS[3], J. D. GREGORY[2], L. M. SHARKEY[4], H. L. PAULSON[5];
[1]Univ. of Michigan- Ann Arbor, Ann Arbor, MI; [3]Neurosci., [2]Univ. of Michigan, Ann Arbor, MI; [4]Neurol. Dept., Univ. Michigan, Ann Arbor, MI; [5]Prof, Neurol, Univ. of Michigan Dept. of Neurol., Ann Arbor, MI

Abstract: Ubiquilin-2 (UBQLN2) is a homeostatic regulatory protein that functions primarily in the ubiquitin-proteasome system and autophagy to shuttle ubiquitinated proteins for degradation. When mutated, UBQLN2 directly leads to frontotemporal dementia (FTD) and amyotrophic lateral sclerosis (ALS), which are adult-onset neurodegenerative diseases characterized primarily by the presence of trans-active DNA binding protein-43 (TDP-43) inclusions in the cytoplasm. To investigate the ability of UBQLN2 to regulate FTD/ALS pathology, we first transfected HEK-293 cells to express TDP-43 in combination with UBQLN2 or with UBQLN2 knocked-down. The ability of UBQLN2 to regulate other common aggregation-prone disease proteins, including tau and alpha-synuclein, was also evaluated. Co-expressed UBQLN2 markedly lowered levels of wildtype TDP-43, as well as other common disease proteins. Conversely,

knockdown of UBQLN2 significantly elevated levels of wildtype TDP-43. However, mutations in TDP43 decreased the ability of UBQLN2 to lower TDP43 levels. To confirm that UBQLN2 directly interacts with disease proteins, UBQLN2 was immunoprecipitated from HEK-293 cells expressing both UBQLN2 and either tau, α-synuclein or TDP43. To determine how UBQLN2 regulates endogenous levels of disease proteins *in vivo,* UBQLN2 transgenic and UBQLN2 KO mice were analyzed for levels of TDP43, tau and α-synuclein via Western blot. While soluble levels of TDP43, tau and α-synuclein were unchanged, UBQLN2 lowered levels of endogenous, insoluble disease proteins when overexpressed. Given that mutated UBQLN2 has been shown to directly cause FTD/ALS, understanding its role in toxic protein regulation may ultimately help elucidate disease progression and onset. Further study will evaluate how disease mutations alter the function of UBQLN2 in regulating disease proteins. Our findings indicate the potential importance of UBQLN2 in regulating ALS/FTD pathology and highlight a new role for regulating levels of other common neurodegenerative disease proteins such as tau and α-synuclein.

Title: Defects in muscle ion channels contribute to motor dysfunction in spinal and bulbar muscular atrophy

Authors: *Y. XU[1], M. KATSUNO[2], H. ADACHI[3], G. SOBUE[2], M. BREEDLOVE[1], C. JORDAN[1];

Abstract: Spinal-bulbar muscular atrophy (SBMA) is characterized by progressive muscle weakness linked to a polyglutamine expansion in the androgen receptor (AR). Contractile dysfunction is a core trait of SBMA. We previously reported that diseased fibers in SBMA mouse models are partially depolarized, suggesting alterations in membrane excitability. To explore specific mechanisms, we examined the action potential (AP), a hallmark indicator of membrane excitability, using two-electrode intracellular recording of fibers in 3 well-studied SBMA mouse models-AR97Q, knock-in (KI) and myogenic. We find APs are uniformly slower

in all three models and smaller in two. The partial depolarization contributed to the reduced AP magnitude, but even at -80 mV, the threshold for excitation was significantly increased, linked to a loss of voltage-dependent sodium channels we reported previously. We also find reduced chloride and potassium conductance, indicating perturbations in these channels that contribute to the prolonged repolarization of APs and reduced input conductance of SBMA fibers at rest. The sodium/potassium pump maintains the normal resting membrane potential (RMP) of muscle fibers is also defective in diseased fibers in all 3 models. In sum, disease impairs specific ion channels and pumps in the muscle membrane, underlying effects on the RMP, the size and kinetics of APs, and decreased membrane excitability, all likely contributing to the striking deficits in contractile force in SBMA. Chronic depolarization of muscle RMP not only impairs excitation-contraction coupling, but also would trigger increases in resting intracellular Ca^{2+}, activating Ca^{2+}-dependent degradative pathways. These several mechanisms underlying muscle dysfunction in SBMA are potential targets for therapeutic invention.

Title: Two tales of one function physicochemical epidemiology evidence that loss of angiogenin function promotes amyotrophic lateral sclerosis onset but improves survival after onset

Authors: *K. C. ALURI[1], J. SALISBURY[2], J. N. AGAR[1];
[1]Chem. and Chem. Biol., Northeastern Univ., Boston, MA; [2]Brandeis Univ., Waltham, MA

Abstract: Over twenty mutations in angiogenin (ANG) are associated with familial (f) Amyotrophic lateral sclerosis (ALS) ALS. The prevailing hypotheses—which had not been statistically evaluated— were that these mutations contribute to fALS through either loss of ANG ribonuclease activity or a loss of nuclear translocation ability. To test these and other hypotheses, we correlated various physicochemical properties of ANG-ALS variants with ALS clinical outcomes. Using well- established statistical methods such as non-parametric correlation coefficients, Kaplan-Meier analysis, and Cox proportional hazards analysis we 1) demonstrate that loss of ANG function strongly correlates with more rapid ALS onset; and 2) demonstrate

that loss of ANG function strongly correlates with longer survival of ALS patients following ALS onset (increased duration). Notably, the observation that loss of ANG function correlates with increased duration contradicts current models of ANG-associated ALS. These data should be taken into consideration for ANG-replacement therapy development and clinical trial design for ALS because they indicate that 1) presymptomatic ANG replacement would extend the life of patients by an average of 13 years, but paradoxically 2) post-symptomatic ANG replacement could decrease the lifespan of ALS patients by two years. In addition, these observations can serve as an exemplar for growth factors "switching" from survival-promoting to toxic following the onset of disease.

Title: Exosomes secreted by diseased ALS cerebral cortex include messages to modulate disease progression

Authors: *E. XIE[1], M. GAUTAM[1], J. R. BRENT[1], N. KOCAK[1], O. GOZUTOK[1], H. Y. SHIN[1], N. L. ANGELONI[2], C. S. THAXTON[2,3], P. OZDINLER[1];
[1]Dept. of Neurol., [2]Dept. of Urology, Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [3]Intl. Inst. for Nanotechnology (IIN), Northwestern Univ., Evanston, IL

Abstract: Exosomes are mediators of intercellular communication between different cells in the body and are small vesicles typically 30-150nm in size. They carry a cargo of important biomolecules (protein, RNA, miRNA and lipids), which is used to transmit signal to recipient cells. Their ability to cross the blood brain barrier enables flow of information to distant locations within central nervous system (CNS), and between the CNS and the periphery. Building evidence suggests the importance and involvement of cortical component of motor neuron circuitry in the establishment and progression of disease pathology in amyotrophic lateral sclerosis (ALS). This study was conceived to identify differential protein content of the exosomes secreted by mixed cortical neuron cultures from 3 day old hSOD1^{G93A} and prpTDP-43^{A315T} mice, two well-defined mouse models of ALS. We investigated if diseased cortical neurons utilize exosomes to inform other cells and neurons about their physiological condition and whether this information serves to propagate the disease or information as a "warning signal" to other cells and neurons. Our preliminary results suggest that hSOD1^{G93A} and prpTDP-

43^{A315T} cortical neurons include a very distinct set of proteins in exosomes, some of which are common and some are unique. Proteins present in these early-age exosomes suggest encoding a "warning signal" to other cells and neurons. This study begins to shed light on how diseased cortical neurons utilize exosomes to communicate their disease state. Our findings may reveal novel treatment strategies to prevent disease progression and to improve motor neuron health in ALS and related motor neuron diseases.

Title: Answer ALS: On the road to identifying biological subgroups in sporadic ALS thru a population based mult-iomics

Authors: *J. D. ROTHSTEIN[1], C. N. SVENDSEN[2], L. M. THOMPSON[3], E. FRAENKEL[4], J. VAN EYKE[5], D. SAREEN[6], N. J. MARAGAKIS[7], J. BERRY[8], T. THOMPSON[9], E. BAXI[1]; [1]Neurol., Johns Hopkins Univ., Baltimore, MD; [2]Regenerative Med., Cedars-Sinai Med. Ctr., West Hollywood, CA; [3]Psychiatry/Neurobiology and Behavior, Univ. California, Irvine, CA; [4]MIT, Boston, MA; [5]Ceders Sinai, Los Angles, CA; [6]Cedars Sinai, Porter Ranch, CA; [7]Dept Neurol, Johns Hopkins Univ. Dept. of Neurol. and Neurosurg., Baltimore, MD; [8]Mass Gen., Boston, MA; [9]UC Irvine, Irvine, CA

Abstract: Answer ALS was conceived and organized as a comprehensive multi-omics approach to ALS to ascertain, at a population level, the various clinical-molecular- biochemical subtypes of ALS. This national program has enrolled over 1000 ALS and ALS/FTD patients along with a cohort of >100 matched control patients. Patients were recruited at 8 national ALS centers and followed longitudinally over one year. A smartphone-based system was employed to collect deep clinical data including fine motor activity, speech, breathing and linguistics/cognition. In collaboration with IBM Watson, analytics of speech pattens reveals a strong correlation between clinical progression indices and speech. In parallel, iPS motor neurons were blood-derived from each patient and these cells underwent multi-omic analytics including: whole genome sequencing, RNA transcriptomics, ATAC-Seq, proteomic, and in a subset microbiome. HIPPA compliant cloud data bases were employed to store all data. More than 500 whole genomes have been completed and over 500 iPS cell liens generated. More than 500 iPS cell lines have already been generated from these patients. Integrated clinical and biological signatures are now being

generated using bioinformatics, statistics and computational biology to establish patterns that may lead to a better understanding of the underlying mechanisms of disease. Early multi-omics analysis of a trial subset of 100 sporadic and familial ALS and control iPS motor neuron cell lines were used to determine if biological subgroups could be identified. Early analytics from this multi-omics data set form this large and first cohort of human motor neurons suggest subset of patient will be identified. C9orf72 patients were found have prominent defect in nuclear transport, chromatin remodeling and RNA metabolism as fundamentally altered pathways with candidate pathways modulating drugs identified. Open access has already provided data and the iPS cell lines to dozens of researchers worldwide. Relevant pathways and molecular targets are being verified in post mortem brain tissue. A web portal for open source sharing of all data has been developed for widespread community based data analytics. These studies demonstrate distinct reliably identifiable subgroups among the sporadic and familial patients and the great utility in iPS based approaches to disease pathophysiology and therapy discovery.

Title: Poly(adp-ribosylation) regulates stress granule dynamics, phase separation, and neurotoxicity of disease-related rna-binding proteins

Authors: *Y. DUAN[1,2], A. DU[1], J. GU[1,2], C. LIU[1,2], Y. FANG[1,2];
[1]Interdisciplinary Res. Ctr. on Biol. and Chemistry, SIOC, Chinese Acad. of Sci., Shanghai, China; [2]Univ. of Chinese Acad. of Sci., Beijing, China

Abstract: Mutations in RNA-binding proteins (RBPs) localized in ribonucleoprotein (RNP) granules, such as hnRNP A1 and TDP-43, promote aberrant protein aggregation, which is a pathological hallmark of various neurodegenerative diseases, such as amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). Protein posttranslational modifications

(PTMs) are known to regulate RNP granules. In this study, we investigate the function of poly(ADP-ribosylation) (PARylation), an important PTM involved in DNA damage repair and cell death, in RNP granule-related neurodegeneration. We reveal that PARylation levels are a major regulator of the assembly-disassembly dynamics of RNP granules containing disease-related RBPs, hnRNP A1 and TDP-43. We find that hnRNP A1 can both be PARylated and bind to PARylated proteins or poly(ADP-ribose) (PAR). We further uncover that PARylation of hnRNP A1 at K298 controls its nucleocytoplasmic transport, whereas PAR-binding via the PAR-binding motif (PBM) of hnRNP A1 regulates its association with stress granules. Moreover, we reveal that PAR not only dramatically enhances the liquid-liquid phase separation of hnRNP A1, but also promotes the co-phase separation of hnRNP A1 and TDP-43 *in vitro* and their interaction *in vivo*. And we also found that both genetic and pharmacological inhibition of PARP mitigates hnRNP A1- and TDP-43-mediated neurotoxicity in cell and *Drosophila* models of ALS. Together, our findings suggest a novel and crucial role for PARylation in regulating the dynamics of RNP granules, and that dysregulation in PARylation and PAR levels may contribute to ALS disease pathogenesis by promoting protein aggregation. Finally, we are trying to investigate the mechanism that PARylation regulates the physiological properties of hnRNP A1, and ongoing experiments include mass spectrometry to identify proteins that interact with hnRNP A1 via the PARylation or PAR-binding to regulate its nucleocytoplasmic transport and stress response.

Title: High spatio-temporal resolution locomotor analysis of Sod mutants revealed distinct modes of hyperactivity in the circadian behavior induced by oxidative stress in *Drosophila*

Authors: *A. U. UEDA[1], C.-F. WU[2];
[1]Dept. of Biol., [2]Univ. of Iowa, Iowa City, IA

Abstract: Functional interplay between K+ channels and reactive oxygen species (ROS) signaling have been implicated in the circadian patterns of sleep-wake cycles (Kempf et al.,

2019). Hyper-excitable mutants of several K+ channel genes have been shown to decrease total time of sleep with increased locomotion activity during both day and night (Cirelli et al., 2005; Bushey et al., 2007). The enzyme Superoxide dismutase (Sod) is responsible for clearance of the harmful ROS generated in oxidative respiration processes. We discovered that *Drosophila Sod* mutants also display increased locomotor activity and altered sleep duration, but in a distinct mode of activity patterns.

We monitored fly locomotion behavior using the TriKinetics multibeam counter, which is capable of continuously recording the locomotor activity of a single fly traversing along a narrow glass tube (65 mm length, 5 mm diameter) in multiple (17) zones covering the entire tube length. The activity counts within each zone are continuously recorded at a 1-minute time bin. The results for wild-type (WT) and K+ channel mutant flies were in general consistent with previous reports based on counts of midline crossing for a fly in the tube of the same dimension. WT flies typically remained inactive for most stretches of time and the majority of activity occurred in bouts around dawn and dusk. In contrast, both K+ channel mutants *Shaker* (*Sh*) and *Hyperkinetic* (*Hk*), which are defective in transient K+ current IA, showed elevated total activity counts in the 24-hour period with decreased number of time periods of inactivity and markedly increased nocturnal activity.

Mutant flies of *sod1* alleles produced greatly enhanced local activity of fragmented translocation movements confined in a few adjacent zones. This is in stark contrast to *Sh* and *Hk*, which produced sustained long-distance translocation activity, especially during light-off periods. Strikingly, total activity in WT and *Sh* mutants were accounted for by a few extremely long-duration runs (about 30 to 40%, > 1 hr) which were rarely observed in *Sod1* mutants (< 10%). Using the definition of inactivity > 5 min for sleep, *Sod* flies clearly showed a deficiency in sleep. Even though they seldom traversed the midline, they displayed sustained short bouts of local activity throughout day and night. Future genetic and circuit analysis may reveal the molecular and cellular bases of the distinction between these two modes of hyperactivity caused by K+ channel defects and ROS stress.

Title: Aberrant production of netrin-1 by astrocytes contributes to motor neuron death in the SOD1-G93A mouse model of ALS

Authors: *D. TROTTI, S. S. MARKANDAIAH, K. KRISHNAMURTHY, K. MCAVOY, M. E. CICARDI, P. PASINELLI;
Neurosci., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Mutations in the SOD1 gene cause ~20% of inherited ALS. The underlying molecular mechanisms involve a combination of intrinsic motor neuron and glia-induced toxicity. Although the contribution of astrocytes towards motor neuron death in ALS has been well established, the identity of the mediators of this toxicity is not well understood. We previously showed in the SOD1-G93A mouse model of ALS that caspase-3 cleaves the astroglial glutamate transporter GLT-1, releasing a sumoylated fragment (CTE-SUMO1), which accumulates in the nucleus of astrocytes over disease. Astrocytes harboring CTE-SUMO1 initiate non-cell autonomous motor neuron toxicity. Microarray analysis of these CTE-SUMO1 astrocytes revealed higher expression of netrin-1. While in the normal adult CNS mainly oligodendrocytes express and release netrin-1 to regulate axon homeostasis and synaptic maintenance, spinal cord astrocytes have not been shown to express netrin-1. We provide here the evidence of netrin-1 expression in astrocytes of the symptomatic SOD1-G93A mice. Interestingly, netrin-1 is also elevated in motor neurons of the presymptomatic and disease onset stages of the SOD1-G93A mice. Expression of netrin-1 was also detected in astrocytes in post-mortem spinal cord tissue and iPS cells-derived astrocytes of sporadic ALS patients. Intrathecal injection of netrin-1 in SOD1-G93A mice decreased the number of ChAT+ motor neurons. Neutralization of netrin-1 in human iPSC derived astrocyte-conditioned media using anti-netrin-1 antibodies significantly rescued the motor neuron directed toxicity. Acute stimulation of mature primary motor neurons with netrin-1 (25 nM) elicits a robust Ca^{2+} influx response. Microelectrode analysis of motor neurons treated with 25 nM netrin-1 showed changes in the frequency of firing both in the short term and long term. Aberrant production and release of netrin-1 by astrocytes may, therefore, be one of the pathogenic, non-cell autonomous mechanisms of motor neuron toxicity and be a potential novel molecular target for intervention.

Title: Progressive changes to nodes of ranvier of motor axons in the SOD1^{G93A} mouse model of amyotrophic lateral sclerosis

Authors: M. KADLECOVA[1], K. P. DIMINTIYANOVA[2], D. B. JENSEN[2], *C. F. MEEHAN[2]; [2]Dept. of Neurosci., [1]Univ. of Copenhagen, Copenhagen, Denmark

Abstract: *Background*: Our electrophysiology experiments (see linked abstract: Dimintiyanova et al.) show a decrease in K^+ currents during periods of active degeneration, suggesting either an alteration in the resting membrane hyperpolarization or a change in the K^+ conductance. The later could due to either a change in the number, density or distribution of proteins at and around the node of Ranvier.
Aim: We performed immunohistochemistry for proteins at both proximal and distal nodes of Ranvier to investigate possible changes at disease onset in the same mouse model.
Methods: Immunohistochemistry was performed on the lumbar ventral roots and the mostly motor quadriceps nerve in 10 SOD1^{G93A} (high copy number) mice (5 male, 5 female) and 10 aged/sex matched wild type littermate controls at 18 weeks of age. Behavioural tests using the rotorod and grip strength test identified this as the time point for symptom onset. We identified nodal Na^+ channels using a Pan-NaV channel antibody and Kv1.2 potassium channels at the juxtaparanode (JPX). The paranode was identified using antibodies against the scaffolding protein Caspr-1.
Results: A significant decrease in nodal width was observed in both ventral roots ($P<0.0001$, 36%) and more distally in the quadriceps nerve ($P=0.0005$, 16%), consistent across sexes. This resulted in an overall reduction in the surface are by 27% in the ventral roots and 14% in the quadriceps nerve. JPX width was also significantly reduced both in the ventral roots ($P<0.0001$, 28%) and quadriceps nerve ($P=0.0463$, 9%) indicating that the reduction in nodal width is not due to a focal constriction of the node. The distance between the node and the JPX (measured by Caspr-1 labelling) was significantly increased in the SOD1^{G93A} mice both at the ventral roots ($P<0.0001$, 12%) and the quadriceps nerve ($P<0.0001$, 18%). The changes in the axonal geometry appear to be similar at proximal and distal regions of the axon. However, at the distal axon we more frequently observed signs of disruption of nodal organization, such as mislocalization of paranodal proteins to the node and JPX.
Conclusion: Our data shows changes in nodes of Ranvier structure in SOD1^{G93A} mice both proximally and distally but with distal nodal disruption consistent with a dying back process.

Title: Impaired axonal potassium channel function in the $SOD1^{G93A}$ mouse model of amyotrophic lateral sclerosis

Authors: *K. P. DIMINTIYANOVA[1], D. B. JENSEN[2], C. F. MEEHAN[3], M. MOLDOVAN[1]; [2]Dept. of Neurosci., [1]Univ. of Copenhagen, Copenhagen, Denmark; [3]Univ. of Copenhagen, Kobenhavn N, Denmark

Abstract: *Background:* Nerve excitability testing using threshold tracking has shown abnormalities in ALS patients, including a reduction in K^+ currents in motor axons. However, a previous study on the most commonly used ALS mouse model ($SOD1^{G93A}$, high copy number) up to 19 weeks of age could not confirm these observations, suggesting that the changes observed in patients are not well represented in this model (Boerio et al., Muscle and Nerve 2010). In contrast, we have observed K^+ channel abnormalities preceding axonal degeneration in another ALS model: the $SOD1^{G127X}$ mouse (Moldovan et al., Exp Neurol. 2012; Maglemose et al. Exp Neurol. 2017).
Aim: The aim of this study was to investigate the progression of nerve excitability changes in male $SOD1^{G93A}$ mice up to 22 weeks of age, with an emphasis on K^+ currents.
Methods: We investigated progressive changes in motor nerve conduction and excitability under Ketamine-Xylazine anaesthesia. Aged-matched wild type littermates served as controls. The right tibial nerve was stimulated at the ankle and the evoked compound muscle action potential (CMAP) was recorded from the plantar muscles. Multiple measures of nerve excitability were tested by threshold-tracking using the clinical TRONDNF protocol. The threshold was defined based on the stimulus-response relationship (MScan) as the current required to evoke a 40% CMAP amplitude. For motor unit number estimation (MUNE) we used the recently developed MScanFit MUNE method.
Results: $SOD1^{G93A}$ mice showed a progressive decrease in CMAP amplitude associated with a 6-fold reduction in the number of motor units which was partly compensated for by an increase in the largest motor unit fraction (a marker of collateral reinnervation). The largest CMAP changes occurred from 18 to 22 weeks and were preceded by progressive abnormalities in excitability measures consistent with a reduction in K^+ currents: larger than normal threshold changes during both depolarizing and hyperpolarizing threshold electrotonus and larger than normal deviations

during the subnormal and supernormal period of the recovery cycle. The other excitability measures provided no evidence for a hyperpolarizing change in the resting membrane potential which could have accounted for the reduction in K^+ currents.
Conclusion: Our data suggest that in $SOD1^{G93A}$ mice there was a progressive reduction in the K^+ conductance along the distal motor axon preceding the drop in CMAP occurring in the late disease stages, similar to changes previously reported in human sporadic ALS by the same measures. Thus, it is likely that the K^+ channel impairment underlies periods of active motor axon degeneration in the patients and ALS models alike.

Title: Aberrant synaptic physiology and morphology in *drosophila* larvae of superoxide dismutase 1 (Sod1) mutant alleles

Authors: *X. XING, A. UEDA, T. O'HARROW, C.-F. WU;
Biol., Univ. of Iowa, Iowa City, IA

Abstract: It has been established that mutations in the gene *Sod1*, which encodes the cytoplasmic Cu/Zn superoxide dismutase (Cu/Zn Sod), are associated with familial Amyotrophic Lateral Sclerosis (ALS), a degenerative disease in motor neurons. The Sod1 enzyme is responsible for scavenging cytosolic reactive oxygen species (ROS). *Drosophila* Sod1 share a highly conserved sequence with human Sod1, and the mutant flies show increased sensitivity to ROS generating agents (e.g. paraquat), greatly decreased lifespan, and weakened motor capability. This provides an opportunity to study the function of Sod1 in *Drosophila* motor neurons, in which the larval neuromuscular junction (NMJ) is widely used as a platform for studying genetic mutations and pharmacological manipulations that affect the development and physiology of motor synapses. The flat and transparent anatomy of the larval NMJ preparation facilitates both electrophysiological recording and optical imaging. We combined these two approaches to reveal the consequences of *Sod* mutations, including Sod^{n108}, the well-characterized functionally null, and Sod^{G85R} and Sod^{H71Y}, the orthologs of two mutations found in

human ALS patients. Focal electrophysiological recording showed that these *Sod* alleles had lower transmission failure rates at low external Ca^{2+} levels and altered frequencies of spontaneous miniature excitatory junction potentials (mEJPs) along the synaptic terminals compared with wild-type (WT) larvae. Treatment with K^+ channel blockers such as 4-aminopyridine (4-AP) or quinidine produced more extreme supernumerary firing in *Sod1* mutants. Similarly, supernumerary transmitter release could be observed in double mutants of Sod^{n108} crossed to K^+ channel mutations such as *ether-a-go-go* or *Sh*. suggesting that *Sod* impaired K^+ channels. The morphology of synaptic boutons was visualized with fluorescently-tagged anti-horseradish peroxidase (antiHRP). Interestingly, Sod^{G85R} and Sod^{H71Y} both displayed oversized boutons compared to WT, without obviously altering the number of synaptic boutons. The results illustrate the importance of Sod1 in the development and function of motor neurons, which may reflect aspects of the early symptoms of ALS.

Title: Mechanisms underlying the neuroprotective effect of phosphofructokinase overexpression in ALS

Authors: *S. LOGANATHAN[1], E. MANZO[1], J. BARROWS[1], D. SHREINER[1], D. BARRAMEDA[1], I. LORENZINI[2], A. STARR[2], T. KOVALIK[2], R. BOWSER[2], R. SATTLER[2], D. ZARNESCU[1,3,4];

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a progressive neurodegenerative disorder for which there is no cure. ALS affects upper and lower motor neurons leading to loss of motor coordination, irreversible paralysis, respiratory failure and eventually death within 2-5 years of diagnosis. 90% of ALS cases are sporadic (sALS) with no clear genetic connection. TDP-43 is

involved in pathology of at least 97% of ALS cases. Our lab has developed a *Drosophila* model of ALS based on overexpression of human TDP-43 that recapitulates multiple disease aspects including cytoplasmic aggregates, neuromuscular junction (NMJ) abnormalities, reduced lifespan, and locomotor defects. TDP-43 alters the synaptic vesicle (SV) cycle at the NMJ in flies. Observations in humans and animal models show evidence of metabolic dysregulation and oxidative stress mediated damages in ALS. Our lab has shown that glycolysis upregulation, specifically an increase in Phosphofructokinase-1 (PFK1; PFK in *Drosophila*) provides a compensatory, neuroprotective effect in *Drosophila* models of ALS based on TDP-43 proteinopathy. Recent findings from other groups show that under stress PFK accumulates in *C. elegans* at synapses where it is required for SV cycling. In addition, pyruvate, the end product of glycolysis, which was also found to be increased in multiple ALS models has been shown to have strong Reactive Oxygen Species (ROS) scavenging capacity, protecting mitochondrial membrane potential and regulating cell metabolism. Based on these findings, we hypothesize two mechanisms by which increased PFK could mitigate neuronal dysfunction in ALS. We are currently testing whether overexpression of PFK mitigates motor neuron dysfunction by 1) mitigating SV cycling deficits at the larval NMJ or by 2) antioxidant activity of pyruvate. I will present our results on SV cycling and oxidative stress under the conditions of PFK overexpression in several ALS models. These findings may uncover therapeutic strategies for ALS.

Abstract: Motor neuron diseases are devastating conditions that selectively affect motor neurons (MNs) and innervated muscle fibers. Recent studies have identified various responsible genes and genetic mutations associated with the disease. However, detailed pathological mechanisms still remain elusive because of the intricate interplay between MNs and muscle fibers following MN denervation and compensatory re-innervation. VAChT-Cre is a Cre driver mouse line that expresses Cre recombinase selectively in FR-type (fast-twitch fatigue resistant) and S-type (slow-twitch fatigue resistant) MNs (Misawa et al., *genesis*, 54, 568-572, 2016). The FR-type and S-type MNs are known as slow-type MNs innervating slow (red) muscle fibers (type IIa and type I muscle fibers) responsible for long-lasting and low-intensity contractions. In order to selectively eliminate the slow-type MNs, VAChT-Cre mice were crossbred with NSE-DTA mice in which the cytotoxic diphtheria toxin A (DTA) subunit was expressed after Cre-mediated DNA recombination. The VAChT-Cre;NSE-DTA mice (designated as "delta SlowMN mice") were born normal but progressively manifested various characteristics that included body weight loss, kinetic tremor, muscular atrophy and an increase in innervation ratio. These features were evident from around 20 weeks of age. Although the delta SlowMN mice showed a short life span (average life was about 40 weeks), they survived long enough to analyze middle- and late-phase consequences caused by type-selective MNs loss. Kinetic tremor was remarkable in the head and neck and occurred possibly due to peripheral mechanisms of unknown origin. Muscular atrophy was apparent in red muscles (such as the soleus and diaphragm) which are innervated by slow-type MNs. Alterations in composition of muscle fiber types were also evident in red/white mixed muscles. The increase of innervation rate was detected with EMG, probably reflecting compensatory re-innervation by remaining fast-type MNs. These features were obviously different from those of ALS-associated mutant SOD1 mice in which fast-type MNs are initially affected. The delta SlowMN mice could be a novel tool to study pathophysiological consequences of type-selective motor neuron degeneration and resulting muscle responses.

Title: Traffic related air pollution nanosized particulate matter shows batch differences in biological activity *in vitro* and *in vivo*

Authors: *H. ZHANG[1], A. HAGHANI[1], A. MOUSAVI[2], M. H. SOWLAT[2], M. CACCIOTTOLO[1], C. AGOSTINO[1], C. SIOUTAS[2], T. E. MORGAN[1], C. E. FINCH[1], H. FORMAN[1];
[1]Leonard Davis Sch. of Gerontology, [2]Viterbi Sch. of Engin., USC, Los Angeles, CA

Abstract: Air pollution is associated with numerous health disorders including increased risk of Alzheimer disease (Cacciottolo et al 2017, PMID 28140404). Assessment of air pollution toxicity is complicated by inherent variations in composition of air pollutants among sources, locations, seasons, and weather, which may result in variable experimental responses. The current study documents divergent biological responses of nano-sized particulate matters (nPM) collected at different calendar times at the same site near a Los Angeles freeway. A new assay for genomic inflammatory responses was developed using human THP1 monocytes transgenic for a NF-κB reporter. A panel of nPM batches showed up to 10-fold variation in NF-κB activation. These batch variations showed corresponding differences in in-vivo responses of young adult C57BL/6J mice exposed to nPM for 8 weeks (exposure similar to Woodward et al 2017, PMID 28212893). The nPM batch with 2-fold higher NFκB activity in vitro (11.7±0.23 vs 5.6±0.77) caused a 2-fold increases in hippocampal Iba1 and soluble Aβ42 peptide in cerebral cortex. While the nPM with less NF-κB activity did not alter Iba1 or Aβ42 peptide levels, it still altered mRNA levels in cerebral cortex. To identify factors contributing to batch differences in biological activities, we compared their endotoxin content, lipid peroxidation, cellular toxicity, total organic compounds (TOC), and inorganic components. Pro-inflammatory activity of nPM batches correlated positively with endotoxin, lipid peroxidation, and TOC, but was negatively correlated with some metals. This in-vitro transcription-based assay for air pollution toxicity may increase the reproducibility of studies by identifying batch differences in air pollution particles. Further studies of fractioned nPM may identify synergies among the components of air pollution that impact neurotoxicity (Forman and Finch 2018, PMID 29407794). This study is funded by NIH grants R01 ES023864 (HJF) and P01 AG055367 (CEF).

Title: Sex specific blood and cerebral cortex transcriptomic changes of prenatal exposure of mouse neonates

Authors: *A. HAGHANI[1], J. I. FEINBERG[2], K. LEWIS[3], C. LADD-ACOSTA[2], R. G. JOHNSON[1], C. SIOUTAS[1], C. E. FINCH[1], D. B. CAMPBELL[4], H. E. VOLK[2], T. E. MORGAN[1];
[1]USC, Los Angeles, CA; [2]Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD; [3]Michigan State Univ., East Lansing, MI; [4]Pediatrics and Human Develop., Michigan State Univ., Grand Rapids, MI

Abstract: Prenatal exposure to air pollutants is associated with higher risks of neurodevelopmental deficits and long-lasting cognitive and behavioral outcomes. Sex specific effects are apparent but little is known on the underlying mechanisms. Furthermore, biomarkers for prediction of future risk are needed. We approach these gaps by examining transcriptomic changes (RNAseq) of the blood and cerebral cortex of male and female mouse neonates that were prenatally exposed to traffic-related nano-sized particulate matter (nPM). In both sexes, cerebral cortex responded to nPM with altered expression of 540 genes, which included calcium and glutamate receptor signaling. Sex differences in nPM responses included 1,254 genes. WGCNA analysis revealed 3 modules of genes with directional divergent nPM response between male and females. Functional analysis by IPA showed nPM:Sex interactions for mitochondrial dysfunction, EIF2, mTOR, sirtuin, androgen, and estrogen receptor signaling. Psen1, mTOR, and NFE2L2 were among the top potential upstream regulators of nPM: Sex interactions. The blood transcriptome had much fewer responses to nPM (186 genes): coagulation and prothrombin pathways were among nPM responses that differed by sex. Several of these blood gene responses were highly correlated with cerebral cortex genes. Future validation of gene responses in human cord blood may provide biomarkers for air pollution-mediated neurotoxicity.

Abstract: Gamma-secretase is a critical target for AD drug development because of its key role in amyloid-b42 (Aβ42) generation. We examined cerebral cortex transcriptome responses to BPN-15606, a recently developed GSM (Wagner 2017 PMID 28416568), in young male and female wild type mice (C57BL/6J, male and female). After treatment with 9 weeks of chow fed BPN-15606, RNAseq showed altered expression of 1031 genes, which included 576 (55%) sex-specific gene responses. Analysis of upstream regulators by IPA identified presenilin-1 (Psen1), a component of the γ-secretase complex, as the top upstream regulator in both sexes. Drug treatment altered expression of genes associated with oxidative phosphorylation and other mitochondrial functions, protein ubiquitination, and sirtuin signaling. The top sex-specific responses included immune responses. Sex differing genes were enriched for SAPK/JNK, ILK, PI3K/AKT and B cell receptor signaling. Mitogen protein kinases were among the top upstream regulators of this GSM:Sex interactions. These pathways are highly responsive to many AD risk factors including air pollution. Ongoing experiments examine the combined effects of air pollution and BPN-15606 on neurotoxicity.

Title: Characterizing methamphetamine (METH)-induced lethal toxicity in 5 days post-fertilization (dpf) zebrafish (Danio rerio) larvae

Authors: *Y. CHEN[1], A. WISNER[2], F. WILLIAMS[3], F. S. HALL[3];
[1]Univ. of Toledo, toledo, OH; [2]Pharmacol. / Toxicology, Univ. of Toledo, Toledo, OH;
[3]Pharmacol., Univ. of Toledo Col. of Pharm. and Pharmaceut. Sci., Toledo, OH

Abstract: Background: Methamphetamine (METH) is psychoactive stimulant drug abused worldwide. METH neurotoxicity is well studied, but much less is known about the mechanisms underlying its lethal effects. METH neurotoxicity affects brain tissue monoamine levels, but the glutamatergic system is also involved and may also be involved in the acute lethal toxicity of METH. In response to efforts to circumvent legal restrictions on METH and other amphetamines, illicit use has turned to the β-ketone analogues of amphetamines. Even less is known about the potential lethal and toxic effects or mechanisms for these synthetic cathinones. To develop a high-throughput approach to the study of this diverse class of illicit drugs an approach has been developed using 5-day post-fertilization (dpf) Zebrafish (*Danio Rerio*) larvae. This initial report examines METH in this model. Methods: METH-induced lethal toxicity was examined in 5 dpf zebrafish larvae in a 96-well plate format. METH (500μM ~ 50mM) was administered by direct immersion of zebrafish larvae for 5 hours. The maximal non-lethal concentration (MNLC) and LC50 were determined. In mice, near-lethal doses of METH increase plasma levels of ammonia. We hypothesized that this may be an essential feature of METH-induced lethality. Ammonia excretion and internal ammonia concentrations were also measured. To examine the glutamatergic role in in METH-induced lethality, we co-administered drugs including MK-801 and GYKI 52466, as well as diazepam, SCH 23390, and raclopride with 50mM METH. Results: Exposure to non-lethal concentrations of METH caused a biphasic effect on heart rate (increase at low concentration, decrease at high concentration) and this effect was time-dependent. Exposure to the MNLC of METH increased ammonia excretion and exposure to the LC50 caused a decrease of internal ammonia, providing further evidence for a role of ammonia in METH-induced lethal toxicity. Furthermore, morphological changes were observed. METH caused sustained muscle contractions (distinct deflection of tail) in zebrafish larvae, suggesting that seizure may occur during the METH exposure (as observed in mice), further suggesting a role of glutamate in METH-induced lethality. In addition, co-administration of GYKI 52466 or raclopride significantly attenuated the METH-induced lethality in zebrafish larvae, suggesting not only glutamatergic systems but also dopaminergic systems are involved in this toxicity. Conclusions: METH caused lethal toxicity in 5 dpf zebrafish larvae and ammonia and glutamatergic systems are involved in this lethality. Continuing work will examine cathinones to determine if similar mechanisms are involved.

Title: Development and validation of a reproducible mouse model of intensive care unit delirium

Authors: M. ILLENDULA[1], B. FERRARESE[2], Z. ZUO[1], *N. LUNARDI[1];
[1]Anesthesiol., Univ. of Virginia, Charlottesville, VA; [2]Anesthesiol., Univ. of Padova, Padova, Italy

Abstract: Background: Intensive Care Unit (ICU) delirium is a form of acute brain failure characterized by fluctuating inattention, memory impairment and disorganized thinking. It affects up to 70% of elderly surgical ICU patients and is associated with increased length of hospital stay, morbidity and mortality, and steep healthcare costs. To date no treatment drugs are available, largely due to the lack of adequate animal models to study the underlying mechanisms. Thus, we set out to develop and validate a clinically relevant mouse model of delirium that faithfully recapitulates the peri-operative state by combining anesthesia, surgery, ICU sedation and sleep disruption, all of which are theorized to contribute to delirium pathogenesis. We hypothesized that Anesthesia/Surgery/ICU (A/S/I) would induce changes in mice behavior consistent with the clinical features of ICU delirium.
Methods: Eighteen month old, male mice (A/S/I: N=6, Control: N=6) were tested in the open field and Y maze 24 h before A/S/I. The following day, they were randomly allocated to A/S/I or control condition. A/S/I mice received 3 h sevoflurane anesthesia and laparotomy, then sedation with intraperitoneal propofol for additional 2 h. After recovering, they were subjected to 12 h of intermittent ICU sounds, bright light and cage rattling. Control mice were kept in a separate cage and did not receive A/S/I. Mice were tested in the open field and Y-maze at the end of ICU (0 h) and at 6, 12, 18 and 24 h. Differences between treatment groups were analyzed using the Mann-Whitney test. Data are expressed as percentage of baseline behavior and mean ± SEM.
Results: A/S/I decreased the number of entries in the Y maze novel arm at 0 h: 50.7% versus 124.3%, P=0.026, 6 h: 18.2% versus 85.0%, P=0.005 and 18 h: 20.33% versus 63.66%, P=0.015) compared to control. A/S/I did not significantly alter the number of entries in the novel arm at 12 h: 34.0% versus 51.17%, P=0.536 and 24 h: 15.66% versus 63.33, P=0.063. A/S/I did not affect the total distance traveled by mice in the open field test.
Conclusions: Laparotomy under sevoflurane anesthesia, followed by sedation with propofol and sleep disruption, impairs spatial memory in aged mice, a behavior that depends on the integrity of attention, memory and organized thinking. Such impairment is acute in onset, fluctuating, and independent of motor performance, and therefore consistent with the clinical hallmarks of ICU delirium.

Title: Neuroactive steroid CDNC24 is an effective gabaergic potentiator and a hypnotic that is not neurotoxic to the developing rat brain

Authors: *V. TESIC[1], S. M. JOKSIMOVIC[2], N. QUILLINAN[3], K. KRISHNAN[4], D. F. COVEY[5], S. M. TODOROVIC[6], V. JEVTOVIC-TODOROVIC[7];

Med., Saint Louis, MO; [6]Anesthesiol., Univ. of Colorado Anschutz Med. Campus, Aurora, CO; [7]Anesthesiol., Univ. of Virginia Dept. of Anesthesiol., Charlottesville, CO

Abstract: Most currently used general anesthetics (GA) are potent positive modulators of postsynaptic γ-aminobutyric acid A $(GABA)_A$ receptors and are invariably neurotoxic during early stages of brain development. Since causality between $GABA_A$ potentiation and GA-induced developmental neurotoxicity has not been established, the question remains whether GABAergic activity is crucial for promoting/enhancing neurotoxicity. We have recently shown that a neuroactive steroid and T-type calcium channel blocker which lacks GABAergic activity, 3β-OH [(3β,5β,17β)-3-hydroxyandrostane-17-carbonitrile], is an effective hypnotic with favorable safety profile when examined during critical stages of brain development. Using a structurally similar de novo synthesized neurosteroid analog that potentiates currents in recombinant $GABA_A$ receptor, CDNC24 [(3α,5α)-3-hydroxy-13,24-cyclo-18,21-dinorchol-22-en-24-ol], we aimed to determine if $GABA_A$ potentiation is the driving force in inducing neurotoxicity during development. Thus, we examined the neurotoxic potential of CDNC24 vis-a-vis clinically-used GABAergic intravenous anesthetic propofol at the peak of rat synaptogenesis. In addition to the morphological neurotoxicity studies of the subiculum and medial prefrontal cortex (mPFC), we assessed the synaptic physiology with the studies of pre- and postsynaptic effects of CDNC24 and propofol on inhibitory transmission in the developing subiculum. We investigated the hypnotic properties of CDNC24 in comparison with propofol by testing the loss of righting reflex (LORR) in post-natal day 7 Sprague-Dawley rats. We found that both CDNC24 and propofol caused dose-dependent hypnosis, with the resulting therapeutic index being surprisingly higher for CDNC24 when compared to propofol (>89.55 for CDNC24

and 23.1 for propofol). We have also shown that CDNC24, despite its GABAergic properties, does not cause developmental neurotoxicity when most vulnerable brain regions, the subiculum and mPFC, were examined. On the other hand, propofol induces significant developmental neurotoxicity compared to both its vehicle and the CDNC24. As expected, our studies of synaptic physiology showed that propofol exhibited mainly postsynaptic effects on sIPSCs (spontaneous post-synaptic currents) as evidenced by increasing sIPSC decay times. In contrast, CDNC24 had strong pre-synaptic effect in addition to a post-synaptic effect in an inhibitory synapse of the subiculum of rat pup, as evidenced by decreased frequency of sIPSCs. We propose that the lack of neurotoxicity of CDNC24 may be related to the suppression of GABA release in the subiculum during brain development.

Title: Properties of excitatory synaptic currents in CA3 neurons following neonatal ketamine exposure

Authors: *O. H. CABRERA, N. QUILLINAN, S. M. TODOROVIC, V. JEVTOVIC-TODOROVIC;
Anesthesiol., Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Objective
Developing neurons in the brains of infant rodents and non-human primates are susceptible to neuroapoptotic death by anesthetic drugs commonly used in human neonatal medicine. The apoptotic reaction is acute and widespread, which is thought to underlie chronic cognitive impairments observed in adult animals treated with anesthetics as neonates. Curiously, ketamine is not neurotoxic to developing hippocampus, yet causes severe hippocampus-dependent memory impairments in adulthood. Thus, acute neuroapoptosis may be sufficient, but not necessary, for long-term cognitive dysfunction, raising the possibility that anesthetics dysregulate cognitive function through non-neurotoxic mechanisms. Area CA3 of hippocampus

is resistant to several neonatal injuries, including anesthesia-induced neuroapoptosis, and a model region to study the intrinsic and synaptic properties of neurons surviving neonatal anesthesia-induced neuroapoptosis. To begin to dissect anesthesia effects on glutamate neurotransmission, we challenged neonatal mice with ketamine and recorded miniature excitatory postsynaptic currents (mEPSCs) seven days later.

Methods

Postnatal day (PND) 7 CD1 mouse pups of both sexes were randomly assigned to either 75 mg/kg ketamine or saline. 300 μm acute hippocampal slices were harvested following brief isoflurane anesthesia and transcardial perfusion with ice-cold artificial cerebrospinal fluid (ACSF) on PND14. Slices were incubated in ACSF at 37C for 30 minutes then maintained at room temperature. CA3 mEPSCs were recorded in ACSF plus TTX and picrotoxin to block sodium and GABA currents, respectively, and using K-gluconate internal pipette solution. Neurons were voltage clamped at -70 mV, and frequency, amplitude, and decay of mEPSCs in CA3 neurons were quantified.

Results

CA3 neurons (n = 3) from PND14 mice treated with ketamine on PND7 had higher mean frequency of mEPSCs than neurons (n = 3) from saline-treated control mice. Thus, ketamine may alter presynaptic glutamate release or the number of excitatory synapses on CA3 neurons. Furthermore, we observed changes in postsynaptic parameters (mean amplitude and decay) suggestive of ketamine effects on recruitment of CA3 glutamate receptors or altered glutamate receptor subunit composition.

Conclusions

We report that brief ketamine exposure during infancy dysregulates pre- and postsynaptic parameters of glutamate neurotransmission in CA3 hippocampal neurons. Thus, anesthetics may compromise learning and memory in the absence of overt neuroapoptosis by interfering with the intrinsic and synaptic properties of neurons that subserve cognitive function.

Title: Isoflurane reduces brain-derived neurotrophic factor release with loss of dendritic spines

Authors: *J. PLATHOLI[1], K. W. JOHNSON[1], R. WILLIAMS[1], F. S. LEE[3], H. C. HEMMINGS, Jr.[2];

[1]Anesthesiol., [2]Dept Anesthesiol & Pharm, Weill Cornell Med., New York, NY; [3]Psychiatry, Weill Cornell Med. Col., New York, NY

Abstract: General anesthetics (GAs) modulate synaptic transmission by acting on multiple pre- and post-synaptic targets including neurotransmitter release, neurotransmitter receptors, and dendritic spine dynamics. Understanding how GAs destabilize dendritic spines is critical to identifying their reversible and durable effects on learning and memory. We hypothesized that isoflurane, a common GA, reduces release of brain-derived neurotrophic factor (BDNF), resulting in reduced dendritic spine size and number. We tested this in dissociated hippocampal neurons from wild-type and loss-of-function BDNF Val66Met knock-in mice that have reduced BDNF secretion. Isoflurane-induced changes in BDNF release dynamics were measured using the genetically encoded biosensor BDNF-pHluorin. Neurons with varying levels of BDNF secretion were used to determine the effect of reduced ambient BDNF levels on dendritic spine morphology and synaptic protein expression using time-lapse imaging and immunohistochemistry, respectively. Isoflurane attenuated BDNF release in a dose-dependent and reversible manner. This identifies a new molecular signaling pathway that might contribute to persistent changes in dendritic spine number and morphology following isoflurane exposure.

Title: Evaluating human nerve conduction velocity *in vitro* as a novel metric for assessing chemotherapeutics-induced peripheral neuropathy

Authors: *A. D. SHARMA[1], L. MCCOY[1], E. JACOBS[1], M. TERRAL[1], L. CURLEY[1], M. J. MOORE[1,2];
[1]Axosim, Inc., New Orleans, LA; [2]Biomed. Engin., Tulane Univ., New Orleans, LA

Abstract: Preclinical models for assessment of toxicity and efficacy has consistently failed to deliver given that a high number (~90%) of clinical trials fail. Animal models do not translate to human success primarily because of the inherent difference in the biology of the different species, and a bridge which translates to human biology is highly desired. A great advancement

in this space has come in the form of physiologically relevant 3D biomimetic tissues using induced pluripotent stem cells (iPSCs)-derived neuronal cells which have greatly enhanced the predictive potential of preclinical assays. However, engineering 3D tissues relevant to the nervous system, especially peripheral nerves (PNs), is challenging because of the unique architecture and the necessity of bioelectrical conduction. Peripheral nerves are prone to injury because of their unprotected long axonal outgrowths throughout the body and a high surface area exposed to possible toxicants. In this study, we have engineered a human 3D nerve *in vitro* that supports axon growth analogous to PN anatomy and provides gold standard clinically relevant metrics such as nerve conduction velocity (NCV) and histological ultrastructure. Previously, these have only been obtainable using animal models. Taking advantage of commonly used 3D spheroid fabrication methods such as ultra-low attachment plates or hanging drops, we generated motor neuron-Schwann cells (coculture) spheroids or motor neuron only spheroids (monoculture) as controls. Both monoculture and coculture spheroids showed robust and dense axonal outgrowth of ~5mm which enabled the measurement of NCV, previously unrealized in an *in vitro* system. The population-level electrophysiological activity was seen in both culture types, with neuron-only spheroids producing a faster peak NCV of 0.18±0.04 m/s while co-culture spheroids had a peak NCV of 0.13±0.02 m/s. Schwann Cell migration, ensheathing, and myelination occurred in the co-culture spheroids as confirmed by S-100 immunostaining, and lamination seen in TEM micrographs. Initial experiments have used vincristine as a model chemotherapeutic drug, and we have successfully generated a dose-response curve (IC50 = ~5nM) demonstrating that chemotherapeutics drugs cause neuropathy in this *in vitro* model of human nerve. In summary, we have successfully engineered a 3D biomimetic model of human peripheral nerve *in vitro* which can provide clinically relevant metrics such as NCV and thus, can be used for modeling peripheral neuropathies and assessing chemotherapy-induced peripheral neurotoxicity.

Title: Activation of KCNQ channels prevents paclitaxel-induced peripheral neuropathy and associated neuropathic pain

Authors: J. LI, D. DANG, ***Q. Y. YANG**;
NCBA, UTMB At Galveston, Galveston, TX

Abstract: Paclitaxel-induced peripheral neuropathy (PIPN) and associated neuropathic pain are the most common and serious adverse effects experienced by cancer patients receiving paclitaxel treatment. These effects adversely impact daily activities and consequently the quality of life, sometimes forcing the suspension of treatment and negatively influencing survival. Patients are usually at high risk of developing PIPN if paclitaxel induces acute pain, which strongly suggests that an acute increase in the excitability of nociceptors underlies the chronic alterations of PIPN. KCNQ/Kv7 channels are widely expressed in the primary sensory neurons to modulate their excitability. In the present study, we show that targeting KCNQ/Kv7 channels at an early stage is an effective strategy to attenuate the development of PIPN. We found that paclitaxel did not decrease the expression level of KCNQ/Kv7 channels in the primary sensory neurons as detected by qRT-PCR and Western blotting. However, retigabine, which is a specific KCNQ/Kv7 channel opener, significantly attenuated the development of PIPN, as shown by both morphologic and behavioral evidence. We also observed that retigabine had no obvious effect on the chemosensitivity of breast cancer cells to paclitaxel. While retigabine has been approved by the FDA as an anticonvulsant, our study suggests that this drug can be repurposed to attenuate the development of PIPN.

Abstract: Cyclohexane (CHX) is an organic solvent commonly used as a drug-of-abuse. This drug increases the oxidative stress and glial reactivity in the hippocampus, which suggests that this brain region is vulnerable to CHX effects. This study aimed to establish the pathological alterations that occur in the Cornu Ammonis 3 (CA3) and Dentate Gyrus (DG) after a long-lasting exposure to CHX. We exposed CD1 mice to a recreational-like dose of CHX (~ 30,000 ppm) for 30 days and explored its consequences on the expression of c-Fos, NMDA receptor 1 (NMDAR1), neuropeptide Y (NPY), and apoptosis in the CA3 and DG subfields of the adult hippocampus. We analyzed the effects of CHX twenty-four hours after the last administration of CHX, we found a significant decrease in the number of c-Fos+ cells in the hippocampal CA3 and DG regions. This event coincided with an increased in NMDAR1 expression and apoptotic cells in the CA3 region. At day 13th without CHX, we found a persistent reduction in the number of c-Fos+ and TUNEL+ cells in DG. At both time points, the CHX-exposed mice showed a strong overexpression of NPY in the CA3 stratum lucidum and the hippocampal hilus. Altogether, this evidence reveals that CHX exposure provokes long lasting changes in the hippocampal subfield. These findings can help understand the deleterious effect of CHX into the adult hippocampus.

Abstract: Worldwide, every year there is an increase in the number of people exposed to inorganic arsenic (iAs) via drinking water. Human populations present impaired cognitive function as a result of prenatal and childhood iAs exposure, while studies in animal models in similar conditions demonstrate neurobehavioral deficits accompanied by protein and enzyme alterations associated to Alzheimer´s disease (AD). In primary cultures of Tg2576 mouse brain, exposure to iAs promotes the release of Aβ and increases the activity of β-secretase, but morphological consequences of such biochemical changes are unknown. In order to determine whether iAs promotes plastic changes in spines of cortical neurons that could be related to the pathophysiological progression of AD, we used the 3xTgAD mouse model since it mimics the development of amyloid plaques, neurofibrillary tangles and behavioral dysfunction. Male 3xTgAD mice were divided into 2 groups: 1) control without arsenic; and 2) exposed to 3 ppm sodium arsenite (iAs-3xTgAD) in drinking water. Animals received the treatment from gestation until 2 or 4 months of postnatal age. We measured levels of Synaptophysin and PSD95, and we also quantified and characterized the number and morphology of dendritic spines in third-layer pyramidal neurons from the prefrontal cortex. PSD95 decreased and Synaptophysin increased in iAs-3xTgAD mice. iAs-3xTgAD also showed a decrease of spine density and of thin spines at 4 months, which was preceded by a transitory increase in the number of thin, stubby and wide spines at 2 months. These results strongly suggest compensatory plastic responses by cortical neurons to iAs exposure, which could be closely linked to neurodegeneration.

Title: Kynurenine pathway metabolites involved in lead toxicity

Authors: *D. RAMIREZ ORTEGA[1], P. OVALLE RODRIGUEZ[1], G. R. ROLDAN[3], D. F. GONZALEZ ESQUIVEL[1], L. A. RAMOS[1], B. PINEDA OLVERA[2], V. PEREZ DE LA CRUZ[1]; [1]Lab. de Neurobioquimica y Conducta, [2]Lab. de Neuroinmunologia, Inst. Nacional De Neurologia y Neurocirugia "Manuel Velasco Suarez", Mexico City, Mexico; [3]Lab. de Neurobiologia de la Conducta, Univ. Nacional Autonoma de Mexico, Ciudad de Mexico, Mexico

Abstract: Lead (Pb) is a neurotoxin. The immature brain is singularly sensitive to Pb neurotoxicity, compromising the cognitive and behavioral attributes which persist even later in adulthood. Several mechanisms have been implicated in the Pb cognitive impairment, including synapse function, redox homeostasis, calcium signaling, neurotransmitter synthesis and release, between others. In this context, kynurenine pathway (KP) could be altered since it is modulated by the redox environment. The KP metabolites have neuromodulatory and redox properties. Specifically, kynurenic acid (KYNA) is considered as a neuromodulator that have an important role in cognitive processes due it is an endogenous antagonist of NMDA and α7-nicotinic acetylcholine receptors. Another metabolite related with neurodegenerative process is 3-hydroxykynurenine (3-HK), which is a redox metabolite that at high concentration induces cell death. The aim of this work was to evaluate if the cognitive impairment induced by Pb intoxication was related with alterations in KP metabolites. Mice pups were exposed to Pb via their dams' drinking water (lead acetate 500ppm) from PND1 to PND23. Control group received normal water. Then, from PND 21 both groups were given normal drinking water until 2 months of age. At PND 60 mice from both groups were subject to the locomotor activity test in open field and the long-term memory test through buried food probe. Different brain regions were obtained to quantify redox environment (reactive oxidative species (ROS), lipoperoxidation (LP) and cell viability), KYNA and 3-HK levels as well as kynurenine aminotransferase (KAT) and kynurenine monooxygenase (KMO) activities. Pb group showed a significant increase in the time looking for food, compared to controls ($p<0.05$) and showed a trend to hypoactivity. No changes were observed in ROS, and PL increased in hippocampus and cerebellum compared to

controls. Cellular dysfunction was observed in all evaluated regions from Pb group vs. control. Both KYNA and 3-HK levels were increased (~2 to 4 times vs control) in all brain regions of Pb group. No change was observed in KAT activity. These results suggest that the increase in 3HK and KYNA levels could be another mechanism by which Pb induces cognitive impairment in adult mice.

Abstract: Purpose: To determine the metabolomic impact of dietary omega-3 polyunsaturated fatty acid (PUFA) supplementation on neurorestorative pathways associated with anti-nociception in participants with type 2 diabetes. Methods: Forty volunteers with type 2 diabetes, with and without neuropathic pain symptoms, enrolled in the "En Balance-Plus" program. The program provided weekly nutrition-diabetes education and daily supplementation with 1,000 mg of docosahexaenoic acid and 200 mg of eicosapentaenoic acid over three months. The study assessed plasma samples from all participants at baseline and three months post-supplementation. Untargeted semiquantitative metabolomic analysis of plasma samples was measured by Metabolon. A bioinformatics approach was performed to elucidate if important neurorestorative metabolomic features and pathways were associated with supplementation. Results: A total of 659 compounds of known identity were classified using an untargeted metabolomics approach. Matched pairs t-test was used, $p<0.05$, to identify biochemicals that differed significantly between experimental groups (baseline and three months). An estimate of

the false discovery rate (q-value) was calculated to take into account the multiple comparisons in this study (a low q-value, q<0.10, is an indication of high confidence in the result). One hundred twenty-four compounds significantly changed from baseline; specifically, 74 increased while 49 biochemicals decreased in relative abundance. Random Forest classification of plasma samples collected at baseline and three months was 91 % accurate in classifying samples. Further, taking several bioinformatic approaches, key features contributing to group separation were enriched with compounds of glycolipids, glucose, cysteine, methionine, and glutathione metabolism. Conclusion: Global metabolic profiling was conducted to observe how dietary omega-3 PUFAs affected the metabolic phenotype of participants with type 2 diabetes (with and without neuropathic pain). High-level analysis of the data by Random Forest and p-value sorting pointed to changes in omega-3 PUFA metabolism, glycerolipid metabolism, cysteine, methionine, and glutathione metabolism, and fatty acid homeostasis.

Title: Effect of astrocytic insulin-like growth factor receptor deficiency on rodent behavior

Authors: *D. PRABHU, S. KHAN, K. BLACKBURN, E. HODGES, J. MARSHALL, N. M. ASHPOLE;
Univ. of Mississippi, Oxford, MS

Abstract: The levels of Insulin-like Growth factor (IGF)-1 are altered in several neurological disorders, including stroke, epilepsy, traumatic brain injury, and neurodegenerative diseases. IGF-1 protects neurons and supports cognitive function. Neuron-specific IGFR KO animals show an impairment in spatial learning and memory. Supplementing rodents with IGF-1 is also shown to reverse some of the cognitive deficit associated with aging and neurodegeneration. A majority of studies have focused on the effects of IGF-1 regulating neurons, and not on astrocytes, despite the fact that it is the astrocytes that are the predominant cell type in the brain and highly express IGFR. This project aims to investigate the involvement of IGF-R on the ability of astrocytes to regulate behavior.To investigate whether astrocytic IGFR is directly involved in influencing rodent behavior, we generated a mouse model of astrocytic IGFR

deficiency by crossing homozygous igfrf/f mice with iGFAP-Cre mice. To knock down IGFR after development, we induced Cre recombinase expression using tamoxifen. We then assessed the role of astrocytic IGFR in regulating behavior using a battery of behavioral assays which included Radial Arm Water Maze and Barnes Maze to examine spatial learning and memory, Elevated Plus Maze and tail suspension to examine anxiety and depression-like behavior respectively, open field and grip strength to assess overall locomotion and muscular strength respectively, and visual assessments. Our results indicate that astrocyte-specific IGFR knockout animals exhibit normal muscular strength, and locomotion, no anxiety or depression-like phenotypes. However, they do exhibit an impairment in learning and memory. Male KO animals show an increase in velocity and a decrease in path length during the acquisition phase of the Radial Arm Water Maze, compared to controls. In the Barnes Maze, female KO mice exhibit a higher path length and latency than the controls. To investigate the mechanism, we plan to explore the pathways responsible for glutamate handling and neurotransmitter cycling, as these are critical functions of astrocytes. Overall, this project will help uncover the role of IGFR in regulating the functions of astrocytes, and associated behavior.

Abstract: Amyotrophic lateral sclerosis (ALS) is caused by the progressive degeneration of motor neurons (MNs) in the central nervous system (CNS), leading to paralysis and eventual death. The identification of familial ALS (fALS) gene mutations has led to the generation of transgenic mouse models which strikingly recreate the physiological and cellular phenotypes of human disease progression. Previous studies have co-cultured fALS mouse astrocytes with

human stem cell (SC)-derived MNs to create an *in vitro* model of MN toxicity, demonstrating that 1) toxicity of neurons is largely caused by soluble factors received and secreted by astrocytes, and that 2) astrocytic neurotoxicity is specific to motor neuron subtypes while other neuron subtypes are spared. In many studies, cytokines have been used to treat wildtype (WT) astrocytes and generate reactive astrocytes for modeling trauma and pathogenic disease states. Inflammatory modeling studies using bacterial endotoxins to stimulate immune cells in the brain have found that certain cytokines together are sufficient to cause astrocytes to become potently neurotoxic. However, this reactive astrocyte state is toxic to many subtypes of neurons. This broad neurotoxicity stands in contrast with the subtype-selective neurotoxicity observed in many neurodegenerative diseases, including ALS. Because reactive astrocytes have been identified at sites of MN degeneration in ALS, we therefore hypothesize that MN-specific neurotoxicity can be used as a functional readout for identifying the inflammatory factors which may induce MN degeneration from healthy astrocytes.

Title: Nucleocytoplasmic transport factors suppress TDP-43 aggregation and toxicity in ALS/FTD disease models

Authors: *B. KHALIL[1], G. FORTIN-NOUEL[1], C. SMITH[1], T. COMYN[1], C.-C. CHOU[2], W. ROSSOLL[1];
[1]Mayo Clin., Jacksonville, FL; [2]Stanford Univ., Stanford, CA

Abstract: TDP-43 is a predominantly nuclear RNA-binding protein that undergoes abnormal cytoplasmic mislocalization, cleavage and aggregation in TDP-43 proteinopathies. In ALS, TDP-43 pathology is present in >97% of patients. Previously, we had used the proximity-dependent biotin identification (BioID) method to study the composition of pathological TDP-43 aggregates. This new approach has led to our discovery that C-terminal fragments of TDP-43 (TDP-CTF) abnormally associate with nucleoporins and transport proteins, which regulate the selective nucleocytoplasmic transport of macromolecules across the nuclear membrane (Chou et al., *Nat Neurosci* 2018). In this study, we also found that the importin karyopherin-β1 (KPNB1)

was able to reduce the formation of insoluble TDP-CTF inclusions. Here we present evidence that KPNB1 expression rescues TDP-CTF-induced cell death in neuronal cell culture. Dis-aggregation through KPNB1 predominantly occurs via its N-terminus, and flexibility of its α-helical HEAT repeats is needed for its function. Interaction with nucleoporins and nucleocytoplasmic transport regulator RAN is also required for KPNB1 to dissolve TDP-CTF aggregates. Interestingly, other importins and several peripheral nucleoporins also exhibit a potent effect on TDP-CTF inclusion formation, whereas exportins and scaffold nucleoporins mostly co-aggregate with TDP-CTF. Our data suggest that KPNB1-induced dis-assembly and/or prevention of TDP-43 aggregation is neuroprotective, suggesting new targets for future therapy development.

Abstract: Introduction: Methamphetamine (MA) is one of the most commonly health issue in women of childbearing age. Neurotoxicity of MA results from excitotoxicity and oxidative stress generated from the redundant dopamine auto-oxidation. MA abuse during pregnancy produces the deleterious consequences in prenatal MA-exposed children including cognitive impairment. Hippocampus is the most critical brain area accounting for learning and memory processes. Hippocampal formation can be influenced by substance used during prenatal developmental processes including neuron differentiation, neurogenesis and synaptogenesis. Therefore, adverse effect of MA on hippocampus might be responsible for learning and memory impairment. **Objective**: This study aimed to determine the effect of prenatal MA exposure on neuronal morphology and synaptogenesis and its mechanisms including brain-derived neurotrophic factor

*(*BDNF)-Tropomyosin receptor kinase B (Trk-B) pathway.**Methods**: Pregnant mice (C57BL/6JNc, n = 4/group) were treated once daily with either MA (5 mg/kg, s.c.) or 0.9% saline solution on gestation day 8-15. Primary hippocampal culture was prepared from fetus at gestation day 16.5. The morphology of axon and dendrite branching was determined at 5 days *in vitro* (DIV5) by immunocytochemistry staining. Pre-synapse and post-synapse were stained using synapsin I and postsynaptic density protein 95 (PSD95) marker, respectively. The number of pre-synapse and the co-localization of pre- and post-synapse were quantified from DIV14 cells. Moreover, BDNF, Trk-B and *cAMP response element binding* (CREB) protein expressions were determined using western blot analysis. **Results**: The axon length and diameter were significantly decreased in MA-treated group *(*p<0.0001). However, MA exposure had no effect on the number of dendrite branching. The number of presynaptic sites and co-localization between pre- and post-synapse in MA group were also decreased significantly compared to control (p<0.0001). In addition, prenatal MA exposure reduced Trk-B expression (p<0.005), while BDNF level and CREB transcription factor were unaltered. **Conclusion**: Prenatal MA exposure impacts axon morphology and synapse formation in primary hippocampal cell. This malformation is related to Trk-B receptor down-regulation, which involved neuronal development and synaptic plasticity. These alterations might explain the learning and memory impairment in prenatal MA-exposed children. Further study will be focused on the molecular pathway of Trk-B receptor including PI3K-Akt and PLC-CaMK pathway which involved with axonal growth and Trk-B synthesis.

Title: Alteration of dopamine homeostasis by organochlorine environmental agents

Authors: *B. S. CAGLE, R. A. CRAWFORD, H. LEHMLER, J. A. DOORN;
Univ. of Iowa, Iowa City, IA

Abstract: Imbalances in dopamine (DA) homeostasis yields toxic intermediates via altered metabolism and trafficking. This imbalance may contribute to neurotoxicity, neurodevelopmental problems and neurodegenerative disease. Environmental organochlorine

pollutants, such as polychlorinated biphenyls (PCBs) and the pesticide dieldrin are proposed risk factors for these neurological conditions. Recent evidence suggests these agents disrupt dopamine homeostasis in dopaminergic cells. While these organochlorine compounds have been phased out of use, they persist in the environment and bioaccumulate in humans. Altering dopamine homeostasis can yield elevated levels of the monoamine oxidase metabolite of dopamine, 3,4-dihydroxyphenylacetaldehyde (DOPAL), which is toxic and highly reactive towards proteins. Our goal here is determine if PCB-52 or its major human metabolite, 4-OH PCB-52, and dieldrin alter levels of dopamine and/or its metabolites including DOPAL, investigate oxidative stress induced by these agents, and finally to identify proteins modified by the reactive dopamine metabolite, DOPAL. Protective mechanisms against DOPAL include carnosine, a dipeptide aldehyde scavenger. Results show that 4-OH PCB 52 is toxic to dopaminergic PC12 and N27 cells at concentrations less than that of PCB-52 (less than 25µM) at 24hrs. Both PCB-52 and 4-OH PCB-52 were found to increase mitochondrial and whole cell reactive oxygen species in dopaminergic N27 cells.

Title: Mouse mutant SOD1 glia cause hyperexcitability of induced cortical projection neurons

Authors: *J. A. GOMEZ[1], Z. S. JORDAN[2], A. M. MAROOF[3];
[1]Biol., [3]Dept. of Biol., [2]Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disorder characterized by progressive loss of both cortical “upper” motor neurons and spinal “lower” motor neurons. The vast majority of ALS research has focused on the degeneration of spinal motor neurons (sMNs). However, cortical projection neurons (CPNs) are also known to undergo selective degeneration, progressing before, or after the sMNs exhibit signs of apoptosis. Using induced pluripotent stem cells (iPSCs) we isolate CPNs expressing GFP regulated by the FEZF2 locus. We next paired CPNs expressing GFP with either mouse wild-type glia or mouse hSOD1 glia. Our results show CPNs co-cultured with hSOD1 glia have a lower survival rate after 10 days. Using multi electrode arrays (MEA), we also show that CPNs co-cultured with hSOD1 glia have a higher firing frequency when compared to CPNs co-cultured with wild-type glia.

Together this suggest that CPNs are also vulnerable to the neurodegenerative progression of ALS.

Title: An adenosine augmentation compound (J4) attenuates abnormal tau phosphorylation in a cell model of tauopathy

Authors: *P.-Y. CHUANG[1], C.-P. CHANG[1], Y.-F. LIAO[2], Y. CHERN[1];

Abstract: Alzheimer's disease (AD) is one of the most common progressive neurodegeneration diseases characterized by accumulation of amyloid plaques and tau aggregates, which leads to cerebral dystrophy and cognitive impairment. Adenosine is an important neuromodulator that regulates bioenergetic network in the brain, and the dysfunction of its homeostasis is often discovered in several neurological diseases such as AD and Huntington' s disease (HD). Results from this laboratory demonstrated that an inhibitor of a nucleoside transporter (ENT1), designated J4, is able to ameliorate several detrimental effects in an AD-like mouse model of tauopathy (THY-Tau22). Chronic-treatment with J4 normalized spatial memory deficiency, synaptic plasticity impairment, hyperphosphorylated Tau and abnormal kinase activities in the hippocampus of THY-Tau22 mice. However, the mechanism underlying the beneficial effect of J4 on tauopathy remain elusive. In the present study, our data showed that a SH-SY5Y neuroblastoma cell line (SH-SY5Y-Tau-P301L), which expresses human Tau (hTau) that carries a P301L mutation and fuses to a reporter (GFP), is an excellent cell model to study tauopathy. We first demonstrated that SH-SY5Y-Tau-P301L cells expressed ENT1 and adenosine receptor 2A ($A_{2A}R$), two components of adenosine homeostasis. Consistent with what we have observed in the hippocampus of THY-Tau22 mice, expression of mutant hTau-GFP protein did not change the transcript levels of these two proteins. The induction of hTau-GFP protein in SH-SY5Y enhanced the levels of hyperphosphorylation and conformational change of hTau, which can be normalized by J4. These results demonstrated that SH-SY5Y-Tau-P301L is a suitable model to study the regulation of Tau hyperphosphorylation. The underlying mechanism for the J4-mediated adenosine augmentation in SH-SY5Y cells will be discussed.

(UMR9199), Fontenay-aux-roses, France

Abstract: Alzheimer’s Disease (AD) is characterized by memory loss, underlined by synaptic impairments promoted by both amyloid and Tau lesions. Various studies pointed-out that chronic caffeine consumption reduces Alzheimer's Disease (AD) risk and associated cognitive deficits. These protective effects are thought to be ascribed to the blockade of adenosine A_{2A} receptors (A_{2A}Rs), known to be crucial for synaptic tuning. Interestingly, A_{2A}Rs are found abnormally upregulated in neurons of AD patient’s brains in correlation with the development of cognitive deficits, suggesting a link between neuronal A_{2A}R dysregulation and memory impairments. We recently demonstrated (SfN2018) that neuronal A_{2A}R upsurge potentiates Tau pathology-induced synaptic loss in a Tauopathy model, through the activation of the C1q complement. Here, we aimed at elucidating the pathophysiological impact of a chronic neuronal A_{2A}R upsurge in a transgenic mouse model of amyloidogenesis (APP/PS1dE9). To this aim, we crossed APP/PS1 mice with our newly developed transgenic TRE-A_{2A} strain, carrying the mouse A_{2A}R under the control of a Tet-responsive-element promoter. This led rise to four genotypic groups: WT, APP, WT/TRE-A_{2A} and APP/TRE-A_{2A}. At 3m of age, all the animals were bilaterally injected in the

hippocampus with an AVV2/5-CBA-ttA allowing the preferential overexpression of ttA transactivator in neurons, and then the neuronal $A_{2A}R$ upsurge in TRE animals. At 6m of age, a time APP mice do not display major deficits, behavioral evaluations revealed that $A_{2A}R$ overexpression strongly worsened spatial memory impairments of APP animals without significantly altering neither amyloid burden (plaques, Abeta levels) nor neuroinflammatory markers (IL1b, CD68, C1q, Trem2, Chemokines⋯). Importantly, using mass spectrometry-based high-throughput proteomics, we identified significant modifications in the molecular profile of APP/TRE-A_{2A} vs. APP mice, with a notable downregulation of a large cluster of synaptic proteins. These data support that pathological upregulation of A_{2A}Rs in the neurons of AD patients contribute to synaptic and cognitive impairments promoted by lesions, paving the way for a therapeutic use of $A_{2A}R$ antagonists.

Title: VGF-derived peptide TLQP-21 modulates microglial function through C3aR1 signaling pathways and reduces neuropathology in 5xFAD mice

Authors: *M. AUDRAIN[1], F. EL GAAMOUCH[1], W.-J. LIN[5], N. BECKMANN[2], C. JIANG[3], S. HARIHARAN[3], P. HEEGER[4], E. E. SCHADT[2], S. E. GANDY[1], M. E. EHRLICH[1], S. R. SALTON[3];
[1]Neurol., [2]Genet. and Genomic Sci., [3]Neurosci., [4]Med., Icahn Sch. of Med. at Mount Sinai, New York City, NY; [5]Sun Yat-Sen Univ., Guangzhou city, Guangdong Province, China

Abstract: Multi-omic studies conducted by the NIH AMP-AD partnership led to the identification of VGF as a major driver of Alzheimer's disease (AD) and reduced VGF expression has been significantly correlated with mean amyloid plaque density, Clinical Dementia Rating (CDR) and Braak scores. Moreover, the VGF-derived C-terminal peptide TLQP-21 (named by its four N-terminal amino acids and length) has emerged as a novel target of interest in pathological conditions such as obesity, amyotrophic lateral sclerosis, neuropathic pain, and AD. TLQP-21 activates the complement C3a receptor-1 (C3aR1), which in the central nervous system, is expressed on neurons, astrocytes, and microglia. Despite recent interest in the roles of the complement system and microglia in AD pathogenesis and progression, TLQP-21 function in this context remains poorly understood. Here, we show that TLQP-21 treatment increases motility and phagocytic capacity in the microglial cell line BV2 and in primary wild-type murine microglia, but not in C3aR1 knock-out primary microglia, which under basal conditions have impaired phagocytic function compared to wild-type. Using RNA sequencing of isolated primary microglia, we observed similar differentially expressed genes (DEGs) induced by treatment with TLQP-21 or C3a superagonist (C3aSA). No DEGs were observed in C3aR1 knock-out or wild-type microglia treated with the mutant peptide TLQP-R21A (which does not activate C3aR1). Most of these C3aSA and TLQP-21 DEGs were linked to cell migration and proliferation. Because proliferation of microglia around amyloid plaques is a major feature observed in AD brains and because VGF is decreased in the CSF of AD patients, intracerebroventricular (icv) TLQP-21 was chronically delivered to 5xFAD mice for 28 days via implanted osmotic pump, resulting in a significant reduction of amyloid plaques, associated dystrophic neurites, and microgliosis. Taken together, our results provide molecular and functional evidence suggesting that VGF and TLQP-21 may modulate microglia function and neuropathological progression in the 5xFAD mouse model of AD.

Title: Frontal cortex neuroinflammatory alterations during the progression of Alzheimer's disease

Authors: *M. MORENO-RODRIGUEZ, M. NADEEM, S. PEREZ, E. MUFSON;
Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Chitinase 3-like proteins (CHI3L1 and CHI3L2) are markers of inflammation in several neurodegenerative diseases, including Alzheimer's disease (AD). While studies have demonstrated that cerebrospinal fluid CHI3L1 protein levels are increased in pre-clinical and prodromal AD, no studies have examined changes in Chitinase like protein levels in the cortex during the early stages of AD. The present study evaluated levels of both CHI3L1 and CHI3L2 and nueroinflammatory-related markers (Iba1, C1q, GFAP, NPTX2 and CD44) in the frontal cortex (FC) of people who died with an antemortem clinical diagnosis of non-cognitive impairment (NCI, n=15), mild cognitive impairment (MCI, n=15), mild/moderate AD (mAD, n=12) and severe AD (sAD, n=11) using immunoblot and immunohistochemical techniques.CHI3L1-immunoreactive (-ir) astrocyte number was significantly increased in FC and white matter (WM) in sAD compared to NCI. On the other hand, GFAP and Iba1-ir cell number was increased only in WM in MCI compared to NCI. Western blot analyses revealed significantly lower FC CHI3L2 levels, while CD44 was increased in sAD. No significant differences for CHI3L1, GFAP, C1q and NPTX2 protein levels were detected between clinical groups. Strong significant correlations were found between FC CHI3L1 and Iba1-ir cell number in WM and CHI3L1 and C1q protein levels in the early stages of AD. C1q and Iba1, CHI3L2 and CD44 and GFAP and CD44 protein levels were associated with disease progression. CHI3L1 and Iba1 cell number were significant associations with episodic memory and perceptual speed performance. These data suggest that CHI3L1 and CHI3L2 changes in the FC occur in later stages of AD. On the other hand, we found GFAP-ir astrocytes and Iba1-ir microglia are increased in FC WM in prodromal AD suggesting that these neuroinflammatory responses occur prior to CHI3L1 expression in astrocytes. The role of this pro-inflammatory markers requires further investigation.

Title: Role of MS4A4A M159V in myeloid cell response in Alzheimer's disease

Authors: *K. P. MACPHERSON, G. E. LANDRETH;
Stark Neurosci. Res. Inst., Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: An accumulating body of work strongly suggests Alzheimer's disease (AD) is the result of a failing complex biological network of protein clearance, neuronal health, and neuroinflammation. However, the specific mechanisms at play are still under investigation. GWAS studies identified risk loci in genes now known to be substantial contributors in the etiology and response to AD pathology in the CNS; however, some risk-associated genes, such as *MS4A4A*, remain under-investigated. Our analysis of public data sets shows *MS4A4A* gene expression is upregulated in AD prefrontal cortex and isolated microglia, CNS-resident myeloid cells. In addition, our preliminary data shows primary human blood-derived monocytes, have increased expression of *MS4A4A* as compared to total blood cell populations. Together this data suggests *MS4A4A* may play a role in myeloid cell function and specifically in microglial response to AD. A recent study suggests MS4A4A plays a role in directing the recycling of KIT to the plasma membrane and away from early endosomes in human mast cells, derived from myeloid cell lineage. However, the function of MS4A4A in relationship to AD pathology and the specific role in microglial cell function is unknown. In AD microglia are crucial regulators of plaque compaction and neuroinflammatory response, dependent upon the expression of TREM2 (triggering receptor expressed in myeloid cells 2). A recent report establishes a link between the SNP rs6591561, a missense variant within *MS4A4A* (p.M159V), with increased AD risk and decreased levels of soluble TREM2 in CSF. In addition, our preliminary data shows a trend for increased MS4A4A expression in human $TREM2^{+}$ vs $TREM2^{-}$ blood-derived monocytes. In this study, we assess the role of MS4A4A and MS4A4A M159V in the function of human microglia and regulation of TREM2-dependent response to AD inflammatory stimuli. Our preliminary studies with THP1 macrophages show MS4A4A expression is significantly decreased by M1 differentiating stimuli, INFγ and LPS, and significantly increased, 3-4 fold, by M2 differentiating stimulus IL-4 but not TGFβ. Studies are ongoing to assess the specific role of MS4A4A and MS4A4A M159V in myeloid cell trafficking, phagocytosis, and the relationship to Trem2 production and processing.

Title: Neurodegenerative microglial activation exacerbated by astrocytes-driven oxidative stress and proinflammation in a human Alzheimer's disease brain model

Authors: *Y. KANG[1,2,3,4], H. CHUN[5], J. LEE[5], H. CHO[1,2,3,4];
[1]Dept. of Engin. and Engin. Sci., [2]Dept. of Biol. Sci., [3]Ctr. for Biomed. Engin. and Sci., [4]The Nanoscale Sci. Program, Univ. of North Carolina at Charlotte, Charlotte, NC; [5]Cognitive Glioscience Group, Ctr. for Cognition and Sociality, Inst. of Basic Sci., Seoul, Korea, Republic of

Abstract: Alzheimer's disease (AD), the most common cause of dementia, leads to neuronal damage and deterioration of cognitive functions in aging brains. Recently, both astrocytes and microglia acquiring reactive properties are involved in the AD progression. However, there are challenges to discover molecular and intercellular mechanisms of astrogliosis and microgliosis in AD progression due to the lack of appropriate model systems that accurately reflect AD-related immunity in human brains. We previously presented effective human AD brain models by tri-culturing human APP neurons, astrocytes, and microglia in a 3D microfluidic platform, which closely reconstructs key aspects of Aβ, p-tau signature, and neuroinflammatory. Here, the AD model was employed to clarify the molecular mechanisms of crosstalk between astrocytes and microglia contributing to neurotoxic inflammation in AD environments. We found the increased reactivity of astrocytes in response to Aβ producing excessive H_2O_2 (5.7 fold) and proinflammatory cytokines (IL-6, IFNr, TNFa) compared to astrocytes in healthy models. The promoted neuronal damages in the co-cultured AD models were confirmed by increased phosphorylated tau (pTau) expression (2.2 fold) and LDH level (3.6 fold) compared to healthy models. The addition of either H_2O_2 scavenger or astrocyte-specific MAO-B inhibitor effectively prevented the tauopathy and neurodegeneration validating that the major neuro toxic factor was the oxidative stress from the reactive astrocytes. To investigate the involvement of microgliosis in the AD progression, we added microglia to the AD models and found the elevated neurotoxic effects by observing increased pTau expression (1.3 fold) and decreased cellular viability (1.3 fold) compared to healthy models. Further single culture study with microglia was performed to explore the potential underlying mechanisms of microgliosis, which may exacerbate the neurodegeneration in AD. We found that synergistic effects of H_2O_2 and IL-6, found in reactive astrocytes in AD models, on M1 microglial polarization (6.5 fold). In addition, the combined treatments of H_2O_2 and IFNr triggered NO production (2.0 fold) from microglia. Currently, we are examining the intercellular pathways of astrocyte-driven microgliosis that promote neuronal damages in AD brains, which may offer a promising target for drug discovery in AD.

Title: Repurposing drugs for modulating microglia mediated neuroinflammation in Alzheimer's disease

Authors: *S. ALOE[1], O. CHAUDRY[1], L. XIE[2], P. A. SERRANO[3], P. ROCKWELL[1], M. E. FIGUEIREDO-PEREIRA[1];

Abstract: Alzheimer’s disease (AD) is a progressive neurodegenerative disorder and is the sixth leading cause of death in the United States. One of the hallmarks of AD is chronic neuroinflammation caused by overactive microglia, the resident immune cells of the CNS. The inability to reduce this inflammatory response leads to chronic neuroinflammation. AD drugs have a 99.6% failure rate and because of the difficulty and costliness of creating novel drugs, the aim of our study is to repurpose existing drugs for potential treatment of AD. A bioinformatics approach identified three drugs with potential targets in the neurodegenerative pathways: Diazoxide (DZ) a potassium channel activator, Ibudilast, a phosphodiesterase inhibitor, and RG2833, an HDAC (histone deacetylase) inhibitor. Upon drug treatment, human microglia (HMC3) were analyzed for viability (MTT assay) and cytokine secretion (ELISA). DZ showed no significant cytotoxicity, while Ibudilast was toxic only at the highest concentration tested and RG2833 showed a significant increase in microglia viability. Microglia were analyzed for secretion of two pro-inflammatory cytokines, IL-6 and IL-1β, and two anti-inflammatory cytokines, IL-13 and TGFβ. Ibudilast treatment revealed a change in the microglia cytokine profile. At 10 µM, Ibudilast increased the levels of IL-13, while at 100 µM, the highest concentration tested, Ibudilast raised the levels of IL-6, a pro-inflammatory, neurotoxic cytokine. These data complement the MTT results. The predicted target of Ibudilast is IRAK1, which is upstream of cytokine production. Down regulation of this kinase could be playing a role in the observed change in cytokine secretion. Based on these results and those of other studies, we are assessing the potential therapeutic effects of Ibudilast and RG2833 in a transgenic rat model of AD. Examining whether these drugs modulate the release of neurotoxic and neuroprotective cytokines by microglia has potential for treating neuroinflammation in AD.

Title: The expression changes of lncRNA associated with miRNA-101a in 5XFAD

Authors: *Y. CHOI[1], Y. LEE[2], D. LEE[1,2];
[1]Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of; [2]Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: The long non-coding RNAs(lncRNA) are non-protein coding transcripts longer than 200 nucleotides and have been reported to regulate gene and protein expression. In addition, lncRNA is involved in various diseases including Alzheimer's disease. In order to understand changes in early-stage AD before cognitive impairment, we isolated RNAs from hippocampus and analyzed lncRNAs at 10- and 20- week-old 5XFAD initiating amyloid beta production and senile plaque deposition And differentially expressed 212 lncRNAs among 16,251 lncRNAs were selected between 10- and 20-week-old 5XFAD compared to wild type mice. We focused on lncRNA X associated with miRNA-101a which is involved in the regulation of APP. To investigate the relationship between lncRNA X and miRNA-101a, the expression level of lncRNA X was measured in mouse primary astrocyte and microglia treated with LPS. In results, the lncRNA X expression was significantly down-regulated under astrocytes and microglia activation and negatively correlated with miRNA-101a expression. We found a change of lncRNA X expression in inflammatory conditions and the relationship between lncRNA X and miRNA-101a. We need to confirm the level of APP expression and the function of lncRNA X in the inflammation. Understanding the expression and function of lncRNA X in inflammatory conditions can confirm the potential of lncRNA X as a diagnostic and therapeutic target for early-stage AD.

Abstract: Development of more translational *in vitro* Alzheimer's disease (AD) models will benefit understanding of neuro-pathology. To enable improved AD models, and to obtain a greater insight on the role of microglia in disease processes, we have developed techniques for long term measurements of cell health, morphology and function in 2D and 3D using live-cell analysis.

Healthy (hN6) and AD patient (hAD2) derived (Axol, Cambridge, UK) neuro-progenitor cells were seeded, differentiated, and matured for up to 90 days and monitored throughout using an IncuCyte® S3 for Neuroscience. After 14 d post differentiation in mono-culture, hAD2 iPSC-derived neurons yielded lower neurite outgrowth compared to the hN6 (neurite length of 80 ± 2.9 or 48 ± 2.6 mm/mm^2 for hN6 or hAD2, respectively, mean ± SEM; 48 replicates). In a 3D spheroid model, culturing in ultra-low-attachment (ULA) plates, hAD2s demonstrated enhanced spheroid growth (63 ± 7 or 119 ± 4 % change for hN6 or hAD2, respectively; 2-5 replicates).

The impact of AD related peptides (Tau and A$\beta_{1\text{-}42}$) on neuronal health and function was quantified using nuclear labeled SH-SY5Y cells or rat primary cortical neurons in mono- or co-cultured with rat primary astrocytes. Tau and A$\beta_{1\text{-}42}$ peptides induced a time- and concentration-dependent neuronal toxicity, with a reduction in neuronal number, neurite length and activity measured by calcium signalling.

Phagocytosis by microglia of pHrodo® labeled aggregated peptides was quantified as an increase in fluorescence following entry into acidic intracellular compartments. Rapid engulfment of aggregated A$\beta_{1\text{-}42}$ peptide was observed in mouse BV-2 cells (fluorescent area 18.1 ± 1.2 mm/mm^2 at 48 h, 3 replicates). Little or no engulfment was observed in undifferentiated SH-SY5Y cells or when the A$\beta_{1\text{-}42}$ was not aggregated. hiPSC-derived monocytes (Axol) were differentiated for 14 d into microglia. Addition of pHrodo® labelled aggregated A$\beta_{1\text{-}42}$ (3.7 - 100 µg/ml) yielded concentration-dependent phagocytosis (maximum fluorescent area: 2.88x10^5 ± 0.02 µm^2 at 24 h for 33 µg/ml peptide, 2 replicates). To elucidate the involvement of scavenger receptors in peptide uptake, CD204 and CD36 antibodies known to block scavenger receptors A and B, respectively, were added with aggregated A$\beta_{1\text{-}42}$ or E.coli bio-particles®. Whilst the CD204 antibody inhibited the uptake of both reagents, CD36 selectively attenuated A$\beta_{1\text{-}42}$ peptide engulfment.

Taken together, these data show that long term monitoring, alongside combining multiple readouts from advanced cellular models, has the potential to deliver greater biological insight into neurological disorders, therefore contributing to drug discovery.

Title: Bioinformatics analysis of TILRR regulated gene activation patterns demonstrates primary effects on the PI3K-AKT-mTOR pathway and links with Alzheimer's disease and inflammation

Authors: B. POYNTER[1], *P. R. HEATH[2], E. QWANSTROM[3], J. COOPER-KNOCK[2]; [1]Neurosci. and Infection, Immunity & Cardiovasc. Dis., [2]Neurosci., [3]Infection, Immunity and Cardiovasc. Sci., Univ. of Sheffield, Sheffield, United Kingdom

Abstract: Toll-like and IL-1 receptors (TIR) are key regulators of immunity and inflammation and activated by ligand binding and co-receptor association. Aberrant control of the systems impacts progression of multiple diseases with an underlying inflammatory component, these include but are not limited to Alzheimer's and other neurodegenerative diseases. Ligand-induced stimulation of the interleukin-1 receptor, IL1R1 is amplified by its co-receptor TILRR (toll-like and IL-1 receptor regulator), leading to marked changes in NF-KB and gene activity(1). Recent studies demonstrate that TILRR is highly expressed at sites of dysregulated NF-KB activity and inflammation and show a central role for TILRR in disease(2). In order to determine gene expression alterations caused by changes in TILRR expression; and to link these gene expression changes to described biological functions such as inflammation, microarray analysis was carried out. RNA samples from spleen and blood monocytes of TILRR-/- and wild-type C57BL/6J mice were harvested, treated and applied to Affymetrix MOE430_2 arrays. Data was normalized and differential expression calculated using PUMA(3). WGCNA(4) was used to divide genes into modules with similar expression. Pearson correlation coefficients were calculated for the association between module expression and TILRR status. Significantly correlated modules ($p<0.05$) were functionally characterized using enrichR(5). Bioinformatics analysis, comparing microarray data from blood and spleen samples from wild type and TILRR knockout mice, identified alterations in expression of gene modules functionally associated with PI3-AKT signalling including the genes; BACE 1, ITCH, CCR2 and CALM 3. Results from the bioinformatics analysis were confirmed by qPCR, which demonstrated changes in the range of the identified genes in the TILRR KO relative to levels in wild type mice. 1. Abstract: Growing evidence suggests that brain glucose hypometabolism is an early phenotype that is detectable long before cognitive decline is manifested, and continues in patients with Alzheimer's disease (AD). Together with the finding of the brain insulin resistance in AD patients, it suggests that disruption of the brain metabolism may contribute to the development of AD pathology. In support, we have published that amyloid-beta (Aβ) peptides disrupt metabolic homeostasis in a mouse model of AD, 5XFAD. To investigate what types of metabolic changes occur in AD, we performed a longitudinal NMR-based metabolomics study using the serum, urine and brain samples from 1-, 3-, and 6-month-old 5XFAD mice. Our analyses demonstrated that serum lactate levels decreased significantly at 6-month-old 5XFAD mice compared to control mice. In tumors, lactate level is increased due to the Warburg effect that results from aberrant expression of pyruvate kinase M2 (PKM2). We asked whether the changes in serum lactate levels also involved dysregulation of PKM2 expression and function in AD. Indeed, we found that the levels of active PKM2 tetramers were significantly increased in cortical lysates from AD patients as well as 6-month-old 5XFAD mice compared to respective age-matched control samples. In addition, PKM2 was primarily expressed in $CD68^+$ inflammatory microglia, and its expression increased after LPS treatment *in vitro* and *in vivo*, both in the control and 5XFAD mice. PKM2 activation appears to facilitate phagocytic activity of microglia, as pharmacological activation of PKM2 with 50 uM DASA-58 increased phagocytosis of oligomeric Aβ in rat primary microglia. On the other hand, inhibiting PKM2 with a pharmacological inhibitor, shikonin at 10 uM, blocked phagocytosis of both Aβ and control dextran beads. These results together suggest that PKM2 may be involved in microglial phagocytic activity, perhaps by altering metabolic state of microglia.

Title: Lysine demethylase 4 inhibitors block TNF alpha-induced adhesion protein expression in human brain microvascular endothelial cells

Authors: *S. A. JO[1], **J.-H. KO**[2];
[1]Dankook Univ., Cheonan, Korea, Republic of; [2]Cheonana, Chungnam Cheonan, Korea, Republic of

Abstract: Lysine demethylase (KDM) proteins are histone demethylases which remove methyl groups from lysine residue of histone. KDMs have been studied in the cancer research as epigenetic modulators, but not much reports regarding to brain diseases are found. Increase of adhesion proteins in vascular endothelial cells contributes to immune cell migration through the blood-brain barrier although their role in pathogenesis of brain diseases is not well understood. Our previous studies demonstrated that the TNFα-induced increase of intracellular adhesion protein1 (ICAM1) is regulated by histone modification at lysine 9 (H3K9me2 and H3K9me3) in human brain microvascular endothelial cells (HBMVECs), and KDM4 is responsible for demethylation of H3K9. Thus, in the present study, we examined the effect of two KDM4 inhibitors, a broad spectrum KDM4 inhibitor (ML-324) and a KDM4A and KDM4B-specific inhibitor on TNFα-induced adhesion protein expression. The results demonstrated that both inhibitors blocked more effectively an increase of vascular cell adhesion molecule 1(VCAM-1) than ICAM1 induced by TNFα. In addition, these compound inhibited the TNFαinduced neutrophil adhesion and infiltration. Thus, KDM4 inhibitors could have the potential as a therapeutic drug for brain diseases. The present study was supported by a research grant of the National Research Foundation of Korea (NRF2017R1A2B4002861).

Title: Development of a systems biology platform to enable drug discovery for neuroinflammatory Alzheimer's disease

Authors: *L. H. MARTENS, **R. NUNES**, K. C. LARSON, M. MARCONI, C. D. DEJESUS, T. MILLER, J. M. LEVENSON, B. TATE;
Tiaki Therapeut., Cambridge, MA

Abstract: Neuroinflammation is a pathological hallmark of multiple CNS degenerative diseases, including Alzheimer’s disease. Genetic and transcriptomic studies have identified microglial dysfunction as a key driver of the chronic neuroinflammation that is associated with neurodegenerative disease. Microglia, the resident CNS innate immune cells, also have non-innate immune cell functions during CNS development and in the adult brain, demonstrating that neuron-glia interactions are required for normal brain function and health. This has led to the hypothesis that modulation of adult microglial function may be a potential therapeutic strategy to protect the aging, diseased brain. One challenge in the field of neuroinflammation is authentic modeling of the complex CNS biology present *in vivo*, including critical neuron-glia interactions. Tiaki Therapeutics has developed a neuroinflammation systems biology platform based on an adult mouse *ex vivo* brain slice assay, which permits the longitudinal analysis of all CNS cell types within their authentic matrix and inter-cellular environment. A neuroinflammatory signature was established using transcriptomes from the whole slice, which encompasses all CNS cell types, and isolated microglia. Early, dynamic gene changes equilibrate and result in a stable, chronic neuroinflammatory state that can be monitored using transcriptomic and protein techniques. Bioinformatic approaches demonstrate a significant correlation between the neuroinflammatory gene expression signature observed in the brain slice assay to gene expression data from Alzheimer’s disease patients. Tiaki’s platform is uniquely positioned to provide longitudinal transcriptomic and protein signatures for CNS health and disease, as well as biomarkers for target engagement and compound efficacy. We have identified targets that, when manipulated, alters the neuroinflammatory signature and benefit neuronal health. Our systems biology platform enables the discovery and development of disease-modifying therapeutics against microglial targets for Alzheimer’s disease.

Title: Interactions between amyloid beta (Aβ) and NLRP3 inflammasome proteins

Authors: *N. J. MAKONI, E. GARRAD, S. GROVER, M. R. NICHOLS;
Dept. of Chem. & Biochem., Univ. of Missouri-St. Louis, Saint Louis, MO

Abstract: A prominent pathway within the innate immune system involves a three-protein complex known as the NLRP3 inflammasome. This complex is comprised of NLRP3, apoptosis-associated speck-like containing a CARD (ASC), and procaspase-1, an enzyme in its inactive form. Activation of the NLRP3 inflammasome results in the generation of active caspase-1 via autoproteolytic cleavage of the pro-form of the enzyme. Ultimately, this facilitates the production of mature interleukin-1β (IL-1β), an inflammatory cytokine. The inflammasome is highly regulated and its activation has been implicated in a variety of inflammatory disorders including Alzheimer's disease (AD). One feature of AD pathology is the accumulation of amyloid beta peptides (Aβ) in the brain. This event causes a mobilization of microglial cells to the site and a localized inflammatory response. Data from our laboratory and others have shown that the NLRP3 inflammasome is activated and IL-1β is produced when microglia are exposed to, and internalize, Aβ. Yet, the mechanism of activation is not fully understood. Thus, we sought to investigate direct interactions between Aβ and the NLRP3 inflammasome proteins. Two Aβ-inflammasome interaction paradigms were utilized, 1) Aβ treatment of primary murine microglia and 2) solution interactions of Aβ with recombinantly-expressed NLRP3 inflammasome proteins. For both paradigms, co-immunoprecipitation strategies were employed. Full-length and truncated NLRP3, ASC, and procaspase-1 proteins were expressed in the ExpiCHO-S mammalian cell system. The proteins were purified with affinity and size-exclusion chromatography. Immunoblot analysis revealed both monomeric and oligomeric forms of each protein. *In vitro* experiments in which Aβ42 protofibrils were incubated with recombinant ASC suggested a direct interaction between the two proteins. Lysates prepared from primary microglia

exposed to Aβ42 protofibrils were immunoprecipitated with NLRP3 and ASC antibodies separately. SDS-PAGE separation and probes of the subsequent transfer membranes with multiple antibodies confirmed an NLRP3-ASC interaction and indicated a likely interaction with between Aβ42 protofibrils and ASC and potentially with NLRP3. In sum, these findings will provide new insights on the convergence of AD and this vital inflammatory pathway and may also provide information on potential targets for therapeutic intervention.

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder, pathologically characterized by extracellular insoluble Aβ plaques and intracellular neurofibrillary tangles. Neuroinflammation and oxidative stress are involved in the onset and progression of AD. The production of inflammatory mediators, ROS and RNS causes synaptic dysfunction that is responsible for memory decline in AD. Therefore, the therapeutic options based on anti-inflammatory and anti-oxidant therapy are of important concern in targeting AD. The aim of this study was to develop a suitable *in vitro* model of Aβ deposition and to determine the role of novel neuroprotective agents for their therapeutic role thus targeting the disease at early stage or delay its onset. Our preliminary studies were conducted using PHA to observe plaques formation that releases cytokines upon stimulation. SH-SY5Y cells were incubated with PHA at the concentrations 5-40 µg/ml for 24 hours. After incubation, cells were observed using phase contrast microscopy. Oxidative stress was analyzed using 2',7'-dichlorodihydrofluorescein diacetate at concentrations of PHA 5-40 µg/ml by fluorimetric method. Immunocytochemistry was conducted to confirm the presence of Aβ plaques after stimulation with PHA. RT-qPCR was performed to analyze the expression of inflammatory markers (TNF-α, IL-1β, iNOS, P38-α and P38-β) and α and β-secretase genes involved in plaques formation. Morphological analysis of PHA stimulated cells showed that 5 µg/ml PHA did not cause any prominent changes in cellular morphology, while 10, 20 and 40 µg/ml concentrations caused visible aggregation when

compared with unstimulated cells. Oxidative stress analysis of PHA stimulated cells demonstrated increased ROS levels upon stimulation with significant increase at 10 µg/ml of PHA. Later, immunocytochemistry analysis at 10 µg/ml PHA concentration showed significantly increased expression of Aβ in stimulated cells. Quantitative gene expression analysis revealed that expression of inflammatory markers and β-secretase gene was increased in PHA-treated cells.Based on our findings, we suggest that PHA is involved in oxidative stress induced Aβ production. Further we have screened different compounds for their neuroprotective effect to use for the treatment of PHA induced AD symptoms and neurodegeneration. Preliminary, quinic acid and its derivatives were found to increase cell viability as compared to control cells. Next, we will use these compounds to check whether they are effective in reducing PHA induced Aβ generation and also, we will determine the molecular mechanism of action involved in the functioning of these compounds.

Abstract: Background: Cerebral Amyloid Angiopathy (CAA) is typified by the cerebrovascular deposition of β-amyloid and has a close molecular relationship with Alzheimer's disease (AD), but remains clinically distinct. Vascular amyloid accumulation is identified in an estimated 85-95% of individuals with AD, positioning CAA as one of the strongest vascular contributors to age-related cognitive decline. Several genome-wide association studies (GWASs) have shown linkage of genes involved in the immune system and AD pathogenesis. Based on this, numerous efforts have been focused on understanding the contribution of the neuroinflammation associated with parenchymal amyloid-plaques to neurodegeneration in AD. Nevertheless, there is still no clear understanding of the mechanisms underlying the contribution of neuroinflammation associated to vascular amyloid deposition to neurodegeneration in CAA related dementias.
Methods: We used a model of CAA in the form of a transgenic mouse for Familial Danish Dementia (Tg-FDD) that accumulates ADan amyloid in the vasculature, to study the contribution of neuroinflammation to neurodegeneration associated to CAA. We performed RNAseq, imaging, protein and Nanostring analysis to establish if the immune system could play a preponderant role in the pathogenesis of CAA related dementias.
Results: We demonstrate that our transgenic mouse model for CAA exhibit severe astrogliosis at early stages of vascular amyloid deposition in comparison to microgliosis and display a shift in astrocytic profiling to A1-like neurotoxic astrocytes. Analysis of neuroinflammatory genes by NanoString technologies also revealed a significant downregulation in genes associated to astrocytic function, lipid metabolism and immunity. Remarkably, our RNAseq analysis revealed immune risk-factors associated to AD, such as ABCA7, TREM2 and CX3CL1, dysregulated in the context of CAA. Importantly, biochemical analysis has revealed significantly decreased expression of TREM2, an important modulator of neuroinflammation and significant LOAD risk factor.
Conclusion: In addition to demonstrating the effect of cerebrovascular amyloid on lipid metabolism in the Tg-FDD model, our results suggest that astrogliosis and astrocytic loss of function is an early event in CAA and how known immune risk factors for AD could play an important role in CAA pathogenesis. Therefore, new therapies in CAA-related dementias should be focused on the influence of this system.

Title: Role of TLR signaling pathways in systemic inflammation and Alzheimer's disease

Authors: *J. YANG, B. DIDIER, L. WISE, K.-I. FUKUCHI;
Univ. of Illinois Col. of Med. at Peoria, Peoria, IL

Abstract: Obesity, diabetes, hypercholesterolemia, infection and aging are strong risk factors of Alzheimer's disease (AD) and associated with chronic/systemic inflammation and activation of toll-like receptor (TLR) signaling. We and others demonstrated that activation of TLR signaling can modulate the initiation and progression of AD pathophysiology. Two distinct pathways, myeloid differentiation factor 88 (MyD88) and toll/interleukin-1 receptor domain-containing adaptor inducing interferon-β (TRIF), are involved in TLR signaling. We previously demonstrated that MyD88 deficiency (MyD88KO) decreases the brain Aβ load in an AD mouse model (TgAPP mice). However, the involvement of MyD88 and/or TRIF in the increased AD risk associated with chronic/systemic inflammatory diseases is unclear. In this study, ten-month-old MyD88KO and MyD88 wild-type TgAPP mice were subjected to weekly intraperitoneal injection of lipopolysaccharide (LPS 0.5 mg/kg) for three months to mimic chronic/systemic inflammation. PBS was similarly injected as a control. Consistent with our previous observations, less Aβ accumulation in the brains of MyD88KO TgAPP mice was found compared with MyD88 wild-type TgAPP mice. After LPS administration, plasma TNF-α and IL-6 levels significantly increased in MyD88 wild-type TgAPP mice, compared with MyD88KO TgAPP mice. LPS administration significantly increased IBA1-immunoreactive areas in the brains of MyD88 wild-type TgAPP mice, compared with PBS. However, there is no significant difference in IBA1-immunoreative areas between LPS- and PBS-treated MyD88KO TgAPP mice. Similarly, LPS administration increased insoluble Aβ42 in the cortex as well as Aβ40 and Aβ42 in the CSF in LPS-treated MyD88 wild-type TgAPP mice, but not in LPS-treated MyD88KO TgAPP mice. Hippocampal RNA-Seq analysis revealed that 131 genes are altered (26 genes down-regulated and 105 genes upregulated) in LPS-treated MyD88 wild-type TgAPP mice and that 192 genes are altered (19 genes down-regulated and 173 genes upregulated) in LPS-treated MyD88KO TgAPP mice, compared with PBS-treated controls. Currently we are investigating the signaling pathways potentially involved in the AD progression in response to chronic/systemic inflammation by bioinformatics.

Abstract: Microglial activation and cognitive decline in a new rat model of Alzheimer Disease
Alzheimer disease (AD) is characterized by amyloid plaques, neurofibrillary tangles y generalized cortical neuronal loss. It is believed that cerebral amyloid produce the neurotoxic events in the dementia. However, the precise mechanism by which the early accumulation of amyloid-B (Aβ) peptides leads to cognitive decline remains unknown. For this reason, the development of animal models has been a priority to understand pathogenic mechanisms and therapeutic strategies. We have established a new model of Alzheimer´s disease in rat to evaluate cognitive decline and neuroinflammation. We injected amyloid-B (1-42) into the hippocampus to establish AD model rats. The male Sprague-Dawley rats at 3 months of age were divided into a control group (saline solution), an AD model group low-dose group (0,5 µg/µl Aβ) and an AD model group high-dose group (1 µg/µl Aβ). Fourteen days later the reference memory was evaluated by the Morris water maze to examine the cognition in this model of Alzheimer-induced cognitive impairment. Then, the rats were sacrifizied and examinated the plaque deposition and gliosis using histology and immunohistochemistry. Samples were immunostained for Iba-1 (microglia), glial firbillary acidic protein (GFAP, astrocytes), visualized using diaminobenzidine tetrachloride (DAB) and sections counterstained with haematoxylin. Ratstrack plugin of ImageJ was used to process recorded videos of the Morris water maze. Alzheimer´s disease was successfully induced by injected of AB peptide in this new model. The microglial activation was reflected by increased levels of microglial markers Iba-1 and the cognitive impairment was evidenced in the AD model group low-dose group (0,5 µg/µl Aβ) and AD model group high-dose group (1 µg/µl Aβ)($p<0.05$). Differences were found in reference memory and changes histopathologicals. These results show that the injection of beta amyloid 1-42 causes cognitive impairment or memory loss, which makes this new animal model very interesting allowing us to continue with research in the pharmacological field.

Title: Periodontal disease modifies the neuroinflammatory process in a mouse model of Alzheimer's disease

Authors: *A. KANTARCI[1], C. TOGNONI[2,3], W. YAGHMOOR[1], A. MARGHALANI[1], D. STEPHENS[1], J.-Y. AHN[2,3], I. CARRERAS[2,3,4], A. DEDEOGLU[2,3,5];

Abstract: Plaque-associated microglia (PAMs) may both provide a protective barrier between Aβ and neurons and thus preventing neuronal dystrophy and play a significant role in Alzheimer's disease (AD)-associated pathological changes. Chronic infections, such as periodontitis (PD), which increase the overall "set point" of systemic inflammation in individual patients, could modify the neuroinflammatory process. We tested the impact of PD on AD-like pathologies in 5xFAD mouse model and the role of PAMs. Fifteen male 5xFAD and 15 non-transgenic littermate 8-month old mice were used. Ligature-induced PD was established for 4 weeks. The bone levels and osteoclasts around the teeth were quantified macroscopically and histologically. Aβ40 and Aβ42 levels and inflammatory cytokines and chemokines were measured in prefrontal cortex. Double-label fluorescent analysis of thioflavin-S (ThS) and Iba1 was used to measure PAMs. 5xFAD mice at baseline had higher levels of bone loss than WT littermates; ligatures significantly increased bone loss with no significant differences between groups. Both Aβ40 and Aβ42 were increased in 5xFAD mice with PD; only the insoluble Aβ42 was significantly increased. The topographical distribution of Aβ42 immunostaining in cortex, hippocampus, and dentate gyrus (DG) showed Aβ42 plaques within L. 4/5 of the cortex, hippocampus, and DG regions of the 5xFAD mice with experimental PD. PD resulted in significantly increased levels of Iba1 immunostaining in WT mice. Microglia cells in 5xFAD mice showed a dense and robust Iba1 staining presenting enlarged cell body and reduced branching characteristic of the activated phenotype of microglia in AD brains. There was a

statistically significant decrease in Iba1 immunostaining in the DG region in 5xFAD mice with PD. In parallel, the % area occupied by Iba1 positive particles bigger than 400 μm^2 significantly decreased and there was a decreased percentage of Iba1+ staining within the immediate proximity of ThS positive plaques in 5xFAD mice with PD indicative of decreased PAMs. 5xFAD mice had significantly lower levels of IL-1β, KC, and IL-10 compared to the WT mice. The data collectively demonstrated that experimental PD leads to an increased neuroinflammatory process in brains of non-AD mice while resulting in an aberrant regulation of inflammation in 5xFAD mice. These results suggest that PD may prime microglia to a significantly activated state that may be detrimental to cognition and increase vulnerability to additional immune challenges or diseases and PAMs may be a crucial link between the systemic chronic inflammation induced by periodontitis and accelerated AD pathology.

Title: Gut microbiome alterations and bacteria derived components in Alzheimer's disease

Authors: *A. CATTANEO[1], S. PROVASI[2], N. LOPIZZO[3], C. PARIANTE[4];
[1]IRCCS Fatebenefratelli, Brescia, Italy; [2]Biol. Psychiatry Lab., IRCCS Ctr. Fatebenefratelli, Brescia, Italy; [3]Biol. Psychiatry Unit, IRCCS Fatebenefratelli Ctr., Brescia, Italy; [4]King's Col. London, London, United Kingdom

Abstract: Alzheimer Disease is a neurodegenerative disease which is characterized by the presence of beta-amyloid plaques and neurofibrillary tangles. Another important feature characterizing these patients is represented by enhanced inflammatory status both in the periphery, reflected by high levels of pro-inflammatory cytokines and also at central levels as indicated by enhanced activation of microglia. However, it is still not clear where this inflammation comes from. Recently, the gut microbiome and gut bacteria have been proposed to play a central role in the development of this inflammatory status as well as in the pathogenesis and progression of the illness. Here we wanted to identify a possible signature of the gut microbiome composition in association with AD pathology and to investigate the possible role of the gut microbiome in modulating inflammatory status of these patients.In particular we tested whether alterations in the abundance of specific gut microbiome taxa could be associated with an

enhanced peripheral proinflammatory status, tested both in term of peripheral pro-inflammatory cytokines as well as in term of bacteria derived components such as the Lipopolysaccharide (LPS) and Short Chain Fatty Acids (SCFAs).We investigated the composition of the gut microbiome by 16s sequencing in 20 controls and 50 AD patients and the blood levels of pro- and anti-inflammatory cytokines by using Meso Scale Discovery platform and of short chain fatty acids (SCFAs). AD patients showed higher levels of NLRP3, CXCL2, IL-6, IL-1b and LPS (all $p<0.05$) as compared to controls. We also found a specific microbiome profile in AD patients as compared to controls, where specific taxa at genus levels, including Blautia correlated negatively with the abundance of IL-1beta and NRLP3 and other taxa such as Escherichia/Shigella correlated positively with IL-1beta, NLRP3 and LPS. We also found a negative correlation between blood levels of LPS and butyrate and acetate ($p<0.05$). Our results suggest that the presence of a specific microbiome signature in AD patients may lead to the passage into circulation and then into the brain, of immune systems mediators as well as bacteria components, such as LPS, but also pro-inflammatory cytokines, contributing to the pathophysiology of AD.

Title: The astrocyte circadian clock regulates amyloid beta deposition and degradation

Authors: *C. MCKEE[1], B. V. LANANNA[2], J. BASAK[3], E. S. MUSIEK[4];
[1]Washington Univ. In St Louis, St Louis, MO; [2]Washington Univ. in St Louis, Saint Louis, MO; [3]Washington Univ. in St Louis, St Louis, MO; [4]Neurol., Washington Univ. In St. Louis, Saint Louis, MO

Abstract: An emerging link between circadian clock function and processes of neurodegeneration has indicated a critical role for the molecular clock in brain health. We have previously reported that disruption in core clock genes induces long-term activation of both microglia and astrocytes. Elevated activation of glia has important implications in chronic neurodegenerative conditions such as Alzheimer's disease (AD). Our goal is to investigate how the circadian clock functions in astrocytes to regulate inflammation, proteostasis, and neuronal support in the context of disease. To address these questions, we generated mice with astrocyte-specific knockout of the master circadian clock gene Bmal1, which renders astrocytes

transcriptionally arrhythmic. We report here that astrocyte-specific deletion of Bmal1 influences astrocyte activation state, lysosomal enzyme expression, and uptake and degradation of amyloid-beta peptide (Aβ). Bmal1-deficient astrocytes upregulate proteins and enzymes involved in Aβ metabolism and may degrade Aβ faster *in vitro*. *In vivo*, astrocyte-specific clock deficiency in the APP/PS1 transgenic mouse model of AD increases activation of astrocytes around Aβ plaques while also altering the accumulation of Aβ into plaques. We are now investigating underlying pathways linking the astrocytic clock to Aβ metabolism by glia in order to define how the molecular clock regulates pathogenesis in AD. This work will help elucidate mechanisms by which the clock in astrocytes influences long-term neuronal health and neurodegenerative disease.

Title: TNFR2 overexpression in astrocytes attenuates Alzheimer-like pathology in Alzheimer's disease mouse models

Authors: D. LI, ***Z. CHEN**, Y. SHEN;
Univ. of Sci. and Technol. of China, Hefei, China

Abstract: TNFα signaling pathway plays essential roles in Alzheimer’s disease (AD) pathology. TNFα has two receptors, TNFR1 and TNFR2, which mediate different effects on cell fate. Our previous work has demonstrated that TNFR2 expression was reduced in human AD brains. Moreover, we have also found that TNFR2 deletion in APP23 mice accelerated plaque formation and microglial activation. Thus, it is a potential therapeutic strategy to reverse AD pathology by up-regulating TNFR2 levels. To test this hypothesis, we have generated astrocyte-specific TNFR2 transgenic mouse model and crossed it with APP transgenic mouse models to evaluate the pathological changes. Amyloid β plaque deposition was significantly decreased in cortex and hippocampus of astrocyte-specific TNFR2 overexpression AD mice than of control mice. Furthermore, reduced BACE1 activity and necroptosis were also found in these mice. Together, we conclude that TNFR2 up-regulation of astrocytes could ameliorate Alzheimer-like pathology.

Title: Evaluation of inflammatory signaling in a novel $GABA_B$ receptor knockout mouse model

Authors: *A. M. LEISGANG[1], A. M. SALAZAR[1], A. A. ORTIZ[2], J. W. KINNEY[1];
[2]Psychology, [1]Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder that is characterized by a learning and memory deficits. Pathologically, AD is characterized by the presence of three core features, beta-amyloid plaques (Aβ), neurofibrillary tangles (NFT), and chronic neuroinflammation. The activated immune response has been demonstrated to exacerbate both Aβ and NFT pathology. Additional data support a connection between Aβ and NFT formation that may be mediated by the inflammatory response, making investigations of inflammation a central target in AD. Activated microglia, the resident immune cells in the CNS mediate the immune response via the production of several pro-inflammatory cytokines. Mechanisms capable of modulating the immune response has considerable promise as potential interventions in AD. Microglia express a number of receptors, including the $GABA_B$ receptor. In the present study, we investigated if the loss of GABAergic signaling on microglia impacts the inflammatory response and AD related deficits. As alterations have been demonstrated in gamma amino butyric acid (GABA) in AD, a change in microglia function may contribute to neuroinflammation in AD. We have developed a novel $GABA_B$ knockout that is restricted to glial populations that were evaluated for alterations in inflammatory signaling following poly I:C, as well as AD related pathology. Our data indicate the loss of $GABA_B$ on microglia alter inflammatory signaling.

Title: BACE1 expression and function in T cells from mice and human

Authors: *L. DAI, Y. SHEN;
Univ. of Sci. and Technol. of China, Hefei, China

Abstract: BACE1, an asparitic-acid protease,also known as beta-site APP cleaving enzyme1(BACE1),is a therapeutic target for Alzheimer's disease(AD) due to its neuronal activities of generating amyloid β peptide(Aβ),which is the major component of amyloid plaques in the brain. Interestingly, however, our recent studies accidently discovered BACE1 abundant expression in T-cells when we were searching biomarkers from the blood of AD patients, suggesting unknown functions of BACE1 in the peripheral immune system. Why and how does BACE1 express in T cells? If we inhibit BACE1 in clinic for AD treatment, do BACE1 inhibitors have side effects that affect the immune system? These are very critical to uncover physiological properties of BACE1 which has been targeting in the brain and also are important to avoid any possible side effects in the immune system. Therefore, study of BACE1 in the T cells is an exciting and brand new area to explore. To investigate the function of BACE1 in T cells , we used the BACE1 knockout mice and also used BACE1 inhibitors to explore the effect of BACE1 knockout or inhibition on T cell function. We found that not only inhibition of BACE1 would inhibit T cell activation, but also we discovered that TCR signaling induces BACE1 expression and causes functional alterations. This observations suggest that BACE1 do play physiological roles in the immune system and might involved in immune diseases. Importantly , these findings will provide guidance for BACE1 inhibitor design to avoid any possible side effects.

Abstract: Growing evidence implicates neuroinflammation as a significant contributor to neurodegenerative disorders, however, the understanding of the relationship between inflammation and disease progression remains unclear. We profiled the gene signature of several neurodegenerative disease mouse models to gain an improved understanding of the neuroinflammatory state within a given model, and to help guide preclinical pharmacodynamic assessment of therapeutic intervention.
Microglia, astrocyte, cytokine, and other pro-inflammatory markers were measured by microfluidic qPCR in the hippocampus, cortex and cerebellum of the transgenic mouse models: J20, APP NL-G-F knock-in, PDAPP, A53T and rTg4510 (n=3-6 each). Animals were assessed at ages where pathology had already been established. All models were compared to age-matched, wild-type mice of an appropriate genetic background. Samples were tested in duplicate for gene expression using Fluidigm DeltaGene assays (133 genes) using the Biomark HD system.
A53T, PDAPP, and rTg4510 mouse cortical and hippocampal tissues showed robust gene expression increases for multiple neuroinflammatory markers profiled, relative to wild-type controls. This included markers of microglia proliferation (*Aif1*, *Trem2*, *Itgam* and *Csf1r*) and activation (*Ctse*, *Cst7*, *Itgax* and *Clec7a*). These models also displayed increased expression of genes for cytokine signaling, lysosomal activation and astrocyte signaling. In contrast, the J20 and APP NL-G-F knock-in models showed less prominent gene expression changes. Ccl subfamily cytokine markers were notably increased, while astrocyte expression was unchanged. Brain regional differences in neuroinflammation signatures were noted within and across the models, and cerebellar tissue showed no significant gene expression changes relative to wild-type controls.
In summary, all models assessed had unique neuroinflammatory signatures with differences in regional expression and fold-changes relative to wild-type controls. Cortical and hippocampal tissues showed an enhancement of cytokine signaling and a robust increase in microglia activation markers.

Abstract: Alzheimer’s disease (AD) is characterized by extracellular plaques composed of Aβ peptide and intraneuronal neurofibrillary tangles composed of tau protein. Beyond tau and Aβ, evidence suggests that neuroinflammation plays an important role in AD pathogenesis. Rare variants in the microglial-expressed Triggering receptor expressed on myeloid cells 2 (*TREM2*) gene increase AD risk 2-4 fold. Compared to the role of TREM2 in influencing Aβ pathology,

few studies have examined the function of TREM2 on tau pathology. Previously our lab showed that TREM2 deficiency attenuated neuroinflammation and neurodegeneration in the PS19 mouse model of tauopathy. Given the emerging role for microglia in tau pathology and tau-mediated neurodegeneration, it will be important to sort out the role of TREM2 in the context of pure tauopathy. To this end, we investigated the impact of the most prominent AD-associated TREM2 variant (R47H) on tau pathology and tau-mediated brain damage using BAC transgenic mouse models expressing human $TREM2^{CV}$ (common variant) or $TREM2^{R47H}$ variant on a TREM2 KO background crossed with the PS19 mice, a model of pure tauopathy. The hypothesis was that $TREM^{R47H}$ results in a partial loss of function that leads to a lower microglial inflammatory response and protects against tau-dependent neurodegeneration. Using immunohistochemical analysis, we first confirmed that $TREM2^{R47H}$-expressing PS19 mice have reduced inflammatory glial activation in the piriform cortex compared to $TREM2^{CV}$ mice. Surprisingly, no change was observed on tau pathology or tau-dependent neurodegeneration between PS19 mice expressing $TREM2^{R47H}$ or $TREM2^{CV}$. These results suggest that the degree of glial inflammation that is suppressed by the $TREM2^{R47H}$ in the presence of tau pathology is not enough to attenuate neuronal loss and brain atrophy. Whether $TREM2^{R47H}$ affects other events relevant to tau-mediated pathogenesis will be important to sort out.

Abstract: Alzheimer’s disease (AD) is a neurodegenerative disease characterized by cognitive dysfunction. One of its pathological hallmarks is the accumulation of amyloid-beta oligomers, which substantially contributes to the synaptic dysfunction and mediates the immune/inflammatory responses in the AD brain. We previously demonstrated a novel role of the signaling of EphA4, a receptor tyrosine kinase, in mediating amyloid-beta-mediated hippocampal synaptic dysfunction. Furthermore, we identified that a small molecule, rhynchophylline, can effectively block EphA4-dependent signaling and restore the synaptic deficits in the APP/PS1 transgenic mouse model of AD. Moreover, rhynchophylline ameliorates the amyloid pathology and microgliosis in the cerebral cortex in APP/PS1 mice. Here, to understand the mechanisms by which the reduction of EphA4 signaling ameliorates the pathological effects of AD progression, we performed microarray analysis to examine the transcriptome changes in the cerebral cortex in APP/PS1 mice treated with rhychophylline. Gene ontology analysis and the top upregulated genes revealed that innate immunity and neuroinflammatory responses are activated in APP/PS1 mice. Accordingly, rhynchophylline ameliorated the upregulation of biological processes such as cytokine secretion as well as the expression of genes (e.g., *spp1* and *Igax*) that are associated with immune/inflammatory responses in the cerebral cortex in APP/PS1 mice. Thus, our results collectively suggest that EphA4 signaling is a critical signaling pathway that mediates the immune responses in AD, making it a novel target for AD therapeutic development.

Abstract: Alzheimer's disease (AD) is the most common form of dementia among the elderly and the number of individuals with AD continues to increase. To develop effective therapeutics in AD, many scientists have been focusing on the development of novel drugs. However, the development of drugs has been known to fail. This failure could possibly be attributed to the administration of the treatment at a late stage in the disease progress. Thus, it is important to establish early diagnosis methods which can predict the risk of AD for effective prevention and treatment. Inflammasome plays a critical role in diverse inflammatory disorders, such as AD. Inflammasome can be activated by various pathogenic insults and induces secretion of IL-1β after cleavage by active caspase-1, an executing protease of the inflammasome complex. Therefore, direct imaging of active caspase-1 *in vivo* may provide enormous advantages for diagnosis, drug discovery, and therapeutic monitoring in AD. Here, we developed an activatable fluorescence probe, comprised of caspase-1-specific cleavable peptide bridging a near-infrared fluorescence dye and a quencher, for visualization of active caspase-1. This novel caspase-1 probe is biocompatible and can be efficiently delivered into cells and tissues, and specifically emit fluorescence upon caspase-1 activation as assessed *in vitro* and *in vivo* inflammatory conditions. We demonstrated efficient *in vivo* imaging of caspase-1 activation in AD. Significant fluorescence emitted from the inflamed sites, as well as their draining lymph nodes, can be detected by macroscopic imaging analysis within 30 min after systemic injection of the probe. This novel synthetic probe could be applied for efficient and rapid detection of caspase-1 activity in a spatiotemporal way by non-invasive imaging and revolutionize the current paradigm for diagnosis and therapeutics in AD.

Abstract: Although many reports have revealed the importance of defective microglia-mediated amyloid β phagocytosis in Alzheimer's disease (AD), the underlying mechanism remains to be explored. Here we demonstrate that neurons in the brains of patients with AD and AD mice show reduction of sphingosine kinase1 (SphK1), leading to defective microglial phagocytosis and dysfunction of inflammation resolution due to decreased secretion of specialized proresolving mediators (SPMs). Elevation of SphK1 increased SPMs secretion, especially 15-R-Lipoxin A4, by promoting acetylation of serine residue 565 (S565) of cyclooxygenase2 (COX2) using acetyl-CoA, resulting in improvement of AD-like pathology in APP/PS1 mice. In contrast, conditional SphK1 deficiency in neurons led to reduction of SPMs secretion and abnormal phagocytosis similar to AD. Overall, these results reveal a novel mechanism of SphK1 pathogenesis in AD that leads to defective microglial phagocytosis due to impaired SPMs secretion, and suggests that SphK1 in neurons has acetyl-CoA dependent cytoplasmic acetyltransferase activity towards COX2.

Title: Interleukin 1 beta mediated inflammation in a tau depositing mouse model

Authors: *A. S. SOLIMAN[1], M. M. ALHADIDY[1], D. J. FINNERAN[1], K. R. NASH[3], D. G. MORGAN[2], M. N. GORDON[4];
[2]Translational Sci. and Mol. Med., [1]Michigan State Univ., Grand Rapids, MI; [3]Mol. Pharmacol. and Physiol., Univ. of South Florida, Tampa, FL; [4]Translational Sci. and Mol. Med., Michigan State Univ. GRRC, Grand Rapids, MI

Abstract: Alzheimer disease is a neurodegenerative disease and the leading cause of dementia. Its pathological hallmarks comprise extracellular insoluble aggregates of amyloid β called plaques and intracellular insoluble aggregates of tau protein called tangles. Furthermore, neuroinflammation is an early event in the disease trajectory that may initiate or propagate

pathology. Interleukin-1 β (IL-1β) is a primary proinflammatory cytokine that has been shown to be implicated in tau phosphorylation and synaptic loss. Hence, we hypothesize that IL-1β-mediated neuroinflammation induces tau pathology and cognitive impairment by stimulating tau phosphorylation and aggregation. Herein, we study IL-1β mediated inflammation in the rTG4510 mouse model and investigate the therapeutic benefit of interleukin 1 receptor antagonist (IL-1Ra).
Temporal changes in IL-1β-mediated inflammation were explored. We quantified mRNA levels of IL-1β and IL-1Ra in the posterior cortex of 2, 4, 6, 9, and 14 mo. rTg4510 by real-time PCR. In addition, western blot and ELISA analyses were performed for IL-1β, IL-1 receptor, IL-1Ra, and the downstream effectors as inducible nitric oxide synthase 2 (iNOS) and nuclear factor κβ p65, as well as kinases known to phosphorylate tau. One-way ANOVA followed by Tukey's post hoc was used for statistical analyses. We observed low IL-1β mRNA levels at 2 and 4 mo. of age followed by a non-significant increase at 6 mo. In contrast, mRNA levels of IL-1β at 9 mo. showed a 9- and 7-fold increase compared to 2 and 4 mo. respectively ($p<0.05$). Surprisingly, IL-1β mRNA level at 14 mo. decreased by 30% compared to 9 mo. Western blot analysis of iNOS showed a similar time course. On the other hand, IL-1Ra protein showed a more linear pattern of increase, with a non-significant 2-fold increase at 9 mo. compared to 4 mo. with larger increases at 14 and 16 mo.
Second, IL-1β mediated inflammation was suppressed by overexpressing IL-Ra. Transfection of cultured cells demonstrated expression and secretion of recombinant DNA constructs. Transfected IL-1Ra blocked IL-1β induced inflammation in vitro using a HEK-IL-1β blue reporter cell line. Effects of recombinant AAV9 overexpressing IL1-Ra on IL1-β-mediated inflammation and tau pathology will be examined after injection into rTg4510 hippocampus and anterior cerebral cortex. These experiments highlight the role of IL-1β-mediated inflammation in tau pathology and the therapeutic potential of IL-1Ra.

Title: Deletion of hematopoietic cell kinase exacerbates amyloid-beta deposits, pre-synaptic protein loss and microglial dysfunction in Tg2576 mice

Authors: *S.-L. LIM[1], D. N. TRAN[2], C. CHEN[2], M. KITAZAWA[1];
[1]Univ. of California, Irvine, Irvine, CA; [2]Univ. of California, Merced, Merced, CA

Abstract: Mounting evidence has shown that microglia plays a key role in modulating neuroinflammation and neuropathology, hence cognitive outcomes in Alzheimer's disease (AD). Recent studies in animal models unveil not only neuroprotective role of microglia by effectively containing and clearing amyloid-beta (Aβ) plaques, but also its potentially detrimental role to synapses and neurons during the disease course. These differences are in part derived from its activation and biological status, cellular signaling and subsequent gene expression profiles. Hematopoietic cell kinase (Hck) is a member of the Src family tyrosine kinases which mediate immunoreceptor-induced phagocytic activation in microglia upon Aβ stimulation. We hypothesize that inactivation of Hck impairs microglial phagocytosis and Aβ clearance, leading to the accelerated buildup of toxic Aβ species and cognitive decline in the mouse model. We have previously shown that the activation of murine microglial/macrophage cells (BV-2) phagocytic activity by Aβ oligomers stimulation was mediated by the Src family tyrosine kinases pathway, and inactivation of the kinases significantly attenuated the phagocytic capacity of BV-2 cells. We have also demonstrated that genetic ablation of Hck in Tg2576 (Tg/Hck-KO) mice resulted in cognitive deficit when compared to age-matched Tg2576, Hck-KO, and wild-type mice as assessed by Morris water maze (n = 9-13). In this study, we quantitatively analyzed Aβ neuropathology in these mice by MSD, western blot and immunohistochemical staining. In correlation with the behavioral study, we found significant reduction of pre-synaptic synaptophysin intensity at the CA3 and overall hippocampal regions in the Tg/Hck-KO mice when compared to Tg2576 mice. However, the genetic ablation did not change post-synaptic PSD95 in these brain regions. While full-length APP and APP processing remained unchanged among all groups, soluble forms of Aβ38 and Aβ40 were substantially elevated and insoluble forms of Aβ38, Aβ40 and Aβ42 were augmented in the Tg/Hck-KO mice. In accordance, $4G8^+$ Aβ plaque burden was elevated in the Tg/Hck-KO mice with significant reduction of $4G8^+$ Aβ plaques internalized in the $CD68^+/Iba1^+$ microglial phagolysosomes. This denotes an impairment of microglial Aβ phagocytic activity owing to Hck deficiency in Tg2576 mice. In addition, significantly higher levels of iNOS and pSyk were expressed in $CD11b^+$ microglial clusters in Tg/Hck-KO mice, signifying induction of inflammatory response upon Hck deletion. Our data suggest that Hck prevents AD neuropathology by promoting microglial phagocytic capacity and suppressing microglial pro-inflammation.

Title: Investigating the relationship between intestinal immune responses and amyloid-beta induced deficits

Authors: *T.-C. HSIEH[1], H.-C. CHIANG[2];
[1]Inst. of Basic Med. Sci., [2]Dept. of Pharmacol., Natl. Cheng Kung Univ., Tainan, Taiwan

Abstract: Emerging evidence indicates that innate immune response is not only involved in the progression of Alzheimer's disease (AD) but also in driving glia cells to clean aggregated Aβ peptides in the brain. The inflammatory response in brain is not only regulated by the local immune response but also the peripheral system. Gut-brain axis usually involves the intestinal microbiota, the immune system, the enteric nervous system (ENS), and the central nervous system (CNS), which displays a complex multidirectional crosstalk. However, whether regulating the intestinal microbiota or the intestinal immune response ameliorates the impairments of Alzheimer's disease is remained unclear. Here, we utilized *Drosophila* AD model, the Aβ42 transgenic fly, and found that pan-neuronal expression of Aβ42 caused gene expression changes within the IMD signaling pathway, an innate immune pathway of *Drosophila,* in the brain and gut compared to the control fly. Downregulated the expression of AttacinA (AttA) either in neurons or gut rescued the Aβ-induced learning deficit. Collectively, overexpression of Aβ42 modulates innate immune response both in the brain and gut. Genetic manipulation of downstream AMPs expression may possess possibility to reverse Aβ-induced deficits.

Title: Characterizing a scalable blunt-force traumatic brain injury model and the injury-induced regeneration in the adult zebrafish

Authors: *J. HENTIG, Jr, M. LAHNE, K. CLOGHESSY, D. R. HYDE;
Biol. Sciences, Ctr. for Stem Cells and Regenerative Med., Univ. of Notre Dame, Notre Dame, IN

Abstract: Traumatic Brain Injuries (TBI) affect 60 million people annually worldwide and contribute to other neurological disorders, such as cognitive decline and stroke. Our goal is to develop a blunt force TBI model that is inexpensive, rapid, and recapitulates the injury seen in humans, in a model organism that exhibits neuronal regeneration. Unlike traditional TBI rodent models, zebrafish potentially fit all these criteria. We modified the well-characterized blunt force TBI method, the Marmarou weight drop, for adult zebrafish. Our modified Marmarou weight drop resulted in a reproducible and scalable mild, moderate, and severe TBI that shares key pathophysiological features found in human TBI, with subdural/intracerebral hematomas, cerebral edema, seizures, visual disruption, and cognitive impairments. Cell death was examined using a TUNEL assay, where we observed a gradient of TUNEL-positive cells across the cerebellum and optic tectum that radiated outward from the impact site, with TBI severity proportional to cell death. To examine the extent of cell death, the TUNEL assay was paired with HuC/D and GFAP immunostaining to label neuronal and glial cells, respectively. We found significantly more neuronal HuC/D-positive cells were TUNEL-positive ($p<0.0001$, n=9) than GFAP-positive glial cells (n.s., n=9). Following severe injury, there was a significant decrease in optical acuity measured by optical kinetic response (OKR) over 3-5 days post-injury (dpi), which returned to near pre-injury conditions by 1-month post-injury ($p<0.01$, n=10). OKR was not significantly decreased in mildly injured fish (n.s., n=10). In response to injury, there was a significant increase in cell proliferation across the brain. At 60 hours post-injury, we observed increased cell proliferation, EdU labeling, at the posterior mesenphalic lamina ($p<0.05$, n=15), mitotic periventricular grey zone (PGZ, $p<0.01$, n=15), and the cerebellar crest, where nestin-positive cells colabelled with EdU ($p<0.01$, n=15 EdU, n=5 nestin/EdU). At 7dpi, all three regions possessed EdU/HuCD-colabeled cells in the PGZ and granular region of the cerebellum. Thus, we developed a TBI model that reproducibly mimics various key aspects of human TBI pathology that exhibited neuronal cell death followed by robust cell proliferation and neuronal regeneration. We will continue to examine these neuronal progenitors, their induction, migration, and differentiation through molecular, genetic, and bioinformatic approaches.

Title: The olfactory bulb of zebrafish regenerates and recovers by 21 days after an excitotoxic focal lesion

Authors: *E. CALVO-OCHOA, C. A. BYRD-JACOBS;
Biol. Sci., Western Michigan Univ., Kalamazoo, MI

Abstract: Unlike mammalian brains, which have a limited capacity to repair following damage, zebrafish effectively repairs brain lesions and constitutively generates new neurons throughout the lifespan, originating from sixteen neurogenic niches. Thus, zebrafish is an excellent model for studying brain repair, regeneration and neurogenesis mechanisms. The olfactory bulb, which contains neurogenic areas, presents extensive neuroplasticity mechanisms to adjust to swiftly changing environmental factors. It has been established that the olfactory bulb of zebrafish recovers after damage to the peripheral olfactory organs. However, the repair and recovery mechanisms of the olfactory bulb following direct injury have not been studied. In this work we establish a new paradigm of focal excitotoxic lesion in the olfactory bulb of zebrafish and investigate the recovery and remodeling of the lesioned olfactory bulb in time. We used adult zebrafish of both sexes and produced a unilateral focal excitotoxic lesion in the right olfactory bulb by injecting 1 µl of 15mM quinolinic acid (QA), while the unlesioned left bulb served as internal control. Next, we assessed several markers of bulbar damage, repair and morphological remodeling following 1, 7, 15, and 21 days post lesion (dpl). For this, we performed histological, immunohistochemical, stereological and morphological analyses of olfactory bulb sections. Our results show that a QA focal excitotoxic lesion greatly damages the olfactory bulb and causes the following: 1) reduction of olfactory bulb volume; 2) severe tissue damage; 3) neuronal death by apoptosis and necrosis; and 4) disruption of olfactory glomerular morphology. We also report that by 21 dpl, lesioned olfactory bulbs are repaired and restored to unlesioned levels: 5) olfactory bulb volume recovers; 6) lesioned tissue presents extensive morphological remodeling; 7) neuronal density is restored; and 8) glomerular structure is reestablished. These results are the first to report a time-course characterization of the regeneration and recovery of the lesioned olfactory bulb in zebrafish, increasing our current understanding of mechanisms of adult brain regeneration and repair following injury.

Abstract: Traumatic brain injury (TBI) is one of the more common forms of injury, affecting millions of individuals around the world each year. Many of these injuries occur in sports events or military operations. The movement of the brain and the resulting forces have been shown to create high amounts of strain within the brain that may differ between axonal tracts and cortical cell layers. Post-mortem analyses of human brain tissue have shown a pattern of pathological outcomes in midline structures and the apex of certain sulci as opposed to the regions adjacent to the gyri. Given that the cingulate sulcus runs adjacent to the corpus callosum, this region may be of particular vulnerability after a traumatic brain injury. Rodents may not be the most appropriate model for TBI-associated pathology as occurs in humans due to their lack of gyrification. In the current work, we explored the utility of a larger, more gyrified pig brain to better represent the dynamical forces the brain experiences during an impact and the biological outcomes. Pig heads were collected from an abattoir and brains were removed within 90 minutes. Whole brains were placed into cold ACSF for 1 hour. After this, 5 mm coronal slabs were collected and subjected to a drop impact from a height of 0.9m at 4m/s. Adjacent slabs from the same brain were used as controls and not subjected to the drop impact. Following impact, the impacted slabs were placed back into bubbling ACSF for 1 hour. One control and one impacted slab were placed into 4% paraformaldehyde and stored at 4°C. The other two slabs (one impacted and one control) were flash frozen using absolute ethanol and dry ice. Fixed tissue slabs were sectioned with a cryostat at 60μm and sections were immunohistochemically stained for microtubule associated protein 2 (MAP-2) and neuronal nuclear protein (NeuN). The MAP2 staining intensity in the cortex appeared lighter in the impacted brains than the controls. This was clearly visible in the sulcus region. The NeuN stain paralleled what was seen with the MAP2 stain. Images showed less NeuN staining in the impacted sections within the sulcus compared to the control sections. These findings shed light on the immediate neural changes that might occur within the sulcus of the brain during an impact using an *ex vivo* pig model of TBI.

Title: Aberrant signal transduction in a novel model of rotational acceleration traumatic brain injury

Authors: *A. UMFRESS[1], D. EPSTEIN[1], A. CHAKRABORTI[2], A. NATARAJAN[3], K. HENSLEY[4], J. A. BIBB[2];
[2]Surgery, [1]Univ. of Alabama at Birmingham, Birmingham, AL; [3]Univ. of Nebraska Med. Ctr., Lincoln, NE; [4]Univ. of Toledo Med. Ctr., Toledo, OH

Abstract: Traumatic Brain injury (TBI) is a prevalent problem with 1.7 million TBI's occurring annually in the United States. In these traumatic brain injuries (TBIs) the head undergoes rapid acceleration and deceleration, resulting in both linear and rotational forces that deform the brain and damage circuitry. While both linear and rotational forces can cause insult, the brain is more sensitive to rotational motion, which introduces shear and tensile forces resulting in diffuse axonal injuries, microvascular insults, or blood brain barrier compromise that develop into more severe or long-lasting effects with less recovery. It is critical that we understand the mechanisms of rotational acceleration-induced TBI. However, there are few reports of reliable or established methods to induce rotational brain injury in preclinical animal models. In order to understand this prevalent problem, we have developed a novel model of mild rotational acceleration TBI. We have characterized this injury model at acute and prolonged time points following repeated mild TBI showing reactive gliosis, calpain protease activation, and neurotoxic signal transduction. We have identified aberrant cyclin dependent kinase 5 (cdk5) activity as a principal perpetrator in cellular death in TBI following glutamatergic excitotoxicity. The Cdk5-activaiting cofactor, p35 is a prime target for calpain. Upon activation, calpain cleaves p35, producing the truncated cofactor p25. The resulting Cdk5/P25 holoenzyme engenders aberrant activity and phosphorylates substrates that mediate neurotoxicity. We screened a library of potential aberrant Cdk5 inhibitors and have selected compounds to test in vivo following TBI. This research is the first step in understanding how rotational TBIs are mediated by aberrant signal transduction, the mechanisms involved, and how treatments targeting this aberrant signaling may be used to improve outcomes for brain injury patients.

Abstract: Traumatic brain injury (TBI) is a multi-faceted ailment resulting from an insult to the head that disrupts the homeostasis of the brain and leads to a variety of deficits and symptoms ranging in severity, from changes in personality to loss of memory or consciousness. Many of these deficits are a result of synaptic damage in addition to changes in neurotransmitter levels. Recent evidence points to D-serine, an endogenous co-agonist for N-methyl-D-aspartate (NMDA) receptors in the hippocampus, as a contributor to synaptic dysfunction and behavioral deficits within the first week after TBI in areas distal to the epicenter of injury that are spared of cell death. D-serine is formed from L-serine by the enzyme serine racemase (SRR), transported mainly by two amino acid transporters (Slc7a10 and Slc1a4), and degraded by the astrocyte-specific enzyme D-amino acid oxidase (DAAO). In naïve (uninjured) conditions, D-serine is mainly synthesized and released by neurons. Following TBI, expression of SRR switches from neurons to astrocytes and results in synaptic dysfunction. I hypothesize that this is the result of a buildup of astrocytic D-serine and increased tonic release from Slc1a4 transporters that contributes to synaptic dysfunction. To investigate this hypothesis, we will utilize 2-4 month C57Bl/6 male mice to first determine a temporal expression profile of D-serine, SRR, Slc1a4, Slc7a10, and DAAO in the hippocampus. mRNA expression of Slc1a4 is significantly increased within the first week following injury, whereas SRR remains constant and DAAO is significantly decreased before restoring to baseline by 7 days post injury (dpi; n=4/group in triplicate). Further, we are analyzing the effect of pharmacologically inhibiting Slc1a4 or Slc7a10 with the small molecule inhibitors L-4-Chlorophenylglycine (L-4-CPG) or BMS-466442 (BMS), respectively, via intraventricular infusion. Following small molecule infusion, we examine fear-conditioned learning and memory (n=14/group) and dendritic spine morphology (n=6/group) at 7 dpi, where we have observed an increase in spine protrusion density and the proportion of mushroom shaped protrusions in CA1 pyramidal neurons following L-4-CPG administration

compared to vehicle in TBI mice. To alleviate off-target pharmacological effects, we have developed transgenic mice to genetically ablate Slc1a4 in a cell-specific manner using the Cre-LoxP system. Together our studies support a role for D-amino acid transporters in regulating astrocytic D-serine release and synaptic damage after TBI.

Title: Sexual dimorphic dysregulation in the hypothalamic-pituitary-adrenal axis after brain injury

Authors: S. W. RIDGWAY[1], Z. E. SWANN[2], C. E. HAIR[1], R. ROWE[1], ***T. C. THOMAS**[1]; [1]Child Hlth., Univ. of Arizona Col. of Med. Phoenix, Phoenix, AZ; [2]Neurosci., Oberlin Col., Oberlin, OH

Abstract: Upwards of 50% of all traumatic brain injury (TBI) results in an endocrinopathy and persisting post-concussive syndrome. Despite these data, the influence of sexual dimorphisms on dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis following TBI have not been studied. The HPA axis regulates circulating glucocorticoid levels, in particular cortisol (corticosterone in rats; CORT), and is mediated by negative feedback through glucocorticoid (GR) receptors. We hypothesized that experimental diffuse TBI incites dysregulation of the HPA-axis, influencing circulating CORT as well as hypothalamic GRs and corticotrophin releasing hormone (CRH) gene expression. We predict that this dysregulation influences neuroinflammatory processes in regions of the brain that are critical for HPA axis regulation and do not demonstrate TBI-induced neuropathology. To test this hypothesis, hypothalamic CRH and GR gene expression, hypothalamic microglial morphology, and plasma CORT levels were evaluated at 7 days following diffuse axonal injury induced by midline fluid percussion injury in young, adult, male and female Sprague-Dawley rats (n=3-8 rats/group/sex). Scientists carrying out experimental assays were blinded to injury status. Extensive measures were implemented to control for stress and diurnal CORT regulation. GR gene expression in the hypothalamus was significantly decreased in injured compared to sham rats, where injury, not sex, accounted for

26% of the variability, respectively ($p<0.05$). These data indicate that males and females both demonstrate some evidence of decreased levels of GR at 7 days post-injury. Decreased levels of GR coincided with lower circulating CORT levels in male rats. Preliminary skeleton analysis of microglial morphology in the paraventricular nucleus of the hypothalamus demonstrate morphological changes indicative of a neuroinflammatory response in male rats, further analysis is ongoing. CRH, GR, and microglial studies are exploratory, however, CORT levels in male rats confirm previously published results. While clinical trials indicate that cycling females are at risk for more post-concussive symptoms in comparison to men, prepubescent girls, and post-menopausal women, the mechanisms mediating these differences are unknown. This injury paradigm provides a potential model by which to study the interaction of axonal injury and sex hormones on HPA regulation and neuroinflammation.

Title: Acute and subacute axonal, neuronal and behavioral changes following repetitive mild traumatic brain injury

Authors: H. ISMAIL[1], L. NASRALLAH[2], F. KOBEISSY[3], *H. J. DARWISH[4];
[1]Anatomy, Cell Biol. and Physiol. Sci., [2]Hariri Sch. of Nursing, [3]Biochem. Dept., [4]Anatomy, Cell Biol. and Physiol. Sci. and Hariri Sch. of Nursing, American Univ. of Beirut, Beirut, Lebanon

Abstract: <u>Introduction</u>: Mild Traumatic Brain Injury (mTBI), represents 70% of all TBIs worldwide. Repetitive mTBIs; such as in football players and boxers, makes the person at higher risk of developing neuro-degenerative diseases in the future. Axonal injury and neuronal damage are assumed to contribute to cognitive deficits following r-mTBI. Phosphorylated Neurofilament Heavy (pNFH) is elevated post-TBI and linked to Alzheimer's disease (AD). We hypothesize that in a mouse model of repetitive mild traumatic brain injury (r-mTBI), pNFH will be elevated and axonal and neuronal damage will be correlated with impaired learning and memory. Aims: 1. To measure the extent of axonal injury, by quantifying the amount of pNFH in the serum, following r-mTBI 2. To evaluate acute and sub-acute novel object and location recognition memory and spatial learning and memory, following r-mTBI 3. To assess for acute and subacute

neurodegeneration and astrogliosis post-r-mTBI **Methods:** C57BL/6 mice (6-8 weeks) were randomly assigned into two groups: A sham group (n=23) underwent anesthesia and incision 3 times, once every 24 hours. And an experimental r-mTBI group (n=24) underwent 3 closed head injuries, using the closed controlled cortical impact model, once every 24 hours. All the animals were tested at 48 hours post-injury and half of them at 7 days post-injury. To assess learning and memory, novel object and location recognition memory test was conducted at 48 hours and 7 days. To explore their spatial learning and memory, Morris water maze test from day 3 to day 7 was performed. ELISA was used to quantify pNFH in the serum. Immunofluorescence staining against Fluorojade-C was used to measure neurodegeneration in the cortex and the Dentate Gyrus (DG). Immunohistochemistry staining against Glial Fibrillary Acidic Protein (GFAP) was used to examine the astroglial injury that follows the trauma. **Results:** We found significant recognition memory and spatial learning deficits at 48 hours that persisted up to 7-days post r-mTBI. Partial recovery of deficits was noted on the 7th-day post-injury. Neurodegeneration was consistently present in the cortex at 48 hours and 7 days post-injury. Neuro-degeneration in the DG was greater (double) at 48 hours than at 7 days post-injury. pNFH was detected in the serum of injured animals at 48 hours but not at 7 days. Axonal injury and neurodegeneration in the DG followed the same temporal pattern of the behavioral changes. **Conclusion:** We found neurobehavioral deficits, accompanied by axonal injury and neurodegeneration post-r-mTBI. All deficits were more prominent at 48 hours, although they diminished by the 7th-day-post-injury, they did not resolve completely.

Title: The effect of binge alcohol and traumatic brain injury on hippocampal neural precursor cell proliferation and survival

Authors: *S. T. TON[1], S.-Y. TSAI[1], J. Y. WU[1], J. P. GERLING[1], R. P. NOCKELS[2], G. L. KARTJE[1];

Abstract: We determined the effects of traumatic brain injury (TBI) and binge alcohol on neural precursor cell (NPC) responses in the dentate gyrus (DG) of the hippocampus.
Rats underwent binge alcohol (3g/kg/day) by gastric gavage for 3 days prior to TBI. We assessed the DG NPC response by utilizing the proliferation marker BrdU along with other markers for neurogenesis such as Doublecortin. We found that TBI injury alone significantly increased DG proliferation 7 days post injury. However, a combined binge alcohol and TBI regimen resulted in decreased DG proliferation at 7 days post-TBI. Long-term survival of DG hippocampal cells was also assessed at 6 weeks post-TBI. We found that TBI did not affect the overall survival of $BrdU^+$ cells, but binge alcohol reduced the number of $BrdU^+$ cells that survived.
Using an AAV2/4 viral vector to increase the expression of brain derived neurotrophic factor (BDNF), we are currently examining how this trophic factor may influence DG neurogenesis in relation to binge alcohol and TBI.
Taken together, these results suggest that TBI and binge alcohol separately increased short-term DG proliferative responses but in combination, attenuated DG proliferation. However, binge alcohol alone decreased the number of surviving DG cells long term. These results point to important consequences for public health as alcohol misuse conditions such as binge drinking are currently on the rise.

Title: Predator odor exposure exacerbates traumatic brain injury outcomes in rats

Authors: *E. A. FUCICH, Z. F. STIELPER, S. F. MOZINGO, N. W. GILPIN, P. E. MOLINA; Physiology, Alcohol and Drug Abuse Ctr. of Excellence, Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA

Abstract: Traumatic brain injury (TBI) is widespread, undertreated, and leads to persistent neurological and neurobehavioral dysfunction. TBI frequently occurs following traumatic stressful events, like military combat, vehicular accidents, or domestic violence. Stress is associated with pathophysiological and behavioral changes that overlap with those produced by TBI. However, whether stress worsens TBI-related outcomes is not understood. This study tested the hypothesis that pre-TBI exposure to predator odor stress exacerbates TBI-induced physiological and neurobehavioral changes. Adult male Wistar rats all received a 5mm craniotomy above the left sensorimotor cortex. After 3-7 days recovery from surgery, rats received a 15-min bobcat urine exposure or no odor control treatment and 24 hours later received mild to moderate TBI (~2 atm) via fluid percussion or sham (anesthesia only) procedures. Physiological changes (respiratory rate, righting reflex, weight gain), neurological severity and neurobehavioral scores, and anxiety-like behavior (elevated plus-maze) were measured following injury. Stress+TBI animals exhibited decreased respiratory rate immediately following injury and decreased weight gain relative to sham controls. Stress+TBI animals also had increased neurological severity and neurobehavioral scores compared to stress or TBI alone 1 day post-injury. At 7 days post-TBI, stress+TBI animals exhibited elevated neurobehavioral scores and trends toward increased anxiety-like behavior relative to sham controls. These results suggest that pre-injury stress exposure may exacerbate post-TBI physiological and behavioral impairments, possibly delaying recovery from injury. Further investigation of neurobiological mechanisms underlying TBI outcomes that are worsened in stressed animals could help identify clinically relevant treatments for co-morbid TBI and stress-related pathology.

Title: Reductions in hippocampal SNARE protein in heterozygous cysteine-string protein alpha knock-out mice after traumatic brain injury

Authors: *S. W. CARLSON, D. EDINBORO, Y. LI, J. HENCHIR, C. DIXON;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Impairments in cognitive function up to one year and longer after traumatic brain injury (TBI) are observed in patients and recapitulated in experimental models of TBI. Previous work implicates neurotransmitter release deficits as a contributor to cognitive impairment after TBI, but additional work is warranted to better understand the mechanisms underlying this dysfunction. Neurotransmitter release is facilitated by the formation of the soluble N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) complex. Cysteine-string protein alpha (CSPα) is a chaperone important for SNARE complex formation. We previously showed reduced SNARE complex formation and CSPα abundance after TBI. To test the importance of CSPα on neurobehavioral function and SNARE complex formation after TBI, CSPα heterozygous (CSPα HET) knock-out mice were utilized. We hypothesized CSPα HET mice exhibit reduced SNARE complex formation and exacerbated neurobehavioral dysfunction post-injury. CSPα HET and wild-type (WT) mice were subjected to controlled cortical impact (CCI) injury (1.8mm, 6 m/s, 150msec dwell) or sham surgery. Two cohorts were generated to test the effects of genetically reduced CSPα at 2 weeks (n=9-10/group) and 3 months (n=10/group) following CCI. In the 2wk cohort, motor performance on 1-5d post-injury revealed no differences between groups. Assessment of spatial acquisition in the Morris water maze task on 9-13d post-injury showed a significant injury effect ($p<0.05$), independent of genotype. Evaluation of spatial memory performance at 14d post-injury revealed no difference between groups. Immunoblotting revealed reduced hippocampal CSPα abundance ($p<0.01$) and reduced SNARE complex formation ($p<0.05$) in sham and CCI-injured CSPα HET mice compared to sham and CCI-injured WT mice at 2wk post-injury. In the 3mo cohort, a significant injury effect ($p<0.05$) was observed in spatial memory performance, independent of genotype. While genetic reduction of CSPα did not alter neurobehavioral function at 2wk or 3mo post-injury, immunoblot data revealed reduced SNARE complex formation. Future work will examine the efficacy of therapeutic interventions, dependent upon CSPα, to promoting SNARE complex formation.

Title: Sex differences in cognitive deficits following repetitive mild TBI in adolescent rats

Authors: T. A. MCCORKLE, L. L. GIACOMETTI, S. KHURANA, *R. RAGHUPATHI; Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Sports-related concussions result in acute and chronic behavioral deficits in high school- and college-age athletes who participate in contact sports. Clinical data suggests that male and female athletes suffer different types of behavioral problems and exhibit a different trajectory of behavioral recovery after the concussion. In this study we compared the effect of single and repetitive mild traumatic brain injuries (TBI) in adolescent (35-40-day old) male and female Sprague-Dawley rats. Mild TBI was induced by subjecting anesthetized animals to an impact on the intact skull centered over the midline suture behind bregma (2.5mm depth at 5.5m/s velocity); sham-injured animals were surgically prepared but did not receive injury. On days 7-11 following injury/surgery, sham-and brain-injured animals were tested for working memory using the Morris Water Maze as previously described (Hamm et al., J Neurotrauma, 13 (1996) 317-323). Sham-injured male rats had significantly shorter latencies in the second trial compared to the first, whereas their brain-injured counterparts did not significantly differ in performance between the first and second trials on any of the test days suggestive of an injury-induced working memory deficit ($p<0.02$ between sham- and brain-injured rats). In contrast, both sham- and brain-injured female rats performed significantly better in the second trial than the first indicative of intact working memory. A separate group of male and female rats were subjected to 3 episodes of mild TBI (2.0mm depth at 5.5m/s velocity) every 3 days; sham-injured rats were anesthetized and surgically prepared on each of the "injury" days but did not receive impacts. On days 3 and 8, sham- and brain-injured male and female rats were tested for short-term working memory using the Novel Object Recognition (NOR) task. On day 3, male brain-injured rats spent significantly more time with the novel object compared to their sham-injured counterparts ($p<0.05$) suggestive of perseverative behaviors; no differences in NOR memory were observed between sham- and brain-injured rats on day 8 post-injury. Female brain-injured rats could not differentiate between the familiar and novel objects on day 3 post-injury suggestive of a deficit in NOR; by day 8, the brain-injured rats were similar to the sham-injured rats in the NOR test. Together these data suggest that either single or repetitive mild TBI result in cognitive deficits in the acute post-traumatic period. However, the nature and type of these deficits appear to be dependent on the sex of the animal and the type of test used.

Title: Pain (nociceptive) input increases lesion site hemorrhage after traumatic brain injury

Authors: *P. BEAN, M. K. HENWOOD, D. T. JOHNSTON, J. W. GRAU;
Psychological and Brain Sci., Texas A&M Univ., College Station, TX

Abstract: Traumatic brain injury (TBI) is a major cause of death and disability in the United States. Many of these injuries are the result of events such as car accidents, combat violence, and falls, and often result in additional injuries (polytrauma) that serve as a source of pain (nociceptive input). Previous work in our laboratory has shown that nociception is detrimental to recovery after spinal cord injury (SCI) and leads to increased lesion site hemorrhage. It is not known whether these findings generalize to other neurologic insults. The present study sought to determine whether nociceptive input expands the area of hemorrhage after TBI. Male Sprague-Dawley rats (N=12) weighing between 275-300 grams were given either a moderate traumatic brain injury in the right parietal region centered over the primary motor cortex, using the Leica One controlled cortical impact device (2mm impactor tip, 4 m/s, deformation depth 3mm), or underwent a sham surgery. A day later, the irritant capsaicin (3%, 50 ml) or vehicle was applied to the contralateral hindpaw via a subdermal injection. Behavioral tests, including cylinder test and catwalk gait analysis, were performed at zero and three hours post nociceptive input. Animals were then euthanized, perfused with 4% paraformaldehyde, and brain tissue was collected. Collected tissue was sectioned and stained with hematoxylin and eosin to quantify hemorrhage extent at the lesion site, and sections were imaged. Images were analyzed for hemorrhage, quantified by percent area of hemorrhage, by a blinded experimenter using Image J software. The results showed that nociceptive input increased the area of hemorrhage at the injury site ($p < .05$) and produced an acute disruption in behavior. Pain-induced hemorrhage was limited to the injured hemisphere. On-going work is examining the circumstances under which pain input fuels hemorrhage after TBI, how it affects behavioral function, and the neurobiological processes involved.

Title: Spreading depolarizations in mild traumatic brain injuries: Blood flow, behavior, cognition, and attention

Authors: C. J. MEHOS[1], H. ZHANG[1], J. M. PACHECO[1], C. STRATTON[1], A. HINES-LANHAM[1], ***R. A. MORTON**[2];
[2]Neurosciences, [1]Univ. of New Mexico, Albuquerque, NM

Abstract: It is estimated that there are 3.8 million sport related concussions per year, in the United States. Dizziness, headaches, balance abnormalities, and/or difficulties concentrating are common short-term symptoms lasting a few days after a concussion. Proper diagnosis and treatment of concussions or mild traumatic brain injury (mTBIs) are severely lacking because we do not fully understand the cellular and molecular effects that underlie these injuries. Our laboratory as well as others have shown that spreading depolarizations (SDs) are initiated by mTBI-like impacts (Bouley et al., 2018). Using a closed skull impact model, we have shown that these impacts result in concussion-like behavior that includes a prolonged period of immobility immediately following the impact. These periods of immobility are correlated with the presence of a SD but do not result in cell death or astrocyte activation. However, it remains unclear if the SD is associated with any short-term behavioral, cognitive, or attention deficit known to accompany these injuries. We utilized a home cage monitoring system and touchscreen based operant tasks test for behavioral, cognitive and/or attention deficits in the week following a mTBI-like injury. Data from our laboratory and others have shown that the SD produces a 30% to 40% reduction in cerebral blood flow that returns to baseline levels within about 90 minutes. Our preliminary data indicates that although the cerebral blood flow recovers to baseline levels within 90 minutes, it is highly variable in the days that follow. Studies are currently underway using a touchscreen based 5-choice serial reaction time tasks paired with a go/no go paradigm testing cognitive and attention deficits 4 hours post-impact and subsequent days. Overall, our data suggests that SDs may be associated with short-term behavioral, cognitive, and attention deficits in mTBIs.

Title: Deciphering the cerebrovascular link between traumatic brain injury and Alzheimer's disease

Authors: *Y. WU[1], J. ZENG[2];
[2]Physiol. & Neurosci., [1]USC, Los Angeles, CA

Abstract: Background: Alzheimer's disease (AD) is an age-related progressive neurodegenerative condition manifesting amyloid plaque and neurofibrillary tangle formation, and cognitive impairment. Traumatic brain injury (TBI) is considered the most robust environmental risk the factor for Alzheimer's disease. Piling evidence has demonstrated that TBI triggers multiple neurodegenerative cascades including axonal and dendritic damages, excitatory toxicity, neuroinflammation, and cell death, as well as cerebrovascular impairment, such as local edema, blood flow reduction and breakdown of the blood-brain barrier (BBB). More importantly, TBI also exacerbates certain pathological events that are specific to Alzheimer's disease, including the brain over-production and accumulation of beta-amyloid. Brain deposition of amyloid and its associated pathologies are consequences of imbalanced amyloid production and clearance during aging. However, whether TBI impairs amyloid clearance pathways associated with brain vasculature has not been investigated.**Aim**: Investigating the relation between vascular impairment induced by TBI and amyloid-related pathogenesis in AD. **Research Strategy**: In our study, we established a mild TBI mouse model, which represents the majority of TBI survivors and recapitulates a body of symptoms including vascular damages and amyloid-related pathologies. And we assessed motor and cognitive impairment based on behavioral tests, determined brain clearance of Aß and AD pathogenesis using in vivo microdialysis, biochemical analysis, ELISA and immunohistochemistry. **Results**: Our results showed that mild TBI induced BBB breakdown and cerebral blood flow reduction. Mild TBI also structurally altered the vascular basement membrane and perivascular space, which impaired brain clearance of β-amyloid (Aβ) through the vascular routes and accelerated amyloid pathologies and cognitive impairment in a mouse model of AD. Our data demonstrated the key role of vascular impairment in TBI pathogenesis and its link between TBI and Alzheimer's disease, indicating that restoring vascular functions might be beneficial for patients with mTBI and might prevent the development of AD.

Title: Long term spatial learning deficits after mild traumatic brain injury

Authors: *N. L. EMMITT[1], V. D. KRISHNA[1], A. CRANE[2], M. CHROSTEK[3], A. W. GRANDE[4], W. C. LOW[4], M. C.-J. CHEERAN[1];
[1]Vet. Population Med., Univ. of Minnesota, St. Paul, MN; [2]Stem Cell Inst., [4]Neurosurg., [3]Univ. of Minnesota, Minneapolis, MN

Abstract: The incidence of traumatic brain injury (TBI) in 2014 increased by 53% since 2006, with approximately 2.87 million people affected with TBI's that led to hospitalization, ER visits, or death. Mild TBI accounts for 69-90% of all brain injuries. Though acute impairments after mild TBI are minor, long-term sequela like increased risk of Parkinson's Disease, Alzheimer Disease, and depression are evident. To investigate if inflammation due to mild TBI is linked to cognitive impairments, we designed experiments to evaluate the changes in neuroimmune responses to mild TBI in 9-week-old female C57bL/6 mice at 3, 7, 14 and 30 days post injury by flow cytometry. Mild TBI was induced with a controlled cortical impactor centered over the primary and secondary motor cortices (velocity=4m/s, depth=1mm, dwell=100ms). Motor deficits were assessed using a beam walk test at 3, 7, 14, and 30 days post TBI while spatial learning deficits were evaluated on a Barnes maze at 30 days post injury. Minor motor deficits were observed in mice with TBI on the beam walk test when precise foot placement was needed to cross the beam. This deficit resolved at 14 days post TBI. However, on the Barnes maze these animals showed spatial learning deficits both during the training period and probe trial. For the training periods in Barnes maze, mice were tasked with identifying an escape hole. On training day 4, mice that had TBI took longer to complete the maze and traveled larger distances to get there compared to sham injured mice. At the probe trial, where the escape hole is taken away, mice with TBI spent less time in the goal zone and much more time in the opposite zone than those with sham injury. The neuroinflammatory response was dominated by neutrophils and macrophages at 3 days post injury with activation markers Ly6c, MHCII and CD86 upregulated on macrophages. The numbers of infiltrating macrophages and neutrophils returned to levels in sham-injured mice by 7 days post TBI, though CD86 remained upregulated in the remaining macrophages through 30 days post TBI. Microglia were also activated at 3 days post TBI with

upregulation of CD86, but returned to control levels at 7 days post TBI. These results show that in mild TBI spatial learning deficits are present in mice even after key markers of neuroinflammation have returned to baseline levels. This suggests that though the initial injury causes mild motor deficits that resolve quickly, the long-term cognitive defects from a mild TBI are present after the initial inflammatory response subsides.

Title: The point mutation of the C152 site in ubiquitin C-terminal hydrolase L1 attenuates axonal injury and promotes functional recovery in mice after traumatic brain injury

Authors: *Z. MI[1,4], H. LIU[1,4], M. E. ROSE[1,4], X. MA[2,3,4], E. C. DIXON[2,3,4], S. H. GRAHAM[1,4]; [1]Neurol., [2]Neurosurg., [3]Critical Care, Univ. of Pittsburgh, Pittsburgh, PA; [4]Geriatric Res. Educ. and Clin. Ctr., VA Pittsburgh Healthcare Syst., Pittsburgh, PA

Abstract: Diffuse axonal injury is a major component of the motor and cognitive sequelae of traumatic brain injury (TBI). Many acute treatment strategies have targeted neuronal cell death mechanisms after TBI, but theseapproaches have not been successfully translated. Ubiquitin C-terminal hydrolase L1 (UCHL1) is a multifunctional protein that is selectively expressed in neurons throughout brain at high levels. UCHL1 may play an important role in axonal and synaptic function. Preservation of axonal integrity and synaptic function play a pivotal role in restoration of motor and cognitive function after TBI. A variety of free radical and reactive lipids species are produced after TBI including cyclopentenone prostaglandin (CyPg) derivatives such as Δ12-PGJ2 and 15-deoxy-Δ12,14-prostaglandin J2 (15d-PGJ2). Binding of 15d-PGJ2 to UCHL1 unfolds the enzyme and results in protein aggregation. Mutation of the C152 cysteine of UCHL1, but not the other five cysteine residues in UCHL1, prevents the unfolding of the protein after CyPg treatment. To investigate whether the binding of CyPgs to the C152 site of UCHL1 is important in the pathogenesis of TBI, we constructed a knock-in mouse bearing a C152A mutation in UCHL1 (UCHL1-C152A). UCHL1-C152A or wild type (WT) mice were subjected to the controlled cortical impact (CCI) model of TBI and sacrificed at 1 and 7 d for amyloid precursor protein (APP) immunohistochemistry to detect axonal damage. Hippocampal samples

were collected for western blot detection of ubiquitin proteasome pathway (UPP) and autophagy markers 1 d after CCI, and motor testing was performed on days 1-5 post injury. Axonal injury was quantified by immunostaining with anti-APP antibody and counting axonal swellings, beads and bulbs in a 400 µm by 400 µm field in thalamus. There were significantly fewer morphologically injured axons in thalamus 24 h and 7 d after CCI in UCHL1-C152A mice than in WT controls. There was significantly reduced expression of K48-linkage ubiquitin (Ub) proteins in hippocampus of UCHL1-C152A mice than in WT controls, but no significant changes in K63-linkage Ub or poly-Ub proteins after CCI. The UCHL1-C152A mice had significantly improved motor performance on the beam balance test than WT after TBI; sham-operated controls exhibited no difference between groups. These results suggest that binding of reactive lipids to the C152 site inhibits the UPP in neurons and plays a significant role in axonal and dendritic injury, and motor dysfunction after TBI.

Title: Aged rats have an altered immune response and worse outcomes after traumatic brain injury

Authors: *M. SUN[1], R. BRADY[1,2], P. CASILLAS-ESPINOSA[1,2], D. WRIGHT[1], B. SEMPLE[1,2], S. MCDONALD[1], R. MYCHASIUK[1], H. KIM[3], C. SOBEY[3], T. O'BRIEN[1,2], A. VINH[3], S. SHULTZ[1,2];
[1]Monash Univ., Melbourne, Australia; [2]The Univ. of Melbourne, Melbourne, Australia; [3]La Trobe Univ., Melbourne, Australia

Abstract: Initial studies suggest that increased age is associated with worse outcomes after traumatic brain injury (TBI), though the pathophysiological mechanisms responsible for this remain unclear. Immunosenescence (i.e., dysregulation of the immune system due to aging) may play a significant role in influencing TBI outcomes. This study therefore examined neurological outcomes and immune response in young-adult (i.e., 10 weeks old) compared to middle-aged (i.e., 1 year old) rats following a TBI (i.e., fluid percussion) or sham-injury. Rats were euthanized at either 24 h or one-week post-injury to analyze immune cell populations in the brain and periphery via flow cytometry, as well as telomere length (i.e., a biomarker of neurological

health). Behavioral testing, as well as volumetric and diffusion-weighted MRI, were also performed in the one-week recovery rats to assess for functional deficits and brain damage. Middle-aged rats had worse sensorimotor deficits and shorter telomeres after TBI compared to young rats. Both aging and TBI resulted in worse cognitive function and reduced cortical volume. These changes occurred in the presence of fewer total leukocytes, fewer infiltrating myeloid cells, and fewer microglia in the brains of middle-aged TBI rats compared to young rats. These findings indicate that middle-aged rats have worse functional deficits, decreased cortical volume, and shorter telomeres after TBI than young rats, and this may be related to an altered neuroimmune response. Although further studies are required, these findings have important implications for understanding the pathophysiology and optimal treatment strategies in TBI patients across the life span.

Title: Entinostat improves acute neurological outcomes after intracerebral hemorrhage

Authors: *S. SUKUMARI RAMESH, F. BONSACK;
Pharmacol. and Toxicology, 1120 15TH STREET, Augusta, GA

Abstract: Intracerebral hemorrhage (ICH) or hemorrhagic stroke is a major public health problem with no effective treatment. Entinostat is a class 1 histone deacetylase inhibitor (HDACi) and in a cell-free system, Entinostat inhibited class 1 HDAC enzymes, HDAC1, HDAC2 and HDAC3 with IC50 of 0.46, 1.29 and 1.57 micromoles, respectively. Given the role of epigenetic mechanisms in the pathophysiology of ICH, we tested the hypothesis that Entinostat attenuates neurodegeneration and improves neurobehavioral outcomes after ICH. To address the hypothesis, we employed a preclinical mouse model of ICH and Entinostat was administered intraperitoneally one-hour post-ICH. Entinostat treatment augmented histone H3 acetylation in the ipsilateral striatum and significantly reduced the number of degenerating neurons and the expression of cleaved caspase-3 (a marker of apoptotic cells) after ICH in comparison to vehicle-treated controls, emphasizing the efficacy of HDAC inhibition in

attenuating neuronal death after ICH. Further, expression of proinflammatory microglial/macrophage marker, CD16/32 was remarkably reduced in Entinostat treated group in comparison to control. Of note, Entinostat treatment significantly improved hematoma resolution and acute neurological outcomes after ICH. Moreover, Entinostat significantly reduced hemin or thrombin-induced release of proinflammatory cytokines from a murine macrophage cell line, Raw 264.7. Altogether, the data implicate the potential of class1 histone deacetylase inhibitor, Entinostat in improving acute neurological function after ICH warranting further investigation.

Title: Is oxytocin effective in ameliorating the social deficits of neonate traumatic brain-injured rats in adolescence and adulthood?

Authors: A. M. RUNYAN[1], D. LENGEL[2], ***J. W. HUH**[3], R. RAGHUPATHI[4];
[2]Neurobio. & Anat., [1]Drexel Univ., Philadelphia, PA; [3]Children's Hosp. of Philadelphia, Philadelphia, PA; [4]Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Social behavioral deficits are often an overlooked facet of traumatic brain injury (TBI) outcomes. New clinical data shows children who suffer a TBI develop social problems later in life. Here we investigated social outcomes in adolescence and adulthood after TBI in neonate rats. Male and female rat pups at post-natal day 11 were anesthetized and received an impact (5m/s, 3mm depth) over the left lateral hemisphere; sham-injured animals were surgically prepared but did not receive an impact. Social behavior, including sociability and social novelty were measured via a three-chamber test in adolescence (4 weeks post-TBI, 39-45 days old, sham N=15, injured N=20) and adulthood (8 weeks post-TBI, 67-75 days old, sham N=6, injured N=7). Sociability was assessed by the amount of time the test rat spent sniffing an empty cup in one chamber compared to a cup with a live rat in a separate chamber. In adolescence and adulthood both sham- and brain-injured rats spent more time with a live rat compared to an empty cup ($p<0.001$), indicative of intact sociability. Social recognition/novelty was assessed by the time spent sniffing a “familiar” rat in one chamber compared to a “novel” rat placed in a separate chamber. Adolescent and adult sham-injured animals spent more time sniffing the novel

rat over the familiar rat indicating intact social recognition/novelty. However, in adolescence brain-injured rats spent about equal time sniffing both the familiar and the novel rat, suggestive of a social recognition/novelty deficit. This phenotype changed in adulthood wherein brain-injured rats preferred to spend more time sniffing the familiar rat compared to the novel rat ($p<0.05$) suggesting a recovery in social recognition, but an impairment in social novelty. Interestingly, these behavioral changes occur in the absence of deficits in the novel object recognition test at both ages suggestive of the social component of these behaviors rather than a cognitive deficit. All behavioral effects were independent of sex. The neuropeptide oxytocin has been implicated in regulating social behavior. Intranasal administration of either oxytocin (20μg/kg) or saline in adolescent sham-injured animals did not affect their preference for the novel rat although oxytocin administration increased the overall sniffing time. Oxytocin administration to adolescent brain-injured rats improved their social recognition/novelty behavior. Ongoing work seeks to define the mechanism of action of oxytocin in regulating social behaviors in brain-injured animals.

Title: Testosterone recovers chronic vestibular impairment following repeat mild traumatic brain injury

Authors: *A. SEGISMUNDO[1], E. WESTFALL[1], A. BOLDUAN[1], D. G. WALLACE[2], D. A. KOZLOWSKI[3], E. B. STUBBS[4], E. FOECKING[1];

Abstract: Traumatic brain injury (TBI) is defined as the impact of an external force to the head and has quickly become a major public health concern. Vestibular symptoms, one of the most common complaints following TBI, and hypogonadism occur acutely following a single TBI and may persist chronically. Vulnerable populations such as military personnel are at an increased risk for repeat mild TBIs (rmTBI), which has been shown to exacerbate impairment. Our lab has previously indicated a neuroprotective role of testosterone (T). Loss of T following TBI disrupts hormonal rhythms and prevents neuroplasticity that is required to repair damage at the time of injury, which may induce greater chronic vestibular impairment. Here, we first sought to create a

clinically relevant rmTBI animal model with chronic vestibular deficits. Using this model, we tested whether T can recover chronic vestibular dysfunction.
TBIs were performed on Long Hooded male rats five times, each spaced 48 hours apart, using an electromagnetic controlled cortical impactor. Sham TBI animals did not receive impact. Animals were subdivided into castrated or gonadally intact, creating 4 separate groups. Castration was performed to remove endogenous T to simulate chronic hypogonadism in a subset of rmTBI patients. Sham surgery animals were incised but gonads were not removed. Vestibular dysfunction was detected by a battery of five behavioral tests. Tests were scored out of 2 points, with the medians of each test contributing to a mean total vestibular score. Higher scores indicated greater vestibular dysfunction. Animals were tested at 1 day, 1 week, and 1 month post rmTBIs to chronicle development of vestibular dysfunction. To test the therapeutic effects of T, half of the animals of each group received T replacement via subcutaneous silicon capsules in the nape of the neck five weeks post TBI #5.
At 1-month post TBI #5, a significant difference was found between all groups, with TBI intact and TBI castrated animals exhibiting the greatest vestibular deficiency scores. Following T treatment, vestibular scores did not improve at 1-week post treatment, but TBI T treated animals were insignificant compared to sham TBI animals at 1-month post treatment. Untreated TBI animals exhibited persistent chronic vestibular deficit at all time points. The therapeutic effects of T continued 6 months post TBI. Therefore, T replacement following TBI induced hypogonadism should be considered as a potential therapeutic strategy for recovery of chronic vestibular dysfunction.
We would like to thank the support of the Loyola University Department of Otolaryngology: Head and Neck Surgery for funding this research.

Title: Snake venom pre-conditioning attenuates neuroinflammation and intraoperative hemorrhage via PLA2/5LOX/LTC4 synthase cascade and PLA2/COX1/TXA2 cascade respectively in a surgical brain injury rat model

Authors: *Z. D. TRAVIS[1], P. SHERCHAN[2], W. KELLN[3], W. K. HAYES[3], A. COOPER[4], J. H. ZHANG[2];

[1]Sch. of Med., Loma Linda Univ. Children's Hosp., Loma Linda, CA; [2]Physiol., [3]Biol., [4]Anat., Loma Linda Univ. Hlth., Loma Linda, CA

Abstract: Inflammatory preconditioning is a mechanism in which exposure to small doses of inflammatory stimuli prepares the body against future massive insult by activation of endogenous protective responses. PLA2/5LOX/LTC4 synthase axis is an important inflammatory signaling pathway that has been noted to increase post-operative complications. *Pseudechis papuanus* venom contains 90.2% secretory PLA2 of its dry weight. The remaining 9.8% of the venom is composed of 3FTXs, SVMPs, CRISPs, and LAAO. Because of the protein composition, the venom causes neurotoxicity, hemolysis pulmonary inflammation, and edema. We investigated whether purified *P. papuanus* venom preconditioning (VPC) reduces surgical brain injury (SBI) induced neuorinflammation via activating the PLA2/5LOX/LTC4 synthase/LTE4 cascade as well as attenuating intraoperative hemorrhage by increasing platelet aggregation via PLA2/COX1/TXA2 cascade using a partial frontal lobe resection SBI rat model. Sublethal doses of venom were injected subcutaneously three consecutive days prior to SBI. We observed that VPC significantly reduced edema and improved neurological function 24 h and 72 h after SBI. Furthermore, our long-term study showed an increase in neurological function 30 days after SBI. The VPC regime also significantly reduced intraoperative bleeding, while the sublethal dose caused no skin inflammation at the injection site and no other toxic effects. These findings suggest that VPC reduces neuorinflammation, intraoperative hemorrhage, and improves neurological outcomes after SBI by activating the PLA2/5LOX/LTC4 synthase and PLA2/COX1/TXA2 cascade respectively. Purified PLA2 VPC may be a beneficial therapy to reduce post-operative neuorinflammation and intraoperative hemorrhage complications from brain surgeries.

Title: Melanocortin agonist reduces microglial activation and neuroinflammation following experimental traumatic brain injury

Authors: *L. SIEBOLD[1], J. ABDALA[2], B. TONE[3], B. BARTNIK-OLSON[4], B. HOLSHOUSER[4], J. FIGUEROA[1], S. ASHWAL[3], C. G. WILSON[2];

Abstract: Traumatic brain injury (TBI) is a leading cause of mortality/morbidity and is associated with chronic neuroinflammation. Melanocortin receptor (MCR) agonists (e.g., ACTH or adrenocorticotropic hormone) that target MC3R/4R ameliorate inflammation and provide a novel therapeutic approach. Following TBI, quiescent microglia become activated resulting in anti and pro-inflammatory responses and morphological changes. We examined the effect of Cosyntropin (synthetic ACTH) administration on microglial activation in a rodent TBI model. We hypothesized that Cosyntropin administration would reduce inflammation and microglial activation following experimental TBI. We used a rodent model of CCI randomized to 4 groups: sham-vehicle, sham-Cosyntropin, CCI-vehicle, and CCI-Cosyntropin. Subcutaneous injections of Cosyntropin (West Therapeutic Development; Grayslake, IL) were given for 7 days following injury. Microglia activation was quantified based on morphology. Sectioned brains were immunostained (Iba1) and imaged followed by morphological quantification with *FIJI* and *FracLac for ImageJ*. Parameters included cell area, fractal dimension, circularity, and cell perimeter and density. Cytokine expression, including TNF-alpha, TGF-beta, IL1beta and IL-10, was compared between groups. CCI animals exhibited increased microglia in the lesion site with no difference in cell count between vehicle and treated. Microglia from CCI animals exhibited decreased cell perimeter and increased density and circularity compared to sham animals. Cosyntropin treatment altered CCI-induced microglia changes in cell area, cell perimeter, and cell density. Cosyntropin-treated CCI animals showed reduced morphological changes in microglia suggesting a reduced activation state. Cosyntropin may decrease microglial activation and neuroinflammation through melanocortin receptor signaling and result in improved functional outcome.

Title: The effects of injury and exosome treatment on biophysical and structural properties of pyramidal neurons in primate premotor cortex

Authors: *M. MEDALLA[1], W. CHANG[1], S. CALDERAZZO[1], V. GO[1], A. TSOLIAS[1], J. GOODLIFFE[1], D. PATHAK[1], S. E. BUSCH[1], D. DEALBA[1], D. L. ROSENE[1], B. BULLER[2], T. L. MOORE[1];
[1]Anat. & Neurobio., Boston Univ. Sch. of Med., Boston, MA; [2]Henry Ford Hlth. Syst., Detroit, MI

Abstract: Functional recovery and circuit reorganization after cortical injury such as stroke in humans is limited by chronic inflammation and oxidative stress. Altering immune and trophic modulators of neuronal plasticity is a viable therapeutic target to facilitate recovery after cortical injury, but the nature of neuroimmune interactions in the primate brain is not well understood. Our recent work has shown that systemic administration of exosomes derived from mesenchymal stem cells enhances recovery of fine motor function in a non-human primate model of cortical injury. Exosomes are circulating nanovesicles that mediate cell-to-cell signaling of peripheral and central immune cells, but the neural mechanisms of exosome-mediated enhancement of recovery after cortical injury is largely unknown. Using *in vitro* whole-cell patch clamp recording and filling in acute slices, we studied the biophysical signaling and structural properties of surviving pyramidal neurons in perilesional premotor cortex, 14-16 weeks post-injury. Compared to control neurons from non-lesioned brains, perilesional neurons from vehicle-treated brains were more excitable, having significantly higher action potential (AP) firing rates in response to depolarizing current stimuli ($p < 0.05$). However, in exosome-treated brains, this lesion-related increase in AP firing was less pronounced; AP firing rates were more similar to non-lesioned controls and significantly lower than the vehicle group at low amplitude depolarizing current injections ($p < 0.01$). Thus, exosome treatment reduces injury-related hyperexcitability in perilesional neurons by lowering AP firing without changing passive membrane properties, which were similar between groups. At the synaptic level, perilesional neurons had significantly lower excitatory, but higher inhibitory postsynaptic current frequency compared to non-lesion neurons. While no significant group difference in the density of excitatory postsynaptic spines was found, the exosome group exhibited a higher density of the inhibitory synaptic marker, VGAT, specifically those apposed to apical dendrites of perilesional neurons. Perilesional neurons in the exosome group also exhibited significantly more complex dendritic apical tufts compared to the vehicle group. These data suggest that cortical injury induces hyperexcitability and synaptic reorganization in surviving perilesional neurons, to presumably compensate for neuronal damage and deafferentation. Further, exosome treatment may normalize these injury-related changes to likely prevent chronic excitotoxicity and restore excitatory:inhibitory network balance.

Abstract: Exosomes are endosome-derived nano-vesicles that are active biological containers transporting nucleic acids and proteins between cells. The efficacy of exosomes harvested from mesenchymal stromal cells (MSCs) to enhance functional recovery and alter inflammation following cortical injury has been demonstrated in rodent and porcine models of stroke and traumatic brain injury. Building on this work, we have utilized exosomes harvested from non-human primate (NHP) bone marrow cells as a treatment in our rhesus monkey model of cortical injury. Ten aged female rhesus monkeys were trained to retrieve a small food reward on a task of fine motor function of the hand and then received a cortical injury to the hand representation in primary motor cortex. Monkeys were then randomly assigned to either the exosome treated or vehicle groups (n=5 each). Exosomes or vehicle were administered intravenously 24 hours and again 14 days post-injury and recovery of motor function was followed for 12 weeks. Post-injury performance on our task of fine motor function revealed significantly greater degree of recovery of function in monkeys treated with exosomes. Specifically, treated monkeys returned to pre-operative performance in terms of speed to retrieve food rewards and the quality of grasp patterns within the first 3-5 weeks after injury. At the completion of testing, monkeys were euthanized and brains were harvested for analysis of markers of inflammation. Using 60 um sections of brain tissue throughout the extent of the lesion, microglia were labeled with Iba1, P2Y12, a purigenic receptor important for motility in homeostatic ramified microglia, and LN3, an MHC II receptor upregulated with immune activation. Confocal imaging, 3D reconstruction, and Sholl analyses revealed that microglial process length was greater in exosome-treated

monkeys compared to vehicle-treated monkeys. Further, exosome treated monkeys expressed lower densities of LN3+ hypertrophic microglia. These data suggest that exosome treatment promotes greater microglial ramification and reduce immune-activated hypertrophic/amoeboid microglia subtypes. Taken together these findings demonstrate that exosomes significantly enhance recovery of function and play a role in reducing inflammation following cortical injury.

Title: Electrophysiologic analysis of excitation/inhibition balance in the ventral hippocampus-medial prefrontal cortex circuit following traumatic brain injury

Authors: *K. M. BEST[1,3], H. METHENY[4], A. S. COHEN[4,2];
[1]Ctr. for Sleep and Circadian Neurobio., [2]Dept. of Anesthesiol. and Critical Care Med., Perelman Sch. of Medicine, Univ. of Pennsylvania, Philadelphia, PA; [3]Dept. of Nursing & Clin. Care Services, [4]Dept. of Anesthesiol. and Critical Care Med., Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Traumatic brain injury (TBI) affects more than 2.5 million people in the United States each year and is associated with long-term cognitive impairments. Although there are diverse inputs to the prefrontal cortex (PFC), the majority of innervation is thought to come from afferent projections from the hippocampus (HPC), which is known to be vulnerable to injury. Strong unidirectional, monosynaptic glutamatergic projections from the ventral HPC to all cortical layers of the medial PFC are implicated in various cognitive functions, including spatial working memory. Previously, we have shown that TBI leads to diminished cortical layer V field potentials evoked by layer II/III stimulation. This study examined the electrophysiological correlates of vHPC-mPFC circuit dysfunction after mild TBI in a mouse model of brain injury, lateral fluid percussion injury (LFPI). Under anesthesia, mild LFPI was induced in 6- to 8-week-old male C57/BL6 mice and electrophysiological experiments were performed 6 to 8 days after injury. For recording, mice were anesthetized and brains were quickly and carefully removed and placed in ice-cold oxygenated sucrose-containing artificial cerebrospinal fluid (aCSF). Slices

were cut at 300 µm thickness on a 10° agar ramp using a VT1200S vibratome in order to isolate projections from the vHPC to the mPFC according to published methods, and transferred to 33-35°C normal aCSF for at least one hour of incubation. Extracellular recordings of field excitatory post-synaptic potentials (fEPSPs) were obtained by placing a stimulating electrode in layer II/III of the prelimbic cortex and a recording electrode also in layer II/III. Recorded fEPSPs were evoked with a single stimulus (100 µs duration) ranging from 50 to 800 µA in 50 µA increments to generate input/output (I/O) curves. All experiments were carried out under protocols approved by the Institutional Animal Care and Use Committee. Data were analyzed with two-way repeated measures ANOVA with Sidak's multiple comparison test in order to evaluate for effects by injury condition and stimulation intensity. Our results showed alterations in excitatory/inhibitory (E/I) balance in the vHPC-mPFC circuit at one week following TBI. Further research is needed to determine whether the observed changes in E/I balance in the mPFC affect performance on working memory tasks.

Title: Cerebral dopamine neurotrophic factor in zebrafish brain repair after traumatic brain injury

Authors: *S. SHARIFULINA[1], S. SEMENOVA[2], Y.-C. CHEN[2], P. PANULA[2];
[1]Neurosci. Center, HiLife, [2]Dept. of Anat., Univ. of Helsinki, Helsinki, Finland

Abstract: Cerebral dopamine neurotrophic factor (CDNF) has been shown to protect dopaminergic neurons against toxic damage, and to inhibit endoplasmic reticulum stress, neuroinflammation, and apoptosis. The role of CDNF in the regenerative ability of adult zebrafish brain after telencephalic stab wound injury was investigated using zebrafish *cdnf* mutant line by quantification of gene expression relevant to neuroregeneration after traumatic brain injury (TBI) and by behavioral assays. *cdnf* mRNA level, assessed by quantitative PCR at 1, 3, 7, 14 and 21 days after the lesion, was increased in the damaged wild type zebrafish telencephalon at 1 day post lesion (dpl). Neurotransmitter measurement by high-performance liquid chromatography showed increased dopamine, serotonin and noradrenaline levels in the whole adult WT zebrafish brain at 1 dpl after TBI. The level of dopamine in WT zebrafish telencephalon was increased at 1dpl. *cdnf* mutant zebrafish showed normal locomotor behavior

without lesion and at 1 dpl after TBI. Novel tank diving test (NTDT) showed significant differences between *cdnf* KO and WT fish at 1 dpl in vertical NTDT exploration. Expression of genes related to neuronal differentiation, such as *sox2* and *notch1a*, was significantly increased in the telencephalon of *cdnf* KO and WT fish after TBI. Expression of *comta*, involved in the inactivation of the catecholamine neurotransmitters, was decreased in *cdnf* WT zebrafish telencephalon after TBI but not in *cdnf* KO at 1dpl. The number of Fluoro-Jade C positive cells was 4-fold higher in *cdnf* KO telencephalon compared with *cdnf* WT telencephalon at 3dpl but not at 1dpl. These differences suggest the involvement of CDNF in zebrafish brain response to TBI.

Title: Assessing the behavioral effects of proton irradiation and polyphenol supplementation on a high throughput fruit fly model of traumatic brain injury

Authors: *T. A. TOGASHI, A. D. TROFIMOVA, C. BARCENAS, W. HARDEMAN, M. HANNA, S. LOONG, M. WHITE, V. WATTS, G. A. NELSON, R. E. HARTMAN; Psychology, Loma Linda Univ., Loma Linda, CA

Abstract: We investigated the effects of traumatic brain injury (TBI) using a blunt force impact fruit fly model. The effects of polyphenols and irradiation were also assessed. The neuroprotective effects of polyphenols have been documented across various species (including flies). Irradiation has been shown to have deleterious effects across several species (including flies). However, both may induce “hormetic” effects, in which large doses are toxic, but smaller doses activate endogenous neuroprotective pathways and provide protection against subsequent injury.

We hypothesized that pretreatment with polyphenols and/or radiation would reduce TBI-induced behavioral deficits, and that irradiation after TBI would exacerbate its effects. We also predicted that TBI deficits would worsen over 7d. Flies were subjected to TBI or a control procedure, and some were irradiated (10Gy protons) 12hrs pre- or post-TBI. Half of the diets were supplemented with pomegranate juice containing ~.24mg/ml ellagic acid throughout the experiment. Climbing behavior was measured 1d and 7d post-TBI, and 24hr activity levels were recorded throughout the week.

Flies that climbed higher tended to be more active. TBI flies demonstrated significantly impaired climbing performance, and the magnitude of the deficit slightly increased over 7d. TBI did not

impact overall locomotor activity, however. Irradiation slightly increased climbing height in the absence of TBI, but significantly reduced climbing height in TBI flies. Irradiation after TBI had a larger effect than irradiation before TBI. Polyphenol supplementation had no effect on climbing behavior. Both irradiation and dietary supplementation reduced 24hr activity levels. In summary, low levels of irradiation significantly exacerbated the effects of TBI, suggesting that further research is warranted. For example, human astronauts on long-term deep space missions will be exposed to proton irradiation with the potential for accidents leading to a TBI. Our data suggest that this fly model of TBI and irradiation produces consistent and long-lasting behavioral deficits that will provide useful behavioral and neuropathological targets for inexpensive and high-throughput testing of various therapeutic approaches (such as prophylactic dietary supplementation).

Title: Exploring the effects of prophylactic & therapeutic dietary polyphenol treatments on traumatic brain injury outcomes in *Drosophila melanogaster*

Authors: *B. E. TOLAN, A. D. TROFIMOVA, R. E. HARTMAN;
Psychology, Loma Linda Univ., Loma Linda, CA

Abstract: Traumatic brain injury (TBI) is a leading cause of neurological deficits and mortality worldwide. In the United States alone, an estimated 2.8 million TBIs were diagnosed in 2013. Neurocognitive deficits associated with TBI include impaired attention, inability to form visuospatial associations, and poor executive functioning. Common psychological consequences include depression, increased impulsivity, poor decision-making, and aggressive behavior. A complex, multimodal neurodegenerative process, TBI presents both primary and secondary injuries. Primary injuries are sustained upon impact, whereas secondary injuries can occur over time as cellular and molecular responses are triggered in reaction to the impact. These secondary injuries have been linked with neurodegenerative diseases later in life. Inflammatory activation plays a critical role in the progression of secondary injuries, and suppressing long-term inflammation may help to reduce neurodegeneration.
A cost efficient and widely available solution might be found in dietary plants containing high levels of bioactive phytochemicals with anti-inflammatory and antioxidant properties (e.g.,

polyphenols). Pomegranates, for example, contain punicalagin, an ellagitannin polyphenol that is hydrolyzed into ellagic acid (EA). Previous research from our laboratory has demonstrated that both pre- and post-treatment with dietary polyphenols can provide neuroprotection in a number of models and clinical settings. This study examined whether prophylactic (pre-) or therapeutic (post-) treatments provide more favorable outcomes in a *Drosophila melanogaster* (fruit fly) model of TBI.
Young adult wild-type flies (N = 500) were raised on standard media (control), media containing pomegranate juice (PJ), or media containing ellagic acid (EA) for 10 days, followed by a mechanical impact designed to induce TBI.
The flies were then transferred into clean food vials and treatment was continued for 24 hours with flies previously raised in treatment transferred to standard media and flies raised on standard media transferred to treatments.
After 24 hours, climbing behavior and activity levels were measured.
Preliminary results suggest that both pre- and post-treatment were effective in reducing locomotor deficits associated with TBI, with PJ producing slightly more favorable results than EA, but polyphenol treatment overall more effective than a standard diet. Female flies recovered better and responded more favorably to polyphenol treatment than males.
This suggests that both prophylactic and therapeutic treatments of polyphenols may be effective in treating TBIs.

Title: Differential expression of estrogen-metabolizing enzymes following traumatic brain injury in adult male and female zebra finches

Authors: *K. A. DUNCAN;
Vassar Col., Poughkeepsie, NY

Abstract: Traumatic brain injury (TBI) induces neuropathological changes, cognitive deficits, and psychosocial dysfunction. Characterized by damage inducing neuroinflammation, this response can cause acute secondary injury that leads to widespread neurodegeneration and loss of neurological function. Estrogens decrease neuroinflammation and increase cell survival and neuroprotection and thus are a potential target for use following TBI. To further explore the relationship between estrogens and brain injury, we examined the expression of estrogen-metabolizing enzymes (EME) following TBI. EMEs are involved in both the initial conversion

and interconversion of estrogens from precursors. EMEs include aromatase, steroid sulfatase (STS), estrogen sulfotransferase (EST), and some forms of 17β-hydroxysteroid dehydrogenase (HSD). Aromatase (CYP19; estrogen synthase) has been studied extensively, but the role of the remaining EMEs following TBI has yet to be determined. Generally, EST and 17β-HSD2 play opposite roles to STS and 17β-HSD1 in the production of estrogens. Adult female and male zebra finches were given a unilateral penetrating injury directed toward the entopallium and collected 24 hours later. Brain tissue was collected for qPCR analysis and analyzed. Following injury, STS, which hydrolyzes biologically inactive estrogen, sulfates to produce active estrogens showed no difference in expression. 17β-HSD1, which is responsible for the interconversion of estrone (E1) and estradiol (E2) was upregulated following injury in both males and females. Inversely, 17β-HSD2, which is involved in inactivation of androgens and estrogens, was downregulated in females, but not in males following injury. These data suggest that increased expression of estrogens occurs at many levels beyond aromatase expression following injury and in a sexually dimorphic manner.

Title: The MAP1B phosphorylation sites specifically localized in the developing brain and in the regenerating peripheral nerves

Authors: *Y. ISHIKAWA[1,2], M. OKADA[3,2], A. HONDA[2], Y. ITO[2], A. TAMADA[2,4], N. ENDO[1], M. IGARASHI[2];

Abstract: The growth cone is an essential structure involved in formation and rearrangement of the neuronal network. Since phosphorylation is one the most important post-translational modifications in all of the cells including neurons, we have focused on “phosphoprotemics”, which enables us to identify both the phosphorylation sites of proteins and their frequency simultaneously and help us understanding the comprehensive signaling pathways. For this reason, we performed phosphoproteomic analysis of the growth cone membrane (Kawasaki et

al., iScience, 2018) and identified 4,600 phosphorylation sites corresponded to 1,200 proteins. In this study, we featured two of the most abundant sites, Ser25 and Ser1201 of rat microtubule-associated protein 1B (MAP1B), which is a protein known to stabilize axonal microtubules and to be involved in axon formation. So far, phosphorylation of MAP1B is thought to be accumulated in the distal portion of growing axons, however, biological functions of the phospho-MAP1B remain to be clarified. The above two sites are highly conserved between rodents and human, suggesting that they may have some important functions.
Here, we produced the phospho-specific antibodies (Abs) against these sites, respectively. The growing axons were preferentially labelled by these Abs in the cultured mouse cortical neurons, and in the embryonic mouse brain using immunohistochemistry. Western blotting analysis revealed that phosphorylation of these sites gradually decrease in postnatal periods. In the crushed sciatic nerve, we found that the immunoreactivity of each Ab was increased at the injury site and extended to the distal side over the injured point. In the transected nerve, the immunoreactivity was increased but remained to be stuck in the proximal segment; after the nerve suture, it was also detected even in the distal segment over the injured point.
These results suggest that these phosphorylation sites are involved in neuronal development and in peripheral nerve regeneration.

Title: An advanced nerve guidance conduit for repairing large peripheral nerve defects

Authors: *Z. KOCI[1,3,4], A. J. HIBBITTS[1,3,4], S. L. KNEAFSEY[1,3,4], L. ZILIC[1,3,4], G. CHEN[2], C. T. BUCKLEY[1,3,4], S. J. ARCHIBALD[5], F. J. O'BRIEN[1,3,4];

(AMBER), Dublin, Ireland; [5]Integra Lifesciences, Plainsboro, NJ

Abstract: Peripheral nerve injuries (PNI) affect millions of patients worldwide and cause motor and sensory dysfunction leading to reduced quality of life and increased healthcare costs. The primary treatment option for repairing large PNIs is to use patient's own nerve graft – an autograft, which is limited by availability and donor site morbidity. In this study, we aim to prepare an off-the-shelf advanced nerve guidance conduit (NGC) with capacity to regenerate critical-sized PNI as effectively, but overcoming the associated limitations of utilising autografts. Advanced NGCs were composed of two phases – an outer tubular shell composed of collagen type I (Coll) and internal matrix composed of collagen type I, chondroitin-6-sulphate and a series of extracellular matrix derived molecules (Coll/CS/ECM). Different ratios of ECM molecules were tested for their neurotrophic potential *in vitro* using primary rat Schwann cells (SC) and a rat dorsal root ganglia (DRG) explant culture. Following this, two formulations: Coll/CS/ECM1 (termed NGC1) and Coll/CS/ECM2 (NGC2) were selected for an *in vivo* study in a very large (15 mm) critical-sized rat sciatic nerve defect model. The nerve regeneration potential was compared to a reversed autograft.

In vitro analysis showed that Coll/CS/ECM1 and Coll/CS/ECM2 conduits supported viability and proliferation of SCs and DRGs. These conduits also significantly up-regulated neuron-specific β-III tubulin as well as NGF and VEGF production by DRGs in comparison to Coll/CS conduits.

In vivo analysis showed that sensory and motor function recovery significantly improved over time in all animals. Notably, the response of the two NGCs to electrical stimulation was similar to the autograft group and no differences were seen in electrophysiological recordings in either NGC1 or NGC2 when compared to the autograft group. Groups implanted with NGC1 and NGC2 displayed similar compound nerve as well as compound muscle action potential recordings. Consistent with these results, no significant differences in muscle weight loss were observed between either NGC and autograft. In addition, most importantly, the number of myelinated axons within both NGCs was similar to autografts showing the ability of the ECM molecules to direct functional nerve growth across a large defect.

In summary, this study demonstrated that enrichment of a NGC with ECM derived molecules resulted in a biomaterial capable of repairing large PNIs to a level equivalent to an autograft indicating its potential as a new clinical therapy for repairing large nerve defects.

Title: Long term neurological effects of acute exposure to a low or mild dose of sarin surrogate

Authors: *K. THIBAULT[1], S. FRANCOIS[2], J. KNOERTZER[1], R. BEL[1], G. DAL BO[1];
[1]Dept. de Toxicologie et Risques Chimiques, [2]Dept. Effets Biologiques des Rayonnements, IRBA, Bretigny sur orge, France

Abstract: The symptoms, neuropharmacological mechanisms and toxic consequences of high dose organophosphate (OP) intoxications have been well documented. However, very little attention has been given to the possible deleterious effects of sub-lethal doses. Previous experiments studying asymptomatic exposure to OP have found various effects on physiological and behavioural functions: modification of cardiac functions, alterations of spatial orientation and disruption of EEG patterns. The aim of this study is to evaluate delayed effects of low dose exposure of sarin surrogate (4-nitrophenyl isopropyl methylphosphonate, NIMP) on mice behaviour. Mice are treated subcutaneously with 0.5 (n=15) and 0.9LD50 (n=16) of NIMP. We analyse time-course of intoxication signs and determine a scoring scale of intoxication. Behavioural tests are realized up to 6 months post-intoxication, to test strength, mechanical and thermal sensitivity, memory and anxiety. Results show anxiety occurrence during the first months after intoxication which disappear 3 months post-intoxication. Interestingly, anxiety is again observed 6 month after intoxication in 0,9DL50 animals. Moreover, we also observed mechanical and thermal sensitivity regardless the dose of interest coupled with a persistant inflammatory state and blood formulation deterioration at long term. Our findings provide evidence that low OP exposure intoxication induced behavioural and physiological long term impairments.

Abstract: The peripheral nervous system (PNS) shows more robust regeneration following injury compared to the CNS. Such differences are due, in part, to the presence of Schwann cells in the PNS. Upon injury, Schwann cells dedifferentiate from their myelinating phenotype, unwrap from axons, and differentiate into a regenerative phenotype.[1] Electrospun fibers are used to support axon regeneration after injury. Fiber scaffolds can provide extended and localized release of therapeutic molecules and contact guidance for directed axon growth. Aligned electrospun fibers, however, promote the expression of the myelinating phenotype in Schwann cells[2], which may reduce the efficiency of Schwann cells to support axon regeneration. Fingolimod - an FDA-approved drug used to treat multiple sclerosis - shifts Schwann cells towards a regenerative phenotype.[3] In the present study, we fabricated fingolimod-loaded electrospun fibers to direct neurite extension, while also shifting the phenotype of Schwann cells towards their regenerative phenotype. Fingolimod-loaded, aligned, poly(lactic-co-glycolic acid) (PLGA) fibers were electrospun on a vertical electrospinner using a 12% w/w polymer/solvent solution. Fibers were imaged using scanning electron microscopy and fiber alignment, diameter, and density were characterized using FIJI software. Primary dorsal root ganglia (DRG), consisting of mainly neurons and Schwann cells, were isolated from P2 Sprague Dawley rats. Whole and dissociated DRG were cultured on the fingolimod-loaded fibers for 4 days or 12 hours, respectively. Cultures were immunostained and imaged using a confocal microscope. Whole DRG neurite extension was measured using FIJI software, and dissociated DRG neurite extension was assessed using Neurolucida neuron tracing software. Finally, Schwann cells were cultured on fingolimod-loaded fibers for 4 days, and qPCR was used to assess gene expression. Fingolimod-loaded electrospun fibers increased neurite extension 1.5-fold from primary whole DRG ($n \geq 14$) and 2.5-fold from dissociated DRG neurons ($n \geq 30$). To our knowledge, this is the first study showing that fingolimod delivered by aligned electrospun fibers modulates Schwann cell phenotype and supports directional neurite extension.

Title: Improving sensory function by utilizing vagus nerve stimulation after peripheral nerve injury

Authors: *M. J. DARROW[1], T. MIAN[2], M. TORRES[2], Z. HAIDER[2], E. MEYERS[1], M. ROMERO-ORTEGA[1], M. KILGARD[2], S. HAYS[1];
[1]Biomed. Engin., [2]Neurosci., Univ. of Texas At Dallas, Richardson, TX

Abstract: There are in excess of 50,000 peripheral nerve repair procedures performed each year in the USA. The vast majority of these injuries occur in the upper limb. Impaired tactile sensation is common after peripheral nerve injury (PNI) and is associated with poor functional outcomes. Currently there is no well-established method to restore tactile sensation following peripheral nerve injury. However, recent evidence suggests that sensory retraining therapy can provide some benefit. When delivered during physical therapy, vagus nerve stimulation (VNS) has shown promise in augmenting neuroplasticity and improving motor function after stroke. VNS is used to reduce seizure frequency in some patients with epilepsy with a 30 seconds on, 5 minutes off stimulation paradigm. Animal research indicates that brief, 0.5 second bursts of 0.8 mA VNS triggers release of norepinephrine and acetylcholine in the cerebral cortex, which can restore synaptic connectivity after brain injury and improve function if delivered during rehabilitative training. It is not yet known, whether brief bursts of VNS paired with tactile discrimination training can improve the recovery of sensory function. Recently, a human case study paired tactile training with VNS and improved sensory function in a chronic stroke patient. We describe a design to test the hypothesis that repeated pairing of VNS with tactile training will drive improvements in tactile sensory function following a peripheral nerve injury. We observed that Tactile + VNS significantly reduced mechanosensory thresholds versus Tactile Alone and were sustained for a substantial period of time following the cessation of the therapy. These data demonstrate a novel method for restoration of sensory function following PNI which is readily translatable to the clinic.

Title: Peripheral nerve repair with magnesium metal filaments and magnesium salts

Authors: ***X. AN**[1], T. M. HOPKINS[4], C. THAPA[2], L. MAILE[3], K. J. LITTLE[5], D. B. HOM[6], S. K. PIXLEY[7];
[1]Pharmaceut. Sci., [2]Pharmacol. & Systems Physiol., [3]Neurosci., Univ. of Cincinnati, Cincinnati, OH; [5]Orthopedic Surgery, [4]Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [6]Facial Plastic & Reconstructive Surgery Head & Neck Surgery, Univ. of California San Diego Med. Ctr., San Diego, CA; [7]Pharmacol. & Systems Physiol., Univ. Cincinnati Col. Med., Cincinnati, OH

Abstract: To repair transected peripheral nerves, biomaterial scaffolds could replace autografts. In our previous experiments, we found that biodegradable metallic magnesium (Mg) filaments, placed inside poly(caprolactone) (PCL) nerve guides, were compatible with axonal regeneration

and Mg filaments can provide physical contact guidance for regenerating axons. Here, we hypothesized that adding a Mg^{2+} solution at surgery (Mg ions are neuroprotective, anti-inflammatory and improve cell attachment), will further promote axonal outgrowth. Experimental gaps made in one sciatic nerve of adult Lewis rats were repaired by placing both nerve stumps in hollow silicone guides. Two experimental groups received single Mg filaments (99.9% pure Mg, d=250μm), touching both nerve stumps, inside guides filled with saline or a $MgSO_4$ solution. Other groups had conduits with no filaments +/- $MgSO_4$ (negative controls) or isografts (positive controls). After 6 weeks, dissected nerves and conduits were imaged via microCT to assess Mg degradation, treated with iodine to provide soft tissue contrast and re-imaged by microCT. In all cases, Mg filaments were biocompatible: tissues encapsulated and surrounded Mg filaments. Mg metal degradation did not differ between groups. In guides with saline and a Mg filament, only 2/6 animals showed continuous tissue strands across the gaps. But in all empty guides and guides with $MgSO_4$ + Mg filament, the number increased to 5/6 animals with tissue strands. The cross-sectional area of tissue in the strands was measured in microCT images. With Mg metal + $MgSO_4$, there was a lack of tissue buildup at the proximal ends and a smoother transition to the center, which suggests better integration of tissue with the filaments. Analysis was done on distal stump tissues fixed with osmium tetroxide, embedded in resin, sectioned and stained with toluidine blue. All groups had comparable axon density, size and myelination. However, extensive amounts of intracellular vacuoles were observed in all conditions except Mg metal + $MgSO_4$. This suggests that the combined treatment resulted in tissue health enhancement and perhaps better resolution of Wallerian degeneration. In vitro experiments showed that adding $MgSO_4$ to culture media increased the degradation rate of Mg filaments and increased the attachment of Schwannoma cells (RT4-D6P2T) to Mg filaments. Our data demonstrated that increasing the concentration of Mg^{2+} at the time of Mg metal implantation had a beneficial effect on nerve repair using Mg metal filaments and this might occur in part via increasing cell attachment to the Mg metal.

Title: Influence of pannexin1 knockout on peripheral nerve regeneration

Authors: E. OROZCO[1], S. ADACHI[1], H. P. MAKARENKOVA[3], ***S. B. SHAH**[2]; [1]Orthopaedic Surgery, [2]Orthopaedic Surgery and Bioengineering, UCSD, La Jolla, CA; [3]Mol. Med., Scripps Res., La Jolla, CA

Abstract: Peripheral nerve injuries are prevalent following traumatic injuries to the extremities, and often have severe consequences. Current strategies for repairing severe nerve injuries are often unsuccessful, leaving patients with motor dysfunction, sensory loss, and chronic pain. Among the factors posited to influence nerve regeneration are rates of axonal outgrowth and the favorability of the regenerative environment surrounding the axon, including inflammation. Pannexins are ATP releasing channels that work in coordination with type P2 purinergic receptors. Pannexins are expressed in almost all cell types, regulating multiple cell functions such as cell regeneration, wound healing, and inflammation.[1] Previous studies using Pannexin-1 Knockout (KO) mice show an increase in axonal density and outgrowth in cultured DRGs,[2] and reduced neuroinflammation.[3] Based on these roles, we hypothesize that reducing levels of Pannexin-1 will enhance nerve regeneration by increasing axonal outgrowth and reducing inflammation following traumatic nerve injury. In our study, we compared several structural and behavioral sensorimotor regenerative outcomes were measured bilaterally in 8-10 week old Pannexin-1 KO and WT mice after unilateral sciatic nerve crush injury, at 0, 1, 4, 8, and 10 weeks of recovery. Von Frey hair testing was used to assess mechanical sensitivity, and hind limb grip strength and rotarod testing were also performed to test motor function. Immunolabeling with SMI-31 antibody (anti-phosphorylated neurofilament subunit H) was used to assess axonal number and density proximal and distal to the injury. Preliminary findings (n=5/group) suggest that knockout of Pannexin-1 channels resulted in no significant difference in mechanical filament sensitivity or hind limb grip strength, with the ipsilateral limb stronger than contralateral in both groups. Pannexin-1 KO mice lasted ~40% longer on the rotarod compared to the WT mice (Log transformed mean±SEM; WT: 2.84±0.28; KO: 3.15±0.08). Morphological assessment of regenerated nerves indicates robust axonal regrowth in Pannexin KO nerves, and assessment of the neuro-inflammatory environment is being performed. Our study shows that Pannexin KO does not enhance sensory regeneration, but may enhance motor recovery after nerve crush injury. *References:* 1. Makarenkova HP et al. Front Physiol. 5:63 (2014). 2. Title: Evaluating vagus nerve stimulation paired with rehabilitation for sensory and motor dysfunction after radial nerve injury

Authors: *K. S. ADCOCK[1], T. DANAPHONGSE[2], Z. HAIDER[1], M. TORRES[1], R. A. MORRISON[1], S. A. HAYS[3], M. P. KILGARD[1];

Abstract: Peripheral nerve injury (PNI) is a leading cause of lifelong disability in the United States. Most injuries occur in the upper limb, with the radial nerve being the most commonly injured. While injury to other forelimb nerves have been characterized in rodents, the effects of radial nerve injury has not yet been studied. In this set of experiments, we aimed to characterize motor and sensory function in rats with radial nerve injury. Additionally, we assessed whether vagus nerve stimulation (VNS), a therapy that has shown to enhance the benefits of rehabilitation when paired with a motor or sensory event, can be delivered as a therapeutic intervention to improve sensory motor impairment in a model of radial nerve injury. To test this, animals underwent behavioral training on a motor task, and were then given a PNI in which the radial nerve was completely transected in the trained forelimb. Following 10 weeks of reinnervation, animals were assessed on motor performance and mechanical sensitivity. A subset of animals received VNS paired with motor rehabilitation. Preliminary data suggests that injury to the radial nerve causes a long lasting motor impairment and mechanical hypersensitivity. Previous studies have shown that VNS paired with motor rehabilitation has been successful in improving motor recovery in animal models of traumatic brain injury, spinal cord injury, and stroke. While a recent study has demonstrated that VNS paired with rehabilitation can improve sensory loss, it is unknown whether VNS can reduce sensory hypersensitivity. These studies could lead to the development of a novel adjunctive therapy that could restore motor and sensory function in patients with peripheral nerve damage.

Title: Inosine enhances the regeneration and anticipates the functional recovery after sciatic nerve crush injury in mice

Authors: F. S. S. CARDOSO, R. CARDOSO, B. S. RAMALHO, T. B. TABOADA, A. S. NOGUEIRA, A. B. MARTINEZ, ***F. M. ALMEIDA**;
UFRJ, Rio de Janeiro, Brazil

Abstract: Trauma to the peripheral nervous system (PNS) results in loss of motor and sensory functions. After an injury, a complex series of events begins, allowing axonal regeneration and target reinnervation. However, this regenerative potential is limited by several factors such as age, distance from the lesion site to the target and severity of lesion. Many studies look for ways to overcome these limitations. Inosine, a purine nucleoside derived from adenosine, emerges as a potential treatment, due to its capacity to regulate axonal growth, neuroprotection and immunomodulation, contributing to motor recovery. However, no studies demonstrated their effects on PNS. C57/Black6 mice were submitted to sciatic nerve crush and received intraperitoneal injections of saline or inosine (70 mg/kg), one hour after injury and daily for one week. To evaluate axonal regeneration and functional recovery, electroneuromyography, Sciatic Function Index (SFI), rotarod and pinprick tests were performed. Our results showed that the inosine group presented a higher number of myelinated fibers and a large amount of fibers within the ideal G-ratio. In addition, the results of electroneuromyography showed greater amplitude of the compound muscle action potentials in the first and second weeks, suggesting anticipation of regeneration in the inosine group. We also observed in the inosine group, motor and sensory neurons survival, reduction in the number of macrophages and myelin ovoids in the sciatic nerves, and an early recovery of motor and sensory functions. Thus, we conclude that the use of inosine accelerates axonal regeneration promoting an early recovery of motor and sensory functions.

Title: Single-unit recording reveal increased conduction delay and reversible conduction block in peripheral nerve axons undergoing tensile stretch

Authors: *N. GANESHBABU[1], T. GUO[2], L. CHEN[2], B. FENG[2];
[1]Physiol. and Neurobio., [2]Biomed. Engin., Univ. of Connecticut, Storrs, CT

Abstract: Background: Peripheral nerves are mechanically stretched in physiological conditions. However, excessive stretch of peripheral nerves can occur during trauma or surgery. Previous biomechanical studies indicate no apparent histological damages to peripheral nerve axons with elongation less than 15%. The impact of nerve tension on action potential transmission has been mainly studied by whole-nerve recordings of compound action potentials (CAP), indicating progressive reduction of CAP amplitude and increase of conduction delay. But the exact effect of nerve tension on action potential transmission at the level of an individual axon is not well understood. In this study, we developed a novel *ex vivo* setup that allows robust single-unit recordings from mouse sciatic nerve axons while delivering computer-controlled tensile stretch to the sciatic nerve trunk. Methods: From C57BL/6 mice, sciatic nerves were dissected from the L3, L4, and L5 entry points to the spinal cord to the distal branches of sural, common peroneal, and tibia nerves. The proximal L4 spinal nerve and the distal common peroneal branch were tied with a fine silk suture at ~20 mm apart and placed in a custom-built tissue chamber perfused with oxygenated Krebs solution. The L3, L4, and L5 spinal nerves were pulled into the adjacent recording chamber filled with mineral oil. The L4 spinal nerve was pinned down and the distal peroneal branch stretched by 60-second steps from 0.5 to 5 mm in 0.5 mm increments(Aurora Scientific, 300D). Action potentials were evoked by a suction electrode from the distal end of the sural nerve and recorded at individual axons from the split filaments of the L5 spinal nerve by a platinum-iridium wire electrode. Results: Conduction delay showed instantaneous increase at the onset of stepped stretch and further progressive increase during the 60-sec step in both myelinated A- and unmyelinated C-fibers. Removal of stretch led to instantaneous but slight reduction in conduction delay. Complete conduction block was observed with excessive stretch. In some axons, the conduction block was reversed after removal of stretch. Conclusions: Action potential transmission in peripheral axons can be significantly affected even by 2-3% of tensile stretch, resulting in instantaneous increase in conduction delay. Excessive stretch can lead to reversible transmission block. The current study provides a solid experimental foundation to enhance our biophysical understanding of stretch-induced peripheral neuropathy.

Title: The transmembrane protein Raw promotes Wallerian degeneration in *Drosophila* by restraining a protective JNK signaling pathway

Authors: *T. WALLER, Y. HAO, C. A. COLLINS;
Mol. Cell. and Developmental Biol., Univ. of Michigan, Ann Arbor, MI

Abstract: Mitogen Activated Protein Kinase (MAPK) signaling via the c-Jun N-terminal Kinase (JNK) is known to regulate multiple cellular responses to axonal injury. Inhibition of JNK impairs the ability of neurons to initiate new axonal regeneration in the peripheral nervous system, and also impairs the ability of distal axons that are removed from their cell body to undergo Wallerian degeneration. Recently, our lab identified the *Drosophila* transmembrane protein Raw as a pro-degenerative protein whose loss strongly delays the degeneration of severed neurites. The delay of degeneration in *raw* mutants is sensitive to dominant negative inhibition of JNK and downstream transcription factors Fos and c-Jun in motoneurons. These observations suggest the existence of a protective pathway mediated by JNK signaling that influences the resilience of axons to degeneration, which contrasts with the previously known roles for JNK in promoting axonal degeneration. In *Drosophila* the dual leucine zipper kinase DLK (known as Wallenda in *Drosophila*) regulates a MAPK signaling pathway that can inhibit degeneration following its activation in a preconditioning injury (Shin et al., 2012). However, our genetic data indicate that Raw and Wallenda signaling function independently. We propose that Raw represents a new inroad to disentangle multiple protective and degenerative pathways regulated by JNK. We will present current work to understand the mechanism of axonal protection in *raw* mutants, which appears resistant to reduced levels of the of the NAD biosynthetic protein NMNAT, an important protective factor in axons.

Title: Tissue nano-transfection drives localized delivery of therapeutics to the peripheral or central nervous system in a minimally invasive manner

Authors: *J. T. MOORE[1], N. HIGUITA-CASTRO[2], C. G. WIER[3], S. J. KOLB[3], I. VALERIO[4], D. GALLEGO-PEREZ[2];

Abstract: Nerve damage and neuropathies can contribute to pain, loss of sensation, weakness, and systemic complications. Localized gene delivery to nerve tissue has the potential to enable many novel therapies for these conditions. Current delivery methods face many practical and translational hurdles, including heavy reliance on viral infection, stochasticity, lack of specificity, and cellular damage. Unique nerve anatomy presents challenges for targeted delivery to axons of motor and sensory neurons which can span both the central (CNS) and peripheral nervous system (PNS)Our novel non-viral tissue nano-transfection (TNT) chip platform can be used to deliver therapeutic cargo to nerve tissue at both levels (i.e., peripherally and centrally) via the use of solid state nanochannels, coupled with nano-electroporation and nano-electrophoresis. Such nanochannels were fabricated via a combination of cleanroom-based manufacturing techniques. This novel platform was then used to controllably deliver a variety of cargos to the CNS and PNS of mice, including plasmid DNA and CRISPR/Cas9 components. Nano-electroporation conditions were optimized by delivering labeled plasmids at different voltages and pulse lengths. Delivery efficacy and retrograde transport from PNS to CNS was evaluated via immunofluorescence microscopy and qRT-PCR at different levels, including peripheral nerve bundles, dorsal root ganglion (DRG), and spinal cord (SC). Laser speckle imaging and electrophysiology measurements were used to evaluate potential alterations in perfusion and functionality post-TNT. Tissue sections collected shortly after transfection revealed successful cargo delivery following a short-lived (<100 ms) pulsed electric field across the nanostructured platform. Fluorescence intensity demonstrated up to ~50,000 fold change with respect to controls when varying voltage alone, and differences across groups of up to 20x when varying the duration of nano-electrophoresis. Immunofluorescence analysis and qRT-PCR confirmed tissue transfection and strong plasmid DNA and CRISPR/Cas9 activity at the peripheral nerve level, with varying degrees of expression/activity at the DRG and SC levels depending on the nano-electroporation conditions. No significant behavioral changes (e.g., paw clenching, gait perturbations) were noted in treated mice. Our nanostructured platform, with the use of non-viral cargo, showed the ability to efficiently transfect peripheral and central nerve tissue in a targeted and controlled manner. Ongoing studies focus on modulating tissue repair via induced tissue plasticity following TNT-based delivery of reprogramming factors.

Title: Rapid depletion of the ESCRT protein Vps4 underlies injury-induced autophagic impediment and Wallerian degeneration

Authors: H. WANG, K. ZHANG, Q. WANG, S. ZHANG, ***Y. (. FANG**;
Interdisciplinary Res. Ctr. on Biol. and Chem., SIOC, Chinese Acad. of Sci., Shanghai, China

Abstract: Axonal degeneration is a prominent feature of acute neural injury and chronic neurodegenerative diseases. In particular, the distal segment of injured axons undergoes an active and highly regulated self-destruction process, termed Wallerian degeneration. Recent work of Wallerian degeneration has been centered on the genes and pathways regulating NAD+ metabolism such as the NAD^+ synthase Nmnat and the NAD^+ hydrolase SARM1. However, apart from the NAD+ mechanism, other crucial signal transduction pathways involved in axonal injury and degeneration remain poorly understood.

In our previous work, we developed an *in vivo* model of nerve injury using the *Drosophila* wing (Fang et al., 2012; Fang et al., 2013; Fang and Bonini, 2015). In this study, we have combined multiple *in vitro* and *in vivo* neural injury models, including the *Drosophila* wing nerve, primary mouse DRG neurons, the mouse optic nerve, and the spinal cord of cynomolgus monkeys to investigate the role and regulation of autophagy in axonal degeneration. We found that the basal levels of axonal autophagy (evident by the formation of mCherry-Atg8a puncta) are low in general, even in aged flies. However, upon axotomy, there is a rapid and massive autophagy induction in the distal segment of the injured axons. The response can be seen as early as 3 hr after injury and is much earlier than when fly axons start to degenerate (12~24 hr).

Next, by performing a transgenic RNAi screen in flies, we identified the ESCRT component *Vps4* as a novel essential gene for axonal integrity (Wang et al., 2019). We found that upregulation of *Vps4* significantly delays degeneration of injured fly wing axons. We further revealed that *Vps4* is required and sufficient to promote autophagic flux in axons and mammalian cells. Moreover, using both *in vitro* and *in vivo* models, we showed that the function of *Vps4* in maintaining axonal autophagy and suppressing Wallerian degeneration is conserved in mammals. Finally, we uncover that the Vps4 protein is rapidly depleted in injured mouse DRG axons as well as the spinal cord of monkeys, which may underlie the injury-induced autophagic impediment and the subsequent axonal degeneration. Together, Vps4 and ESCRT may represent a novel signal transduction mechanism in axonal injury and Wallerian degeneration.

Title: Integrin protects nociceptive neurons in models of paclitaxel-mediated peripheral sensory neuropathy

Authors: *G. J.-E. SHIN[1], M. PERO[2,4], L. HAMMOND[1], A. BURGOS[1], A. KUMAR[2], F. BARTOLINI[2], W. B. GRUEBER[1,3];
[1]Zuckerman Inst., [2]Pathology and Cell Biol., [3]Neurosci., Columbia Univ., New York, NY; [4]Dept. of Vet. Med. and Animal Production, Univ. of Naples Federico II, Naples, Italy

Abstract: Chemotherapy induced peripheral neuropathy (CIPN) is a major side effect from cancer treatment with no known method for prevention or cure in clinics. CIPN primarily affects unmyelinated nociceptive sensory terminals. Despite the high prevalence of CIPN, molecular and cellular mechanisms that lead to CIPN are still poorly understood. Here, we used a genetically tractable *Drosophila in vivo* model and primary sensory neurons isolated from adult mouse to examine the mechanisms underlying CIPN and protective pathways. Using nociceptive neurons in *Drosophila* larvae we found that chronic treatment with paclitaxel resulted in neuronal degeneration and a change in branch distribution across the sensory terminal field. These larvae also showed a reduced thermal nociceptive response, mimicking the pathology of CIPN patients presenting loss of thermal nociception. We subsequently found that nociceptive neuron-specific overexpression of integrins, heteromeric receptors that link cell membranes to the extracellular matrix, protected *Drosophila* larvae from paclitaxel-mediated cellular and behavioral phenotypes. We found that this protection is specific to integrins, suggesting that facilitating connections between neuronal arbors and surrounding extracellular matrix is critical in maintaining the morphology and the function of nociceptive neurons against paclitaxel insult. Using primary dorsal root ganglia neuron cultures isolated from adult mouse, we further show that overexpression of human ITGB1, a common β subunit in integrin heterodimers expressed in vertebrate sensory neurons, also prevented degeneration following paclitaxel treatment. Our preliminary results indicate that endogenous integrin protein levels decrease following paclitaxel treatment in *Drosophila in vivo* and primary sensory neurons isolated from adult mouse, suggesting a paclitaxel-mediated induction of lysosomal integrin degradation. Using live

imaging and superresolution approaches, we provide supportive evidence that paclitaxel treatment changed the endosomal-lysosomal pathway in *Drosophila in vivo*. We found that lysosomes were often enlarged by paclitaxel treatment, whereas recycling endosomes co-localized less with integrins and showed reduced mobility. Altogether, our study suggests conserved mechanisms of paclitaxel-induced integrin degradation and the therapeutic potential of restoring integrin levels to antagonize paclitaxel-mediated toxicity in sensory neurons.

Title: Antiallodynic effect of GPR55 and GPR119 receptors in processing neuropathic pain in rat

Authors: *A. ZUÑIGA[1], H. ROCHA-GONZALEZ[1], F. FLORES-MURRIETA[2], J. REYES-GARCIA[1];
[1]ESM-IPN, Mexico, Mexico; [2]INER, Mexico, Mexico

Abstract: Orphan G-protein coupled receptors are proteins that represent a wide range of new therapeutic targets with biological functions to be discovered. GPR55 and GPR119 receptors have been reported on neurons of the nervous system, so they could play an important role in the modulation of neuropathic pain. The aim of this work was to evaluate the antiallodynic effect of GPR55 and GPR119 receptors in the treatment of neuropathic pain induced by L5-L6 spinal cord ligation in rat. Mechanical allodynia was measured using von Frey filaments by the Kim and Chung model. Male Wistar rats (180-200 g) were submitted to L5-L6 spinal nerves ligation to induce neuropathic pain. After two weeks of recovery, the rats were administered intrathecally with saline, or increasing doses of antagonist CID16020046 (GPR55 antagonist, 1-300 µg), O-1062 (GPR55 antagonist, 30-300 µg), AS1269574 (GPR119 agonist, 1-300µg) or G-protein antagonist peptide (non-selective GPR119 antagonist, 0.001-1ng). After administration, CID16020046 and AS1269574 had an efficacy of 52.1% ± 2.3 and 58.8% ± 1.9, respectively. In addition, intrathecal administration of O-1062 and the G-protein antagonist peptide decreased the antiallodynic effect induced by CID16020046 and AS1269574, respectively. Data suggest that GPR55 and GPR119 receptors participate in the modulation of neuropathic pain.

Title: Blood-glutamate scavenging: An effective neuroprotective treatment in spinal cord injury model

Authors: *A. MATUZANY-RUBAN[1], Y. GOLDSHMIT[2], E. BANIAS[3];
[2]Steyer Sch. of Hlth. Professions, Fac. of Med., [3]Fac. of Med., [1]Tel Aviv Univ., Tel Aviv, Israel

Abstract: Neurotrauma causes immediate elevation of extracellular glutamate levels, which creates excitotoxicity, scar formation and consequently neuronal death. We have implanted a novel strategy to reduce excitotoxicity by administration of a blood Glu scavenger (BGS) such as the blood resident enzyme and its co-substrate. In our recent study, we demonstrated that administration of BGS induces a remarkable protection of neurons and axonal regeneration, and as a result, a significant functional recovery in spinal cord injury model.
The role of exercising in enhancing recovery following spinal lesions has also been studied extensively. Although exercising does not facilitate axonal regeneration, a combination of BGS with exercise has the potential to reduce scar formation and neuronal death, and to enable regeneration through the lesion site.
Objective To evaluate the effect of BGS treatment and/or exercises on survival of neurons at lesion sites, as well as on scar formation and axonal regeneration after spinal cord injury.
Study design
In this study, we induced a spinal cord injury (hemisection) in mice. Immediately after SCI mice were randomly divided into (1) untreated (n=7), (2) BGS treated (n=9), (3) exercise (n=7) and (4) BGS treatment combined with exercises groups (n=9), in accordance with power analysis. Mice were treated with BGSs for five consecutive days, followed by exercises for three months. Immunostaining was performed in order to characterize the neuroprotective effects of BGS. In addition, anterograde tracing was carried out fourteen weeks after lesion induction and the labeled axons were quantified.
Results So far, our results have demonstrated that the combined treatment has decreased the inflammatory cell's activation significantly more than each treatment by itself (% of decrease of Iba1 immunofluorescence vs. vehicle-control: BGS 25.6±9.5, exercise 21.6±12.3, combined treatment 43.6±12.3). Examination of lesion size and GFAP density around the lesion site, has revealed that only the BGS treatment has decreased lesion size and attenuated the astrocytic gliosis, while treadmill training alone had no effect on these parameters (% of decrease of GFAP

immunofluorescence compared to vehicle-control: BGS 32.5±11.5, exercise 13.9±7.9, combine 31.9±6.3) $p<0.05$; one way ANOVA, Bonferroni's Multiple Comparison Test). Effect of the treatments on axonal regeneration currently under analysis

Summary

Our results strongly support the hypothesis that excess Glu plays a significant negative role in contributing to motor decline and early mortality in SCI. Thus, its removal is of particular therapeutic relevance.

Abstract: Compared to the central nervous system (CNS), peripheral nervous system (PNS) neurons mount a limited regenerative program after axonal injury that can be further enhanced by activity-dependent therapies, such as exercise. The mechanism by which neuronal activity enhances axon regeneration is incompletely understood, and defining how injured neurons respond to activity-dependent therapies may reveal new therapeutic targets to improve recovery following both CNS and PNS injuries. We hypothesized that exercise utilizes an oxygen-sensitive transcription factor, HIF1a, to enhance axon regeneration following injury. We found that running exercise caused nuclear translocation of HIF1a in axotomized sensory and motoneurons leading to enhanced axon regeneration and improved functional recovery following nerve injury. Additionally, we identified a pharmacologic inhibitor (FG4592) of prolyl hydroxylases that stabilizes HIF1a. FG4592 increased DRG neurite outgrowth in vitro and enhanced axon regeneration *in vivo*. Manipulation of HIF1a via activity-dependent therapies or pharmacologically may lead to significant improvements in axon regeneration and functional recovery.

Title: Neuroprotection and immunomodulation by dimethyl fumarate after ventral root avulsion and reimplantation

Authors: *P. R. KEMPE[1], G. B. CHIAROTTO[1], B. BARRAVIERA[2], R. S. FERREIRA, Jr[2], A. L. OLIVEIRA[1];

Abstract: Brachial plexus lesion within the spinal canal, including the avulsion of roots, is a recurrent outcome of high-energy trauma following impact of the forequarter, with dislocation of the shoulder girdle. Experimentally, ventral root avulsion (VRA) can be obtained in rats after an abrupt separation of the motor roots from the surface of the spinal cord, what results in ipsilateral paralysis of the affected limb. As a result, most of the axotomized motoneurons degenerate up to the second week post-injury, combined with a significant loss of synapses and increased glial reaction, triggering a chronic inflammatory state. It is believed that pharmacological treatment associated with roots reimplantation can overcome the degenerative effects of VRA. Therefore, our goal was to test if dimethyl-fumarate (DMF), an FDA approved drug with neuroprotective and immunomodulatory effects, associated with fibrin sealant (FS), a biological glue used for tissue repair, could improve regenerative response and lead to motor function recovery. Thus, adult female Lewis rats were subjected to unilateral VRA of L4-L6 roots followed by reimplantation and daily treatment with DMF (15 mg/Kg) for one or four weeks. Control group was VRA followed by vehicle treatment. The evaluated survival times post-surgery were 1 and 12 weeks. The analysis involved neuronal survival by Nissl staining, glial reactivity by immunofluorescence (anti-GFAP for astrocytes and anti-Iba-1 for microglia), synapse preservation (anti-VGLUT1 for glutamatergic inputs and anti-GAD65 for GABAergic inputs), gene expression (pro- and anti-inflammatory cytokines and interleukins) and motor function recovery (Catwalk system). Our results indicate that DMF treatment is neuroprotective and immunomodulatory since it preserves 36% of motoneurons and around 70% of GABAergic and glutamatergic synapses. DMF also decreased astrogliosis and microglial reaction combined with downregulation of pro-inflammatory gene transcripts. Importantly, the pharmacological treatment was further enhanced when associated with root reimplantation using FS, reaching 70% of motoneuron survival and more than 80% of synaptic inputs preservation. Also, glial

reaction decreased almost by a half. Conversely, such protective effects reflected in 50% motor function improvement, showing the efficacy of employing combined regenerative approaches following spinal cord root injury.

Title: The efficacy of C5a receptor antagonist for human iPSC-derived neural stem/progenitor cell transplantation in the injured spinal cord of mice

Authors: *R. SHIBATA[1,2], N. NAGOSHI[1], M. KHAZAEI[3], M. G. FEHLINGS[3], M. MATSUMOTO[1], H. OKANO[2], M. NAKAMURA[1];

Abstract: [Introduction] We previously reported the efficacy of human-iPS derived neural stem/progenitor cell (hiPSC-NS/PC) transplantation for spinal cord injury (SCI) in the subacute phase. However, this procedure is not effective in the acute phase due to the inflammatory response occuring immediately after SCI, which impacts transplanted cell survival and differentiation. C5a, which is one of the complement components, is a powerful chemoattractant and recruits inflammatory cells through binding C5a receptor. Therefore, the objective of this study is to suppress the inflammatory response immediately after SCI using C5a receptor antagonist (C5aRA) as an immunosuppressant, thus improving the efficacy of hiPSC-NS/PC transplantation for SCI in acute phase. [Methods] We used immuodeficient SCID-Beige mice that lack lymphocytes and NK cells. First, to evaluate the influence of C5aRA on the inflammatory response post-SCI, we induced a thoracic spinal contusion injury in mice. We quantified inflammatory cytokines and inflammatory cells in injured spinal cord tissues using qPCR and flow-cytometry. Next, we divided the SCI mice into 4 groups (PBS only, C5aRA only, PBS + transplantation (PBS+TP), C5aRA + transplantation (C5aRA+TP)). Immediately after SCI, C5aRA or PBS was administrated once a day for 4 consecutive days, and then, 5.0×10^5 hiPSC-NS/PCs were transplanted into the lesion epicenter on day 4. We evaluated cell survival rate by Bioluminescent Imaging (BLI), hindlimb motor function by BMS score, and the

differentiation profile of the graft hiPSC-NS/PCs by immunohistochemistry. [Results] C5aRA administration significantly reduced IL-1b, IL-6 and TNFα at 12 hours and macrophages at 4 days after SCI ($p<0.05$). The C5aRA+TP group had better functional improvement as compared to the PBS only group ($p<0.05$). BLI revealed that the C5aRA+TP group had a significantly higher cell survival rate compared to the PBS +TP group ($p<0.05$). There was no significant difference in the differentiation profiles of the graft hiPSC-NS/PCs between C5aRA+TP group and PBS+TP group. [Conclusion] The present study demonstrated that administration of C5aRA could suppress the inflammatory response during the acute phase of SCI, and also improve the survival rate of transplanted hiPSC-NS/PCs and enhance motor functional restoration. hiPSC-NS/PCs transplantated with C5aRA are a promising treatment for acute phase SCI patients.

Title: TRPV4 instigate endothelial disruption and secondary damage in spinal cord injury

Authors: *H. KUMAR[1], I. HAN[2];
[1]CHA Univ., Seongnamsi, Korea, Republic of; [2]CHA Univ., Seongnam, Korea, Republic of

Abstract: Transient receptor potential vanilloid type 4 (TRPV4), is a polymodal ionotropic receptor and plays a vital role in a multitude of physiological processes and upregulated in a variety of pathological conditions. TRPV4 expression and function is not known after spinal cord injury (SCI). We examined the TRPV4 role and its involvement in major biological cascades in the pathology of SCI. We studied in a clinically relevant model of moderate compression (35 g for 5 min at T10 level in rats) for SCI. Also, we checked the TRPV4 expression in injury dependent manner (compression using 20 g, 35 g and 50 g for 5 min) and transaction model of SCI. We quantitatively estimate Ca^{2+} at the same time points using two-photon microscopy and co-related the TRPV4 expression with Ca^{2+} after SCI. Interestingly, the TRPV4 expression was increased during the inflammatory phase after SCI and was linked with endothelial damage. Activation of TRPV4 was associated with endothelial damage and TRPV4 inhibition using specific antagonist (RN-1734 5 mg/kg, i.p.) attenuated the inflammatory cytokines, chemokines,

promotes vascular stabilization and prevented the tight junctions protein degradation and blood-spinal cord barrier (BSCB) break down after SCI. Likewise, TRPV4 KO mouse showed reduced inflammation and prevented the tight junctions protein degradation and BSCB breakdown after SCI (20 g for 1 min). Moreover, TRPV4 KO mouse abridged secondary damage as observed by a reduction in glial scar formation and protection of endothelial cell as compared with wild-type mouse. Thus, our result suggests that increased TRPV4 expression was associated with the early inflammatory phase of SCI, tissue damage, vascular destabilization, BSCB breakdown, and cell injury. TRPV4 inhibition serves as a promising therapeutic strategy to attenuate neuropathic pain, secondary damage and promoting vascular stabilization after SCI.

Title: The success of onabotulinumtoxina in treating neurogenic bladder after spinal cord injury: Mechanisms beyond SNAP-25 cleavage

Authors: *R. OLIVEIRA[1,3], S. CHAMBEL[1,3], F. CRUZ[2,3,4], C. D. CRUZ[1,3];
[1]Dept. Biomedicina, [2]Dept. Cirurgia e Fisiologia, Faculdade de Medicina da Univ. do Porto, Porto, Portugal; [3]IBMC - NeuroUrology Group, Inst. de Investigação e Inovação em Saúde, Porto, Portugal; [4]Dept. Urologia, Hosp. São João, Porto, Portugal

Abstract: Introduction & Aims Injections of onabotulunumtoxinA (Onabot/A) into the bladder wall is the gold-standard treatment for neurogenic detrusor overactivity (NDO), leading to long-lasting improvements on urinary function. Onabot/A impairs vesicle-mediated neurotransmission on motor, autonomic and sensory bladder fibers by specifically cleaving the synaptic associated protein (SNAP-25). However, mechanisms underlying the enduring effects of the toxin on the lower urinary tract are still mostly unknown, but likely reflects neuronal stress. Here we investigated signs of neuronal injury and stress in bladder afferents after treatment with Onabot/A. **Material & Methods** Female rats were submitted to T8/T9 largely incomplete spinal

cord transection (SCT). Control animals underwent sham surgery. Awake cystometries were performed at baseline, 1 week and 4 weeks after SCT to evaluate the development of urinary dysfunction. At 4 weeks post-SCT, when NDO is typically present, rats received 10 bladder injections of Onabot/A 10U diluted in 50uL of saline. Control rats received saline. Three days later, awake cystometries were performed, after which rats were euthanized and bladders, dorsal root ganglia (DRG) L5-S1 and spinal cords (SC) collected. Bladders and SC were processed for immunohistochemistry and western blotting (WB) to evaluate the catalytic activity of Onabot/A and DRG were processed for WB to measure levels of cell stress markers and primary cell culture to evaluate neuronal growth and dendritic branching. **Results** Four weeks after SCT, rats presented increased bladder pressure and frequent bladder contractions associated with high voided volumes. Onabot/A treatment cleaved SNAP-25 in the bladder wall and improved urinary function. This was accompanied by upregulation of cellular stress markers, such as ATF3 and PERK. In vitro assays, used to evaluate intrinsic ability of terminal growth, suggested a tendency for reduced dendritic length in Onabot/A-treated SCT rats, but not in control animals. **Conclusions** Preliminary results suggest that improvements in NDO following bladder treatment with Onabot/A may reflect the occurrence of metabolic injury in affected bladder afferents, along SNAP25 cleavage. Induced neuronal stress could justify the prolonged duration of Onabot/A beneficial effects in SCI-induced bladder dysfunction.

Title: Targeting intra-axonal RyR and IP_3R mediated Ca^{2+}reduces secondary axonal degeneration following a contusive-SCI *in vivo*

Authors: *B. C. OREM[1], A. RAJAEE[2], D. P. STIRLING[3];
[1]Anatom. Sci. and Neurobiology, Kentucky Spinal Cord Injury Res. Ctr., [2]Kentucky Spinal Cord Injury Res. Center, Neurolog. Surgery, Univ. of Louisville, Louisville, KY; [3]Neurolog. Surgery & Microbiology and Immunol., KSCIRC, Univ. of Louisville, Louisville, KY

Abstract: Preventing axon loss after traumatic spinal cord injury (SCI) is an important therapeutic goal. Axonal Ca^{2+} overload is established as a key facilitator of axonal injury following SCI. Previously we showed that intracellular calcium release through both RyRs and IP_3Rs contributes to axonal dieback and axonal loss following an *ex vivo* laser-induced SCI.

Here, we use an intravital imaging approach to assess the role of RyR- and IP_3R-mediated Ca^{2+} release on secondary axonal degeneration following a clinically-relevant *in vivo* contusion model in real-time. We hypothesize that blocking intracellular Ca^{2+} release from RyR and IP_3R will diminish secondary axonal degeneration after SCI. Briefly, adult, 6-8 week old *Advillin*-Cre:Ai9 mice that express "floxed" tdTomato in ascending dorsal columns of the spinal cord were imaged using two-photon excitation microscopy. Mice were subjected to a mild, 30 kdyn contusion at T12 and received the RyR blocker Ryanodine (50 μM) or the IP_3R blocker 2-APB (100 μM) intrathecally 3 hr and 24 hr post-SCI. We found that Ryanodine treatment significantly increased axonal survival at 24 hr post-SCI (Ryanodine, 54.1 ± 12.9 %; mean percentage normalized to baseline ± SD; control, 34.6 ± 7.7 %, $p<0.05$; t-test, N = 5-7 mice per group) compared to vehicle controls. Similarly, inhibition of IP_3R with 2-APB significantly increased axonal survival (2-APB, 55.8 ± 16.3 %; control, 35.6 ± 10.7 %, $p<0.05$, Mann-Whitney Rank Sum test, N = 6 mice per group) compared to vehicle at 24 hr post injury. Together, these data reveal a role of RyRs and IP_3Rs on axonal degeneration *in vivo* after SCI and suggest that blocking intracellular Ca^{2+} release is axoprotective in a clinically relevant contusion model.

Title: Chemogenetic modulation of afferents via DREADDs affects kinematics in a rat contusion model of SCI

Authors: *K. M. KEEFE[1], J. T. EISDORFER[1], T. HALLOWELL[3], O. HAJI-MAGHSOUDI[4], K. M. RAUSCHER[1], G. M. SMITH[2], M. LEMAY[1], A. J. SPENCE[1];

Abstract: Spinal cord injury (SCI) causes life-long neurological impairment, significantly affecting quality of life. Previous studies demonstrate that epidural stimulation of sensory neurons can improve functional outcomes after SCI. However, this type of stimulation is not selective to neuronal subtypes and thus the contribution of specific fibers to recovery is difficult to discern. Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) are

chemogenetic tools used to selectively control neurons with administration of its ligand, clozapine-N-oxide (CNO). DREADDs could therefore be used to evaluate how subsets of sensory neurons (e.g. proprioceptors vs. cutaneous afferents) influence recovery after SCI. This study aimed to determine whether modulation of large diameter sensory afferents with DREADDs can affect locomotor functional outcomes after a contusive SCI. An adeno-associated viral vector (AAV2) encapsulating the excitatory DREADD (hM3Dq) was injected into L1-L3 dorsal root ganglia (DRG) prior to SCI. Excitatory DREADDs act to depolarize neurons and increase their baseline excitability. The lumbar DRG were chosen as their rostral segments are hypothesized to contain central pattern generating circuitry in rats. High-speed video kinematics were recorded at 3, 4, and 6 weeks after contusion with administration of CNO (4 mg/kg). A PCA of 28 kinematic variables was analyzed in no-injury, contused with CNO administration and sham DRG surgery, and contused with excitatory DREADDs afferent activation by CNO groups. The first 3 principal components (PCs) of the PCA explained 77% of the variance (n=11 rats). DREADDs activation caused an increase in PC2, which was most heavily loaded on maximum hip extension. These data are consistent with our targeting of L1-L3 DRGS, which supply muscles primarily about the hip, and simulation results by other groups suggesting that afferent stimulation extends joints. Subsequent examination of mean hip angle specifically showed a significant difference between SCI-DREADDs-CNO and SCI-Sham-CNO animals (t-test; $p<0.05$; n=11 rats). These results suggest that chemogenetic modulation of afferents can affect kinematics in a rat contusion model of spinal cord injury.

Title: Neuroprotective effect of sodium propionate in neuroinflammation models

Authors: *I. PATERNITI, M. LANZA, G. CASILI, A. FILIPPONE, M. CAMPOLO, S. CUZZOCREA, E. ESPOSITO;
Univ. of Messina, Messina, Italy

Abstract: Sodium propionate (SP) is one of the main short chain fatty acids (SCFA) that can be produced naturally through host metabolic pathways. The physiological effects of SP have been documented and include the reduction of pro-inflammatory mediators in *an vivo* model of colitis. Thus, the aim of this study was to evaluate the neuroprotective effects of SP in reducing inflammatory process associated to neurological disorders. We performed both *in vitro* model of

Alzheimer's disease, induced by oligomeric $A\beta_{1-42}$ stimulation, and in *in vivo* model of spinal cord injury (SCI) in which neuroinflammation plays a crucial role. For *in vitro* model, the human neuroblastoma SHSY-5Y cell line was first differentiated with retinoic acid (100 μM) for 24 hours and then stimulated by oligomeric $A\beta_{1-42}$ (1μg/ml) and treated with SP at three different concentrations (0.1- 1- 10 μM) for another 24 hours. Instead, the *in vivo* model of SCI was induced by extradural compression of the spinal cord at T6-T7 levels, using an aneurysm clip, and animals were treated with SP (10-30-100 mg/kg *o.s*) 1 and 6 h after SCI. Our results demonstrated that both in *in vitro* neuroinflammatory model and *in vivo* model of SCI the treatment with SP significantly reduced NF-κB nuclear translocation and IκBα degradation, as well as decreases COX-2 and iNOS expressions evaluated by Western blot analysis. Moreover, we showed that SP treatment significantly ameliorated histopathology changes and improved motor recovery in a dose-dependent manner. In conclusion, our results demonstrated that SP possesses neuroprotective effects, suggesting it could represent a target for therapeutic intervention in inflammatory disorders such as neurodegenerative disease and central nervous system injury.

Title: Nimodipine prevents the development of spasticity after spinal cord injury by blocking Ca_V 1.3 calcium channels

Authors: M. MARCANTONI[1], P. LOW[2], A. FUCHS[2], O. KIEHN[1], ***C. BELLARDITA**[1]; [1]Neurosci. Dept., University of Copenhagen, Denmark; [2]Neurosci. Dept., Karolinska Institute, Sweden

Abstract: Spasticity, one of the most frequent comorbidities of spinal cord injury (SCI), has been show to disrupt motor recovery and quality of life. Despite major progress in neurorehabilitative and pharmacological approaches, no curative treatment for spasticity exists. Here, we investigated the possibility that early onset and long-term blockage of the Ca_V 1.3 calcium channels in a mouse model of chronic SCI prevent the development of spasticity.

Constitutive knockout of Ca_V 1.3 channels or conditional deletion in neuronal subtypes abolished increased muscle tone and spasms typical of chronic SCI. Furthermore, pharmacological blockade of Ca_V 1.3 channels with nimodipine starting in the acute phase of SCI completely prevented the development of increased muscle tone and spontaneous spasms. Notably, the aberrant muscle activities were permanently blocked even after termination of the treatment. This study has identified a specific target and a potentially curative treatment protocol for the prevention of spasticity after SCI.

Title: The neurokinin 2 receptor agonist [Lys^5,$MeLEU^9$,Nle^{10}]-$NKA_{(4-10)}$ produces urination and defecation in rats: Involvement of neurokinin 1 and neurokinin 2 receptors

Authors: *J. B. COOK, R. PIATT, L. MARSON;
Dignify Therapeut., Research Triangle Park, NC

Abstract: Individuals with spinal cord injury or neurodegenerative disorders such as multiple sclerosis and Parkinson's disease, often have bladder and/or gastrointestinal dysfunction that require the use of catheters and bowel programs to empty the bladder and bowel. Similarly, bladder and bowel dysfunction is prevalent in the aging population. Therefore, there is a need for drugs that promote emptying of the bladder and/or bowel. Our group is investigating neurokinin 2 receptor (NK2R) agonists for this indication. In the current study, we tested the ability of subcutaneous injection of [Lys^5,$MeLEU^9$,Nle^{10}]-$NKA_{(4-10)}$ (LMN-NKA) to induce urination and defecation in awake naïve rats. Since a potential side effect of LMN-NKA is flushing of the ears and paws, we examined the role of neurokinin 1 receptors (NK1R) and NK2R in the LMN-NKA induced flushing responses. Adult Sprague Dawley rats (n=23) were habituated to metabolism cages and handling for 3 days. Behavior was monitored before (10-20 min, pre-observation period) and after injections of LMN-NKA (3-100 µg/kg) and the time to urination and defecation, the voided volume and fecal weight, and flushing, was monitored for 30 min post LMN-NKA. In the antagonist study, vehicle (Veh), the NK1R antagonist CP-99,994 (1 mg/kg), or the NK2R antagonist GR159897 (1 mg/kg) were administered prior to the pre-observation period and then either saline (Sal) or 100 µg/kg LMN-NKA was injected, and behavior observed for 30 min. Injection of Sal, Veh, CP-99,994, or GR159897 alone resulted in minimal voiding or defecation and no flushing was observed. LMN-NKA induced a dose related increase in voiding,

defecation, and flushing at 10-100 μg/kg with a 100% responder rate at the highest dose. Urination, defecation and flushing occurred within 10 min of LMN-NKA dosing. The LMN-NKA induced urination was not reduced by the NK1R antagonist, however, pre-dosing with the NK2R antagonist reduced urination. LMN-NKA induced defecation was blocked by the NK2R antagonist, but the NK1R antagonist had no effect. Pretreatment with the NK1R antagonist significantly reduced the onset and duration of flushing produced by LMN-NKA, while flushing was still observed after the NK2R antagonist. Therefore, LMN-NKA induced voiding and defecation appears to be mediated via the NK2R and flushing by the NK1R. The results suggest that more selective NK2R agonists could be developed to promote voiding without concomitant side effects, such as flushing.

Title: The fatty acide amide hydrolase inhibitor, PF-3845, attenuates inflammation and improves functional recovery in mice with spinal cord injury

Authors: *M. L. LANZA, G. CASILI, A. FILIPPONE, M. CAMPOLO, I. PATERNITI, S. CUZZOCREA, E. ESPOSITO;
Univ. of Messina, Messina, Italy

Abstract: The endocannabinoid (eCB) system has emerged as a prominent lipid signalling network widely expressed in the body and involved in multiple adaptive responses. The eCB system comprises endogenous lipid transmitters such as N-arachidonoylethanolamine (AEA) and 2-arachidonoylglycerol (2-AG) known as endocannabinoids, eCBs that are synthesized “on demand” are primarily involved in neuroprotective pathways producing neuro-modulatory, anti-inflammatory and anti-oxidative effects. It is noteworthy that increased AEA concentrations after SCI is thought to prevent neuroinflammation by regulating key-processes overall triggering anti-apoptotic, anti-oxidative and anti-inflammatory mechanisms.
However, AEA is short-lived mediator and its levels are tightly regulated by a rapid enzymatic degradation mediated by fatty acid amide hydrolase (FAAH).
The aim of the study is to considered this enzyme as potential drug targets and its inhibition could enable the pharmacological modulation of AEA levels to take advantage of their effects.

We performed an *in vivo* model of SCI, using a compression model, and we treated animals with PF3845, a selective and potent FAAH inhibitor, 1 hour and 6 hour after SCI. At 24 hours we scarified animals to evaluate the anti-inflammatory and neuroprotective effects of PF3845.
The results obtained demonstrated that PF3845 significantly reduced the histological alterations induced by SCI; considerably decreased GFAP expression, NF-κB translocation and degradation of IκB-α, as well as diminished the expression of pro-inflammatory mediators COX-2, iNOS, TNF-α and IL-1β.
Thus, inhibition of FAAH can boost the endogenous levels of AEA enhancing its protective effect, suggesting that FAAH inhibitors could represent a novel therapy to control neuroinflammatory conditions of SCI.

Abstract: Spinal cord injury (SCI) results in irreversible sensory, motor, and autonomic impairments with high social and medical care costs. SCI pathophysiology involves several aspects including cell death and neural tissue loss, dysfunction of the cell metabolism and the inflammatory reaction of the immune system. Current SCI therapies aim at minimize the spinal cord damage and a therapeutic approach able to promote functional recovery is still lacking. Our hypothesis is that rewiring neural cell metabolism could improve SCI outcome. We designed a novel formulation made by essential amino acids, TCA cycle precursors and co-factors capable to increase oxidative metabolism and mitochondrial function and explored its effect *in vitro* on NSC neuronal differentiation and *in vivo* in a mouse model ofsevere SCI. We found that the

treatment greatly enhances oxidative phosphorylation, ATP production in differentiating neurons derived from both murine meningeal and SVZ NSCs and human iPSCs. The enhanced mitochondrial function was associated with an increase in the neuronal differentiation and spine maturation. Global transcriptomic analysis further indicates that treated neurons strongly induce Nrf2 mediated gene expression that greatly increases glutathione metabolism and improved ROS scavenging mechanism. Therefore, we evaluated the effect of treatment *in vivo* in a severe contusive SCI mouse model. Importantly, we start our treatment following the sub-acute phase (therapeutic setting). We found that the treatment significantly increased functional recovery and limited the instauration of a spastic condition of the ankle joint. In line with the behavioural data, we observed a reduction of the cyst and glial scar volumes and higher number of preserved/regenerated neurons in the treated injured spinal cord. Metabolomic analysis revealed that the treatment significantly increases energy metabolism and oxidative phosphorylation of the injured spinal cord tissue. In conclusion, our results indicate that nutrient induced metabolic switch toward oxidative metabolism, increases the ROS defences and enhances neuronal differentiation with potential therapeutic impact in severe SCI.

Title: Mitochondrial uncoupling with 2,4-dinitrophenol exerts age dependent effects after spinal cord injury

Authors: *A. N. STEWART[1], K. E. MCFARLANE[1], H. J. VEKARIA[2], W. M. BAILEY[1], B. ZHANG[1], S. P. PATEL[1], P. G. SULLIVAN[2], J. C. GENSEL[1];

Abstract: The average age at time of spinal cord injury (SCI) is increasing. Aging exacerbates SCI in part by increasing reactive oxygen species (ROS) damage, however the contribution of mitochondria derived ROS to age-dependent recovery after SCI is not well understood. Here we tested the age-dependent effects of 2,4-dinitrophenol (DNP), a mitochondrial uncoupler that increases nutrient consumption and decreases ROS formation. Graded doses of DNP were delivered for 1-week after SCI in young- (4-month-old; 4-MO) and middle-aged (14-MO) mice. We detected a significant neuroprotective effect of DNP (1-mg/kg/day) at 7-days post-injury (DPI) for 14-MO SCI-mice but toxic effects of the same dose for 4-MO SCI-mice. Specifically, 14-MO SCI-mice treated with 1.0 mg/kg/day DNP had improved tissue sparing and lowered 3-nitrotyrosine (3-NT; protein nitration product) accumulation, with no apparent effects on neuron survival. In contrast, 4-MO SCI-mice treated with DNP had a significant loss of motor neurons surrounding the lesion and no reduction of 3-NT accumulation. Similar age-dependent effects of DNP were observed at 28-DPI in both aged and young mice. Specifically, treatment with DNP significantly improved locomotor function of 14-MO mice but worsened locomotor abilities of 4-MO mice (BMS scale). No DNP-mediated increase in tissue sparing was detected in 14-MO mice at 28-DPI, while 4-MO mice treated with DNP experienced a significant decrease in tissue sparing at the lesion epicenter. Collectively, these data demonstrate that mild mitochondrial uncoupling exerts age-dependent effects on SCI pathophysiology. Further, our data implicate metabolic processes in age-specific secondary injury events after SCI.

Title: Targeting alpha-tubulin acetylation to promote neurite outgrowth and functional recovery after injury

Authors: *V. WONG[1], C. PICCI[3], M. SWIFT[5], M. LEVINSON[6], D. GOLDBERG[1], A. SAUVE[7], B. LANGLEY[4], D. WILLIS[2];

Abstract: Damage to the central nervous system (CNS), such as spinal cord injury, results in neuronal and axonal degeneration and subsequent neurological dysfunction. Endogenous repair in the CNS is impeded by inhibitory cues, such as chondroitin sulfate proteoglycans (CSPGs) and myelin-associated glycoprotein (MAG), which prevent axon regeneration. Previously, it has been demonstrated that the inhibition of histone deacetylase-6 (HDAC6) can promote microtubule α-tubulin acetylation and restore the growth of CSPGs- and MAG-inhibited neurites. Since the acetylation of α-tubulin is regulated by two opposing enzymes, HDAC6 (deacetylation) and α-tubulin acetyltransferase-1 (αTAT1; acetylation), we investigated the regulation of these enzymes downstream of a growth inhibitory signal. We used dissociated mouse cortical neurons incubated with CSPGs or MAG for various indicated times. We examined changes in tubulin acetylation levels, HDAC6 and αTAT1 expression, and neurite growth using molecular and imaging techniques. Our findings show that exposure of neurons to soluble CSPGs and MAG substrates cause an acute and RhoA-kinase-dependent reduction in α-tubulin acetylation and αTAT1 protein levels, without changes to either HDAC6 levels or HDAC6 activity. The CSPGs- and MAG-induced reduction in αTAT1 occurs primarily in the distal and middle regions of neurites and reconstitution of αTAT1, either by Rho-associated kinase (ROCK) inhibition or lentiviral-mediated αTAT1 overexpression, can restore neurite growth. Lastly, we demonstrate that CSPGs and MAG signaling decreases αTAT1 levels post-transcriptionally via a ROCK-dependent increase in αTAT1 protein turnover. Together, these findings define αTAT1 as a novel potential therapeutic target for ameliorating CNS injury characterized by growth inhibitory substrates that are prohibitive to axonal regeneration. This study represents a paradigm shift as αTAT1 provides a new target to promote axonal regrowth, in addition to HDAC6, which has received considerably more attention. Our immediate future plan is to complement these findings *in vitro* to *in vivo* setting using transgenic (namely HDAC6 and αTAT1) knockout mice with spinal cord injury. Moreover, we are currently conducting a high throughput drug screen to discover compounds that can promote α-tubulin acetylation in neurons *in vitro*. We will perform *in vivo* dosing studies of candidate compounds in spinal cord injured animals and examine their potential for functional recovery.

Title: Development of SOX9 antagonists for the treatment of neurological injuries

Authors: *T. HRYCIW[1], N. M. GEREMIA[1], M. DINUNZIO[1], B. URQUHART[2], A. BROWN[1];
[1]Robarts Res. Inst., [2]Physiol. and Pharmacol., Western Univ., London, ON, Canada

Abstract: The transcription factor SOX9 plays key roles during development, being required for male sex differentiation and chondrogenesis. In adults, SOX9 is found in astrocytes and in several stem cell niches where it serves to maintain "stemness". After spinal cord injury (SCI) or stroke, SOX9 expression in reactive astrocytes promotes production of chondroitin sulfate proteoglycans (CSPGs) that inhibit axonal growth. Conditional *Sox9* ablation reduces CSPGs in the injured spinal cord, increases reparative axonal sprouting and improves locomotor recovery. Similarly, in the middle cerebral artery occlusion model of stroke conditional *Sox9* ablation improves recovery by promoting axonal sprouting from uninjured areas of the brain onto targets denervated by the injury. To inhibit SOX9 activity on extracellular matrix gene promoters, we designed a fusion peptide consisting of the TAT cell-penetrating sequence and a SOX9 interfering peptide. This peptide was able to decrease the expression of SOX9 target genes in primary astrocyte cultures and in the chondrogenic cell line ATDC5 as assayed by real time PCR. Intravenous injection of the SOX9-targeting peptide in SCI mice at 24 and 48 h post-injury resulted in uptake by glial cells in the injured cord as assessed by immunohistochemistry, and decreased SOX9 target gene expression assayed at 72h by real time PCR. A computational screen of ~12 million compounds for small molecules predicted to interfere with SOX9 identified ten candidate SOX9 inhibitors. One candidate, designated as Z02, decreased SOX9 target gene expression *in vitro*. Mass spectrometry studies showed that intravenous administration resulted in accumulation of Z02 in the spinal cord of both uninjured and spinal cord injured rats indicating that Z02 is capable of crossing the blood-spinal cord barrier. Staining cord sections with Wisteria Floribunda lectin showed that treatment of SCI rats (T8 contusion) with Z02 resulted in a reduction of perineuronal nets surrounding neurons compared to vehicle-treated controls. Behavioural studies are underway to determine whether the reduction of CSPG levels in perineuronal nets by Z02 correlates with locomotor improvements following spinal cord injury.

Title: Enhancing KCC2 activity reduces development of spasticity after spinal cord injury

Authors: *J. N. BILCHAK, K. YEAKLE, G. CARON, M.-P. COTE;
Neurobio. and Anat., Drexel Univ., Philadelphia, PA

Abstract: Within a year after a spinal cord injury (SCI), the majority of patients find themselves thwarted in the recovery of motor function by the development of spasticity. Among the multifaceted factors contributing to the hyperexcitability of spinal networks after chronic SCI is a shift in chloride homeostasis. SCI triggers a significant decrease in the expression of KCC2, a chloride transporter, which leads to a decrease in chloride extrusion capability and subsequently intracellular chloride accumulation in neurons. This shift in chloride homeostasis significantly contributes to reflex dis-inhibition and spasticity. Interestingly, exercise training can improve spastic symptoms via an increase in KCC2 expression in lumbar motoneurons. However, SCI is accompanied by a substantial number of co-morbidities that often delay the onset of exercise-based therapies or cause safety concerns for the patient during training sessions. Thus, patients are routinely medicated with anti-spastic medications. While these work efficiently to suppress spastic events, they induce significant side effects and depress the overall spinal excitability, making them incompatible with activity-based therapies. A promising alternative is to instead directly restore endogenous inhibition by restoring chloride homeostasis. We have previously shown that acute treatment with the KCC2 enhancer, CLP257, reduces signs of spasticity in chronic SCI rats.
Here, we sought to increase KCC2 activity chronically after SCI, and assess spastic symptoms as they develop in the weeks following injury. In addition, we investigated the effects of combining this novel compound with an exercise-training regimen. Adult female Sprague-Dawley rats were implanted with chronic EMG electrodes, received a severe contusion injury at T9, and were treated daily with either CLP290 or vehicle starting one day after injury and continuing for 4 weeks. Exercised animals were step-trained on a treadmill daily. Once a week, EMG activity was recorded in awake, behaving animals to assess spontaneous spasms, responses to muscle stretch, and stepping ability on a treadmill. Our results suggest that chronic treatment with CLP290 reduces the development of spontaneous spasms, helps maintain normal responses to stretch, and improves stepping ability. Importantly, CLP290 treatment in exercised animals showed no visible detriment to the benefits of exercise on locomotor function. This work reveals the substantial potential for KCC2 enhancers as a novel spasticity treatment that can be used in tandem with activity-based therapies.

Title: Testing combinatorial treatments of promising FDA approved neuro-protective drug candidates in a cervical hemi-contusion model of rats

Authors: *W. PLUNET, N. JANZEN, J. LIU, E. RAFFAELE, S. KAMAKARI, O. SEIRA, K. KOLE, Y. JIANG, L. MCPHAIL, W. TETZLAFF;
ICORD, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: A significant number of FDA approved drugs have demonstrated efficacy in preclinical spinal cord injury (SCI). However, when tested clinically they have failed to produce meaningful results. This lack of robustness is due to a number of factors in the pre-clinical testing including injury model, treatment timing, and the studies being underpowered, to name a few. We therefore wanted to test the most promising FDA approved drugs, alone and in combination, when these are administered 3 hours after a cervical spinal cord hemi-contusion injury using group sizes of n = 16-21. We initially tested 8 different FDA approved drugs (riluzole, valproic acid, fluoxetine, metformin, inosine, rosuvastatin, glibenclamide, tamoxifen) that had been reported to improve functional recovery in SCI models. In our experiments none of the 8 treatments improved recovery compared to control groups, and only glidenclamide improved the amount of spared spinal cord tissue. Having poor success with numerous individual treatments we decided to test combination treatments. We tested glibenclamide plus taxmoxifen (G + T), and in another group: glibenclamide, tamoxifen plus inosine (G + T + I). We found that both treatment groups showed a modest ($p < 0.05$) improvement in the staircase compared to the control group, while on the ladder test G + T + I resulted in a nearly 50% reduction of mistakes compared to controls. These results suggest a combinational approach may allow a recovery level that is not observed with single treatments, in particular when initiated somewhat delayed at 3 hours after injury. Title: Evaluation of cABC delivery methods on the response of oligodendroglia after spinal cord injury

Authors: *D. J. OSTERHOUT[1], J. R. SIEBERT[3], A. CHENG[2], B. AHMAD[2];
[1]Cell and Developmental Biol., [2]Upstate Med. Univ., Syracuse, NY; [3]Biol., Slippery Rock Univ., Slippery Rock, PA

Abstract: The tissue surrounding a spinal cord lesion is well known as being inhibitory to regenerative and repair processes, due to the expression of chondroitin sulfate proteoglycans (CSPGs). The deposition of CSPGs at the lesion starts immediately after injury and forms a glial scar, which hinders both axonal regeneration and the migration of oligodendrocyte progenitor cells (OPCs). However, many studies have demonstrated that treating CSPGs with the enzyme chondroitinase (cABC), which removes the glycosaminoglycan (GAG) side chains from the protein core of the molecule, creates a permissive environment for both axonal sprouting and OPC migration. While cABC treatment of a spinal cord injury (SCI) *in vivo* has shown promise in stimulating axonal regeneration, the labile nature of the enzyme means biological activity is typically lost only a few days post-administration. This poses an interesting problem: how to protect the biological activity of cABC for long term treatment of the glial scar.
In our recent studies, we have been testing a biodegradable nanosphere delivery system designed to provide a slow continuous release of active cABC. We have previously demonstrated that this drug delivery method can significantly enhance the axonal regeneration response as compared with an injection of cABC. In this study, we examined the migration of OPCs to the lesion with two different cABC delivery methods: nanospheres and injection. The total number of OPCs surrounding the lesion site was significantly increased after cABC administration by either method, compared to controls. The enhanced OPC migration is evident at early times post-injury, and continues through one month. However, nanosphere delivery of cABC provided more continuous digestion of CSPGs, along with an increasing number of OPCs at 1, 2 and 4 weeks post injury when compared to a direct injection of cABC. While the number of OPCs tends to plateau at one month, the extended digestion of CSPGs allows for a persistent accumulation of OPCs in and around the lesion. Collectively, these data demonstrate that utilizing a biodegradable delivery system, allowing for a steady release of enzymatically active cABC, will maximize its effects of on both axonal sprouting and OPC migration after SCI.

Ctr. at UC Davis, Davis, CA

Abstract: Conus medullaris (CM) / cauda equina (CE) forms of spinal cord injury (SCI) represent about 20% of all SCI cases in the United States. Paralysis, sensory damage, and loss of bladder, bowel, and sexual functions are common after this injury. Neurodegenerative reactions, including neuronal death, contribute to the functional impairments and there are no treatments available to reverse these deficits. The present study investigated a new approach to replace degenerating motor neurons in a non-human primate model of CM/CE form of spinal cord injury at 24 hours after surgery (n=1), 2 months post-surgery (n=3), and 7 months post-surgery (n=4). A total of 8 female rhesus macaques were subjected to a new immunosuppression protocol that included anti-thymocyte globulin, tacrolimus, prednisone, and anti-CD40 treatment. The animals underwent an L6-S3 ventral root avulsion (VRA) injury, replantation of the avulsed L6 and L7 ventral roots into the lateral funiculus, and injection of approximately 250,000 human stem cell-derived motor neuron into the L5 spinal cord segment. Anatomical studies showed survival of human cells in the spinal cord of all animals. Formation of rosettes expressing neural progenitors SOX2, and NESTIN were identified at 2 months post-surgery. The human cells also showed labeling for motor neuron and oligodendrocyte progenitors, such as OLIG2, but no markers for astrocytes (GFAP) or microglial cells (IBA1) were identified. At 7 months post surgery no rosettes, astrocytes, or microglial cells were identified, although oligodendrocyte progenitors

were present. No tumor formation was detected and a human neuronal phenotype was confirmed by STEM 121 and βIII-tubulin markers. The integration of human cells in the primate spinal cord was confirmed using pre-embedding immuno-gold labeling for analysis of STEM121 in the electron microscope. Human cell processes formed parallel tracts in the grey and white matter, and human cells were able to form synapses with host motor neurons, demonstrated by synaptophysin and STEM 121 staining. Behavioral analysis showed a VRA-induced left leg weakness, but preserved ability to use the affected limb for climbing, balancing, and stepping. Functional analysis using cystometrogram and pelvic floor EMG recordings showed preserved micturation reflexes and absence of adverse functional effects. We conclude that grafted human cells supported by a new immunosuppression protocol, may show long-term survival and form neural circuits in the primate spinal cord after a CM/CE injury.

Abstract: Spinal cord injury (SCI) is a disabling neurological condition with a high impact on the quality of life of patients. After the initial mechanical damage, several biochemical mechanisms occur in the neuronal, vascular, and immune systems (secondary damage). One of the main goals for therapy is to achieve motor and sensory recovery. New therapies have been

explored, and have shown significant effects on motor recovery as well as on structural features. We present the proposal of a combinatorial therapy of immunomodulatory peptides that have already shown significant effects on motor recovery in rats with SCI, which resulted more effective than individual use. The objective was to evaluate combinations of the peptides MLIF (A), A91 (B), and GSH-MEE (C) and their effects in acute and chronic stages of SCI to know their specific responses. Female Sprague Dawley rats (230-250g) underwent a laminectomy at the T9 vertebra and a moderate contusion. They were divided into 6 groups (n=36): 1) Sham, 2) PBS, 3) A + B, 4) A + C, 5) B + C, and 6) A + B + C. The presence of lipid peroxidation metabolites (HNE, MDA and nitrites) and gene expression were evaluated 3 and 7 days post-injury and treatment (acute stage); motor recovery and histology of spinal cord were evaluated two months post-injury (chronic stage). In the acute stage, the concentration of nitrites along with IL-1β, IL-6 and IFN-γ expressions were significantly lower in the A + B + C group vs PBS at 3 and 7 days, respectively. No significant changes were observed in levels of HNE or MDA. In the chronic stage, there was a significant motor improvement in the A + B + C group vs all groups, in addition to greater preservation of parenchyma and motor neurons in the area of injury, greater white matter in the caudal area, and less presence of collagen. In conclusion, 3-peptide combinatorial therapy improves the motor recovery in rats, modulating inflammation in the acute stage, therefore preserving the integrity of the tissue in the chronic stage.

Title: Modulation of enhancer of zester homolog 2 (EZH2) activity promotes innate inflammatory response alteration and leads to tissue regeneration and better motor function recovery after rat spinal cord injury

Authors: *F. F. CORREIA[1], B. C. MORENA[1], F. R. C. GONÇALVES[1], V. PASCHON[2], A. H. KIHARA[1];
[1]UFABC, São Bernardo do Campo, Brazil; [2]Univ. Federal Do ABC, São Bernardo Do Campo, Brazil

Abstract: Spinal cord injury (SCI) is a traumatic neurologic disorder with clinical relevance due to the disruption of neuronal communication between the peripheral and central nervous system (CNS). After the primary injury, often caused by mechanical trauma, the condition may be aggravated by local tissue inflammation. Nowadays, it is already known that epigenetic-related processes contribute to the spread of CNS damage. Epigenetic is usually related to alterations in the chromatin structure which are capable to change the genetic expression without altering the DNA and are mainly related to histones modifications through methyl and acetyl group addition. Within this context, global methylation and specially the methylation on lysine 27 of histone 3 produced by Enhancer of Zeste Homolog 2 (EZH2) was related to modulation of inflammatory response and cellular death in CNS infections. However, the role of EZH2 after neuronal injury is not well described. The aim of this work was to describe the role of EZH2 activity on inflammation progress and tissue regeneration through pharmacology inhibition (GSK343) one hour after rat SCI. To this end, we combined immunofluorescence (IF) analyses with motor function evaluation as provided by Basso, Beattie, and Bresnahan (BBB) test and grid scale. Results were compared by student test T or two-way repeated measures ANOVA followed by appropriate post-hoc test. All procedures were conducted in accordance with UFABC Animal Care Ethics Committee (#2066300916). IF results in sections of the spinal cord revealed that after acute SCI (24h after injury) the number of CD86 positive cells changes in the white matter. When compared to controls (only vehicle) the treatment with GSK343 increases the number of CD86-positive cells (588 ± 251 vs. 1298±150; N= 5; $P<0.01$), while the pixel intensity analysis demonstrated a reduction on individual brightness of this marker (0.01±0.002 vs. 0.007 ± 0.001; N= 5; $P<0.01$). Moreover, when compared to controls, GSK343 treatment after SCI increased the score in BBB test 6 weeks after injury (7.28±1.6 vs. 14.55±2.2; N= 9; $P<0.05$), grid scale (0.0% ±33.3 vs. 83.33% ±36.07 vs.; N= 6; $P<0.05$) and subBBB scale (4.28±1.04 vs. 7.88±1.50; N= 9; $P<0.05$). In addition, 6 weeks after injury, IF results evidenced that when compared to controls, growth associated protein 43 (GAP43) pixel intensity is higher in the rostral region of the spinal cord (8.64 ± 0.05 vs. 17.3±1.95; N=3; $P>0.01$). All these data suggest a participation of EZH2 in the immunological innate response, especially on CD86 expression. The presence of EZH2 may influence in the adaptive response, which is related to the axonal regeneration and motor function recovery.

Title: Effect of clozapine-N-oxide (CNO) on H-reflex of naive female Sprague Dawley rats

Authors: *J. T. EISDORFER[1], K. M. KEEFE[1], K. M. RAUSCHER[1], G. M. SMITH[2], M. A. LEMAY[1], A. J. SPENCE[1];
[1]Bioengineering, [2]Lewis Katz Sch. of Med., Temple Univ., Philadelphia, PA

Abstract: Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) are chemogenetic tools that can selectively control excitability of neurons. DREADDs are activated by clozapine-N-oxide (CNO), a ligand thought to otherwise be pharmacologically inert. However, recent studies report CNO is back-metabolized to clozapine and can cause confounding effects as clozapine blocks neurotransmitter release at several endogenous receptors. Our study evaluated whether CNO modulates the H-reflex, an assay of spinal cord circuit function. The H-reflex measures the fraction of motor units activated by a stretch reflex pathway upon electrical stimulation of a peripheral nerve. Electrical stimulation causes an orthodromic volley of spikes in large afferents that elicits a reflex EMG response (H-wave). It also activates efferents which directly produce a muscle response (M-wave). Changes in maximum H-to-M-wave (H-M) ratio reflect changes in reflex pathway excitability. Further, changes in the difference in current between H- and M-wave threshold (deltaHM) indicate changes in excitability of the afferents responsible for the reflex pathway. Our study recorded the H- and M-wave from the interosseous muscle in the hind paw via electrical stimulation of the tibial nerve. We performed H-reflex on naïve female Sprague Dawley rats in the absence of DREADDs with and without intraperitoneal injection of CNO (4 mg/kg). H-reflex experiments were conducted at ‘pre’, ‘active’ and ‘post’ phases that correspond to: immediately before CNO injection; during strongest CNO effects (30 min); and after CNO wash-out (2 h), respectively. We found maximum H-M ratio was not significantly different across phases within the same group (pre 0.30 +/- 0.07; CNO active 0.25 +/- 0.13; mean +/- s.d., n=6; p=0.92 and p=0.83 for control (n=7) and CNO (n=6) groups, respectively; 2-way ANOVA on pre condition baselined data) and between groups for all phases (p=0.35). With our sample size and observed standard deviation, we would have detected a 0.13 difference in H-M ratio with 80% statistical power, corresponding to approximately half the change seen after spinal cord transection. We also found deltaHM was not significantly different within the same group (CNO active 0.23 +/- 0.16; post

0.26 +/- 0.25; mean +/- s.d., n=6; p=0.87 and p=0.55 for control (n=7) and CNO (n=6) groups, respectively; 2-way ANOVA on baselined data) and between groups (p=0.55). These results indicate CNO or back-metabolized clozapine does not affect the H-reflex in naive rats to within our statistical power. This suggests at this dosage of CNO, the H-reflex may be used to assay spinal cord circuit function in conjunction with DREADDs.

Title: Differential effects of low frequency (0.2 Hz) and high frequency (20Hz) spinal electromagnetic stimulation in modulating parameters of H-reflex responses in chronic spinal cord injured rats

Authors: *L. LIANG[1,3], H. A. PETROSYAN[1,3], S. A. SISTO[4,2], V. L. ARVANIAN[3,1]; [1]Neurobio. and Behavior,, [2]Dept. of Physical Therapy, Sch. of Hlth. Technol. and Mgmt., Stony Brook Univ., Stony Brook, NY; [3]Northport Veterans Affairs Med. Ctr., Northport, NY; [4]Univ. at Buffalo, Buffalo, NY

Abstract: Spinal cord injury (SCI) is a devastating condition that affects many important body functions of individuals. Significant deficits in transmission is one of the reasons behind functional shortfalls. In our previous animal studies, using intracellular recordings from individual motoneurons we have demonstrated that after mid-thoracic SCI synaptic transmission to lumbar spinal cord is significantly diminished. Various treatment interventions that enhance transmission in damaged spinal cord lead to recovery of motor and sensory function. Our recent results revealed that non-invasive spinal electromagnetic stimulation (SEMS) applied at low (0.2 Hz) frequency was able to induce facilitation of synaptic transmission in chronic SCI animals. In contrast to facilitatory effects of low-frequency SEMS, transcranial electromagnetic stimulation (TMS) applied at low frequencies has been reported to be inhibitory, while high frequency TMS is known to induce facilitation. In this study, we have examined and compared effects of repetitive SEMS applied at low (0.2 Hz) and high (20Hz) frequencies on H-reflex in non-injured and chronically injured rats. H-reflex is recognized as a reliable neurophysiological measure of

spinal circuitry that is distorted following SCI. Using animal models of SCI, we have also examined underlying mechanisms of SEMS induced plasticity. In particular, we have examined the role of NMDA receptors reported to be involved in modulation of transmission in damaged spinal cord.Our results revealed that high frequency (20Hz)spinal stimulation significantly reduced the amplitude of H-reflex and induced rightward shift of the H-reflex threshold current in chronic SCI rats. In contrast, low frequency (0.2Hz) spinal stimulation induced increase of H-reflex amplitude and the leftward shift of the threshold. These effects of both low and high frequency SEMS were long lasting and lasted for about 2 hours post SEMS. Most importantly SEMS induced significant improvements in recovery of frequency dependent depression (FDD) of H-reflex. Importantly, after SEMS administration there is a statistically significant difference in H-reflex amplitude at all frequencies tested i.e. 0.2, 0.5, 1, 2, 5, and 10Hz stimulations in chronic SCI rats. These results suggest that, depending on frequency of stimulation, SEMS may induce differential effects on spinal plasticity and could be used as a novel non-invasive technique for modulation of neuro-muscular circuits after chronic SCI or other neurological disorders. In fact, our current study examines effects of low (0.2) frequency and high (20 Hz) frequency SEMS in humans.

Title: Repetitive paired brain and spinal cord stimulation strengthen spared circuits and reduces hyperreflexia after cervical spinal cord injury

Authors: ***A. PAL**[1], A. RAMAMURTHY[1], H. PARK[1], T. BETHEA[1], A. GARCIA-SANDOVAL[2], S. RATNADURAI-GIRIDHARAN[3], W. VOIT[2], J. B. CARMEL[1];

Abstract: Pairs of stimuli engage associative learning mechanisms to change the nervous system. We developed a paired stimulation approach that relies on proper timing of motor cortex and spinal cord stimulation to alter spinal sensorimotor circuits. When pairing is performed repeatedly, there is a lasting and robust increase in cortical and spinal excitability in uninjured

rats. The present study tests the efficacy of paired stimulation in rats with spinal cord injury (SCI). We hypothesized that the tissue spared by SCI would enable paired stimulation to augment motor responses but decrease hyperreflexia. Cortical and biceps EMG electrodes were implanted in adult rats, and baseline testing was done a week before SCI. A moderate C4 contusion (200 k dyne) was performed, and thin and softening electrode arrays were inserted over C5-C6. Beginning 11 days after SCI, we tested the effects of repetitive paired stimulation over 10 days. The protocol uses intermittent bursts to deliver 3000 stimuli over 30 minutes every day for 10 days. After this protocol, rats with SCI had large (>150%) augmentation of both cortical and spinal motor evoked potentials (MEPs) that decreased over 2 hours to 50% increase. The magnitude and the duration of the effects were similar in rats with and without SCI, indicating that spared circuits mediate pairing effects. In the group of rats with repetitive stimulation, but not an injury only control group, MEPs increased more than 2-fold over the 10-day stimulation period. The difference between groups was maintained weeks after SCI, indicating a durable change in physiology. In both groups, SCI diminished the rate-dependent decrease in the H-reflex, consistent with hyperreflexia. After 10 days of paired stimulation, rats with stimulation had much less hyperreflexia than injury-only controls. Thus, paired stimulation produces stronger cortical and spinal MEPs, decreased hyperreflexia and the circuits spared after SCI were sufficient to enable long-term plasticity.

Abstract: One of the major devastating consequences following severe SCI is the destruction of local cells that are required for proper function and neuromodulation of spino-muscular motor circuitry. We examined the advantage of a transplantable source of neurons and oligodendrocytes into damaged spinal cord in combination with SEMS and exercise. We have recently demonstrated that SEMS could strengthen transmission and facilitate NMDA receptor function in damaged spinal cord. Importantly, exercise training, applied after SEMS, induced sustained improvements of transmission and most importantly function following contusion SCI. In the current study, adult rats received T10 contusion SCI and human induced pluripotent stem cell (hiPSC)-derived neural stem cells (NSC) were implanted 2 weeks post injury; one week after implantation the rats received SEMS followed by treadmill training, every other day for 6 weeks. Three groups of animals were examined. Gr.1 received control PBS injections and no other treatment or NSCs; Gr.2 received implantation of NSCs only; Gr.3 received implantation of NSCs followed by SEMS and treadmill exercise. All rats received injections of cyclosporine daily during survival period to protect human derived NSCs from immune-mediated rejection in rat spinal cord. Locomotor function was assessed using BBB scoring and automated Catwalk. Bladder function was assessed with metabolic chambers weekly. Electrophysiological recordings were performed at the end of survival period to examine effects of treatment on transmission at spino-muscular circuitry. After completion of behavioral and electrophysiology evaluations, the rats were perfused, and spinal cords removed and prepared for immunochemistry evaluation. Results revealed no adverse effects from implantation of NSCs. Animals that received NSCs combined with chronic SEMS/exercise treatment exhibited better recovery of locomotor function, bladder control and transmission compared with rats that received NSCs only. However, no significant difference was observed between NSCs only group and control group with no NSCs. Immunohistochemistry results revealed that survival rate of NSCs was very low, thus significant improvements of motor and bladder function in combination group could potentially be attributed to the beneficial effects of SEMS, secreted factors by implanted NSCs and exercise. Currently, the use of neural progenitor cells driven to a more mature phenotype and development of new implantation techniques are being tested in our lab that will increase the survival rate of implanted stem cells and to induce functional changes in chronic stage of severe spinal cord injury

Title: Hyperexcitation in mouse sympathetic neurons after spinal cord injury

Authors: K. TIAN[1], Y. LI[2], M. L. MCKINNON[2], *S. HOCHMAN[3], A. A. PRINZ[1];
[1]Dept. of Biol., [2]Dept. of Physiol., Emory Univ., Atlanta, GA; [3]Emory Univ. Sch. Med., Atlanta, GA

Abstract: Thoracic sympathetic postganglionic neurons (tSPNs), innervated by preganglionic neurons in the spinal cord, integrate synaptic inputs from the spinal cord to regulate downstream effector targets including vasculature. Vasomotor disorders such as autonomic dysreflexia after spinal cord injury (SCI) have been know for decades, yet little is known about the cellular and synaptic plasticity of tSPNs after SCI. We have recently characterized the cellular properties of mouse tSPNs using whole-cell recording and computational modeling [1]. Preliminary studies comparing tSPN cellular properties after high thoracic cord transection showed recovery of firing properties (similar f-I curves) measured 3-6 weeks after injury but with increased frequency in spontaneous synaptic events [2]. Furthermore, a previous RNA-Seq study identified two types of tSPNs, NA2 and NA3, that innervate the vasculature [3], but whether and how the mechanisms regulating their excitability differ is unknown.
To investigate the questions above, we employed an ensemble modeling approach to build a database of physiologically-realistic tSPN models that encompass a wide range of cellular dynamics and cell sizes [4]. From the database we identified NA3-like neurons and found that compared to all the other neurons in the database, NA3-like neurons have (i) higher densities of currents modulating spike rate adaptation with lower densities of leak current, and (ii) greater ability to integrate modeled synaptic inputs, which may lead to hyperexcitation after SCI.

Title: Electrophysiological mechanisms underlying cervical epidural stimulation in adult rats

Authors: *P. D. SHARMA, P. TENDOLKAR, P. SHAH;
Sch. of Hlth. Technol. and Mgmt., Stony Brook Univ., Stony Brook, NY

Abstract: Regaining upper limb function remains the top priority of population that have sustained a cervical spinal cord injury (cSCI). There is growing indication that electrical epidural stimulation (ES) of the spinal cord can restore volitional leg movements and promote functional upper limb motor recovery post-cSCI. Collective evidence from rodent, human and computational studies suggest that the physiological recovery following lumbar ES is mediated via direct activation of sensorimotor spinal neural networks. However, the mechanisms underlying cervical ES have not been directly studied. Identifying neural pathways that are affected with cervical ES is a critical step prior to establishing the use of cervical ES as a potential neuromodulatory therapy after a cSCI.

In this work, we electrophysiologically identified spinal structures that are activated with cervical ES using *in-vivo* spinal motor evoked potentials (sMEPs). Three stimulation protocols were implemented for this purpose: single pulse, paired-pulse with different inter-stimuli intervals (ISI) and tonic stimulation at multiple frequencies. For each protocol, bipolar stimulation at C6 and C8 spinal segments (pulse duration = 0.2ms) was utilized. Simultaneous recordings were obtained from four chronically implanted forelimb muscles in 11 non-injured awake rats.

Single pulse stimulation revealed that sMEPs are comprised of three distinct waveforms. Based on the latency, amplitude and spike morphology, we termed these waveforms as afferent (AfR), efferent (EfR) and polysynaptic (PsR) responses. The AfR appeared at lower intensities at 4-6ms, while the EfR generally appeared at higher intensities at 1.5-3ms. The PsR was present at all intensities, had a long latency window of 15-25ms, and consisted of unsynchronized spiking activity. Paired-pulse and different frequency stimulation revealed a significant reduction in AfR and PsR activity at lower ISIs and higher frequencies (10-100ms, 1-30Hz) respectively. The EfR remain unchanged in both protocols.

The EfR and AfR evoked by cervical ES share similarities to the early and middle responses elicited by lumbar ES, which has been shown to directly interact with efferent and afferent

fibers. The long latency of the PsR is indicative of polysynaptic activity with likely contribution from supraspinal pathways. The suppression of AfR activity during paired-pulse and different frequency cervical ES suggests that this modulation is most likely mediated via afferent fibers. There is a high chance that similar to lumbar ES, cervical ES mediated recovery following cSCI is dependent on this path.

Title: Serotonin supersensitivity and injury severity contribution to spasm intensity in chronic spinal cord injury

Authors: *O. A. SHELTON[1], V. M. TYSSELING[2], M. JIANG[3], D. BIRCH[1];
[2]Dept. of Physical Therapy and Human Movement Sci. and Physiol., [3]Dept Physiol, Feinberg Sch. Me, [1]Northwestern Univ., Chicago, IL

Abstract: Spinal cord injuries (SCI) disrupt messages between the brain and the body distal to the injury. This results in paralysis below the injury level and severely impairs function. In addition, most people with SCI develop hyperreflexia and involuntary muscle contractions, or spasms, that cause even more movement dysfunction as well as pain, contractures, and safety issues. One contribution to the generation of spasms is the interruption of 5-HTergic descending projections from the raphe nuclei. These projections modulate neuronal excitability through 5-HT signaling onto spinal neurons. In the intact cord, 5-HT signaling increases the net excitability of the spinal cord and enhances the motor output of the spinal cord. Following chronic SCI, diminished 5-HT signaling alters the excitability of the spinal cord and its sensitivity to 5-HT caudal to the injury and these changes contribute to the development of spasms. While changes in 5-HT sensitivity have been shown to contribute to development, it is unclear how much of the variability in the intensity of spasms is dependent upon the degree of 5-HT sensitivity. In this study we examine whether the difference in intensity of spasms can be explained by the degree of increase of 5-HT sensitivity of the spinal cord. We used a chronic impact injury mouse model of SCI. We assessed the amount of functional locomotor recovery at 10wks and compared this recovery to the electrical outputs from muscle and nerve tissue in the SCI mice. To compare how muscle contractions were impacted by our drug interventions we tested spasms *in vivo* by recording the flexor withdrawal EMG response to an electrical stimulus three months post injury.

To directly measure the spinal reflexes, we removed the sacral section of the spinal cord, stimulated the dorsal roots, and recorded the ENG response through the ventral roots. Changes in 5-HT response in multiple spinal neuron types has been shown to contribute to spasm generation. The current study investigates how much the variability in spasm intensity correlates with the degree of 5-HT sensitivity.

Title: Mapping cerebrovascular reactivity in response to breath-hold task after spinal cord injury: A functional near-infrared spectroscopy study

Authors: *K. KARUNAKARAN[1,2,3], N. D. CHIARAVALLOTI[4], B. B. BISWAL[5];
[1]Anesthesiology, Critical Care and Pain Med., Boston Children's Hosp., Boston, MA; [2]Rutgers Grad. Sch. of Biomed. Sci., Newark, NJ; [3]Harvard Med. Sch., Boston, MA; [4]Kessler Fndn., East Hanover, NJ; [5]Biomed. Engin., New Jersey Inst. of Technol., Newark, NJ

Abstract: Impairment of the sympathetic control after spinal cord injury results in cardiovascular deficits such as supine hypotension, orthostatic hypotension and cardiac arrhythmia. Injuries above T6 level further experience an impairment of cerebrovascular reactivity and neurovascular coupling properties of cerebrovascular control. It is unclear if cerebrovascular control is also affected in lower-level injuries. Functional near-infrared spectroscopy (fNIRS) is a promising technique to non-invasively and reliably measure the hemodynamic response of the brain in an upright position at a high temporal resolution. Using a breath-hold paradigm with fNIRS, the cerebrovascular reactivity can be quantified in response to global hypercapnia. Thirteen individuals with paraplegia resulting from SCI and 13 HC were recruited and scanned during a 15 second breath holding task for a total duration of 5 minutes. Hemoglobin concentration changes were quantified from the sensorimotor cortex, supplementary motor area and prefrontal cortex. Results indicate that SCI group (including 7 subjects with injuries below T6) exhibit a greater delay and larger pre-stimulus undershoot in oxy-hemoglobin concentration change to breath holding in bilateral lateral sensorimotor areas. The overall increase in oxy-hemoglobin change was similar in both healthy and SCI groups. Current findings suggest an intact static autoregulation but impaired dynamic autoregulation of cerebral blood

flow after paraplegia. Further, the application of fNIRS to assess cortical reorganization following SCI is unique and expands our understanding of the neurophysiology after SCI.

Title: Intraspinal neural synchrony: Oscillating between interpretations

Authors: *J. G. MCPHERSON[1,2,3,4], M. F. BANDRES[3,4], V. MELERO[4], M. BUCHANAN[3,4]; [1]Physical Therapy, [2]Anesthesiol., [3]Biomed. Engin., Washington Univ. in St. Louis, St. Louis, MO; [4]Biomed. Engin., Florida Intl. Univ., Miami, FL

Abstract: In supraspinal neural structures, band-specific local field potential (LFP) power and oscillatory neural activity are associated with particular behavioral states and underlying neural processes. Supraspinal LFPs can also be controlled volitionally. As such, supraspinal LFPs and neural oscillations are thought to convey meaningful information. Little is known about LFPs and oscillatory activity in the spinal cord, however. Indeed, many questions remain open. For example, does spontaneous intraspinal oscillatory activity even exist? Can intraspinal LFPs be compartmentalized into discrete, physiologically relevant frequency bands? If so, does sensorimotor integration predictably modulate band-specific power in intraspinal LFPs? In this exploratory study, we characterize laminae-specific spontaneous intraspinal LFPs and oscillatory activity. We then characterize intraspinal LFPs and oscillatory activity during periods of increased neural transmission in spinal pain pathways, non-pain-related sensory pathways, and motor pathways (respectively). Finally, we characterize changes in intraspinal LFPs and oscillatory activity associated with altered spinal Gaba-ergic signaling. All experiments were approved by the FIU IACUC and conducted in adult male Sprague-Dawley rats (n=20). After T13-L2 laminectomy, microelectrode arrays were implanted at the L5 dorsal root entry zone. Electrodes were distributed from the superficial dorsal horn to the ventral horn. Sensory transmission was modulated by mechanical stimulation of the L5 dermatome, motor transmission was modulated via intraspinal microstimulation, and Gaba-ergic signaling was modulated through use of different anesthetic agents. Outcome measures included: time-frequency analysis of LFP power during sensorimotor integration; presence, location, and frequency of spontaneous oscillations; coherence between multi-unit neural activity across laminae; and temporal measures

of synchrony amongst co-active units across laminae. Our primary finding is that intraspinal LFP power is modified in a frequency- and lamina-specific manner by changes in pain, non-pain-related sensory, and motor transmission. Analyses of firing synchrony between co-active units suggests that these changes may reflect information processing and functional connectivity across laminae. We also find evidence of spontaneous, lamina-specific bursts of oscillatory activity that can likewise be modified by sensorimotor integration. Future work is required to investigate intraspinal LFP and oscillatory activity in awake, behaving animals and to determine if it can be volitionally controlled.

Title: Changes in spinal dorsal horn neuron characteristics from the early stage of peripheral nerve injury to chronic pain transition

Authors: *M. KURABE, M. SASAKI, H. BABA;
Anesthesiol., Niigata Univ, Sch. Med., Niigata, Japan

Abstract: Background: Chronic pain is a major health issue and its treatment presents a challenge. The plasticity of neuronal transmission in the spinal dorsal horn (SDH) is thought to be a key mechanism in developing chronic pain. The functional and temporal changes of SDH neurons that cause the transition to chronic pain remain unknown. Clarifying long-term remodeling processes in the SDH after nerve injury will aid in developing treatments for chronic pain. In this study, we aimed to clarify remodeling processes in the SDH after nerve injury.
Methods: We divided adult male Wistar rats into 2 groups: control and chronic constriction injury (CCI) model rats. *In vivo* patch-clamp recordings were prepared from the SDH neurons. We compared spontaneous excitatory postsynaptic currents (sEPSCs), neuronal response properties, and time-dependent changes of receptive field (RF) after nerve injury. We next identified excitatory neurons indirectly through the absence of staining for Pax2, and positive labeling with the pan-neuronal marker NeuN. The number of excitatory neurons was analyzed at various times after nerve injury.
Results: We observed evoked EPSCs induced by noxious or innoxious stimuli and categorized neurons into 4 types: response to only noxious stimuli; response to only innoxious stimuli;

response to both noxious and innoxious stimuli; and nonresponding neurons. The relative proportion of the 4 types of neurons differed significantly between naïve and CCI rats. In addition, the RF in CCI rats was significantly increased on days 14 and 28 after nerve injury. Then, we recorded sEPSCs and evoked EPSCs.. Both the frequency and amplitude of sEPSCs from CCI rats were significantly increased until 14 days after injury. However, they all gradually decreased thereafter and reached almost control levels on the 28th day. In accordance with this result, the number of Pax- and NeuN+ neurons was decreased at day 28.
Conclusions: This study is the first to demonstrate long-term remodeling processes in the SDH after nerve injury. The changes of properties and excitatory inputs in SDH neurons may have contributed to the RF expansion in CCI rats. Hence, the inhibition of early remodeling caused by nerve injury in
the SDH may be a strategy for reducing the transition to chronic pain.

Title: Spasticity and spasms in knee extensor muscles in people with incomplete spinal cord injury

Authors: *B. A. DEFOREST[1,3], S. SANGARI[1,3], J. BOHORQUEZ[2], M. PEREZ[1,3,4];

Abstract: Spasticity (i.e. velocity-dependent resistance to stretch) and spasms (i.e. involuntary and uncontrolled muscle contractions) are common symptoms present in humans with spinal cord injury (SCI). These two complications are commonly thought to be related, but there is no conclusive evidence that support this view. Clinically, spasticity is evaluated in individual muscles with the Modified Ashworth Scale (MAS), while spasms are assessed with the Penn Spasm Frequency scale (PSFS). To examine relationships between spasticity and spasms, we examined the MAS, PSFS, and the cutaneous reflex in the knee extensor muscles in people with motor incomplete SCI. Spinal reflexes are thought to contribute to the short-latency component

of the cutaneous reflex while persistent inward currents are thought to contribute to the long-latency component of the cutaneous reflex. We found that the area of the short-latency component of the cutaneous reflex was correlated with the MAS but not the PSFS (onset to 500 ms post stimuli; Spearman rho=0.884; p=0.001). The long-latency component of the cutaneous reflex (>500 ms post stimuli) was not correlated with the MAS (rho=0.477; p=0.164) and the PSFS (rho≤0.467; p≥0.173). Notably, the area of the short- and long-latency components of the reflex were correlated (r=0.961; p<0.001). These results suggest that while there is no relationship between clinical assessments of spasticity and spasms, the cutaneous reflex reveals a physiological relationship between these two complications. We argue that the cutaneous reflex might be a useful tool for making inferences about spasticity and spasms following SCI.

Title: Bilateral asymmetries in assessments of sensory function after spinal cord injury

Authors: *B. CHEN[1,2], M. A. PEREZ[1,3,2];
[1]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL; [2]Shirley Ryan Ability Lab., Chicago, IL; [3]Bruce W. Carter Dept. of Veterans Affairs Med. Ctr., Miami, FL

Abstract: Sensory function is typically altered following spinal cord injury (SCI). Therefore, using sensitive assessments to detect changes in spared sensory pathways is critical for rehabilitation procedures and plasticity outcomes. Previous studies showed discrepancies in the level of spared sensory function detected by the international standards for neurological classification of spinal cord injury (ISNCSCI) and the electrical perceptual threshold (EPT). The goal of the present study was to compare spared sensory function as revealed by light touch and pinprick tests of the SNCSCI and the EPT exams in 16 individuals with chronic incomplete cervical SCI bilaterally. In the evaluation per dermatome, we found that the light touch component of the ISNCSCI exam detected asymmetries in 17 to 29 % of the subjects tested and the pinprick component of the ISNCSCI exam detected asymmetries in 17 to 47 % of the subjects tested. Notably, the EPT exam detected asymmetries in 82 to 94 % of the subjects

tested. Our results demonstrate that EPT is a more sensitive tool to detect bilateral asymmetries in spared sensory function after SCI.

Title: Altered neural activity and functional connectivity in injured cervical spinal cord in monkeys

Authors: P. F. YANG, T. L. WU, N. BYUN, J. C. GORE, ***L. M. CHEN**;
Radiology and Radiological Sci., Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Our previous high-resolution fMRI study of monkey spinal cord revealed that spinal grey matter horns demonstrate strong resting state functional connectivity (rsFC) within and cross spinal segments. Traumatic spinal cord injury (SCI) reduced the strengths of these rsFC below injury segments, but these later returned to their pre-injury strengths. This dynamic process correlated strongly with the recovery of hand use behavior in squirrel monkeys after a unilateral section of the dorsal column (DCL) [Chen et al. 2015 PNAS]. Inter-horn rsFC thus appears to reflect the functional integrity of intraspinal circuits, suggesting that rsFC metrics may serve as a biomarker of SCI severity and for predicting recovery. An improved understanding of the dynamic processes involved in the functional plasticity of intraspinal circuits, and their relationships to functional and behavioral impairments, would provide critical mechanistic information for identifying targets and time-windows for therapeutic interventions. The current study aims to (1) validate rsFC fMRI findings by comparing directly rsFC with FC measures of local field potential (LFP) coherence at 2 or 6 months after SCI, and (2) relate changes in LFP coherence to the recovery of impaired digit use in performing food reaching-grasping-retrieving tasks. To date, we have studied 4 monkeys with repeated fMRI acquisitions at high field (9.4T) followed by microelectrode electrophysiology recordings at 2 or 6 months after a DCL. All MRI images were acquired under light isoflurane anesthesia using a surface transmit-receive coil. High-resolution structural and BOLD fMRI images were acquired with the same geometry. Four 16-channel microelectrode arrays were placed bilaterally at two segments. Both fMRI and LFP signals were acquired in response to 8 Hz vibrotactile stimulation and at rest. Standard fMRI data preprocessing and LFP denoising steps were applied. We found that broad-band LFP coherence

between dorsal horns of the segment below injury was stronger than that of the above-injury segment. Across LFP bands, the differences between above and below-lesion horns varied. Coherence of gamma band signals was stronger, and coherence of theta and delta bands were weaker, below the segment of the injury compared to their corresponding measures above the segment at 6 months post-injury, a time when each monkeys' hand use returned to pre-injury levels. Preliminary analyses also revealed reduced fMRI responses to tactile stimulation in below-injury segments compared to the normal cord. These results confirm the interpretation of BOLD rsFC as markers of changes in spinal cord circuits following injury.

Title: Loss of tactile input differentially alters the responsiveness and functional connectivity of primate somatosensory cortices

Authors: L. CHEN, A. MISHRA, F. WANG, *P.-F. YANG, J. C. GORE;
Radiology and Inst. of Imaging Sci., Vanderbilt Univ., Nashville, TN

Abstract: The somatosensory system undergoes drastic reorganization after the loss of its sensory inputs following spinal cord injury (SCI). This plastic process is believed to play a critical role in mediating recovery of some lost functions through mostly unknown mechanisms. Despite its high functional importance, the dynamic process of plasticity has not been systematically characterized in primates. The primary goal of the present study is to fill in this critical knowledge gap by (1) using stimulus-driven and resting state fMRI (rsfMRI) to characterize and monitor longitudinally the plasticity that occurs within the somatosensory cortices following loss of tactile input by a targeted unilateral dorsal column transection of the cervical spinal cord, and (2) relating changes in fMRI responses and resting-state functional connectivity (rsFC) to impairments in skilled hand use in squirrel monkeys over a period of two months. An improved understanding of the dynamic processes of mesoscale functional circuits and their relationship to the degree of recovery of impaired hand use would provide critical mechanistic information for identifying targets and time window for therapeutic interventions. The fMRI study was conducted in six monkeys under light isoflurane anesthesia at ultra-high

field (9.4T), which offers high contrast- and signal-to-noise ratios. A 3-cm surface transmit-receive coil was positioned over the primary (S1), secondary (S2) somatosensory, and insular cortices. High-resolution T2*-weighted anatomic (68x68µmx2000 μm^3) and fMRI (547x547x2000 μm^3) images were acquired. Vibrotactile stimuli (8Hz in 30s off/on cycles) were used to map digit locations, quantify cortical responsiveness, and locate digit regions before (baseline) and at different time points after a unilateral dorsal column lesion (DCL). Standard fMRI data preprocessing steps were applied. We measured the voxel-wise temporal fMRI signal magnitude at the task frequency using FFT and identified those voxels that showed statistically significant differences in BOLD signals between stimulus on and off periods. We found that the signals in deeper cortical layers dropped drastically compared to superficial regions in S1 after an injury, whereas they were more uniform beforehand. Pair-wise rsFC analyses of areas 3a, 3b, 1, and 2 revealed weakened FC across areas. In summary, a near complete loss of ascending tactile inputs following spinal cord injury leads to differential effects in cortical responsiveness to 8 Hz vibrotactile stimulation in S1 versus S2 and insular areas as well as functional connectivity strengths between S1 subareas.

Title: Discovery of PIPE-505, a small molecule therapeutic for the treatment of sensorineural hearing loss (SNHL) associated with cochlear synaptopathy

Authors: *D. LORRAIN, M. POON, K. J. STEBBINS, G. EDU, A. BROADHEAD, J. SEIDERS, J. ROPPE;
Pipeline Therapeut., San Diego, CA

Abstract: PIPE-505 is a gamma secretase inhibitor (GSI) in development for the treatment of SNHL associated with cochlear synaptopathy. A series of in vitro and in vivo studies in animal models of auditory loss have demonstrated two distinct mechanisms of action (MOA) that may restore hearing function in patients with SNHL. Specifically, treatment with PIPE-505 lead to 1) regeneration of synapses between Type I (spiral ganglion neuron) SGN and (inner hair cell) IHC via the Netrin/DCC pathway and 2) increased outer hair cells via the Notch pathway. Mouse dissociated cochlea cultures were used to demonstrate that inhibition of GS induces neurite outgrowth of Type I SGNs. Function blocking antibodies against the axon guidance pathway (e.g., deleted in colorectal cancer [DCC] and netrin) prevented PIPE-505 induced neurite

outgrowth, indicating that neurite stimulation is generated by PIPE-505 via the netrin-DCC pathway. Importantly, inhibition of GS prevented the cleavage of DCC, resulting in persistent expression of select receptors and consequent increased axonal length. This observation with PIPE-505 has been extended to in vivo models of hearing loss. In a noise-induced cochlear synaptopathy model local administration of PIPE-505 regenerated IHC sensory synapses and improved ABR Wave I function. In a guinea pig kanamycin ototoxicity model, intratympanic PIPE-505 restored IHC synapse number and this effect was long lasting. To our knowledge this is the first time this effect has been observed and described. From a more established perspective, PIPE-505 treatment showed evidence of generating outer hair cells (OHC). This effect has been well described and involves notch-mediated Atoh1 expression. In summary, nonclinical studies have demonstrated the potential for PIPE-505 to restore synaptic function at the IHC, as well as regenerate OHCs through a separate mechanism. The lead therapeutic MOA, regeneration of the cochlear synapse, should augment signal-to-noise processing and manifest as improved speech-in-noise comprehension, a chief auditory complaint and unmet need of patients with SNHL.

Title: Electrophysiological characterization of type II spiral ganglion neurons

Authors: *M. C. PEREZ-FLORES, J. HAN LEE, S. PARK, M. KANG, E. N. YAMOAH; Physiol. and Cell Biol., Univ. of Nevada Reno, Reno, NV

Abstract: In mammals, spiral ganglion afferent neurons (SGNs) that innervate cochlear hair cells, comprise two distinct population. Myelinated type I SGNs represent ~95% of the afferent neuron population and extend one peripheral process which form a single synapse with one inner

hair cell (IHC). The type II SGNs are unmyelinated and constitute only 5% of the population, they receive synaptic inputs from ~9 outer hair cells (OHCs). Type I neurons have been extensively characterized because they overpass the number of type II neurons in a relation of 20:1. In contrast, type II neurons have small size and thin axons, making them difficult for in vivo recording. Biochemically, type I and II SGNs comprise molecularly distinct cell populations. Type I neurons are characterized as consisting of three molecular subtypes with additional variations existing across the tonotopic axis. In type II neurons an average of 6,320 genes/cell were detected. Even if such molecular profile can be used for subtype classification, further functional characterization remains unknown. Recent studies in type II fibers suggest that they may mediate the sensation of auditory pain. However, their very extensive neurite projection from the soma is not amenable for adequate current and voltage clamp characterization. Thus, the best strategy to study type II neurons is cell isolation for their subsequent recording. In this work we have identified strategies to record from the bonafide type II neurons, we have benefited from the fact that a) the neurons are unmyelinated which is an advantage to use patch electrodes; b) as type II are peripherin positive, we could potentially use EGFP-positive transgenic mouse model to isolate type II SGNs and identify them accurately. We took advantage of the transgenic mouse model to provide evidence that 1) all peripheral neurons express peripherin at early stages, and this expression is time-dependent. 2) In three weeks old mice, peripherin expression remains specifically in type II neurons. Myelination of type I neurons suppresses their peripherin expression. 3) In culture, after 24 hr the number of peripherin-positive neurons increased in a time-dependent manner, as myelin detached from type I neurons. Thus, removal of myelin may trigger EGFP expression of the transgenic mouse model. For this reason, we only recorded from peripherin positive neurons maintained in culture for less than 24 hr. 4) type II neurons expressed heterogeneous firing properties, from slow to fast adapting. This work was supported by the funding the NIDCD (1R01 DC016099) to ENY.

Sci. and Engin., Univ. of Maine, Orono, ME

Abstract: Congenital Zika Syndrome caused by vertical transmission of Zika virus (ZIKV) to the gestating fetus often results in microcephaly, ventriculomegaly, and sensorineural hearing loss. It has been reported that ~6% of ZIKV-associated microcephalic newborns show diminished otoacoustic emissions and auditory brainstem responses, suggesting at least some pathogenesis may originate within the cochlea and/or the statoacoustic ganglion (SAG). Both the sensory cochlea and the SAG derive from a common neurosensory domain of the otocyst that also gives rise to vestibular sensory organs. Previous research has demonstrated that ZIKV preferentially infects neural progenitor cells of the central nervous system and causes increased cell death and reduced proliferation of infected cells. Thus, we hypothesized that the neurosensory primordium would be more susceptible to ZIKV infection than other inner ear tissues. To investigate this hypothesis, we mapped the spatio-temporal susceptibility of the embryonic cochlea and SAG to ZIKV during development in two vertebrate models – chicken embryos and mouse cochlear cultures.

For chicken embryos, ZIKV was delivered into the fluid cavity of the otocyst at embryonic day (E)2 to 5 when it is most accessible for injection, followed by histological evaluations of the inner ear 2 to 8 days-post-infection (dpi). Cells harbouring replicating virus were detected by immunostaining of double-stranded RNA. We observed infection of both sensory and nonsensory otic epithelia, the SAG, and the periotic mesenchyme. In some cases, we also noticed smaller than normal SAGs about a week after E2 and E3 ear injections; this pathology may result from increased cell death observed within the ganglion at 2 dpi.

Mouse cochlear cultures were used to deliver ZIKV at different developmental stages from proliferative prosensory cells to post-mitotic differentiated cells. Cochleas were explanted at E12.5, E15.5 or postnatal day 2, exposed to ZIKV for 1 to 2 days, and cultured for 1 to 5 dpi. Infection was blocked when cochlear cultures were preincubated with the ZIKV-117 antibody. Like the chicken data, we detected ZIKV in hair cells (HCs), supporting cells and periotic mesenchyme. At all ages, inner HCs were somewhat more susceptible to infection than outer HCs.

Apart from the SAG of chick embryos, there was limited evidence that ZIKV increased cell death in the inner epithelium in either model system, although various post-infection time points remain to be studied. Our findings suggest the possibility that direct ZIKV infection of the peripheral auditory system may be a contributing factor to hearing loss associated with congenital Zika syndrome.

Title: Non-invasive induction of mild therapeutic hypothermia mitigates noise-induced hearing loss

Authors: *S. RINCON SABATINO[1], R. SANGALETTI[4], M. HOFFER[2], C. KING[5], S. RAJGURU[3];
[1]Biomed. Engin., Univ. of Miami, Coral Gables, FL; [2]Otolaryngology, Univ. of Miami, Miami, FL; [3]Biomed. Engin. and Otolaryngology, Univ. of Miami, Coral Gables, FL; [4]Physiol. and Biophysics, Univ. of Miami, Miller Sch. of Med., Miami, FL; [5]Lucent Med. Systems, Kirkland, WA

Abstract: Motivation: Noise-induced hearing loss (NIHL) is a leading sensorineural conditions, with an estimated 1.1 billion people at risk of NIHL due to occupational and recreational exposure to hazardous sounds (>85 dB SPL). In the present study, we assessed the use of localized mild therapeutic hypothermia (*mTH*) in the preservation of neural structures post-exposure to acute noise trauma. **Methods:** Male and female juvenile Brown Norway rats (15-20 weeks old) were randomly separated into four groups: Normothermic NIHL, *mTH*-treated NIHL, *mTH* Control, and Non-exposed Control. Auditory brainstem responses were performed to quantify changes in hearing threshold in anesthetized rats prior to NIHL and up to 3 months post-exposure. NIHL animals were subjected, under isoflurane anesthesia, to two hours of continuous 4-8 kHz noise at 105 dB SPL. Mild hypothermia (31-33 ºC) was induced locally in cochleae of *mTH*-treated rats at 15 minutes post-exposure for a two-hour period. Following completion of experiments, cochleae were harvested for immunohistological quantification of inner and outer hair cell survival, ribbon synapse density and strial edema. To study neuroprotective mechanisms of *mTH* for NIHL, transcriptomic changes in apoptosis-related genes were performed by RNA-sequencing of cochlear sensory epithelium and further pathway analysis was performed by qRT-PCR. **Results:** At 1-day post-exposure, Normothermic animals had significantly higher threshold shifts than *mTH*-treated animals across all frequencies tested. Mild hypothermia treatment showed greater recovery in ABR thresholds and wave I and IV amplitudes in the days following noise exposure with nearly full recovery to control values, whereas the normothermic group elicited significantly higher thresholds at early timepoints and only a partial recovery at 28 days

post-exposure. Significant synaptic ribbon loss was observed in representative regions corresponding to 8 and 16 kHz only in normothermic cochleae at 1- and 3-days post-exposure. Results of RT-PCR show that *mTH* prevents additional damages by inhibiting the activation of caspase 3 and 8, thus interrupting the extrinsic apoptotic pathway. **Conclusions**: Delivery of non-invasive, controlled and localized mild therapeutic hypothermia to the inner ear is feasible and safe. Mild therapeutic hypothermia post-NIHL is efficacious and significantly lowers hearing threshold shifts and preserves residual hearing. Therapeutic hypothermia provides significant protection from neuropathy and synaptopathy likely via downregulation of apoptotic pathways and inflammation.

Title: Noise damage and repair in zebrafish: Modeling acoustic overstimulation in lateral-line organs

Authors: M. HOLMGREN[1], M. E. RAVICZ[2,3], K. E. HANCOCK[2,3], M. E. WARCHOL[1], ***L. SHEETS**[1];
[1]Dept. of Otolaryngology–Head and Neck Surgery, Washington Univ. Sch. of Med. In St. Lo, St. Louis, MO; [2]Dept. of Otolaryngology–Head and Neck Surgery, Harvard Med. Sch., Boston, MA; [3]Eaton-Peabody Lab., Massachusetts Eye and Ear, Boston, MA

Abstract: Sensory hair cells are specialized receptors for hearing and balance. Loud or extended noise exposure damages hair cells, often resulting in either loss of synaptic connections with auditory nerve fibers in the cochlea or hair-cell death. Currently, the cellular mechanisms underlying hair-cell damage following noise exposures are poorly defined. Determining these mechanisms is a critical step toward understanding the underlying causes of sensorineural hearing loss.

Zebrafish lateral-line neuromast hair cells are similar to mammalian hair cells at the molecular and cellular level, but are superficially localized on the skin, making them pharmacologically and optically accessible within intact larvae. We therefore exposed 7-day-old free-swimming zebrafish larvae to strong water current (60 Hz; 1.04 +/- 0.01 m/s^2) in a multi-well dish attached to an electrodynamic shaker. Fish exposed to either a brief pulse followed by 2 hours of uninterrupted stimulation or short, repeated stimulation spanning a total of 2 hours showed a subset of neuromasts with disrupted morphology and significantly reduced hair-cell innervation. Additionally, fish exposed to the uninterrupted stimulus showed a significant loss of hair cells accompanied by recruitment of macrophages, indicating noise-induced injury. Hair-cell function, as measured by uptake the cationic dye FM1-43, was also significantly reduced in noise-exposed neuromasts. Notably, noise-induced damage appears to repair within hours; hair-cell morphology and number returned to normal 4-8 hours following noise and corresponded to clearance of damaged hair cells by macrophages. Moreover, exposed hair cells with recovered morphology showed normal afferent innervation, suggesting nerve contacts also repair. Functionally, FM1-43 uptake completely recovered 48 hours following noise exposure. These observations support zebrafish as a useful model for defining the cellular pathways that contribute to hair-cell damage resulting from noise and for determining how hair-cell organs may repair following noise damage.

Title: Contrasting mechanisms for hidden hearing loss: Synaptopathy vs myelin defects

Authors: *M. BUDAK[1], K. GROSH[2], G. CORFAS[5], M. R. ZOCHOWSKI[3], V. BOOTH[4]; [1]Biophysics, [2]Mechanical Engin. & Biomed. Engin., [3]Physics, [4]Mathematics & Anesthesiol., Univ. of Michigan, Ann Arbor, MI; [5]Kresge Hearing Res. Inst., The Univ. of Michigan, Ann Arbor, MI

Abstract: Hidden hearing loss (HHL) is an auditory neuropathy characterized by normal hearing thresholds but reduced amplitude of the sound-evoked auditory nerve compound action potential

(CAP). It has been proposed that in humans HHL leads to speech discrimination and intelligibility deficits, particularly in noisy environments. Animal models originally indicated that HHL can be caused by moderate noise exposures or aging, and that loss of inner hair cell (IHC) synapses could be its cause. Recently, Wan and Corfas (2017) provided evidence that transient loss of cochlear Schwann cells also causes permanent auditory deficits in mice, which have characteristics of HHL, showing, that the only histological finding in the mice after Schwann cell regeneration is a permanent disruption of the myelination patterns at the heminode of auditory nerve (AN) peripheral terminals. To shed light on mechanisms of HHL and to test their impact on AN activity, we constructed a reduced biophysical model for a population of AN fibers. We found that the amplitude of simulated sound-evoked AN CAPs is lower and has a greater latency when the heminodes are disorganized across the population, i.e. they are placed at uneven distances from the hair cell synapse rather than at the stereotypic distance as seen in the normal cochlea. Model analysis confirms that disruption of the position of the heminode causes loss and desynchronization of AN spikes, thus leading to a disruption of temporal resolution and reduction of the sound-evoked AN CAP. We also simulated synaptopathy by removing high threshold IHC-AN synapses and found that the amplitude of simulated sound-evoked AN CAPs decreases while latency remains unchanged, corresponding with observations in noise exposed animals. Thus, model results explain the differential effects caused by demyelination and synaptopathy underlying auditory deficits in HHL.

Title: Pou3f4 expressing otic mesenchyme cells promote spiral ganglion neuron survival

Authors: *P. M. BROOKS, M. L. MACRAE, K. M. RANGOUSSIS, T. M. COATE; Biol., Georgetown Univ., Washington, DC

Abstract: Current therapies to improve hearing, including hearing aids and cochlear implants, require intact and functional auditory neurons. Within the inner ear, the primary auditory neurons, spiral ganglion neurons (SGNs), are surrounded by mesenchyme cells which express the transcription factor Pou3f4 (also known as Brn4). Mutations in *Pou3f4* have been associated with DFNX2, the most common form of X-linked deafness and typically include developmental

malformations of the middle and inner ear, and profound lifelong hearing loss. Presently, it is known that interactions between Pou3f4-expressing mesenchyme cells and SGNs are important for proper axon bundling during development. However, although Pou3f4 remains expressed into adulthood, the functional significance of Pou3f4 for postnatal SGNs remains elusive. To address this question, we first carefully documented Pou3f4 protein expression in early postnatal mouse cochlea followed by comparisons of SGNs in *Pou3f4* knockout mice (*Pou3f4*$^{y/-}$) and littermate controls (*Pou3f4*$^{y/+}$). In *Pou3f4*$^{y/-}$ mice, SGN density begins to decline by the end of the first postnatal week, with approximately 25% of SGNs ultimately lost. Interestingly, this period of neuronal loss coincides with a transient population of Pou3f4-expressing cells particularly around and within the spiral ganglion. Given the developmental interaction between Pou3f4 and SGNs, we used a sparse labeling model to confirm that there is no difference in the percentage of neurons making contact with the sensory domain which could account for the observed neuronal loss. Instead, these data suggest that Pou3f4-expressing mesenchyme cells play a role in maintaining SGN populations during the early postnatal period. We are currently determining the extent to which Pou3f4 is necessary to maintain all, or only select, SGN subtypes.

Title: Molecular mechanisms of alcohol-induced developmental defects in the zebrafish inner ear

Authors: *L. Y. ZAMORA[1], I. SKROMNE[2], Z. LU[1];
[1]Biol., Univ. of Miami, Miami, FL; [2]Biol., Univ. of Richmond, Richmond, VA

Abstract: Alcohol exposure is known to cause fetal alcohol spectrum disorders (FASD) that may manifest as lifelong physical, cognitive, and behavioral anomalies of human development. In our previous studies, we uncovered an alcohol-sensitive period, 12 to 17 hours post-fertilization (hpf) when the developing inner ear and lateral line were most vulnerable to alcohol insult. However, the mechanisms by which early alcohol exposure affects the developing

auditory system is still largely unknown. In this study, we determined if biological processes necessary for inner ear development are adversely affected by alcohol using transgenic, *in situ* hybridization, and immunocytochemical techniques. To model fetal alcohol exposure, zebrafish (*Danio rerio*) were treated in 2% alcohol from 12 to 17 hpf. Vital biological processes that contribute to inner ear development were examined to uncover the mechanisms that underlie alcohol-induced inner ear defects. We focused on the Fibroblast Growth Factor (FGF) pathway, which is known as the major signaling required for inner ear development. First, we found *Tg(HSP70:XFD)* embryos with heat-inducible FGF-inhibition had similar defective inner ear phenotypes compared to alcohol treatment. Next, we examined the effects of embryonic alcohol exposure on FGF signaling with an antibody targeting a FGF signaling marker, phospholyrized extracellular signal-related kinase (pERK). Results showed a reduction of inner ear pERK expression after alcohol exposure. In addition, we observed that alcohol exposure decreases gene expression of *fgf3,* a critical ligand for initiation of FGF signaling, and an FGF target gene, *sprouty4.* Furthermore, we administered SU5402, a pharmacological drug to inhibit FGF signaling at the intracellular receptor level. Treatment with SU5402 alone and SU5402 with alcohol resulted in similar inner ear defects, indicating that alcohol, like SU5402, may also affect FGF receptors. Our results provide evidence of molecular effects from alcohol exposure during inner ear development and serve to initiate the unraveling of complex and intricate mechanisms which lead to defective inner ear organogenesis. Overall, this is the first study to reveal that embryonic alcohol exposure suppresses FGF signaling, leading to decreased hearing capacity.

Title: A backward encoding approach to recover subcortical auditory activity

Authors: *F. SCHMIDT[1], G. DEMARCHI[1], F. GEYER[2], N. WEISZ[1];
[1]Ctr. for Cognitive Neurosci., [2]Univ. of Salzburg, Salzburg, Austria

Abstract: Several subcortical nuclei along the auditory pathway are involved in the processing of sounds. One of the most commonly used methods of measuring the activity of these nuclei is the auditory brainstem response (ABR). Due to its low signal-to-noise ratio, ABRs have to be derived by averaging activity evoked by a high number (several thousand) of repetitions of e.g. clicks or tone bursts. To date no approach exists that can be used to non-invasively investigate both auditory brainstem activity following natural sounds (e.g. speech, music) and silent periods, for example, within selective attention tasks. For several cognitive neuroscientific questions this

is a severe limitation. We propose that by training a backward encoding model to reconstruct evoked ABRs from electrophysiological data, spatial filters (channel weights) can be obtained that are tuned to auditory brainstem activity. Since these filters can be applied to any other dataset (i.e. generalized) using the same spatial coverage, this could allow for the estimation of auditory brainstem activity from any continuous sensor level data. In this study, we established a proof-of-concept that by employing a backward encoding model generated using a click stimulation rate of 30 Hz we could predict the expected ABR activity recorded via electroencephalography (EEG) from an independent measurement, using a stimulation rate of 9 Hz. By showing that the individually predicted and measured ABRs are highly correlated ($r \sim 0.67$), we laid the necessary foundation to use this paradigm in more naturalistic listening situations.

Title: Towards the optical cochlear implant: Optogenetic stimulation of the auditory pathway

Authors: *D. KEPPELER[1], A. DIETER[1], E. KLEIN[2], M. SCHWAERZLE[3], P. RUTHER[4], T. MOSER[5];
[1]Inst. for Auditory Neurosci., Goettingen, Germany; [2]IMTEK, Univ. of Freiburg, Freiburg Im Breisgau, Germany; [3]IMTEK, [4]Univ. of Freiburg, Freiburg im Breisgau, Germany; [5]Inst. for Auditory Neurosci., Univ. Med. Ctr. Goettingen, Goettingen, Germany

Abstract: With 500,000 patients worldwide, the cochlear implant (CI) is the most successful neuroprosthesis. In the majority of patients, direct electrical stimulation of the auditory nerve restores open speech perception bypassing the defective sensory organ. However, the major bottleneck of current CIs is the poor coding of spectral information, which results from broad current spread from each electrode contact within the saline solution filled cochlea. As light can

be more conveniently confined, optical stimulation of the auditory nerve presents a promising perspective for a fundamental advance of CIs. In this study, we established reliable expression of the ultra-fast channelrhodopsin (ChR) Chronos in mouse spiral ganglion neurons (SGNs) and demonstrated its support of high temporal fidelity in the auditory nerve. Further, we developed multichannel optical CIs based on micro-fabricated light-emitting diode (LED) arrays. We characterized them for optical stimulation of channelrhodopsin-2 (ChR2)-expressing SGNs in transgenic rats or gerbils using optical auditory brainstem responses (oABR) stimulated by individual or multiple LEDs. Positioning of the probes and atraumatic implantation was validated with micro-CT imaging. Multielectrode array recordings along the tonotopic axis of the inferior colliculus (IC) indicate spectral selectivity of optical stimulation closer to acoustic than electrical stimulation. This contribution will summarize the current state of optogenetic stimulation of the auditory pathway and report on recent breakthroughs on achieving high temporal fidelity, frequency resolution and establishing multichannel optical CIs.

Title: Radixin modulates outer hair cell stereocilia function

Authors: *S. PRASAD, A. FRIDBERGER;
Linköping Univ., Linköping, Sweden

Abstract: The RDX gene encodes the actin-binding protein radixin. In humans, RDX mutations cause congenital hearing loss, but radixin is expressed at high levels also in the mature inner ear, suggesting an important but yet undefined functional role. Based on its localization within sensory cell stereocilia, its actin-binding properties, and abundance, we hypothesized that radixin could affect the amount of force required to deflect stereocilia during sound stimulation. Previous work suggested that stereocilia stiffness may be actively regulated, but the underlying molecules were not determined. We applied quantitative time-resolved phase locked confocal imaging in combination with electrophysiology in semi-intact preparations of guinea pig

temporal bones to simultaneously visualize sound-evoked motion of stereocilia and record electrical potentials. The extracellular potentials are tuned to a particular sound stimulus of 84 dB SPL frequency near 220 Hz to get a maximum response. The acquired image sequences were low-pass filtered and motion quantified through optical flow analysis using Matlab. We show that blockage of radixin leads to increased stereocilia deflections during sound stimulation and increased electrically evoked motion of sensory cells. Both findings are consistent with reduced stiffness of stereocilia. However, blockade of radixin also decreased the electrical potentials produced by the sensory cells and showed mild loss in the hearing sensitivity measured from *in vivo* compound action potentials during sound stimulation, causing an acutely developing hearing loss. Thus, the present data shows that radixin is required for the mechanical stability of stereocilia and their ability to transduce sound into electrical potentials, thereby contributing strongly to the maintenance of hearing sensitivity in the adult inner ear. To conclude we have investigated the physiological relevance of radixin protein by looking into the importance of the regulation of radixin-mediated signaling processes as a novel mechanism for the regulation of stereocilia.

Title: Cochlear activity during silent periods shows a theta rhythmic pattern and is correlated to classical intermodal attention alpha effects

Authors: *M. H. A. KOEHLER, G. DEMARCHI, N. WEISZ;
Ctr. for Cognitive Neurosci., Univ. of Salzburg, Salzburg, Austria

Abstract: It is well established that the auditory efferent network can influence cochlear processes via direct and mediated projections from the auditory cortex to the superior olivary complex (SOC). Though, there is an ongoing controversy where in the processing hierarchy of this network attention processes take effect. So far all studies showing attentional modulations of cochlear responses have been limited to sound evoked responses (e. g. Wittekindt et al. 2014). The present study uses a trial-wise cueing paradigm to investigate audiovisual selective attention in humans simultaneously at the cortical and cochlear level during a stimulus-free cue-target period.
First, it was found that cochlear activity in silent cue-target periods was for both auditory and visual selective attention intrinsically modulated by a theta-rhythmic pattern (~4 Hz). Second, during periods of auditory selective attention slow modulations of cochlear activity were enhanced. Functional brain data revealed that posterior alpha and beta activity was enhanced during auditory selective attention. Interestingly, the found cochlear and 'classical' cortical posterior alpha attention effects showed a significant negative correlation.
It is hinted that the attentional sampling of the cochlea is putatively driven by a theta rhythm. Eventually, the correlation between cochlear and cortical attention effects suggests that participants showing the 'classical' posterior alpha modulations to a lesser extent appear to engage more strongly the efferent auditory system.

Title: Low Notch and high Wnt signaling determines hair cell fate in neuromast regeneration

Authors: Y. WU, F. ZHAO, P. WANG, F. RAO, X.-J. SONG, ***D. LIU**;
SUSTech Ctr. for Pain Medicine, Dept. of Biol., Southern Univ. of Sci. and Technol., Shenzhen, China

Abstract: The neuromast is a peripheral sensory organ of the lateral line system composed of the hair cells (HCs) and supporting cells (SCs). Numerously present on the body surface, teleost

neuromasts are ideal for study of mechanisms underlying damage-induced HC regeneration. We illustrate here that cisplatin-damaged zebrafish neuromasts generate new HCs within 12 hours post cisplatin treatment (12hpt), followed by proliferative HC regeneration, i.e., two new HCs are produced in pair. If the mitotic SCs of neuromasts are arrested at the S phase of the cell cycle before cisplatin treatment, some of them become new HCs within 12hpt, whereas if mitotic SCs are arrested at the M phase prior to cisplatin treatment, only proliferative HC regeneration happens. We find that a combined low Notch activity and high Wnt signaling state favors HC fate determination in some mitotic SCs, which are likely around the G1 phase, during and after HC damage. To support this view, in a mutant that lacks proliferative HC regeneration, unusual high Wnt activity is evident shortly after the cisplatin treatment and very few mitotic SCs enters the S phase. Therefore, a state of low Notch and high Wnt signaling somehow specifies the HC fate in some HC progenitor cells of ototoxin-damaged neuromast.

Title: Functions of stereocilia base in auditory perception

Authors: *B. ZHAO;
Dept. of Otolaryngology Head & Neck Surgery, Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: The integrity of stereocilia, the mechanosensing organelles of inner-ear hair cells, is critical for auditory perception. The base of stereocilia shows a striking structural organization including the formation of a taper as well as cytoskeletal specializations including rootlet filaments. This region is critical for the morphogenesis of stereocilia and hair cell function since stereocilia pivot at their base during mechanical stimulation. However, molecular machineries that shape the stereocilia base are just beginning to be elucidated. By performing a screening, we have found several proteins localized at the basal region of stereocilia, including GRXCR2. Mutations in *GRXCR2*, which encodes a protein of undetermined function, cause hearing loss in humans and mice. We found that GRXCR2 forms a complex at the base of stereocilia with

taperin, another protein of unknown function required for human hearing. Stereocilia lacking GRXCR2 are longer than normal and disorganized due to the mislocalization of taperin, which could modulate the actin cytoskeleton in stereocilia. Remarkably, reducing taperin expression levels could rescue the morphological defects of stereocilia and restore the hearing of *Grxcr2*-deficient mice. Thus, our findings suggest that GRXCR2 is critical for the morphogenesis of stereocilia and auditory perception by restricting taperin to the stereocilia base.

Title: Apoptosis signal regulating kinase 1 (MAP3K5) inhibition attenuates aminoglycoside ototoxicity

Authors: *J. M. OGIER[1], B. NAYAGAM[3], R. BURT[1], E. DUNNE[2], P. J. LOCKHART[1]; [1]Neurogenetics, [2]Infection and Immunity, Murdoch Childrens Res. Inst., Parkville, Australia; [3]Genet., The Univ. of Melbourne, Parkville, Australia

Abstract: More than one hundred medicines are ototoxic, meaning toxic to the ear. Of these, two drug classes are particularly problematic. The platinum based chemotherapeutics used in most anti cancer treatments, and, the aminoglycoside antibiotics used to manage chronic or multi drug resistant infection. These drugs save lives, but also destroy sensory hair cells within the ear. As a result, patients can experience devastating side effects, including permanent hearing loss, tinnitus, ataxia, nausea and vertigo. Ototoxic medicines have disabled millions of people worldwide, including approximately 1,280,000 children. We must find a way to prevent drug induced hair cell death, however, the process by which hair cells die remains uncertain. The c-Jun N-terminal kinase (JNK) pathway has been identified as a mediator of hair cell death. However, the role of upstream apoptotic regulator, Apoptosis signal-regulating kinase 1 (MAP3K5) has not been investigated in hair cells. Importantly, MAP3K5 is ubiquitously expressed, redox sensitive and drives the prolonged, apoptotic activation of JNK. However, MAP3K5 does not impact short term, homeostatic JNK activity. Therefore, we considered MAP3K5 as a target for preventing JNK mediated hair cell death. We hypothesised that MAP3K5 deficiency would prevent sensory cell death and protect against ototoxic drug-induced hearing loss. We used *in vitro* cochlear explants to (1) investigate the effect of MAP3K5 knockout on resistance to aminoglycoside-induced sensory hair cell death and (2) investigate the

efficacy of a MAP3K5 small molecule inhibitor in promoting sensory hair cell survival. We also investigated whether the MAP3K5 inhibitor changed aminoglycoside antibiotic efficacy. MCRI Animal Ethics approval A844. *In vivo,* MAP3K5 knockout has no effect on the development of the ear and hearing, as assessed by histology and the Auditory Brainstem Response. *In vitro*, MAP3K5 deficiency attenuates neomycin induced hair cell death. MAP3K5 inhibition significantly enhances the survival of aminoglycoside treated hair cells and the MAP3K5 inhibitor does not impair aminoglycoside activity against *pseudomonas aeruginosa.* Overall, MAP3K5 is a promising target for the prevention of drug induced hearing loss.

Title: Neuronal frequency tuning in human auditory cortex: A 7T fMRI adaptation and modelling approach

Authors: *J. BESLE[1], R.-M. SANCHEZ-PANCHUELO[2], S. FRANCIS[2], K. KRUMBHOLZ[3]; [1]Dept. of Psychology, American Univ. of Beirut, Beirut, Lebanon; [2]Sir Peter Mansfield Imaging Centre, Sch. of Physics and Astronomy, [3]Inst. of Hearing Research, Div. of Clin. Neuroscience, Sch. of Med., Univ. of Nottingham, Nottingham, United Kingdom

Abstract: Frequency selectivity is a ubiquitous property of auditory neurons. Measuring it in human auditory cortex may be crucial for understanding common auditory deficits, but current non-invasive neuroimaging techniques can only measure the aggregate response of large populations of cells, thereby overestimating tuning width. Here we attempted to estimate neuronal frequency tuning in human auditory cortex using an fMRI-adaptation paradigm. We measured the BOLD response (sparse 2D GE-EPI sequence, 1.5mm resolution, TR=7.5s) in 12 participants to a high frequency (3.8 kHz) probe presented alone or preceded by adaptors at different frequencies (0.5 to 3.8 kHz). Adaptation tuning curves (the degree to which adapters at different frequencies decrease the response to the probe, assumed to reflect neuronal tuning) were constructed by subtracting the BOLD response to adaptors presented alone. Responses to adaptors alone were also used to estimate population response tuning curves. In addition, we delineated primary and secondary cortex in each subject using a combination of tonotopic and in-

vivo myelin mapping (phase-sensitive inversion recovery sequence, 0.6 mm resolution). Both adaptation and response tuning curves were narrower in primary than secondary auditory cortex but, contrary to expectation, adaptation tuning curves were as wide as population response tuning curves in both regions. To further examine this result, we implemented a simplified model of neuronal (frequency-specific) and BOLD (non-specific) adaptation effects in a tonotopically-organized neuron population and we showed that apparent adaptation tuning can result from non-specific BOLD adaption effects combined with tonotopic organization. We then fitted the neuronal tuning width and other parameters of the model to our fMRI adaptation and population response tuning curves and found neuronal tuning width parameter values that were consistent with extrapolations from the primate electrophysiological literature. Our results show that it may be possible to estimate neuronal population tuning in auditory cortex using an fMRI frequency adaption paradigm, provided that BOLD adaptation effects and the properties of tonotopic organization are adequately taken into account.

Title: Targeted cortical manipulation of auditory perception

Authors: *S. CEBALLO[1], Z. PIWKOWSKA[2], J. BOURG[1], A. DARET[1], B. BATHELLIER[1]; [1]Paris-Saclay Inst. of Neurosci. (Neuropsi), Gif-Sur-Yvette, France; [2]Dynamic Neuronal Imaging Unit, Inst. Pasteur, Paris, France

Abstract: Driving perception by direct activation of neural ensembles in cortex is a necessary step for achieving a causal understanding of the perceptual code and developing central sensory rehabilitation methods. Here, using optogenetic manipulations during an auditory discrimination task in mice, we show that auditory cortex can be short-circuited by coarser pathways for simple sound identification. Yet, when the sensory decision becomes more complex, involving temporal integration of information, auditory cortex activity is required for sound discrimination and targeted activation of specific cortical ensembles changes perceptual decisions as predicted by our readout of the cortical code. Hence, auditory cortex representations contribute to sound discriminations by refining decisions from parallel routes.

Title: Decoding complex sounds using broadband population recordings from secondary auditory cortex of macaques

Authors: *J. LEE[1], C. D. HEELAN[1,4], L. LYNCH[1], R. O'SHEA[1], D. BRANDMAN[5], W. TRUCCOLO[2,3], A. V. NURMIKKO[1,3];
[1]Sch. of Engin., [2]Neurosci., [3]Carney Inst. for Brain Sci., Brown Univ., Providence, RI; [4]Connexon Systems, Providence, RI; [5]Dept. of Surgery (Neurosurgery), Dalhousie Univ., Halifax, NS, Canada

Abstract: Direct electronic communication with auditory and speech areas of the neocortex is a challenging addition for brain-computer interfaces. We report the first successful neural decoding of many English words with high intelligibility from intracortical spike-based neural population activity recorded from the secondary auditory cortex of macaques. Whereas the core of the secondary auditory cortex lies in the lateral sulcus, significant portions of the adjacent belt and parabelt lie on the superior temporal gyrus (STG). The STG is accessible to chronic implantation of microelectrode arrays (MEAs) for broadband population recording of spikes and field potentials. Our goal was to access auditory cortical circuits at a much higher spatial and temporal resolution than provided by ECoG or other epicortical electro- physiological techniques. We implanted two 96-channel intracortical arrays in the parabelt areas of the secondary auditory cortex in the rhesus macaque model and successfully decoded multiunit spiking activity to reconstruct intelligible English words and macaque calls. Using a novel neural processing toolkit (NPT), we performed an end-to-end neural decoding grid-search to explore the effects of signal properties, decoding algorithms, neural preprocessing, audio presentation, channel count and hyperparameters on reconstructing audio from full-broadband neural data recorded in STG. This computational experiment resulted in neural decoding models that successfully decoded neural activity into intelligible audio on the training, validation, and test data sets. We found that the LSTM RNN decoder outperformed other common neural decoding

algorithms. This is consistent with the findings of other studies in decoding neural activity recorded from the human motor cortex, and recent work from our group has demonstrated the feasibility of using LSTM RNN decoders for real-time neural decoding. We also showed that optimizing the neural frequency content via a bandpass filter prior to multiunit spike extraction provided a marginal decoding performance improvement. In sum, the results illuminated a view of the auditory cortex as a spatially distributed network and a general purpose processor of complex sounds. While we will continue to improve the performance of our neural decoding models, the presented results provide one starting point for future neural encoding work to "write in" neural information by patterned microstimulation to elicit naturalistic audio sensations towards the potential development of an auditory cortical prosthesis. Such future work can guide steps towards the potential development of an auditory cortical prosthesis.

Title: Temporal and resolved harmonic pitch encoding in auditory cortical neurons

Authors: Q. GAUCHER[1], A. Z. IVANOV[3], M. PANNIELLO[2], A. J. KING[2], ***K. M. M. WALKER**[2];
[1]Dept. of Anatomy, Physiol. and Genet., [2]Physiology, Anat. & Genet., Univ. of Oxford, Oxford, United Kingdom; [3]The Univ. of Oxford, Oxford, United Kingdom

Abstract: Pitch is one of the most salient and behaviourally relevant perceptual features of sound. It is the foundation of musical melody, and it plays a key role in human and animal communication. Previous research in ferrets has helped to elucidate how the pitch of artificial vocal calls is encoded by auditory cortical neurons. We have shown that ferrets can classify the pitch of sounds as "low" or "high", primarily using temporal periodicity cues (Walker et al., 2019). Neurons that are sensitive to pitch cues are distributed widely across the auditory cortex (Bizley *et al.*, 2010; Walker *et al.*, 2011), and correlate with ferrets' trial-to-trial pitch judgments (Bizley *et al.*, 2013). However, these studies did not examine whether the "pitch-sensitive" neurons were able to maintain their tuning to a preferred fundamental frequency (F0) across a variety of stimuli ("pitch-selective" neurons), like those described in the marmoset pitch area

(Bendor & Wang, 2005). Here, we investigated the resolved harmonic and temporal periodicity cues that underlie pitch responses in ferret auditory cortex, and whether a subset of "pitch selective" neurons may integrate these cues across sounds with different spectra. We recorded the responses of large populations of individual neurons to a variety of sounds that varied in F0 (17 F0 values; 250 - 4000 Hz). The stimuli included click trains with varied temporal periodicity, pure tones, and harmonic tone complexes with filtering and phase manipulations to alter resolved harmonic or temporal envelope cues. Neural responses were measured from ketamine and medetomidine anesthetized adult ferrets using (1) high-channel-count multielectrodes (Neuropixels), and (2) 2-photon imaging of calcium dynamics in neurons expressing GCaMP6. We found that auditory cortical neurons often show greater sensitivity to temporal cues than resolved harmonic cues, in keeping with our recent behavioural findings (Walker et al., 2019). We also identified a subset of neurons with pitch-selective responses, similar to those previously reported in marmoset (Bendor & Wang, 2005), suggesting that specialized pitch processing also exists in non-primates.

Title: MEG correlates of periodicity relevant to pitch perception in human auditory cortex

Authors: *S.-G. KIM[1], T. OVERATH[1,2,3,4,5], W. SEDLEY[6], S. KUMAR[5,6], S. TEKI[5], T. D. GRIFFITHS[5,6];

Abstract: Pitch is a property of many sounds for which the cortical substrate is still debated. In this study we used MEG to estimate neural ensemble activity in sensor and source space using three types of pitch-evoking periodic stimuli at rates below and above the lower limit of pitch. The stimuli were harmonic complex tones (HC), click trains (CT) and iterated rippled noise (IRN). Trials consisted of noise-periodic-noise (NPN) or periodic-noise-periodic (PNP) segments in which the periodic segment was either above (250 Hz) or below (20 Hz) the lower limit of pitch.
For ten healthy volunteers (age = 26 ± 7, 5 females), neuromagnetic responses while listening to

NPN and PNP trials were recorded using a 274-channel MEG system (CTF systems, Canada), and T1-weighted anatomical MR images were acquired. Using the minimum norm estimation (MNE) Python package, source activity of evoked responses was estimated via noise-normalized MNE.The pitch-associated periodic stimuli (at 250Hz) were all associated with marked evoked responses at ~130 ms at both sensor and source levels after the NP transition (Figure 1). Evoked responses for PN transitions were much weaker (HC, CT) or absent (IRN). The non-pitch associated stimuli (at 20 Hz) were associated with weak or absent evoked responses at ~130 ms after the NP transition.On the supratemporal plane, evoked responses in Heschl's gyrus showed the greatest peaks, particularly to NP transitions in 250-Hz trials involving HC and CT. Responses to pitch-associated periodicity also occurred in the more anterior temporal lobe and on the temporal convexity (Figure 1b). In an interval of 100 to 160 ms around the NP peak response, a repeated-measures ANOVA of sensor-level data revealed significant main effects for all factors (Periodicity-type, Fundamental-frequency, Transition-type, all $p < 0.02$), as well as for an RM ANOVA at source level with the additional factor region-of-interest (all $p < 0.003$).The data demonstrate cortical sensitivity to periodicity associated with pitch that is consistently present across different pitch-associated stimuli in the region of HG.

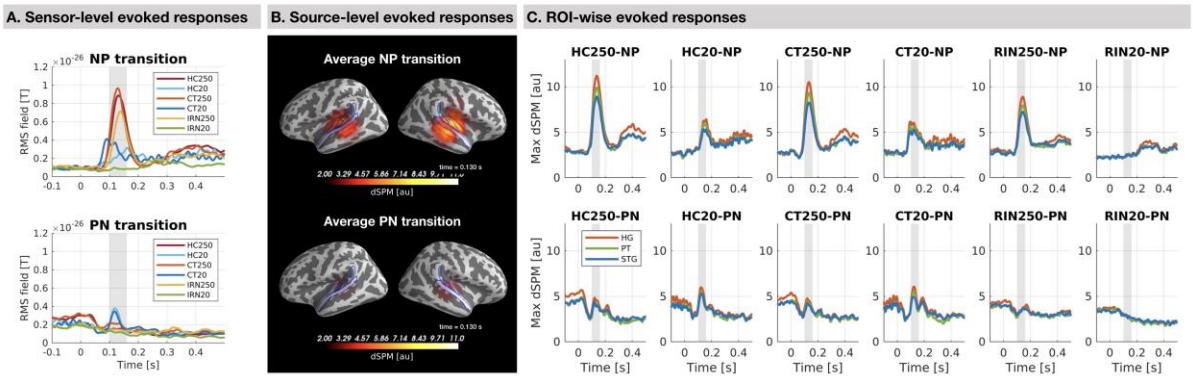

Figure 1. MEG evoked responses to onset and offset of pitch-eliciting periodicity. (A) Root mean squared (RMS) of all MEG sensors with respect to noise-to-periodic (NP) or periodic-to-noise (PN) transitions for various conditions (HC, harmonic complex; CT, click train; IRN, iterated rippled noise) with F0 of 250 Hz or 20 Hz. A time interval of [100, 160] ms for statistical inference is marked by shades. (B) Inter-subject average source activity estimated on cortical surface sources for NP and PN transitions, averaged over all types of conditions. (C) Region-of-interest (ROI)-wise source timeseries (maximal values within an ROI at each timepoint) over NP or PN transitions for auditory cortical ROIs (HG, Heschl's gyrus; PT, planum temporale; STG, superior temporal gyrus; ROI contours are marked in (B)). A time interval of [100, 160] ms is also marked.

Title: Cortical mapping of prediction error responses to multiple sensory features

Authors: *H. AN[1], R. AUKSZTULEWICZ[3], J. W. SCHNUPP[2];
[2]Biomed. Sci., [1]City Univ. of Hong Kong, Hong Kong, Hong Kong; [3]Dept. of Psychiatry, Univ. of Oxford, Oxford, United Kingdom

Abstract: Predictive coding is widely accepted as a comprehensive theory of neural processing underlying perceptual inference. However, it is unknown to what extent prediction violations of different sensory features are mediated in regions in auditory cortex, with different dynamics and by different mechanisms. This study investigated the neural responses to synthesized acoustic syllables which could be expected or unexpected along several features. By using electrocorticography (ECoG) in rat auditory cortex, we mapped regional differences in mismatch responses to different stimulus features. The subjects were 8 adults female Wistar rats with normal hearing and no prior exposure to the stimuli. Morphed syllables formed roving oddball sequences in which each stimulus was repeated 2-43 times (thereby forming a standard) with the inter-stimulus interval fixed at 300ms, and subsequently replaced with a deviant stimulus, differing from the standard along one of several acoustic features (duration, pitch, interaural level differences (ILD) and consonant identity). Each of these features could assume one of 9 different levels (durations: 55-95ms in 5ms steps ; pitch mean F0: 0.7-1.4kHz logarithmically spaced; ILD : 60-68 dB SPL difference in 2 dB steps; consonant: /da/-/ba/ in equidistant steps), and the resulting deviance magnitude ranges between +4 and -4 steps. The deviant stimuli were then repeated to form new standards. We analyzed responses to the last repetition of a given stimulus (standard) and the first repetitions of a new stimulus (deviant). For the ECoG recording, we implanted urethane-anaesthetised rats with 8x8 electrode arrays covering a 3x3mm cortical patch encompassing primary and higher-order auditory cortex. In each rat, we presented a total 3800 stimuli, amounting to ~40 deviant stimuli (and their preceding standards) for each feature and level of deviance magnitude. We identified different the topographies and latencies of population activity in the rat auditory regions sensitive to expectation violation along different acoustic features. Responses to deviant stimuli increased in amplitude with increasing deviance magnitude. Mismatch response to both duration and ILD violations were observed in anterior auditory regions but at slightly earlier latencies for duration vs. ILD violations. In contrast, mismatch response to pitch and consonant identity were observed at posterior and dorsal electrodes, with consonant violations evoking earlier mismatch responses than pitch violations. This suggests differences in cortical regions and populations dynamics subserving prediction error signaling along different stimulus features.

Title: Variation in temporal coding of vocalizations along the anterior-posterior extent of marmoset auditory cortex

Authors: *X.-P. LIU[1], X. WANG[2];
[1]Johns Hopkins Sch. of Med., Baltimore, MD; [2]Dept Biomed Engin, Johns Hopkins Univ. Sch. Med., Baltimore, MD

Abstract: To gain insight into functional properties of the multiple fields in primate auditory cortex, we examined the responses of neurons to vocalizations across the anterior-posterior extent along the lateral sulcus in the marmoset (Callithrix jacchus), a highly vocal monkey species. Studies that have ventured anterior to the primary auditory cortex (AI) have seen longer response latencies and temporal integration windows and a scarcity of neurons with well synchronized responses to click trains and sinusoidal amplitude modulation, suggesting that anterior field neurons transform periodic auditory patterns into a rate code (Bendor and Wang, 2008; Camalier et al., 2012; Scott et al., 2010; Wang, 2007). In this study, we examined time domain processing of natural stimuli in both anterior and posterior fields by recording single unit responses to a set of 20 marmoset call types as well as sets of exemplars of each call type. To quantify temporal precision of evoked spike trains, we calculated the correlation index (CI) of the responses to multiple presentations (Joris et al., 2006), which indicates the degree of temporal variability in spike timing between repetitions. A subset of low spontaneous rate neurons displayed high CI values indicating timing variability less than a millisecond in response to some vocalizations. These neurons tended to have onset responses and be more prevalent in the posterior region. While the anterior region generally lacked such temporal precision, it featured other specializations, such as an area enriched in neurons with narrow frequency tuning, selectivity for slowly modulated vocalizations like *phee* calls, and robustness to broadband background noise. These specializations may form parallel forms of processing, for example, integrating across spectrum to enhance temporal resolution for detection of temporal edges or integrating across time to enhance selectivity for slower features. Neurons with higher and lower CI values responded in diverse ways to different exemplars of the same call types and may respectively use temporal or rate codes to encode these calls. These observations are reminiscent of recent studies in humans showing anterior-posterior differences in temporal responses along

Heschl's gyrus or superior temporal gyrus (Hamilton et al., 2018; Hullett et al., 2016; Jasmin et al., 2019; Norman-Haignere et al., 2015; Santoro et al., 2014), suggesting this may be a conserved organizational feature of the primate auditory cortex. These parallel processing strategies may help identify temporal and spectral features that are key to speech or music processing as well as animal communication sounds.

Title: Structural changes in primary auditory cortex neuronal networks impact encoding fidelity in noisy environments

Authors: *K. V. SHILLING-SCRIVO[1], P. O. KANOLD[2], B. BABADI[3], A. SHEIKHATTAR[4];
[1]Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Biol., [4]Dept. of Electrical and Computer Engin., [3]Univ. of Maryland, College Park, MD

Abstract: Navigating complex auditory environments requires the ability to identify behaviorally meaningful sounds. In mouse auditory cortex, sound features in a quiet environment are encoded by small populations of neurons (Francis et al 2018;Liu et al 2019). However, most sounds exist in the presence of other background sounds that overlap it spectrally and temporally. To date it is unknown how populations of neurons encode sounds in the presence of a noisy background. We thus investigated how populations of neurons simultaneously encode both tonal foreground and noisy background sounds. We used *in vivo* two photon calcium imaging to record from 100s of neurons in primary auditory cortex (A1) in transgenic Thy1-GCaMP6s X CBA mice passively listening to tones in a broadband noise background. For each mouse, before imaging, A1 location was determined by widefield imaging. While imaging in A1, we presented 8 SAM tones (4-48 kHz ½ octave spacing, 5Hz carrier frequency, 10 repeats) at three levels (60,50,40dB) in the presence of 40dB broadband noise or in quiet. We imaged ~900 neurons and for each neuron, calculated the relative change in fluorescence for each trial (dF/F). Based on the average response to all stimuli, neurons clustered into three classes: (1) Neurons maximally responsive during the noise background (Noise-On); (2) Neurons maximally

responsive during tone onset (Tone-On); and (3) Neurons maximally responsive during tone offset (Tone-Off). Initial results showed that as the signal to noise ratio (SNR) decreases, Noise-On neurons remain more responsive than Tone-On or Tone-Off neurons. Noise correlation analysis showed that as SNR decreases, there was a corresponding decrease in noise correlation in the two tone-responsive classes of neurons (Tone-On and Tone-Off). Since neurons can be embedded in functional subnetworks, we utilized Granger causality (GC) analysis to identify neurons' functional connectivity among these three classes (Francis et al 2018;Liu et al 2019). GC analysis showed that for the two tone-responsive classes of neurons decreasing SNR increased the number of GC linked neurons. In contrast Noise-On neurons showed no change in the number of GC linked neurons across SNR. Finally, we trained a naïve Bayes classifier on our data and found that as SNR decreases, more neurons are required to correctly identify the tone presented. Together, our results support a model in which different features of a stimulus are encoded by different populations of neurons in A1 and that as SNR decreases, more neurons are needed to differentially encode those stimulus features. Thus, the size of the active population in A1 seems to relate to coding fidelity.

Title: Responses to changes in amplitude modulation rate and spatial location in neurons in the auditory cortex in an awake macaque monkey

Authors: *B. M. BORMANN[1], D. A. BEAUREGARD CAZABON[1], K. E. NEVERKOVEC[1], K. B. CHEUNG[1], *G. H. RECANZONE[2];

Abstract: Acoustic signals are commonly thought to be processed in the primate auditory cortex in two main pathways, a caudal spatial pathway and a rostral non-spatial pathway. This

hypothesis predicts that particular spatial or non-spatial features of an acoustic stimulus are extracted from core auditory areas by belt and parabelt auditory areas, which are then further processed in the parietal and frontal lobes. It may also be that this segregation begins as early as primary auditory cortex (A1). We are currently testing this hypothesis by comparing the responses of the same auditory cortical neurons to complex stimuli that vary only in their temporal properties (amplitude modulation rate, AM) or spatial location. We presented two sequential 500 ms duration AM noise stimuli from free-field speakers to an alert male macaque monkey (20 years old) while extracellularly recording single neurons or small clusters of neurons in different auditory cortical fields. The first stimulus was a broadband noise with an AM rate of 25 or 33 Hz. The second stimulus could either vary in AM rate, from 13 to 50 Hz or 16 to 65 Hz, compared to the 25 or 33 Hz stimulus, respectively, or to the left or right by up to 12 degrees. The overall results showed that the AM frequency of the first stimulus had no effect on the firing rates of either presumptive core or belt neurons. In the core, however, neurons did tend to have higher firing rates to the second stimulus when it changed in AM rate as opposed to location. This was not seen in presumptive belt regions that were located medial or caudal to the core. Further, the normalized difference in firing rate across tested AM rates or locations to the second stimulus, a simple metric of AM and location tuning, was greater in the core than in the belt areas, with larger differences in the firing rate for changes in location compared to changes in AM rate. Again, such differences were not seen in presumptive belt areas. These results indicate that differences in the firing rate as a function of the temporal (AM rate) and spatial (location) attributes are present in primary auditory cortical areas, and that the extraction of these attributes in belt areas is likely to be a non-linear process.

Title: Tracking the building blocks of pitch perception in auditory cortex

Authors: *L. GWILLIAMS, **E. ABRAMS**, A. MARANTZ;
New York Univ., New York, NY

Abstract: While there is a general consensus that fundamental frequency, spectral content, and musical context contribute to pitch perception, it is currently unclear how and when these aspects of perceived musical pitch are neurally encoded during early auditory processing. To investigate this, we recorded brain responses to two types of tones: i) pure tones of fundamental frequency only (F0); ii) complex tones of five partials (integer multiples of, but not including, F0). Participants listened to musical tone sequences, ranging from 220-624Hz (the notes of the A, C, and Eb major scales), while magnetoencephalography (MEG) was recorded. Although the two tone-types have non-overlapping spectral content, they are perceived as the same pitch, thus creating an orthogonal relationship between the sensory input and perceptual output. Multivariate analyses were used to decode frequency and tone-type from the activity across MEG sensors. High decoding accuracy across time would suggest that these features are in fact encoded in the spatial pattern of neural responses to musical pitch. We found that a classifier trained at ~50 ms after the onset of the tone could accurately decode whether a listener was presented with a pure or complex tone based on the spatial pattern of activity. At 100ms, we could decode F0 from both tone-types, even for complex tones for which F0 was absent. Further, we were able to use a classifier trained on pure tones to accurately predict the frequency of the complex tones, suggesting that the missing fundamental is restored at this latency. From 200-300ms, tone-type decoding accuracy increased, and the F0 spatial pattern no longer generalised from one tone-type to the other. In sum, we confirm that central aspects of musical pitch perception are indeed encoded in early auditory neural responses. Overall, this suggests that independent neural mechanisms track the spectral content of musical tones and the present, or restored, fundamental frequency.

Title: Complex frequency interactions revealed by two-tone stimuli in awake mouse A1

Authors: *J. LIU, P. O. KANOLD;
Biol., Univ. of Maryland, College Park, MD

Abstract: Environmental sounds have rich spectral content and are characterized by specific spectral shape, e.g. harmonic structures. The auditory system has been traditionally probed with

pure tones but these spectrally simple stimuli might not be sufficient to capture how the auditory system integrates information over the frequency band. For example, the two-tone paradigm could reveal the inhibitory sideband flanking the characteristic frequency (CF), while pure tones typically fail to do so. In cat auditory cortex, two-tone paradigm has revealed diverse inhibitory sideband structures, with most cells having multi-peaked sidebands[1]. Thus, we investigated the response to both pure tones and two-tone stimuli in L2/3 of the primary auditory cortex of awake CBA/CaJ x Thy1-GCaMP6s mice. We found a diverse response pattern to two-tone stimuli. Although a large portion of neurons showed wide flanking inhibitory sidebands (~2-3 octaves), some neurons showed a mixture of two-tone suppression and two-tone facilitation, suggesting that the interactions of the simultaneously presented frequencies can be highly nonlinear and frequency specific. We also found that with the addition of a second tone, the signal correlations between neurons decreased, suggesting a decorrelation of neural responses by more complex stimuli. Furthermore, we separated onset and offset responses and found that offset responses can have distinct degrees of nonlinear interactions from onset responses. The complexity of these interactions suggests that the responses of A1 neurons can be spectral context dependent and likely encodes spectrally rich sound with high selectivity.

Title: High frequency time-locking in human auditory cortex to continuous speech

Authors: *J. P. KULASINGHAM[1], C. BRODBECK[1], A. PRESACCO[1], S. E. KUCHINSKY[2], S. ANDERSON[1], J. Z. SIMON[1];
[1]Univ. of Maryland, College Park, MD; [2]Audiol. and Speech Pathology Ctr., Walter Reed Natl. Military Med. Ctr., Bethesda, MD

Abstract: The neural processing of natural sounds, such as speech, changes along the ascending auditory pathway, and is often characterized by a progressive reduction in representative frequencies. For instance, the well-known frequency-following response (FFR) of the auditory

midbrain, measured with electroencephalography (EEG), is dominated by frequencies from ~ 100 Hz to several hundred Hz, and time-locks to acoustic features (waveform and envelope) at those rates. In contrast, cortical responses, whether measured by EEG or magnetoencephalography (MEG), are thought to be characterized by frequencies of a few Hz to a few tens of Hz, time locking to acoustic envelope features at those rates. In this study we show that this separation by frequency is overly simplistic, even for non-invasive electrophysiological recordings in humans. Using MEG we investigate high-frequency responses (80-300 Hz) to continuous speech using neural source-localized reverse correlation, whose kernels are called temporal response functions (TRFs). Continuous speech stimuli were presented to 40 subjects (17 younger, 23 older) with clinically normal hearing and their MEG responses were analyzed in the 80-300 Hz band. Consistent with the insensitivity of MEG to many subcortical structures, the spatiotemporal profile of these response components indicate a purely cortical origin with ~40 ms peak latency and a right hemisphere bias. TRF analysis was performed using two separate aspects of the speech stimuli: a) the 80-300 Hz band of the speech waveform itself, and b) the 80-300 Hz envelope of the high frequency (300-4000 Hz) band of the speech stimulus. Both of these aspects contributed to the TRF, with the envelope dominating the response. Age-related differences were also analyzed to investigate a reversal previously seen along the ascending auditory pathway, whereby older listeners have weaker midbrain FFR responses than younger listeners, but, paradoxically, have stronger low frequency cortical responses. In contrast to these earlier results, this study did not find clear age-related magnitude differences in high frequency cortical responses. Together, these results suggest that the traditional EEG-measured FFR has distinct and separate contributions from both subcortical and cortical sources. The cortical responses at FFR-like frequencies share properties with both midbrain responses at the same frequencies and cortical responses at much lower frequencies.

Title: Functional architecture of auditory cortex in awake marmosets revealed by multi-scale multi-modal optical imaging

Authors: *X. SONG[1], Y. GUO[2], C. CHEN[2], X. WANG[3];
[1]Dept. of Biomed. Engin., [2]Johns Hopkins Univ., Baltimore, MD; [3]Dept Biomed Engin, Johns Hopkins Univ. Sch. Med., Baltimore, MD

Abstract: The common marmoset (Callithrix jacchus), a highly vocal New World monkey species with a largely flat brain surface, has emerged in recent years as a promising non-human primate model for neuroscience research. Unlike most of the Old World primates, a significant proportion of auditory cortex in marmosets is directly accessible under the skull with optical imaging methods. Here, we applied wide-field enhanced intrinsic imaging, wide-field calcium imaging, and nearly silent two-photon calcium imaging methods in awake marmosets to study the functional architecture of auditory cortex. Previous studies have shown that primate auditory cortex consists of three layers of hierarchy, the core, the belt, and the parabelt. Responses to pure tone stimuli were largely confined to the putative core region through wide-field imaging. The low-frequency tonotopic reversal between A1 and R was clearly seen in all subjects. By increasing the bandwidth of sound stimuli, the responsive areas grew more laterally towards putative belt region, suggesting the belt region preferentially responds to a wider spectral content and may carry out spectral integration over a broad frequency range. Variety of natural sounds can elicit responses that collectively cover the entire superior temporal gyrus (STG). However, data from wide-field calcium imaging revealed that the area close to superior temporal sulcus (STS), putatively the parabelt, carried more spontaneous or endogenic rhythm that appeared largely independent of sound stimulation. This form of rhythm may reflect the behavioral state of the subject. Zooming into the fine details, the general response patterns within each two-photon field-of-view were consistent with wide-field imaging results. However, individual neurons' responses can be heterogeneous even for nearby neurons. The multi-scale multi-modal optical imaging approach reported here thus provides a new experimental paradigm for mapping the functional architecture of auditory cortex in awake condition in a high throughput way over conventionally electrophysiology methods. Title: Sound representation in the mouse temporal association cortex (TeA)

Authors: *L. FEIGIN[1], G.-I. TASAKA[3], I. MAOR[4], A. MIZRAHI[2];
[1]ELSC, [2]Hebrew Univ. of Jerusalem, Jerusalem, Israel; [3]Dept. of Neurobiology, ELSC, The

Hebrew Univ. of Jerusalem, Jerusalem, Israel; [4]The Edmond and Lily Safra Ctr. For Brain Sci., The Hebrew Univ., Jerusalem, Israel

Abstract: Background: Temporal association cortex (TeA) is ventral to the secondary auditory cortex and dorsal to the Rhinal fissure. Only few studies reported the activity from TeA in response to sounds. TeA was reported to be tonotopically organized and suggested to be invariant to frequency and temporal modulations of natural sounds. But otherwise, TeA remains largely unstudied.
Results: To define the inputs to TeA, we first performed monosynaptic retrograde rabies tracing from starter cells in TeA. We found a surprisingly large number (>100) of brain regions projecting into TeA including cortical and subcortical regions. Quantitative analysis of the connectivity into TeA showed that the primary auditory cortex (A1) is its most prominent source of input (~45% of TeA's total inputs). We, thus, recorded spiking activity from TeA with reference to A1.
To define the physiological responses of TeA to sounds, we used the newly developed high density multielectrode array "Neuropixels". We recorded spiking activity from A1 and TeA simultaneously in ketamine anesthetized as well as in head restrained awake mice. An initial analysis shows that representations of pure tones are surprisingly similar in A1 and TeA. TeA spans a similar frequency range and response bandwidth to that of neurons in A1. Interestingly, neurons in TeA exhibit higher response latencies. For example, units in layer 5/6 have mean latencies that follow A1 by ~50 msec. Signal correlations, calculated for pure tone stimuli as well as complex sounds, and noise correlations are slightly elevated within units in TeA compared to units in A1. We are currently analyzing population responses within and across regions to uncover the transformation of sound representation from A1 to TeA, under normal condition and following experience dependent plasticity.
Conclusions: Our work shows that TeA is a higher order auditory field directly downstream of A1. The diverse connectivity into TeA, and its physiological signature suggests that this brain region sub-serves higher order auditory computations.

Title: How do structural constraints guide asymmetry in cortical organization of auditory steady state responses (ASSR)?

Authors: *N. KUMAR, S. KUMAR, D. ROY, A. BANERJEE;
Natl. Brain Res. Ctr., Gurugram, India

Abstract: Characterizing hemispheric dominance in the functional specialization of sensory processing is a fundamental question in cognitive neuroscience. Several studies have shown that structural and functional brain networks involved in auditory stimulus processing are distributed in the brain. One way to characterize the functional networks of auditory processing is to investigate the brain networks engaged in generating steady-state auditory responses (ASSR) - a neurophysiological marker of complex auditory processing.
Our earlier EEG studies with ASSR have revealed that entrainment of 40 Hz rhythms occurs in large-scale neural networks visible from scalp and source connectivity analysis. Interestingly, our results indicate there is a right hemisphere bias of leadership role in a community interaction during the binaural hearing of 40Hz rhythms. During the monaural stimulations, ipsilateral hemisphere was more dominant than contralateral in terms of information processing metrics, e.g., power spectra, global coherence, imaginary coherence, and Granger causality.
In this study, we have asked whether constraints in whole-brain structural connectivity with auditory brain regions as seed, is the cause of the asymmetry in brain functional organization. Diffusion imaging data was collected in normal healthy volunteers from which the structural connectome was computed. DTI data was collected from a total of 49 participants (25 young and 24 old). Obtained structural connectivity matrix was parcellated in 68 regions according to the Desikan-Killiany brain atlas. Structural connectivity matrix was used to estimate the length of fibers between any pair of parcels. Using a value of velocity 42 m/s as communication speed, we estimated the time delays that are involved in transmitting information between any pair of nodes. These time delays were used to couple the Kuramoto oscillators at the 68 parcels. The auditory parcels were triggered with 40 Hz intrinsic frequency while other parcels were set at an intrinsic frequency of 1 to 100 Hz.
The dynamical states of the network were investigated to interpret the underlying mechanisms of hemispherical asymmetry that we observed in empirical EEG data. Secondly, the computational model reveals that whole brain 40 Hz can be obtained by locally exciting the auditory brain parcels when the intrinsic frequency of neural oscillators reaches at least 20 Hz for the dorsal attention network and more than 30 Hz for the visual network.

Title: Stimulus dependent transformations between synaptic and spiking receptive fields in auditory cortex

Authors: *K. X. KIM, C. A. ATENCIO, C. E. SCHREINER;
Dept. of Otolaryngology–Head and Neck Surgery, Univ. of California San Francisco, San Francisco, CA

Abstract: Sound signals are transmitted via the ascending auditory pathway and arrive at the auditory cortex. The primary auditory cortex (A1) neurons, which are tonotopically arranged, integrate many synaptic inputs across frequencies, and the subthreshold activity is subsequently transformed into a spiking output. Although tonal receptive fields (TRFs) for responses to pure tones have been studied at the synaptic level, little is known about synaptic and spiking spectrotemporal receptive fields (STRFs) regarding responses to complex sounds. We examined the degree of synaptic integration generated from two different stimuli, pure tones and complex sounds (the dynamic moving ripple sound), and their output by characterizing receptive fields. *In vivo* whole-cell recordings were made from A1 neurons of anesthetized mice using the blind patch-clamp approach. Spectral tuning in STRFs from both spiking and subthreshold responses was more selective than that in TRFs. Specifically, the TRF bandwidths were approximately 1 octave wider than the STRF bandwidths. Furthermore, complex sounds carrying modulation information allowed us to determine filter modulation properties and nonlinearities. We found that STRFs derived from subthreshold activity illustrated more diverse frequencies and temporal modulation preferences than did spiking STRFs. Finally, STRF nonlinearities revealed the transformation from the synaptic input to the spiking output, with reduced event-generating noise and an increased feature selectivity. Our results suggest that stimulus-specific convergence and cortical dynamic processes determine the input-output transformation in A1 neurons.

Title: Nicotine enhances temporal responsiveness in mouse A1

Authors: *I. INTSKIRVELI[1], E. PROVENZANO[2], R. METHERATE[1];
[1]Dept. Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA; [2]Dept. of Cognitive Sci., Univ. of California San Diego, La Jolla, CA

Abstract: Neurons in primary auditory cortex (A1) adapt to repetitive sounds, i.e., they exhibit progressively decreased response magnitude to repetitive sounds. Since studies have demonstrated that systemic nicotine enhances sensory-evoked cortical responses, here we address how nicotine modulates response adaptation. We placed a 16-channel silicon multiprobe in A1 of adult, urethane anesthetized FVB mice and derived current-source density (CSD) profiles in response to 1 s trains of characteristic frequency (CF) tones presented at 2 Hz, 5 Hz, 10 Hz, 20 Hz and 40 Hz (30 dB above threshold, trains repeated 25 times). We analyzed two main current sinks in middle (approx. layer 4, L4) and deep (L5/6) layers. Stimulation produced adaptation of the L4 response that was weak at 2 Hz, stronger at 5-10 Hz and complete at 20-40 Hz. In contrast, the L5/6 sink exhibited no adaptation at 2-10 Hz, and simultaneously recorded brainstem responses (ABR) showed no adaptation even at 40 Hz. Systemic nicotine (2.1 mg/kg, s.c.) enhanced the L4 response to the first tone in each stimulus train and reduced its peak latency, consistent with prior studies. Additionally, nicotine enhanced adapted responses for stimulus trains at 2-10 Hz, but did not prevent complete adaptation of responses at 20-40 Hz. Nicotine also reduced response (peak latency) variability across 25 trials. In contrast to the effects in L4, nicotine had no effect on responses in L5/6. Although nicotinic enhancement in L4 was seen on both initial and later responses in each train (2-10 Hz), initial effects were stronger, leading to a greater degree of adaptation in nicotine. We suggest that nicotine modulates response properties in A1 to improve temporal consistency and to emphasize initial responses to repeated stimuli.

Title: Cooling of the auditory cortex modulates temporal processing of auditory thalamic neurons in awake marmosets

Authors: *Y. ZHANG, S. BAI, X. WANG, R. LI, H. SUN, L. GAO;
Interdisciplinary Inst. of Neurosci. and Technology, Key Lab. for Biomed. Engin. of Ministry of Education, Col. of Biomed. Engin. and Instrument Science, Zhejiang Univ., Hangzhou, China

Abstract: Temporal information is essential for perception and discrimination of communication sounds, such as human speech and animal vocalizations. So far, it remains largely unknown the thalamocortical circuit mechanisms underlying sound temporal processing in awake animals. In the present study, single unit recordings were performed in medial geniculate body (MGB) when the primary auditory cortex (A1) of awake marmosets were reversibly inactivated by cooling technique. We found that cooling of A1 has great influences on the temporal processing of MGB neurons. Firstly. A1 modulated differently on the onset and sustained sound driven responses of MGB neurons: sustained and late phase auditory responses diminished when A1 was cooled and retrieved when the temperature recovered to normal whereas onset responses were less affected. The result suggests that onset responses of MGB neurons largely inherited from the ascending auditory inputs whereas their sustained responses were due to the cortical feedback. Our results also support the hypothesis that sustained responses of A1 neurons were generated by intracortical inputs instead of thalamocortical inputs. Regarding the temporal responses of MGB neurons to time-varying stimuli, we found that cortical cooling either enhanced the synchronized responses of MGB neurons to slow repetition rates or weakened the non-synchronized responses of other MGB neurons to fast repetition rates, which suggests that cortical feedback control changed the temporal coding schemes of MGB neurons to time-varying stimuli: cortical feedback weakened the ability of MGB neurons to use temporal coding instead strengthen their ability to use rate coding strategy.

Abstract: We examined the brain basis for the processing of auditory time windows in stimuli with similar spectro-temporal complexity to human speech or macaque vocalisations. We created a synthetic stimulus by manipulating spectral flux, a timbral dimension, to systematically vary the time window duration required to analyse it. We conducted functional magnetic resonance imaging in awake macaques using this stimuli to test how the anatomy of their response patterns of time window processing compares to humans.Window of temporal integration was characterised in terms of the Pearson correlation (r) between amplitude spectra of adjacent timeframes [PMID 19052218] or in terms of time window within which any two frames show a minimum level of correlation thus shorter windows have lower r while longer windows have higher r. Individual core and belt areas were defined on 3 animals using tonotopic mapping and myelin mapping [PMID 25100930]. Sparse EPI images were acquired on a 4.7T vertical scanner whilst they carried out visual fixation. A general linear model analysis [SPM12] allowed single-subject inference to determine the relationship between BOLD and r in individual core and belt areas.Despite a similar overall pattern of changing preference, from shorter time windows in postero-medial areas to longer time windows in antero-lateral areas, monkeys exhibited a reduced sensitivity to longer time windows as compared to humans [PMID 19052218]. This difference in sensitivity is in line with recent behavioural results and might be explained by a specialization of the human brain for speech processing which requires sensitivity to longer time windows. We highlight specifically human response patterns that suggest an adaptation of a general primate brain mechanism, possibly an outcome of divergent evolution alongside the development of speech.

Title: Neural circuits underlying spectro-temporal integration of sounds

Authors: *A. M. KLINE, D. A. APONTE, H. K. KATO;
Dept. of Psychiatry and Neurosci. Ctr., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: The brain's capacity to integrate the features of sensory stimuli is essential to understand and respond to our environment. In the auditory system, even in the face of multiple sound sources, our brain integrates acoustic components originating from the same source to reconstitute individual sound objects. In particular, integration of harmonic components is critical to accurately perceive physiologically relevant sounds such as language. In humans, one of the factors influencing the binding of harmonic components is timing of the spectral components' onset within a 30-ms window. However, the neural circuits by which the auditory system integrates sounds in a timing-dependent manner remain unknown. In this study, we investigated the temporal integration of harmonic sounds in mouse auditory cortex. Using macroscopic imaging of all auditory cortical areas, we determined that higher-order area, A2, preferentially responds to harmonic vocalizations over pure tones. Furthermore, using two-photon calcium imaging in awake mice, we found that A2 neurons display preferential response to coincident harmonics compared to harmonic tones whose onsets are shifted in time. This timing-dependence was not observed in primary area A1, suggesting that A2 plays a unique computational role in processing harmonics. Finally, we developed a Go/No-go task in which mice were trained to discriminate between coincident harmonics and time-shifted distractors. Interestingly, we found that mice have a similar 30-ms window for integrating harmonic components, suggesting conserved neural circuitry across species. In the future, we will manipulate A2 activity during this task to investigate its causal role in the perceptual integration of harmonics. Determining the mechanism by which the auditory cortex integrates harmonic sounds will contribute to our knowledge of how we process language, as well as inform us about how speech perception could be affected in neurodevelopmental disorders.

Title: Imbalanced excitatory synaptic charge shapes direction selectivity in primary auditory cortex

Authors: *D. APONTE, A. M. KLINE, H. K. KATO;
Dept. of Psychiatry and Neurosci. Ctr., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Frequency Modulation (FM) is a prevalent sound feature found in both human speech and animal vocalization. The brain's ability to detect the direction of frequency modulation is critical for vocal communication. Neurons in the primary auditory cortex (A1) have been reported to show selective firing to their preferred FM direction. However, it remains debated how direction selectivity maps spatially onto A1, and what circuit mechanisms underlie this selectivity. Here, we determined the FM tuning properties of a large population of A1 neurons using in vivo two-photon Ca^{2+} imaging in awake mice. We found that more than 70% of A1 neurons show direction-selective firing, and that the selectivity was topographically ordered along the A1 tonotopic axis. Interestingly, A1 neurons also showed robust direction selectivity to ethologically relevant slow-rate FM sweeps, which previous studies did not observe in anesthetized animals. To investigate the synaptic mechanism underlying the direction selectivity to slow FM sweeps, we measured synaptic currents using in vivo whole cell recordings. In contrast to previous models that explained direction selectivity based on different onset timings of EPSCs and IPSCs, we found that direction selectivity is rather driven by a difference in the total excitatory charge triggered by preferred and null directions. Null-direction FM sweeps evoked both significantly attenuated EPSCs and IPSCs, which is explained by a suppression of recurrent circuits in the cortex - a phenomenon we recently reported as “network suppression”. Taken together, our findings revealed a non-classical circuit mechanism that ensures direction selectivity of A1 neurons to slow FM sweeps which play important roles in our vocal communication.

Title: Functional segregation of the marmoset auditory cortex by data-driven decomposition of responses to naturalistic sounds with wide-field optical imaging

Authors: *Y. GUO, X. SONG, C. CHEN, X. WANG;
Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: The common marmoset (Callithrix jacchus) is a highly vocal New World monkey species and has garnered considerable interest in recent years as a promising non-human primate model in neuroscience. To study the functional organization of the auditory cortex using this animal model, we developed techniques to perform multi-scale and multi-modal chronic optical imaging in awake marmosets. The imaging interface is a removable artificial dura (AD) based window with a diameter of 1/4 inches that covers the region between the lateral sulcus (LS) and superior temporal sulcus (STS). While previous studies have extensively evaluated neural activities in the core region of auditory cortex driven by pure tone stimuli, how the auditory cortex is spatially organized to process naturalistic sounds, especially in the secondary auditory areas, is still poorly understood. In this study, we used a hypothesis-free data-driven method to probe the functional organizations of the marmoset auditory cortex. This method was first developed by Norman-Haignere et al. (2015) for human fMRI studies. We played the same set of 165 naturalistic sounds to marmosets and measured activities in the auditory cortex with wide-field optical imaging. In contrast to the pure tone responsive area (mostly limited to the core region), this set of sound stimuli activated more lateral areas in marmoset auditory cortex (presumably the belt and parabelt regions), suggesting that the secondary auditory areas are sensitive to higher-order features in naturalistic sounds. With the matrix decomposition method used in Norman-Haignere et al. (2015) study, we found independent components located in both primary and secondary auditory areas that were sensitive to different sound features and sound categories. This approach provides a potential way to reveal new functional areas in the auditory cortex of non-human primate. In addition, we analyzed trial-to-trial variance of the responses to the natural sound stimuli. Some lateral areas showed neural activities that were more variable than areas closer to the lateral sulcus (putative core region) under the same stimulus context, suggesting that the activities in these areas may be influenced more by internal processing or the state of the animal, rather than solely dependent on stimulus driven responses.

Title: Spike decoding of signals from noise stimuli in the auditory cortex of an awake macaque monkey

Authors: *D. BEAUREGARD CAZABON[1], B. BORMANN[1], K. NEVERKOVEC[1], K. CHEUNG[1], G. H. RECANZONE[3,2], B. J. MALONE[4];

Abstract: Most natural listening conditions consist of a multitude of different sounds from a variety of different locations. We currently have little understanding of how these different signal streams are decoded by core and belt auditory cortex into perceptually distinct events or objects. We therefore used spike train decoding techniques to determine the effects of various background distractors on the responses of neurons to amplitude-modulated sounds with complex spectra. We presented free-field stimuli to a passively listening, alert male macaque monkey (20 years old) while extracellularly recording single neurons or small clusters of neurons in different auditory cortical fields. Spike trains were analyzed in terms of their firing rates and their temporal patterns at timescales of milliseconds, using decoding algorithms based on simple linear classifiers. Target stimuli consisted of a 100% amplitude-modulated (AM) carrier composed of interleaved 1/3 octave bands of pink noise from 0 - 18 kHz, modulated at either 25 Hz or 33 Hz. Three classes of distractors were tested: 1) carriers with similarly constructed bands having the frequency ranges of the bands interleaved with that of the target ranges, but modulated at the other AM rate (i.e. 33 Hz target and 25 Hz distractor); 2) pink noise modulated at 5 Hz; and 3) unmodulated pink noise. All distractors were presented at three different intensities (+10, 0 and -10 dB relative to the target) and at locations either 45 degrees from the target in the ipsilateral or the contralateral hemifield relative to the target. Targets and distractors were presented either independently or in combination of one target and one distractor. Preliminary analysis suggested that cortical firing patterns were sensitive to multiple acoustic

features of the targets and distractors, including intensity, location, and modulation frequency. Although the spike trains of neurons in the core fields carried more information in their timing, on average, than did neurons in belt areas, prominent response modulation was not limited to the core fields. These findings suggest that both rate and temporal information in the firing rate patterns of auditory cortical neurons can accurately encode complex, concurrent acoustic stimuli.

Title: Effects of amplitude-modulated signal-in-noise auditory stimuli on the firing rates of auditory cortical neurons in an awake macaque monkey

Authors: *A. N. SANCHEZ[1], D. B. CAZABON[1], B. BORMANN[1], K. NEVERKOVEC[1], K. B. CHEUNG[1], G. H. RECANZONE[1,2];
[1]Ctr. for Neurosci., [2]Neurobiology, Physiol. and Behavior, UC Davis, Davis, CA

Abstract: The natural acoustic environment is normally very complex, with different types of sounds simultaneously emitted from various source locations. It remains unclear how the auditory system is able to disambiguate the different acoustic signatures into different sound sources. This raises the interesting questions of how neurons encode multiple sounds; if this encoding is a summation of firing rates, or if cells are performing more nuanced computations of the stimuli. Given that auditory cortex is necessary for the perception of complex stimuli, and the auditory cortex is known to be composed of a number of distinct cortical fields, another question is whether there are differences in how multiple stimuli are processed between auditory fields. We hypothesize that the addition of a second, or 'distracter' stimulus will predictably change firing rates of auditory neurons to a primary, or 'target' stimulus. We presented one or two stimuli to a passively listening, alert male macaque monkey (20 years old) while extracellularly recording single neurons or small clusters of neurons in different auditory cortical fields. Free-field stimuli consisted of an amplitude-modulated (AM) noise with broadband carriers (the target) presented independently or concurrently with an AM noise distracter which had 1) a spectrally different broadband carrier, 2) one of three different intensities (+10, 0 and -10 dB

relative to the target) and 3) a location 45 degrees from the target in the ipsilateral or contralateral hemifield. Generally, we found an effect of both distracter intensity and location for most neurons. Overall these effects were greater for presumptive core compared to presumptive belt cells. In most cases the responses for 'distracter + target' conditions were higher than the sum of the 'target' and 'distracter' conditions alone, yet were well correlated with measured responses. Regression analysis of the predicted and measured values showed that the regression coefficients were greater, and the slopes were closer to one, in presumptive core neuron responses compared to neuron responses in rostral and caudal regions. These findings suggest that the processing of concurrent sounds involves both linear and non-linear properties in the auditory cortex.

Title: The roles of NPY neurons and NPY signaling in the inferior colliculus

Authors: *M. A. SILVEIRA[1], J. D. ANAIR[1], N. L. BEEBE[3], L. L. BURGER[2], B. R. SCHOFIELD[4], M. T. ROBERTS[1];
[1]Dept. of Otolaryngology-Head and Neck Surgery, [2]Mol. & Integrative Physiol., Univ. of Michigan, Ann Arbor, MI; [3]Anat. & Nuerobiology, [4]Anat. & Neurobio., Northeast Ohio Med. Univ., Rootstown, OH

Abstract: Located in the midbrain, the inferior colliculus (IC) integrates information from numerous auditory nuclei and is an important hub for sound processing. Despite its importance, little is known about the function and molecular identity of neurons in the IC. Using a multi-faceted approach, we have identified Neuropeptide Y (NPY) as a marker for a distinct neuron class in the IC. In the NPY-hrGFP mouse line, hrGFP-positive neurons are distributed throughout the IC, and hrGFP selectively-labels IC neurons that express NPY. Immunostaining showed that NPY neurons in the IC are GABAergic (98.5% of hrGFP-positive neurons co-label with an antibody against GAD67; total NPY neurons counted: 2673). Using design-based stereology, we found that NPY neurons represent ~25% of the GABAergic neurons in the IC. To examine the physiology of NPY neurons, we targeted whole cell patch clamp

recordings to hrGFP-expressing neurons in acute brain slices. These recordings demonstrated that NPY neurons exclusively exhibit a sustained firing pattern (spike frequency adaptation ratio < 2), express little *Ih* (*sag ratio* at -80mV = 0.88±0.09) and have a propensity to spontaneously fire, suggesting they might tonically release NPY in the IC. In post hoc reconstructions of recorded neurons, we found that NPY neurons have a stellate morphology and extend their dendrites across the laminar plane of the IC (n=24). Because we found that the NPY Y1 receptor is widely expressed in the IC, we next investigated the functional role of NPY signaling in the IC. Previous studies demonstrated that activity in the IC can induce a variety of unconditioned fear responses, and, in other brain areas, NPY is involved in fear and stress responses. To investigate if NPY signaling is involved in fear responses in the IC, we exposed mice to a novel environment for one hour, and we collected IC tissue 4 hours later to evaluate changes in expression of the *Npy* and *Y1R* genes. Our preliminary results show an increase in *Npy* expression in mice that were acutely exposed to a novel environment compared to mice that were habituated to the novel environment (n=8 - 9 mice per group, one-way two-tailed ANOVA followed by Tukey's post hoc, p=0.001). No significant difference was observed between the control and habituated groups (p>0.05).
Interestingly, for *Y1R* we observed a decrease in relative expression in the habituated group when compared to the control group (n=8 - 9 mice per group, one-way two-tailed ANOVA followed by Tukey's post hoc, p=0.01). Thus, we propose that the release of NPY from NPY neurons influences unconditioned fear responses in the IC.

Title: Dopamine heterogeneously alters processing in the inferior colliculus independent of stimulus type

Authors: *J. M. HOYT[1], D. J. PERKEL[2], C. V. PORTFORS[1];
[1]Washington State Univ. Vancouver, Vancouver, WA; [2]Depts. Biol. & Otolaryngology, Univ. of Washington, Seattle, WA

Abstract: Background: The ability to understand speech relies on accurate auditory processing of complex sounds. However, communication disorders can arise from disruptions in the way

individual neurons process sounds or in the ways neurons interact with one another. For example, individuals with Parkinson's disease suffer from speech perception deficits, suggesting that dopamine is involved in the encoding of complex sounds. The primary auditory nucleus in the midbrain, the inferior colliculus (IC), is rich in both dopaminergic terminals and dopamine receptors. Recent studies from our lab demonstrated that dopamine can increase or decrease responses of many neurons in the IC of mice, although the stimuli used were pure tones or white noise. Thus, it is currently unknown whether dopamine alters processing of complex, salient sounds, and whether the observed heterogeneous effects might differ between types of stimuli. In this study, we tested whether dopamine alters responses of IC neurons to vocalizations. We also tested whether the type of stimulus affects the directional (i.e., increased or decreased) effects of dopamine in the IC. **Methods:** We recorded extracellular responses of single neurons in the IC of awake mice. We compared evoked responses to tones, white noise, and mouse vocalizations, as well as spontaneous activity before and after iontophoretic application of dopamine. **Results:** The effects of dopamine were heterogeneous, resulting in either increased or decreased evoked and spontaneous firing of many IC neurons. Given the apparent behavioral relevance of conspecific vocalizations, we expected that dopamine would increase responses of IC neurons to these sounds while decreasing responses to non-salient stimuli. Surprisingly however, dopamine decreased responses to vocalizations in the majority of neurons, and dopamine also decreased responses to all stimulus types. **Conclusions:** We found that dopamine alters firing properties in the IC, and that such modulation is independent of the presence of and/or type of stimulus. Our results demonstrate changes in the same direction for evoked and spontaneous firing, suggesting that dopamine alters the spiking properties of IC neurons in a general fashion, possibly as a type of bidirectional gain control. Understanding how dopamine modulates auditory processing is a crucial first step toward therapies for disordered dopamine signaling underlying communication- and auditory-based disorders.

Abstract: The central nucleus of the inferior colliculus (ICc) is the hub of the ascending auditory system, as it is a nearly obligatory processing center for the output of the auditory brainstem. To better understand how sounds are processed in the ICc, it is important to identify the classes of neurons that make up the ICc and determine how they function within neural circuits. By using a combination of genetic, anatomical, and physiological methods, we recently identified a novel class of stellate cells that are labeled in Vasoactive Intestinal Peptide (VIP)-IRES-Cre mice. VIP neurons in the ICc are glutamatergic, have a sustained firing pattern (214 / 237), have a stellate morphology, represent ~ 20% of stellate cells in the ICc, and 94% (81 / 86) have spiny dendrites. Via axonal tract tracing studies, we found that VIP neurons project to auditory thalamus, auditory brainstem, the periaqueductal gray, and superior colliculus. Using Channelrhodopsin assisted circuit mapping (CRACM), we found that VIP neurons receive input from the contralateral IC (n = 39) and the contralateral DCN (n = 25). Commissural inputs could be excitatory or inhibitory, or a combination of both. Excitatory commissural inputs were mediated by AMPA and NMDA receptors, while inhibitory inputs were mediated by GABAA receptors. EPSPs evoked by optical stimulation of DCN afferents were excitatory, surprisingly slow (halfwidth: 15.8 ± 9.8 ms) and had no NMDA receptor contribution. Activation of DCN afferents also elicited feedforward inhibition (FFI), which limited EPSP duration (n = 5). This FFI was blocked by tetrodotoxin, confirming it results from disynaptic transmission. Having identified VIP neurons as a distinct neuron type in the IC, we are now probing their functional role in sound processing. In *in vivo* extracellular recordings we found that VIP neurons exhibit narrow tuning curves and are only weakly driven by sinusoidal-amplitude modulated (SAM) tones. Yet, VIP neurons respond well to broadband and SAM noise, indicating that they might need to integrate inputs over a range of frequencies to be driven faithfully. This is consistent with their stellate morphology in which their dendrites cross multiple isofrequency laminae. Using two-color CRACM *in vitro*, we also are working to identify how inputs from the DCN and contralateral IC combine with FFI to shape the output of VIP neurons. These experiments are a critical step toward defining how ICc neurons integrate diverse streams of inputs and influence sound processing in the IC.

Title: Sound-evoked after-discharge: A new form of plasticity in the auditory midbrain

Authors: *A. L. BURGHARD[1], C. M. LEE[1], D. L. OLIVER[2];
[1]Neurosci., UConn Hlth., Farmington, CT; [2]Neurosci., Sch. of Medicine, Univ. of Connecticut, Farmington, CT

Abstract: The auditory system is our fastest and temporally most precise sensory system. It can decipher timing differences down to the µs scale. All the more puzzling is the existence of neurons in the auditory system that fire during sound but also continue to fire for seconds to minutes after the offset of an acoustic stimulus. The long-duration sound-evoked after-discharge (LSA) response requires an acoustic stimulus that is greater than 20 seconds in duration. LSA neurons were discovered by Ono et al. (2016) in the inferior colliculus (IC), a major hub in the auditory system. The IC receives ascending inputs from lower brainstem nuclei and descending inputs from the cortex, and sends both excitatory and inhibitory projections to the thalamus. LSA is present in both excitatory and inhibitory neurons. However, the role of LSA in auditory processing is unknown. The goal of the present study was to further study the properties of LSA. We used multi-channel single shank electrodes (16 channels/shank) to record multi-unit activity in the IC of anaesthetized mice. This approach allowed us to record from several frequency laminae in the IC simultaneously. We recorded spontaneous firing before and after the presentation of a long duration sound (≥ 60s). LSA was defined as spontaneous firing after sound offset that was two standard deviations above the mean spontaneous firing rate before the long-duration sound. We found LSA in at least 23% of the recording sites. We could identify two basic response patterns. LSA could begin immediately after the offset of the sound, or it could exhibit a build-up response that began as late as 20 s after the sound offset. Both response patterns could last for over a minute. The response type, immediate vs build-up, could not be predicted by the neural response during the long duration sound. The sound induced after-discharge behavior observed in our study could be a form of plasticity with intermediate-duration potentiation. Especially, as the observed firing after the sound offset resembles acoustically driven activity and is therefore of special interest in the context of tinnitus, a disease that is defined as the perception of a sound in the absence of an external sound stimulus.

Title: Monosynaptic auditory inputs to the cerebellar flocculus and paraflocculus

Authors: G. SEKERKOVA, *C.-P. RICHTER, M. MARTINA;
Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Several papers suggest that cerebellar unipolar brush cells (UBCs) located in the flocculus/paraflocculus (Fl/PFl) play an important role in the generation of tinnitus. However, no evidence exist that these cells are embedded in the auditory network. Thus, we tested the hypothesis that UBCs receive auditory inputs. In a first set of experiments we performed cFOS staining on cerebellar sections form animals exposed to acoustic stimuli (90 to 110 dB SPL) and we found that several neurons the Fl/PFl showed cFos expression. These cells were by and large located in the granule cell layer and were identified as presumptive UBCs. In a second set of experiments we performed in vivo recordings in Fl/PFl to study the electrophysiological response to auditory stimulation. We found that numerous cells responded to auditory stimuli. Interestingly, in a majority of the responsive neurons the delay time for the first spike was between 3 and 4 ms, which suggests that these cerebellar neurons receive a monosynaptic input from primary auditory fibers. The spontaneous firing rate of the responsive neurons varied, suggesting potential cellular heterogeneity. However, in 16 of 21 cells in which we could establish the maximum firing frequency, this was relatively slow, suggesting that they are not granule cells. These neurons show spontaneous firing properties of UBC previously reported in other cerebellar and cochlear nuclei regions. Additionally, our tract tracing studies show that BDA labeled primary auditory fibers are not only present in Fl/PFl but they contact UBCs. In conclusion, our data suggest the existence of monosynaptic auditory inputs to UBCs of the cerebellar flocculus.

Title: Putative amygdala-brainstem synaptic mechanism important for sensory gating

Authors: *J. C. CANO[1], K. FENELON[2];
[1]Univ. of Texas At El Paso, El Paso, TX; [2]Biol., Univ. of Massachusetts Amherst, Amherst, MA

Abstract: Sensorimotor gating (SG) is a pre-attentive inhibitory neural mechanism that filters out irrelevant sensory information. SG therefore contributes to focus attention and cognitive processes. Impaired SG is observed in patients suffering from schizophrenia, obsessive-compulsive disorder and other neuropsychiatric disorders. Clinically, SG is measured using the prepulse inhibition (PPI) of the acoustic startle reflex task. PPI occurs when a mild sound (prepulse) inhibits the startling effect of a subsequent startling sound (pulse). Uniquely positioned to relay sensory inputs from several brain regions to motor neurons, the brainstem caudal pontine reticular nucleus (PnC) is at the core of the neural circuit underlying PPI. Afferents from the pedunculopontine tegmental nucleus (PPTg) to the PnC form part of a "cortico-striato-pallido-pontine" network important for PPI. Interestingly, PPTg lesions reduce PPI without abolishing it, suggesting that other PnC-connected regions might contribute to PPI. The central nucleus of the amygdala (CeA) also sends monosynaptic projections to the PnC in rodents. We previously showed that inhibiting the CeA-PnC excitatory synapses disrupts PPI. Here, to further confirm the contribution of this alternative pathway to PPI, we photo-activated the CeA-PnC excitatory connection to mimic its physiological activation by an acoustic prepulse in mice. This resulted in a 19-30% PPI, compared to a 40-60% PPI elicited by an acoustic prepulse. We then aimed to identify the post-synaptic targets of CeA excitatory inputs in the PnC. We first determined whether CeA excitatory inputs presynaptically modulate auditory neurotransmission. Using extracellular field recordings in PnC slices, activation of CeA fibers did not significantly change the probability of neurotransmitter released by auditory fiber stimulation in PnC neurons. Then, injecting AAV-CamKIIa-mCherry in the CeA of mice that express the green fluorescent protein under the control of the Glycine transporter type 2 (GlyT2) promoter, confocal imaging revealed close appositions between CeA axonal projections and GlyT2-expressing PnC interneurons. In sum, our results suggest that CeA excitatory inputs activate PnC inhibitory neurons and this mechanism likely contributes to PPI. We thus provide some insights on the paradoxical contribution of an excitatory pathway to an inhibitory

phenomenon. Ultimately, better understanding the neural substrates of PPI is crucial to identify potential therapeutic targets for SG and cognitive impairments.

Title: Neural circuits for somatosensory control of auditory thalamo-cortical processing

Authors: *M. LOHSE, J. C. DAHMEN, V. M. BAJO, A. J. KING;
Univ. of Oxford, Oxford, United Kingdom

Abstract: Considerable attention has been focused on the involvement of cortical areas in multisensory processing. Although visual and somatosensory influences on auditory responses can arise via direct corticocortical pathways, it is likely that some aspects of multisensory cortical processing are inherited from the thalamus. In recent years, the thalamus has received renewed interest, and several studies have suggested that sensory processing at this level may be dependent on a range of contexts, often guided by cortico-thalamic feedback. However, very little is known about the neural circuits that might implement multisensory interactions at the level of the thalamus. We have investigated this by examining the circuitry underlying the influence of tactile inputs on processing in the auditory thalamus in mice. Our *in vivo* electrophysiological recordings demonstrated that the mouse auditory thalamus as a whole is influenced by stimulation of the whiskers in diverse, but pathway-specific ways, with primary auditory cortex inheriting signals from the thalamus that are divisively scaled by whisker stimulation. This somatosensory suppression is dependent on a primary somatosensory corticofugal projection and is at least in part implemented via neurons in the higher-order auditory midbrain receiving input from somatosensory cortex. Furthermore, we demonstrate the presence of a parallel direct cortico-thalamic pathway from primary somatosensory cortex to the medial sector of auditory thalamus, which is capable of driving spiking activity and facilitating auditory responses. Together, these results reveal a previously underappreciated role for auditory thalamus in the implementation of multisensory processing, and the circuits which allow for such thalamic multisensory interactions.

Title: Dissection of auditory thalamocortical circuit dynamics using targeted lidocaine microinjections

Authors: *P. LAKATOS[1], M. N. O'CONNELL[4], A. BARCZAK[2], T. M. MCGINNIS[3], S. A. NEYMOTIN[5], T. M. MOWERY[6];

Abstract: While previous anatomical studies provided enough data to form the backbone of influential theories on how thalamocortical circuitry supports the transformation of sensory information on its way to conscious perception, a systematic verification of these influential theories in awake behaving animals is still lacking. The goal of our present study was to verify one of these theories in particular: the core-matrix organization of thalamic nuclei proposed by Jones (1998, Neuroscience). According to this theory, while core components of the thalamus submit detailed information about the properties of sensory stimuli, the matrix is responsible for orchestrating modulatory mechanisms and for orchestrating synchrony amongst cortical neuronal ensembles processing behaviorally relevant inputs. To verify this type of dual-purpose functional and anatomical organization, we located and selectively injected different nuclei of the medial geniculate body (MGB) with lidocaine in awake macaque monkeys. We targeted either the ventral nucleus of the MGB, which forms the auditory thalamic core and projects to the granular layer of the auditory cortex, or the dorsal and medial nuclei of the MGB, which are part of the auditory thalamic matrix and project to the extragranular layers. As anticipated, injections resulted in a dose dependent, local silencing of neuronal activity in the targeted nuclei. Our laminar auditory cortex recordings revealed that while lidocaine injections into the MGB core resulted in an attenuation of responses to auditory stimuli mostly in the granular layer, MGB matrix injections suppressed extragranular layer responses. As expected, we found marked differences between thalamic silencing's effect on cortical responses to pure tones vs. broadband noise bursts, but response latencies to both types of stimuli significantly increased following core silencing. Additionally, cortical frequency tuning was also affected in distinct ways in the case of

core vs. matrix thalamic lidocaine injections: while core silencing sharpened, matrix silencing broadened tuning. Finally, in line with the matrix's role in orchestrating cortical rhythmic modulatory mechanisms and synchrony, neuronal oscillations were also modulated following matrix injections. In summary, our study was able to verify and add electrophysiological detail to the theory of the core-matrix organization of thalamic nuclei.

Abstract: Auditory cortex (ACtx) pyramidal neurons are suppressed during movement, which reduces sound-evoked activity and behavioral detection of faint sounds. Movement-related suppression of ACtx pyramidal neurons is thought to arise through projections from the basal forebrain and secondary motor cortex (M2) that engage local GABA circuits within the ACtx. While some fraction of pyramidal neuron suppression reflects monosynaptic connections from M2 onto GABA neurons, the influence of neuromodulatory inputs are often brokered by intermediaries in layer (L) 1 or L6 that directly adjust local excitability and tuning. Ntsr1-expressing layer 6 corticothalamic (L6 CT) neurons regulate sensory gain throughout the column by recruiting specialized networks of fast-spiking inhibitory neurons, suggesting that L6 CTs could be activated by motor preparatory signals to drive local GABA networks and suppress

excitatory activity. To test this prediction, we used 2-photon calcium imaging to measure activity from L6 CT neurons or L2/3 Thy1+ pyramidal neurons while mice performed a simple task that isolated the contribution of movement, sensory, and reward-related inputs. We confirmed reports that self-generated movements such as licking or running suppressed spontaneous and sound-evoked activity in L2/3 pyramidal neurons. By contrast, L6 CTs were activated immediately prior to and during movement onset. Unlike L2/3 pyramidal neurons, sound-evoked responses in L6 CTs were not attenuated during movement, and were often enhanced. Pseudo-typed rabies tracing identified substantial numbers of long-range monosynaptic inputs onto L6 CT neurons from cholinergic and non-cholinergic neurons at the border of globus pallidus and the basal forebrain. Few input neurons were identified in M2. These findings suggest that L6 CTs may act as an intermediary between long-range motor inputs from the basal forebrain and basal ganglia, but that M2 may bypass L6 CTs and connect directly onto local GABA cells within ACtx. To better identify the sequence of ACtx neural activation during movement with millisecond precision, our ongoing experiments rely on electrophysiological recordings from optogenetically identified L6 CT neurons as well as local regular- and fast-spiking neurons.

Abstract: Auditory brainstem implants (ABIs) are neuroprosthetic devices that provide sound sensations to profoundly deaf patients who are not candidates for cochlear implants due to a damaged or absent cochlear nerve. Recognition of complex sounds such as speech is poor with ABIs compared to performance with cochlear implants. Efforts to improve ABI technology are hampered by a poor understanding of how ABIs recruit the central auditory pathways, particularly the auditory cortex. Here, we developed a novel ABI mouse model that enables *in vivo* imaging of auditory cortical neuronal activity in response to sound or electrical stimulation of the cochlear nucleus (CN). Mice are chronically implanted with a flexible multichannel array placed onto the CN, a contralateral cranial window is made, and transduction of cortical neurons is achieved using viral vector injection for expression of the calcium indicator GCaMP6s. Using two-photon calcium imaging, we analyzed L2/3 auditory cortical neurons in awake mice and compared their activity in response to either broadband frequency noise bursts or an electrical ABI impulse delivered to the CN. Our preliminary data suggest that the subset of auditory cortical neurons that respond to noise bursts are also activated by ABI stimulation. We then determined whether ABI stimulation induced an auditory percept by training implanted mice in a bi-modal auditory/ABI behavioral detection task. We found that mice previously trained to detect sound rapidly generalized to detecting ABI stimulation at high pulse rates. Ongoing work is determining which cortical neuron subtypes are activated by sound versus ABI-evoked representations. Together, these experiments may offer insights into improving ABI design, and ultimately lead to better outcomes in patients who must learn to interpret sound signals through these implants.

Title: Cell morphology-specific nicotine regulation of excitatory synapse in mouse auditory cortex

Authors: *T. NAGAYAMA[1], R. METHERATE[3], H. D. KAWAI[2];
[1]Soka Univ., Hachioji, Japan; [2]Dept. of Sci. and Engin. for Sustainable Innovation, Soka Univ., Tokyo, Japan; [3]Univ. of California Irvine Dept. of Neurobio. and Behavior, Irvine, CA

Abstract: Previous in vivo studies have shown that systemic nicotine exposure enhances the responses evoked by characteristic frequency (CF) tone but suppresses those evoked by non-CF tone in primary auditory cortex (A1). These nicotinic regulations need the activation of α4β2* nicotinic acetylcholine receptors and extracellular signal-regulated kinase (ERK). Although protein kinase A (PKA) is known as an upstream effector of ERK, it is unclear whether PKA mediates these nicotinic regulations. To examine this, we recorded local field potentials (LFPs) in A1 with a 16-channel multiprobe and examined how PKA blockade affected the systemic nicotine effects by analyzing current source densities (CSDs). While nicotine exposure increased initial 3 ms (the "input" phase) and 3-20 ms (the "early intracortical" phase) current sinks of CF tone-evoked CSDs in the thalamocortical input layer as reported previously, the local injection of a PKA inhibitor, myristoylated PKI 14-22 amide (PKI), inhibited the nicotinic enhancement of both phases. As for the non-CF tone-evoked CSDs, PKI injection prevented the nicotine-induced suppression of initial 20 ms current sink (the "early" phase) but did not inhibit the 30-80 ms current sink (the "late" phase). These data suggest that there are distinct excitatory neurons and their synaptic inputs under different nicotinic regulations. We began to test this possibility by recording spontaneous and evoked excitatory postsynaptic currents (EPSCs) in layer 4 of A1 using the whole-cell voltage clamp technique. A local nicotine perfusion increased the frequency and amplitude of spontaneous EPSCs (sEPSCs) and miniature EPSCs (under tetrodotoxin) in cells with 3 or less first branches out of the apical dendrite (less-branching cells), but it decreased them in cells with 4 or more first branches (more-branching cells). The nicotinic enhancement in less-branching cells was PKA-dependent, while the nicotinic suppression in more branching cells was PKA-independent. The amplitude of the polysynaptic EPSCs evoked by stimulation at a horizontally distant (>500 μm) site was increased in less-branching cells but decreased in more-branching cells. Nicotine didn't affect the thalamocortical monosynaptic EPSCs on either cell type. It was noted that the thalamocortical synapses were detected primarily in less-branching cells, while the horizontal inputs were detected mostly in more-branching cells. We hypothesize that less-branching cells process mainly thalamocortical and subsequent intracortical inputs, which nicotine enhances via PKA, while more-branching cells process horizontal intracortical inputs, which nicotine suppresses.

Title: Regional expression of parvalbumin and calbindin in macaque auditory cortex

Authors: *L. A. DE LA MOTHE[1], S. HUBBARD[1], H. WALKER[1], T. A. HACKETT[2];
[1]Psychology, Tennessee State Univ., Nashville, TN; [2]Hearing & Speech Sciences, Psychology, Vanderbilt Univ., Nashville, TN

Abstract: In order to have a greater understanding of sensory perception and behavior, including communication, the structural and chemical organization of the brain must be established. Previous work by Kubota et al. (1994) examined the expression patterns of several calcium binding proteins including parvalbumin and calbindin in frontal cortex. While additional studies of this subset of inhibitory interneurons have expanded this work to include various species and cortical areas (Cruikshank et al., 2001; Kawaguchi and Kubota, 1997; Markram et al., 2004), our understanding of the expression of CBP within auditory cortex of primates remains to be fully characterized. The current working model of primate auditory cortex consists of three regions that correspond to levels of processing: the primary core region, a secondary belt region, and the parabelt region (Hackett, 2011). This study aims to examine expression of the CBPs parvalbumin and calbindin across the various regions of auditory cortex. Single and multi-fluorescent immunohistochemistry (IHC) were performed to visualize parvalbumin and calbindin positive cells. Samples were taken from the three regions in auditory cortex to compare distribution of these CBP. Cells labeled with parvalbumin and calbindin were plotted as well as those co-expressing both. Results indicate largely distinct populations of parvalbumin and calbindin, with few cells co-localized, clear laminar patterns, as well as decreasing expression of the CBP with increasing hierarchical regions (core, belt, parabelt).

Title: State-dependence of spontaneous and sound-evoked responses across layers and cell types of mouse auditory cortex

Authors: *S. JO[1], T. DONOR[1], E. MCCARTHY[2], D. A. MCCORMICK[1];
[1]Inst. of Neurosci., [2]Computer Sci., Univ. of Oregon, Eugene, OR

Abstract: The ability to identify meaningful auditory signals requires the ability to rapidly modulate neural responses in a manner relevant to an animal's behavior and internal state. State-dependent variations in neural responses have been observed in auditory cortex; however, the characteristics of different cortical layers and roles of different cell types in mediating this effect are not well understood. To gain a better understanding of auditory state-dependence, we used multiple techniques, from extracellular recording to wide-field and two-photon mesoscale calcium imaging, to record neural activity in auditory cortex of head-fixed mice. We simultaneously monitored pupil size, walking speed, and whisker movement to quantify state while the mice listened to white noise, tone pips, or nothing. To observe responses on a large scale, we performed wide-field single-photon calcium imaging of superficial excitatory neurons in Thy1-GCamp6s and CaMKII-GCamp6s mice. Next, we probed the effect of state on each layer of cortex using extracellular recordings with silicon probes. Wide-field imaging and extracellular recording revealed an inverted-U relationship between pupil diameter and sound-evoked responses in superficial layers. Extracellular recordings confirmed that this relationship is also present in deep layers of auditory cortex. Furthermore, state was found to exhibit a substantial relationship with spontaneous activity. Finally, to reveal the roles of different cell types in state-dependent circuit mechanisms, we are performing cellular resolution calcium imaging of excitatory neurons, as well as parvalbumin (PV), somatostatin (SOM), and vasoactive intestinal peptide (VIP) interneurons using a two-photon mesoscope. We crossed PV, SOM, and VIP mouse CRE lines with reporter line Ai148 and/or Ai162 which are expressing GCamp6f and GCamp6s, respectively. Preliminary results suggest that the activities of individual excitatory and VIP neurons exhibit heterogenous, but significant relationships with state and movement. Our research combines multiple techniques to contribute an overall understanding of state-dependent neural mechanisms across layers and cell types of auditory cortex.

Title: Modulation of glutamatergic and GABAergic circuits produce frequency and region-specific effects on auditory evoked responses

Authors: I. GONZALEZ-BURGOS[1,2,3], M. BAINIER[1], M. J. NICOLAS[2,3], P. SCHOENENBERGER[1], M. VALENCIA[2,3], ***R. L. REDONDO**[1];

Abstract: Auditory state responses (ASSR) constitute a useful tool for evaluating cortical oscillatory activity, as they appear altered in several neuropsychiatric disorders. ASSR are oscillatory responses to rhythmic auditory stimuli. By using a tone modulated in amplitude at increasing frequencies, the chirp evoked potentials assess the response to a wide range of frequencies in a single test. Since gamma band oscillatory activity (30-120 Hz) is involved in higher-order cognition and perception, alterations in electrical activity of schizophrenia patients have been related to these symptoms of the disease (Alegre, M. *et al.* 2017).
We hypothesized that dizocilpine (MK-801) -which recapitulates part of the physiology responsible for schizophrenia- would disrupt the chirp and ASSR in rodents in a similar way to that described in patients. Furthermore, we hypothesized that diazepam (DZP) -shown to disrupt gamma band synchronization- would also disrupt the responses. Moreover, if chirp and ASSRs can discern distinct pharmacological modulations, the effects of MK-801 would differ from those of DZP.
We recorded electroencephalographic (EEG) responses in the rodents. In the primary auditory cortex, the effects at the 40-Hz band in ASSR were similar. The chirp under MK-801 produced a decrease in the high-gamma range while under DZP it remained stable. In the prefrontal cortex, DZP produced a decrease in the low-gamma range in both ASSR and chirp, while under MK-801 responses remained stable. Lastly, in the parietal cortex, no effect was obvious in the 40-Hz ASSR, while the chirp showed a decrease in low-gamma under DZP and in high-gamma under MK-801.
Disruptions in the glutamatergic and GABAergic circuits have region-specific effects on evoked responses. The chirp shows that disruptions are specific to the neurotransmitter system affected. We conclude that the responses to chirp and ASSR are sensitive to the fine regulation of different neuronal populations, and hypothesize that the modulation of specific cell types at a microcircuit level results in distinct responses.

Title: Diverse brain regions targeting layer 1 interneuron subtypes in auditory cortex

Authors: *C. G. SWEENEY[1,2], A. C. CASTRO[1], B. M. GLICKMAN[1], J. D. MCLENNAN[1,3], E. HE[1,3], A. E. TAKESIAN[1,2];

Abstract: The primary auditory cortex (A1) receives sensory input from the auditory thalamus as well as neuromodulatory centers throughout the brain. Neuromodulatory projections powerfully filter and modify ascending auditory signals from the thalamus, thereby influencing sound perception and sound-driven behaviors. Moreover, the convergence of ascending sensory and neuromodulatory signals in A1 can induce long-lasting changes in cortical sound responses that may underlie auditory learning. Recent work from our laboratory and others implicates layer 1 (L1) of A1 as a key site for integrating both sensory signals and information about behavioral state and outcome. The interneurons that populate L1 are composed of multiple subtypes, characterized by the selective expression of distinct molecular markers, such as vasoactive intestinal peptide (VIP), neuron-derived neurotrophic factor (NDNF) and gamma synuclein (SNCG). Our recent results demonstrate that these subtypes differentially receive input from thalamic nuclei. Further, they differentially express receptors for neuromodulators such as acetylcholine, serotonin, and corticosteroids, suggesting that distinct brain regions may preferentially innervate these interneuron subtypes. Our ongoing work using 2-photon calcium imaging is revealing parallel differences in the *in vivo* activity patterns of these interneuron subtypes in response to a range of sound and other behaviorally-relevant stimuli. Together, these studies will expand upon our current understanding of the anatomical and functional diversity of L1 circuits in A1 for conveying distinct auditory and neuromodulatory information.

Title: The development of circuits to L1 neurons in the mouse auditory cortex

Authors: *X. MENG[1], J. P. Y. KAO[2], P. O. KANOLD[1];
[1]Biol., Univ. of Maryland, College Park, MD; [2]Ctr. for Biomed. Engin. and Technology, and Dept. of Physiol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Layer 1 (L1) of neocortex is unique in that most L1 neurons are GABAergic interneuron and they can have profound impact on the responses of neurons in other layers, especially the neurons whose dendritic tufts reside within L1, to the sensory stimuli. During development the pattern of sensory evoked activity plays a crucial role in shaping cortical organization. Since L1 neurons are positioned to control activity across the cortical column they might play a key role. L1 neurons receive intra- and inter- cortical inputs as well as subcortical inputs. However, the development of these circuit to L1 is unknown.
To address this question we performed Laser-scanning photo stimulation (LSPS) combined with whole-cell patch clamp recoding of L1 neurons in thalamocortical slices from P5 to P28 mice and measured the spatial pattern of excitatory and inhibitory connections. We found that at P 5-8 L1 neurons receive excitatory input from all layers, especially L5/6 and the cortical subplate, whereas the inhibitory GABAergic inputs to L1 neurons are most from within L1, L5/6 and subplate. During development the inhibitory input from L2/3 and L4 increases. Both the excitatory and inhibitory connection from subplate decreases. Moreover, we observed that the functional circuits diversify during development.
Together, our results revealed distinct laminar changes in the intracortical connections to L1 neurons over development.

Title: Rewiring the deafferented thalamic and cortical neurons to the remaining auditory inputs: A model for treatment of tinnitus patients

Authors: *P. JENDRICHOVSKY, Y. YANG, X. CHEN, J. HE;
City Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Introduction Tinnitus is the auditory phantom sensation when no external sound is present. Our working theory is that tinnitus is caused by the parasitic positive feedback oscillation in the thalamocortical circuit, neurons of which become hypersensitive due to lack of cochlear input and cause tinnitus after hearing loss. Cholecystokinin (CCK) has plasticity enabling properties towards cortical neurons. In the present study, we aim to rewire weak connections from the remaining inputs towards the deafferented ones. We hypothesize that this will suppress the hypersensitivity and therefore silence tinnitus permanently. **Materials & Methods** To accomplish the aim of this study, a reliable animal tinnitus induction and assessment models had to be established first. Gap-prepulse inhibition of the acoustic startle reflex (GPIAS) is used for the assessment of tinnitus, whereas unilateral noise induced hearing loss was chosen as model to induce tinnitus. Various applications of CCK4 together with sound treatment were chosen as the potential candidates for permanent tinnitus treatment. **Results** We obtained long term GPIAS observations from multiple mice before hearing loss induction, during two-month-long chronic tinnitus transition period and after the CCK treatment. After CCK therapy mice improved the GPIAS performance.

Title: Experience based changes to auditory corticostriatal E/I receptor function gates LTP and permits associative learning

Authors: N. PARAOUTY, ***T. M. M. MOWERY**;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Associative learning is facilitated by cortical glutamatergic excitatory inputs onto medium spiny neurons of the sensorimotor striatum. When salient stimuli are repeatedly paired with positive or negative rewards, learning occurs as the desired behavioral response becomes

extremely reliable. While LTP is the most likely neural mechanism governing this process, the experience-based changes to synaptic properties along the corticostriatal circuit that drive synaptic strengthening remain unclear. Here we used an appetitive reinforcement operant conditioning procedure to train gerbils on a discrimination task. Behavioral performance was assessed daily and correlated with experience-based changes to synaptic properties in a corticostriatal slice preparation. Our primary aim was to determine how the changes in striatal cellular properties gate the LTP that is correlated with task acquisition. Mongolian gerbils were trained on a Go-Nogo task. Here, animals learned to discriminate a 12-Hz amplitude-modulated noise stimulus which indicated the availability of food reward from a 4-Hz stimulus which indicated no reward. Following each training session, a sensitivity measure, dprime, was computed and a corticostriatal brain slice was obtained. Inhibitory $GABA_B$ or excitatory NMDA synaptic properties were recorded from medium spiny neurons in the auditory striatum. Theta burst stimulation of auditory cortex L5 pyramidal neurons was used to assess the probability of LTP induction in the striatum. Our data indicate that as the animals learn the task, $GABA_B$ inhibitory receptor strength is reduced, while NMDA receptor strength is increased. Following task acquisition (d-prime >1.5), both $GABA_B$ and NMDA receptor strengths return to baseline values, i.e., pre-task acquisition. In addition, LTP probability increases contemporaneous to task acquisition. Together these results suggest that a reduction in $GABA_B$ receptor strength may facilitate NMDA receptor activation leading to cortically-induced LTP expression in the striatum. The short time window during which experience induces a change in E/I receptor functions permits learning to occur by allowing stimuli-evoked responses to briefly have a greater potentiation effect.

Abstract: Sensory systems rely on intricately connected networks of feedforward and feedback circuitry to encode sensory information and guide behaviors. In the auditory system, incoming sound information is transduced by hair cells in the cochlea and transmitted into the brain by spiral ganglion neurons (SGNs). Early auditory computations occur largely in the brainstem, where specialized circuits in the superior olivary complex (SOC) aggregate sensory information from both ears to mediate sound localization. The SOC also houses a group of auditory feedback cells that project back into the cochlea to target both hair cells and SGNs. These olivocochlear efferent neurons (OCNs) are known to play numerous roles in the auditory system, including protecting the cochlea from acoustic injury and aiding in speech-in-noise detection. Mammalian OCNs are typically classified into two or three major categories based on their anatomical projections. Little is known, however, about the molecular or genetic factors that distinguish these major subsets of OCNs from each other or from other brainstem neurons. As such, no markers exist to identify or manipulate subsets of OCNs, and virtually nothing is known about any heterogeneity within these major OCN subtypes. To address this gap, we've used a high-throughput, single-cell sequencing approach to profile the transcriptome of individual neurons in the SOC, including OCNs. Our analysis has identified several populations of SOC neurons, including two major clusters of OCNs. We've discovered several new markers for each of these OCN clusters, offering new insights into these key regulators of cochlear function.

Title: Behavioral detection of optogenetic stimulation in macaque inferior temporal cortex

Authors: *S. BOHN, A. AFRAZ;
Lab. of Neuropsychology, NIMH, Bethesda, MD

Abstract: We injected AAV5 engineered to express the opsin C1V1 (a light-activated neural depolarizing agent) to the inferior temporal (IT) cortex of a rhesus macaque. In a second surgery twelve weeks later, we verified virus expression and implanted an LED array over the transduced region. The array is composed of a 5x5 grid of LEDs, each capable of producing up to 60mW of green light (527nm). As a control, we implanted another LED array on the animal's other IT cortex that was not transduced with virus.

The animal was trained to behaviorally detect optogenetic stimulation of its IT cortex while looking at images of different objects. After acquiring a trial by fixating on a central fixation point, an image of an object appeared on the animal's screen for one second. Then, in half of the trials, randomly selected, a 200ms optical impulse was delivered to IT cortex via the LED array halfway through the trial. The animal was rewarded for correctly identifying whether the trial did or did not contain an optical impulse by looking at one of the two subsequently presented response targets.
The animal learned to detect optical impulses delivered to its transduced cortex significantly above chance level after 17 days of training (Chi-squared, $p < .01$) and improved its average performance across all images to 89% correct after 21 more days of training (Chi-squared, $p < .0001$). Optical impulses delivered to the control side (no virus injection) remained undetectable. We also found that the animal's performance in detecting cortical stimulation heavily depends on the image presented during stimulation, ranging from 74% to 100% correct for images of different objects. The lowest performance (69%) was observed when only the fixation point was shown on a blank screen. Even in this condition, performance remained significantly above chance (Chi-squared, $p < .01$). Overall, we found a significant effect of image on detectability of the optogenetic stimulation of IT cortex (bootstrapping, $p < .001$).
These results show that it is possible to induce large behavioral effects using optogenetics in nonhuman primates. The results also indicate that detectability of IT cortical stimulation depends on visual input. This suggests that stimulation of IT cortex causes specific distortions to incoming visual stimuli.

Title: Functional imaging of excitatory neurons in an entire column in mouse visual cortex

Authors: *R. ABBASI-ASL, J. LARKIN, K. TAKASAKI, D. MILLMAN, D. DENMAN, J. LECOQ, A. ARKHIPOV, N. W. GOUWENS, J. WATERS, R. C. REID, S. E. J. DE VRIES; Allen Inst. for Brain Sci., Seattle, WA

Abstract: Characterizing the relationship between neural function and connectivity is a central problem in visual sensory processing. In order to explore this relationship, we have recorded visual responses from pan-excitatory neurons within an 800X800 um region of primary visual cortex, spanning all visual layers from pia to white matter. This includes ~35,000 neurons per mouse in 5 mice total, collected from 750 2-photon and 35 3-photon calcium imaging planes

spaced by ~16 um. This dataset will be used to examine the single-cell and population activity in primary visual cortex, and along with electron microscopic reconstruction from the same tissue, will serve as a valuable resource in studying the functional connectome in mouse cortex. A wide variety of visual stimuli were used to characterize neural responses, including drifting gratings, sparse noise, natural movies and natural images. We assessed multiple metrics, including receptive field profile, direction and orientation selectivity indices, reliability of response, signal and noise correlations, and sparseness of response. Here, we describe these metrics as a function of depth and explore their heterogeneity. For example, we characterize the spatial receptive field organization at different depths and quantify both spatial scatter and the degree of overlap between ON and OFF sub-fields.

Title: A bi-directional optical-genetic toolkit for reading and writing topographic neural population codes in behaving macaque cortex

Authors: ***Y. Y. CHEN**[1], G. BENVENUTI[1], D. MILLER[2], C. T. SULLENDER[2], F. RADAEI[2], A. DUNN[2], C. RAMAKRISHNAN[3], K. DEISSEROTH[3], W. S. GEISLER[1], E. SEIDEMANN[1]; [1]Ctr. for Perceptual Systems, [2]Biomed. Engin., Univ. of Texas at Austin, Austin, TX; [3]Bioengin & Psych, Stanford Univ. Dept. of Psychology, Stanford, CA

Abstract: In primates, visual perception is likely to be mediated by large populations of V1 neurons organized into multiple overlaid topographic maps. The distributed and topographic nature of V1's representations raises the possibility that in some tasks, downstream areas that decode V1 signals in order to mediate perception could combine V1 signals at the relevant topographic scale—e.g., at the scale of the orientation columns. If this were the case, then the fundamental unit of information would be individual columns rather than single neurons, and to account for the subject's behavior in a perceptual task, it would be necessary and sufficient to

consider the summed activity of the thousands of neurons within each column.
To test this topographic-code hypothesis, we developed a bi-directional optical-genetic toolkit for reading and writing topographic neural population codes in macaque cortex. First, we used viral-based methods to co-express a calcium indicator (GCaMP6f) and a red-shifted opsin (C1V1) in excitatory V1 neurons for extended periods (>1 year). Second, we developed a DMD projector that allows us to project arbitrary light patterns into the cortex. Third, we built a widefield imaging system that allows simultaneous GCaMP imaging and patterned optogenetic stimulation.
Here we focus on our initial attempts to develop a quantitative model that would allow one to determine the light stimulation necessary to recreate a desired topographic pattern of population response. Our first model has two components: a transfer function between light power and evoked neural activity, and a spatial impulse response. To estimate these components, we employed checkboard patterns with different power densities and spatial frequencies. Our results reveal that: 1) reliable response can be elicited at low power density (< 0.02 mW/mm^2); 2) above threshold, response increases linearly with power density until a saturating nonlinearity is reached; 3) the spatial impulse response contains a narrow peak (HWHH of ~0.22mm) and a widespread tail. Importantly, this method allows us to elicit responses at the scale of orientation columns.
Our long-term goal is to use this toolkit to recreate neural responses that are indistinguishable at the relevant topographic scale from those evoked by visual stimuli, and then use the animal's perceptual report to test the extent to which these visual and optogenetic stimulations are perceptually equivalent (i.e., are neural metameres). These experiments could address fundamental questions regarding the nature of the neural code in primate cortex and could have important implications for future brain-machine-interfaces.

Title: Neural and perceptual correlates of nonlinear interactions between visual and optogenetic stimulation in behaving macaque V1

Authors: *S. KUMAR, S. C.-Y. CHEN, Y. Y. CHEN, G. BENVENUTI, M. P. WHITMIRE, W. S. GEISLER, E. SEIDEMANN;
Ctr. for Perceptual Systems, Univ. of Texas at Austin, Austin, TX

Abstract: A central goal of visual neuroscience is to understand the relationship between neural activity and behavioral performance in visual tasks. Opto-genetics can provide powerful methods for testing specific hypotheses about this relationship. Recently, we began developing a bi-directional optical-genetic toolkit that allows simultaneous measurement and modulation of neural population activity in the cortex of behaving macaque monkeys. Specifically, we use viral-based methods to co-express, in the same population of excitatory V1 neurons, a calcium indicator (GCaMP6f) and a red-shifted opsin (C1V1). Wide-field imaging is then used to measure the GCaMP activity produced both by normal visual stimulation and/or by patterns of light projected onto the visual cortex (optostim).Our long-term goal is to use this toolkit to test specific hypotheses about the encoding and decoding of neural responses in macaque V1 by using optostim to modulate neural activity while monkeys perform specific visual discrimination tasks. As a first step, we trained a monkey to detect a small Gaussian visual target positioned at locations corresponding to either GCaMP/C1V1 expression site or a nearby GCaMP-only control site in the monkey's V1. Our preliminary results revealed strong nonlinear (sub-additive) interactions between visual and optostim-driven neural responses. Furthermore, at the joint expression site, we found that the monkey's detection accuracy decreased when the visual stimulus was presented together with optostim; whereas, at the control site there was no effect of optostim. This reduced behavioral accuracy at the joint expression site was consistent with the sub-additive interactions between the visually-driven and optostim-driven GCaMP responses. To further examine these nonlinear interactions, we performed additional imaging and electrophysiological experiments in passively fixating monkeys, for a wider range of visual stimuli and optostim power densities. We found: (1) strong multi-unit responses and strong GCaMP responses to optostim; (2) that both measures have a low optostim threshold ,i.e., < 0.15 and 0.02 mW/mm^2, respectively; (3) that above threshold, both responses rise linearly with power density until a saturating limit is reached; (4) that normal visual stimulation and optostim nearly always combine in a sub-additive fashion. We are currently testing various quantitative models of these nonlinear interactions.

Title: All-optical interrogation of functional connectivity in mouse visual cortex during behaviour

Authors: *L. E. RUSSELL[1], Z. YANG[1], M. FISEK[1], A. M. PACKER[2], H. W. DALGLEISH[1], M. HAUSSER[1];
[1]UCL, London, United Kingdom; [2]Univ. of Oxford, Oxford, United Kingdom

Abstract: Understanding how the structure of connectivity underlies the processing carried out by cortical circuits is a fundamental problem in neuroscience. Layer 2/3 of mouse visual cortex consists of functionally distinct subnetworks of recurrently connected neurons. Neurons sharing similar stimulus response properties (i.e. cotuned to the same stimuli) preferentially share monosynaptic connections. This specific synaptic connectivity rule may facilitate and maintain robust representations of visual stimuli even under situations when those stimuli are weak or degraded. Here we have trained mice on a visual detection task and used simultaneous two-photon calcium imaging and two-photon optogenetics to ask: 1. How does this pattern of paired connectivity extend to, and influence, activity at the population level *in vivo*? and 2. How does the functional signature of subnetworks impact upon the neural representation, and ultimately the behavioural salience, of weak or ambiguous stimuli? To address these questions, we performed targeted photostimulation of ensembles of either cotuned, non-cotuned or non-stimulus responsive L2/3 visual cortex neurons and observed the response of the local network as well as the animal's performance in reporting the current visual stimulus. We find that the dominant effect of photostimulation on the local network is inhibitory, with both enhancement and degradation of the population representation of the sensory stimulus. The resulting behavioural bias follows the sign of modulation to the network response. We also find that the behavioural effect of photostimulation depends on the animals baseline performance in the task suggesting a state-dependent gating of cortical influence in guiding this behaviour. These results provide a bridge between connectomics, sensory stimulus coding and behaviour.

Title: Optogenetic stimulation of area V6 improves visual detection in the marmoset

Authors: *P. JENDRITZA[1,2], F. KLEIN[1], P. FRIES[1,3];
[1]Ernst Strüngmann Inst. (ESI) For Neurosci., Frankfurt, Germany; [2]Intl. Max Planck Res. Sch. for Neural Circuits, Frankfurt, Germany; [3]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands

Abstract: Understanding communication between brain areas is a fundamental challenge for systems neuroscience. Causal evidence can be obtained by targeted manipulation of neuronal activity. Therefore, we developed an approach to simultaneously record from visual areas V1 and V6, while optogenetically stimulating V6 during a visual detection task in the marmoset. We were able to monitor and manipulate neuronal activity and show that the animal's behavior is influenced by the optogenetic stimulation. To achieve this, we implanted a 3D-printed titanium chamber that houses multiple high-density silicon probes with a total of 192 channels. To stimulate excitatory neurons with high temporal precision, we injected an adeno-associated viral vector into V6 in order to express the fast channelrhodopsin variant 'chronos' under the control of the CaMKIIα promoter. Recordings of single units and LFPs as well as optogenetic stimulation were reliable for several months. We were able to accurately map receptive fields in both areas and show that their location matches well the previously described retinotopic organisation of the marmoset visual cortex. Interestingly, visual stimulation induced prominent gamma oscillations in V1, reminiscent of those observed in cats, macaques and human subjects. To investigate the impact of V6 optogenetic stimulation on behavior, the marmoset was trained to perform a detection task. After maintaining gaze to a central fixation spot, the animal was rewarded for a) detecting a visual target, b) detecting an optogenetic stimulus, c) detecting a combination of visual target and optogenetic stimulus, or d) maintaining fixation in the absence of any stimulus. Our results show that optogenetic stimulation significantly increased detection performance for low contrast visual targets. Remarkably, the marmoset was also able to detect optogenetic stimulation of V6 in the absence of a visual target. Furthermore, preliminary results indicate that these effects are dependent on the frequency of stimulation. In conclusion, the combination of recordings in two connected areas, optogenetic manipulation, and behavioral report, enables us to identify causal factors that influence inter-areal communication.

Title: Stable, multi-day, functional measurement to study cellular level plasticity in mouse primary visual cortex by fast 3-dimensional imaging

Authors: *A. PLAUSKA[1], M. MAROSI[1], G. SZALAY[1], K. OCSAI[1], D. PINKE[1], T. TOMPA[1], D. NAGY[1], C. CSUPERNYÁK[1], A. BOJDAN[1], A. SZEPESI[1], G. KATONA[1,2], B. ROZSA[1,2]; [1]IEM-HAS, Budapest, Hungary; [2]Pázmány Péter Catholic Univ., Budapest, Hungary

Abstract: We investigated how 3D representation of the visual information, which is perceived and understood by the behaving animals in the primary visual cortex (V1), is changed while the animal engaged in a visual task. To reach this goal we use *in vivo* two-photon acusto-optic microscopy (with AAV-Syn-GCaMP6s or AAV-Syn-jRGECO1a) to record cellular responses (through different cortical layers) to visual stimuli in V1 before (baseline) and after visual training (effect). During training period, the mice learn to discriminate visual landmarks in a virtual reality (VR).
To study cellular plasticity in time we had to measure the same neuronal ensembles (up to 200 cells) during the baseline and effect period which can be apart in time (10-20 days). As neuronal responses are very sensitive to the spatial inconsistency of recording coordinates, therefore, orientation tuning and other properties of the recorded visually evoked responses could be contaminated with recording artifacts. To resolve this critical issue, we used 3D AO drift scanning microscopy, which can extend each scanning point to small 3D line-, surface- or volume-elements. With Multi-cube scanning, we are able scan small volumes (40x40x40 μm) around each cell bodies in 3D, and use this mini-volume information to carefully and precisely realign all individual scanning regions at each measurement day, significantly reducing the chance of misalignments of recording coordinates. AO scanning (ie. Chessboard scanning) of hundreds of cells at cortical depths up to 1 mm makes it feasible to examine the effect of learning in behavior experiments both at single-cell and at network scales.

We found that, in contrast to previous theories, adult mice brain is plastic as visual representation can dynamically change as a function of time at multiple temporal scales following visual learning in individual neurons.

Title: The effect of optogenetic stimulation of basolateral amygdala on declarative memory in rats

Authors: *D. S. REIS[1], L. E. DIFAZIO[1], N. S. AHLGRIM[2], J. R. MANNS[1];
[1]Psychology, [2]Grad. Program in Neurosci., Emory Univ., Atlanta, GA

Abstract: Electrical or pharmacological activation of the basolateral complex of the amygdala (BLA) can enhance the consolidation of declarative memory through modulation of hippocampal activity in rodents, non-human primates, and humans. However, the specificity and precise mechanisms underlying these effects remain relatively unclear. In particular, we were interested in whether optogenetic stimulation restricted to putative glutamatergic BLA principal neurons would also facilitate memory prioritization for non-emotional declarative memories. A recent study showed that optogenetic stimulation of putative glutamatergic BLA principal neurons elicited theta-modulated gamma activity in the hippocampus, an oscillatory pattern previously associated with good memory. Here, we used the same approach to optogenetically stimulate the BLA in rats following correct responses in an object-context association task. In a subsequent novel object recognition task, we stimulated the BLA following object exploration and tested memory retention the following day. We hypothesized that optogenetic activation of glutamatergic neurons in the BLA would facilitate performance during the object-context association task and in the novel object recognition task. Our results supported the role of the BLA in facilitating the prioritization of neutral, declarative memories and demonstrated the effects of glutamatergic activation of the BLA on hippocampal-dependent memory tasks.

Abstract: In the past decade, novel microscopy methods and genetically-encoded sensors have been revolutionary to understanding neural circuits in rodents and invertebrates. Using these methods in non-human primates (NHPs) has proven difficult due to technical hurdles that are now being overcome. NHP advances have brought the technology closer to use in humans, such as with high-quality cortical imaging windows that are both larger than an entire mouse brain—allowing for unprecedented ultra-large-scale circuit analyses over periods of years (longer than a mouse's entire lifespan). This provides for the possibility of long-term all-optical interrogation of ultra-large neural circuits over a time period relevant to human cognitive development. Here we present a multicolor labeling of neurons in macaque area V1. We infected V1 pyramidal neurons—using cortical and thalamic convection-enhanced delivery (CED)—with adeno-associated viruses (AAVs) encoding 5 different fluorophores with different emission spectra (mTagBFP2, mCerulean, eGFP, SYFP2, and Requorin). We also infected V1 cells with a GCaMP6/jGCaMP7 transgene for calcium imaging in the same injections. We further infected ipsilateral LGN neurons with either ChR2 optogene or with the red-shifted opsin Chrimson, to enable optogenetic activation of LGN inputs into V1. We imaged cells with a Bruker Ultima IV two-photon imaging microscope driven by a MaiTai DeepSee Ti:Saph laser at a wavelength of 830 nm. We captured an entire 2-cm diameter imaging window (3.14 cm^2 area) by tiling the window with 64 (8 x 8) 500 µm deep z-stack scans (each stack 2.8mm on a side). We stitched

the z-stacks into a single image to visualize the whole ultra-large imaging window and performed cell counts. We quantified the color-combinations achieved and determined that our methods result in a Brainbow-like distribution of ~5,000 colors, allowing for single-cell imaging even within densely labeled areas. Optogenetic stimulation of LGN inputs into V1 was achieved, resulting in strong Ca-imaging responses from GCaMP indicators in V1 cells.

Title: Optogenetic activation of GABAergic neurons in primate V1 impairs detection performance through indirect effects on excitatory neurons

Authors: *V. E. SCERRA[1], M. AVERY[2], J. DIMIDSCHSTEIN[3], G. J. FISHELL[4], J. H. REYNOLDS[1];
[1]Systems Neurobio. Lab., Salk Inst. for Biol. Studies, La Jolla, CA; [2]Case Western Reserve, Cleveland, OH; [3]Harvard Med. Sch., Cambridge, MA; [4]Neurobio., Harvard Med. Sch., Boston, MA

Abstract: Accurate stimulus detection is guided by the veridical transmission of information (signal) amongst unrelated externally- and internally-generated activity (noise). When visual detection performance suffers, is this because noise is insurmountable, or because the signal itself is attenuated somewhere along the visuomotor pathway? To address this question, we used an AAV-Dlx5/6 viral construct (Dimidschstein et al., 2016) to drive expression of an excitatory opsin, C1V1 in GABAergic interneurons in macaque primary visual cortex. We then activated interneurons via laser stimulation delivered through an optically clear artificial dura (Nassi et al., 2015) as monkeys performed a simple target-detection task. Targets were stationary Gabor patches of varying luminance contrast, of the preferred orientation of neurons at the opsin site. Responses of single-units and multi-units were recorded, and laser was randomly and unpredictably paired with the target, enabling us to examine neuronal responses and behavioral performance with and without activation of inhibitory interneurons. Behavioral performance was

impaired on laser trials, on which there were fewer correct detections, longer reaction times, and decreased perceptual sensitivity (d'), particularly for stimuli with contrasts near perceptual threshold. Nandy et al (2019) found that optogenetic activation of pyramidal neurons impairs perception, suggesting one possible interpretation of the present behavioral results: that the laser-induced increase in local interneuron firing rates act similarly, as a source of background noise, which obscures the target-evoked response, thereby impairing target detection. Alternatively, optogenetic activation of interneurons may serve to suppress and/or delay the stimulus-evoked signals that are conveyed to higher order visual areas via pyramidal projection neurons. Our neural data militate in favor of the latter hypothesis. While some neurons (putative inhibitory interneurons) were facilitated by the laser, a greater proportion of recorded neurons were suppressed by optogenetic activation. Further, in cells suppressed by the laser, trials in which a target was missed were trials in which firing rates were lower, on average, than for hits – an effect that was amplified by the laser, both in terms of firing rate, and the likelihood of missing the target. These results indicate that increased inhibition in primary visual areas impairs perceptual performance, at least in part, via suppression of the target-responsive signal conducted by pyramidal neurons.

Title: BonVision - An open-source software to create and control visual environments

Authors: G. LOPES[1], K. FARRELL[2], E. A. B. HORROCKS[2], T. MUZZU[2], M. M. MORIMOTO[2], A. PAPANIKOLAOU[2], T. WHEATCROFT[2], S. ZUCCA[2], S. G. SOLOMON[2], *A. B. SALEEM[2];

Abstract: Real-time rendering of closed-loop visual environments is necessary for the next generation of experiments to understand brain function and behaviour. Currently, this is prohibitively difficult to implement for non-experts and limited to few laboratories world-wide. We have developed a novel open-source software package, BonVision, to generate and control visual environments.
Current software is limited to either studying 'classic' visual stimuli with exquisite control of specific features, or exploiting game development software to create virtual reality environments. BonVision provides a single framework for classical visual stimulus presentation, and virtual or augmented reality. We achieved this by defining visual environments in an ego-centric framework, rendering scenes onto a sphere, and by treating display devices as windows looking onto that sphere. Visual environments can therefore be specified in terms of visual angle (enabling classical visual stimuli) or real-world units (enabling 3D virtual worlds). BonVision is based on reactive programming and leverages the Bonsai visual programming framework, which allows native integration with experimental hardware, including electrophysiology recording systems, cameras (e.g. eye tracking, $^{Ca2+}$ imaging), and standard data acquisition hardware (e.g. Arduino, NI). This allows BonVision experiments to gather data from sensors such as rotary encoders, lick ports, or infrared sensors; control effectors such as water valves or motors; and update visual stimuli.
Using visual environments created and controlled by BonVision, we have successfully recorded responses of neurons in primary visual cortex of awake mouse and recovered standard tuning curves. We have also implemented 2D and 3D stimuli to investigate visually-driven behaviors: two-alternative forced choice experiments; and loom or sweep stimuli that drive escape behaviors. In addition, we have established online learning tools (bonvision.github.io) for building new stimuli, allowing easy control and replication of experiments.
BonVision enables easy implementation of closed-loop experiments and communication with behaviour and physiology measurement devices, while being open-source, easy to install, and able to run on standard windows computers including laptops.

Title: Large scale characterization of a visual change detection task using a high throughput two-photon calcium imaging *in vivo* pipeline

Authors: *S. M. SEID, N. Y. ORLOVA, F. NAJAFI, I. KATO, S. CALDEJON, K. MACE, E. LEE, T. V. NGUYEN, F. GRIFFIN, A. WILLIFORD, L. CASAL, K. NORTH, S. LAMBERT, A. CHO, J. SWAPP, C. NAYAN, N. Allen Inst. for Brain Sci., Seattle, WA

Abstract: The Allen Brain Observatory Visual Coding dataset contains the activity of more than 63,000 neurons recorded using two-photon calcium imaging across 13 transgenic mouse lines. This important dataset surveyed the visually evoked response of cortical neurons in passive viewing conditions and established a standardized database of cell metrics across all cortical layers and cell classes. Standard models of the visual cortex can be tested using this dataset (de Vries et al., 2018), however it is now established that behavior variables play a big role in neuronal activity even early in the visual pathway (Niell & Stryker, 2008). In addition, our initial survey revealed that patterns of neural activity showcase a high degree of variability across animals.

To understand this neuronal activity in the context of a behavior task, we have built and validated a visual behavior data pipeline that leverages a change detection task at scale. Using this data we can investigate differences in cellular response to a passively viewed stimulus vs. an actively attended stimulus, and see how neuronal population activity changes in response to generalization of the task to a new set of images. Here we introduce all data collected in this pipeline and discuss its challenges in the context of neurophysiological recordings. We present our protocol to optimize behavioral performance during training and rig transition, our quantification of behavior performance, and overall change in neuronal activity during training. In addition, we demonstrate the impact of variability in behavioral performance on the activity of neurons, and showcase how our data collection pipeline will allow us to capture the variability in future data released on the Allen Institute data portal.

Title: A large-scale, standardized survey of spiking activity across the mouse visual system

Authors: *J. H. SIEGLE, X. JIA, S. DURAND, G. R. HELLER, T. RAMIREZ, N. GRADDIS, W. WAKEMAN, J. A. LUVIANO, A. WILLIFORD, S. CALDEJON, R. DIETZMAN, C. SLAUGHTERBECK, D. SULLIVAN, K. TURNER, R. Allen Inst. for Brain Sci., Seattle, WA

Abstract: The mammalian visual system is one of the most widely studied sensory systems, yet much about the function of individual visual areas and the mechanisms by which they interact remains unknown. As an initial step toward a more systematic interrogation of visually evoked spiking activity, we have extended the Allen Brain Observatory to include a standardized platform for extracellular electrophysiology in head-fixed mice. Each mouse proceeds through the same series of steps, carried out by highly trained technicians and scientists according to a set of standard operating procedures. On the day of the experiment, we use visual area maps obtained via intrinsic signal imaging to simultaneously target Neuropixels probes to all layers of primary visual cortex and 5 higher visual areas (LM, AL, RL, PM, AM). Probes are inserted up to 3.5 mm into the brain, allowing us to obtain concurrent recordings of single-unit activity from thalamic and midbrain visual areas. Each experiment begins with a receptive field mapping stimulus consisting of localized drifting gratings, followed by a series of full-field flashes. Next, we present one of three stimulus sets: a battery of natural and artificial stimuli, shown with the same parameters as those from the Allen Brain Observatory two-photon imaging rigs; many repeats of drifting gratings and natural movies; or 162,000 unique frames from nature documentary clips (plus an 18,000-frame test set). Recordings have been carried out in C57BL6/J mice and 3 transgenic lines (Pvalb-IRES-Cre x Ai32, Sst-IRES-Cre x AI32, and Vip-IRES-Cre x Ai32), to facilitate the identification of genetically defined cell types via optotagging. Each dataset passes through a rigorous quality control procedure, to ensure that data quality is consistent across experiments. Units extracted by Kilosort are mapped to structures in the Allen Common Coordinate Framework by imaging fluorescently labeled probe tracks with optical projection tomography. The final data files will be distributed in Neurodata Without Borders 2.0 format, with all sessions passing QC made publicly available via the AllenSDK and brain-map.org. This comprehensive, open dataset will make it possible to characterize spiking activity across the mouse visual system with an unprecedented level of detail.

Title: Adventures in motion correcting high noise multiphoton microscopy data

Authors: *J. M. GALBRAITH, L. KUAN, L. NG, J. WATERS, D. MILLMAN, J. LECOQ; Technol., The Allen Inst. For Brain Sci., Seattle, WA

Abstract: Novel multiphoton applications are often constrained by the noise robustness of data processing methods, including motion correction. Phase correlation is a popular frequency domain motion correction algorithm, and offers excellent rigid translation performance on multiphoton data of sufficient signal to noise ratio (SNR). Here, we describe a novel method for computing motion correction on data of low SNR, and applications of deep and multiplane imaging. These noisy data produce very high erroneous maxima in the phase cross-correlation matrix, and simply choosing the absolute maximum fails to compute the correct offsets in these cases. We demonstrate that biasing the cross-correlation matrix with a Kalman prediction of the motion offset offers excellent noise rejection performance in these situations where the correct peak is not the maximum peak.

Title: Neuropixels recordings across cortical visual hierarchy during change detection in mice

Authors: C. BENNETT, S. GALE, C. NAYAN, J. SWAPP, S. LAMBERT, A. CHO, J. SIEGLE, P. GROBLEWSKI, ***S. R. OLSEN**;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: Behavior and perception require coordinated activity across distributed neural circuits. Here we used Neuropixels probes to record simultaneously from multiple brain regions across the visual hierarchy in mice during active visual behavior. We trained mice on a change detection task in which natural images were continuously flashed and mice were rewarded for licking when the image identity changed. Neural activity was recorded in six visual cortical areas (V1, LM, AL, RL, PM, AM) while mice actively performed the task or were passively presented with the same sequence of images experienced during task performance. Detection of change (hit trials) was associated with an enhanced response to the image flash relative to miss trials or to image change during passive viewing. This modulation arose concurrently in V1 and higher order areas beginning ~10-20 ms after visual response onset in V1 and increased in magnitude along the visual hierarchy. Rapid modulation of visual responses to detected image change may reflect recurrent interactions between visual cortical areas involved in detection or a common feedback signal from other areas.

Title: Comparing spike sorting quality metrics for high-density electrophysiological recordings

Authors: *G. R. HELLER[1], J. H. SIEGLE[1], X. JIA[2], D. DENMAN[1], S. OLSEN[1];
[1]Neural Coding, [2]The Allen Inst., Seattle, WA

Abstract: Recently developed silicon probes with active CMOS electronics, such as Neuropixels, can simultaneously sample *in vivo* extracellular spike waveforms across more channels than was previously possible. This higher sampling density provides more information about individual spikes, making it easier to discriminate waveforms produced by nearby neurons. However, there is still substantial variation between the quality of units recorded in the same experiment, and the field lacks a widely accepted standard for determining which units are sufficiently well isolated to include for further analysis. In this study, we calculated a suite of quality metrics for all of the units recorded in the Allen Institute Brain Observatory, which were acquired on Neuropixels probes and sorted using Kilosort. The metrics analyzed include ISI violations, nearest-neighbors contamination rate (Chung et al., 2017), Fisher's LDA (Hill et al., 2011), isolation distance and L-ratio (Schmitzer-Torbert et al., 2005). An aggregate metric using

PCA-based dimensionality reduction of the metric space was able to explain 50% of the variance across metrics, meaning the individual metrics are somewhat redundant, but still contain unique information. We therefore examined the correlation between metrics in greater detail, as well as their relationship to subjective measures of unit quality, obtained from ratings made by trained experts. We also sought to estimate how the variability of cluster metrics (and their computation time) changes as a function of the number of spikes included. We assessed how parameters such as the percentage of spikes sampled and the size of the feature space affect the accuracy and reliability of the outcome. Finally, we applied the same quality metrics to simulated ground truth data to determine how well they track hit rate and false positive rate when these values are known.

Title: Tracking single cell response properties across days during performance of an image change detection task

Authors: *K. ROLL[1], M. GARRETT[1], F. LONG[2], L. KUAN[1], R. S. LARSEN[3], N. D. PONVERT[2], J. LECOQ[4], J. M. GALBRAITH[5], S. R. OLSEN[2];
[1]Allen Inst. for Brain Sci., Seattle, WA; [3]Neural Coding, [2]Allen Inst. For Brain Sci., Seattle, WA; [4]Structured Sci., Allen Inst., Seattle, WA; [5]The Allen Inst. For Brain Sci., Seattle, WA

Abstract: One of the unique advantages of two-photon calcium imaging is the ability to track individual neurons across multiple days to observe how cellular response properties change with experience and behavior. However, standardized tools for reliably identifying the same cells across days are lacking in the field. Here we describe the validation of a novel cell matching algorithm and its application to studying changes in response properties across days in the mouse visual cortex during performance of a behavioral task. In these experiments, the same population of cells is targeted across 7 two-photon imaging sessions. During each experiment session, mice perform a change detection task with natural images where they must lick in response to changes in stimulus identity to earn a reward. In addition to observing the behaviorally relevant stimuli, which can vary across days, mice are presented with a natural movie stimulus that is the same in every session. This repeated stimulus is used to compute cell response metrics that describe the reliability of activity patterns across days. The cell matching algorithm first creates a common coordinate space across the 7 sessions through affine registration. It then matches cells between

all the possible combinations of pairwise sessions using bipartite graph matching with degree of cell overlap and centroid distance as metrics in the cost function. Finally matching cells across all the sessions are identified by fusing pairwise matching results and resolving their conflicts. Accurate registration of the two-photon field of view from day to day is critical to the function of the cell matching algorithm, and relies on precise day to day positioning of head fixed mice under the microscope. We characterized the impact of experimental conditions on the output of the matching algorithm by relating the activity and morphology of matched cells with quantification of day to day registration. We then compared measures of cell morphology across sessions with signatures of neural activity in matched cells to evaluate the relationship between recording stability and neural response variability. Finally, we use these relationships to identify quantitative metrics that can be used to predict the quality of cell identification across sessions. These results have important implications for the interpretability of measurements of single cell response properties measured across multiple days with two-photon calcium imaging, and provide tools for validation of cell matching across sessions.

Title: Two-photon microscope compatible immersive virtual reality system for mice

Authors: *D. PINKE[1], G. DOBOS[1], M. MAROSI[1], B. GULYÁS[2], B. ROZSA[1];
[1]Inst.of Exptl. Med., Budapest, Hungary; [2]Pázmány Péter Catholic Univ., Budapest, Hungary

Abstract: Introduction: The understanding of plasticity in learning requires methods that allow neuronal activity to be recorded at large and stable cell population level. However, long visual discrimination and learning protocols raise difficulties in maintaining imaging stability and performing sufficient experiments.
Aims: Our objective was to develop a behavior protocol that is rapid and robust enough to investigate cortical plasticity effectively. Designing a system that allows for a short training period is important as it helps limit other sources of change, such as the instability of surgery techniques, cell structural changes and tissue deformations. We hypothesize that learning speed is highly correlated with the immersion of the virtual reality used, which arises from perspective

correction, large field of view and binocular vision. During the development process of our own system we focused on improving these attributes.
Methods: We demonstrate a novel, two-photon microscope compatible virtual reality system, that covers approximately 260° degree of the mouse visual field, and provides perspective-corrected 3D environment with binocular vision. Also, we implemented a 3D imaging technique that allows the measurement of multiple cell assemblies during behavior, and tracking the activity of several hundreds of cells during the experiment.
Results: Our preliminary data show stable and significant learning in 3-5 day with this device when associating some of the visual clues with a conditioning stimulus. During the protocol we used a 3D two-photon laser scanning microscope which was developed in our lab, to investigate single-cell level change of the neuronal responses associated with learning.
Conclusions: Here we present a 3D two-photon microscope compatible virtual reality system and training protocol, that allows us to investigate visual cortex plasticity at a relatively short timescale, compared to currently long-term behavior visual discrimination protocols. Title: Population responses of backward masking in V1 of behaving monkeys

Authors: H. EDELMAN KLAPPER, **H. SLOVIN**;
Multidisciplinary Gonda Brain Res. Ctr., Bar Ilan Univ., Ramat Gan, Israel

Abstract: Visual backward masking (BM) is a powerful behavioral paradigm where the visibility of a brief stimulus can be dramatically reduced when followed by a second stimulus, the mask. Behavioral studies showed that the time interval between stimulus onset and mask appearance (stimulus-to-mask onset asynchrony; SOA) affects the stimulus detection rate: as the SOA becomes shorter, the stimulus visibility is reduced. Despite past research, the neuronal mechanisms underlying BM in the visual cortex are mostly unknown. To investigate this two monkeys were trained on a texture discrimination task (TDT) and were required to discriminate between vertical and horizontal targets embedded within a homogeneous patterned background. We used voltage-sensitive-dye imaging to measure population responses at high spatial (meso-

scale) and temporal resolution in the primary visual cortex (V1) while the monkeys performed TDT with BM at variable SOAs. As was previously reported, target discrimination was higher for longer SOAs and reaction times (RTs) were shorter. Population responses showed two separate temporal phases at long SOAs: an early phase that was evoked by the stimulus, and a second delayed response which was related to the mask appearance. When decreasing the SOA, the mask response shifted in time towards the stimulus evoked response, until they merged. We computed the figure-ground modulation (FG-m), i.e., the population response in the target versus the background elements sites and found a positive FG-m when the animal was performing TDT alone or TDT combined with BM. For long SOAs, where target discrimination rate was high, we found a positive and significant FG-m that developed around 120 ms after stimulus onset. However, for short SOAs, where target discrimination rate was low and closer to chance level, no significant early FG-m was found, suggesting that the mask interfered with this process. Interestingly, in short SOAs trials where RTs were longer, we found a significant positive FG-m that developed at late times. Finally, the mask influence on neuronal population responses at the target and background sites was different and depended also on the SOAs. Our results shed new light on the neuronal mechanisms underlying BM and reveal different impact of the mask on target and background regions in the visual cortex.

Title: Increased spine dynamics in the visual cortex of PSD-95 knockout mice: Chronic two-photon imaging of neuronal morphology in the awake brain

Authors: A. TIPPMANN[1,2], B. JOACHIMSTHALER[3], S. TREUE[2,4], C. SCHWARZ[3], O. SCHLÜTER[5,6,4], ***S. LÖWEL**[1,4,7];

Ctr., Goettingen, Germany; [7]Campus Inst. for Dynamics of Biol. Networks, Goettingen, Germany

Abstract: The postsynaptic signaling scaffold PSD-95 is present in excitatory synapses in the brain and hypothesized to influence their function and stability. We previously showed that in primary visual cortex (V1), adult PSD-95 knockout (KO) mice have 9 times more AMPA-silent synapses than wildtype littermates (WT), retain a lifelong and juvenile-like ocular dominance plasticity and experience-induced network changes happen faster compared to WT mice (Huang et al 2015). Thus, PSD-95 KO mice display enhanced cortical plasticity, but the neuronal circuits are less stable, suggesting that dendritic spines may be more dynamic in V1 of the KOs. To test this hypothesis, we chronically imaged spine dynamics of V1-neurons in awake head-fixed PSD-95 KO and WT mice (>P145) using two-photon microscopy through a cranial window (Joachimsthaler et al 2015). Nerve cell morphology was visualized with LifeAct-GFP via AAV-injections into V1; LifeAct labels the F-actin of neurons, which is the major cytoskeletal component of dendritic spines (Hotulainen & Hoogenraad 2010). Mice were thoroughly habituated to the head fixation under the two-photon microscope for at least 3 weeks. We repeatedly imaged the same dendrites and spines of layers 2/3 and 5 pyramidal neurons over nine consecutive days and recorded changes of dendritic spine numbers and dynamics (gained/lost spines). Our data show that PSD-95 KO mice have a higher spine turnover rate, reduced numbers of stable spines, and higher numbers of both eliminated and new spines compared to PSD-95 WT mice. Notably turnover rates of PSD-95 WT mice were similar to values previously published for visual cortex of anesthetized mice (Holtmaat et al 2005). These results support the hypothesis that the postsynaptic signaling scaffold PSD-95 is critical for stable neuronal networks in mouse cortex.

Title: Does ketamine modify the neuronal network of the rodent visual cortex?

Authors: *A. OUELHAZI[1], R. LUSSIEZ[2], S. MOLOTCHNIKOFF[3];
[1]Univ. De Montreal, Montreal, QC, Canada; [2]Univ. of Montreal, Montreal, QC, Canada; [3]Sci. Biologiques, Univ. de Montreal, Montreal, QC, Canada

Abstract: Studies have shown that the brain reorganizes itself in response to changing stimulation and this capability continues into adulthood. The mechanisms of brain reorganization in response to varying experiences are still largely unknown.
Our goal was to investigate the physiological mechanisms governing plasticity in the adult primary visual cortex, V1. We stimulated cells in V1 of anesthetized mice with eight drifting gratings. Electrophysiological recordings were made of single neuronal activity in control condition, after adaptation, and following local application of ketamine.
The results show that after adaptation, V1 cells change their preferred orientation. Following ketamine application, this new orientation selectivity is not maintained and a new orientation preference emerges (different from the original). This suggests that ketamine abolished the adaptation effect and shortened its duration. The cross-correlogram analyses showed that both adaptation and ketamine affect the organization of the network inducing a new state of equilibrium. In spite of the connectional modifications between recorded cells in all conditions, control, post-adaptation and post-ketamine application, the sum of connection probabilities remained the same under all conditions, which suggests that plasticity doesn't affect homeostasis. Finally, we show that, unlike after adaptation, ketamine decreases the OSI. We conclude that maintaining the effects of adaptation might require NMDA receptors, and blocking them changes the functional connections between V1 neurons which affects the excitation-inhibition balance and promotes the acquisition of new orientation selectivity.

Title: Cortical thickness in sight-recovery and congenitally blind individuals

Authors: *C. HÖLIG[1], M. J. S. GUERREIRO[1], I. SHAREEF[2], S. LINGAREDDY[3], R. KEKUNNAYA[2], B. RÖDER[1];

Abstract: Non-human animal studies have shown that the structural development of the visual cortex critically depends on postnatal visual input. Brain-imaging studies in humans blind from birth have repeatedly reported a higher cortical thickness of early visual areas, which has been linked to a lack of experience dependent developmental synaptic pruning. A preliminary early study in a small group of sight-recovery individuals suggested that the process of experience dependent pruning might occurs during a sensitive phase in early development. Here we studied cortical gray matter thickness in a larger group of individuals treated for bilateral dense congenital (n = 22) with age at surgery spanning a range from 1 month to 18 years. Their data were compared to age matched sighted controls (n = 26) and congenitally permanently blind individuals (n = 10). Magnetic resonance imaging (MRI) was performed at a 1.5 T GE scanner. Cortical reconstruction and statistical analysis of surface-based cortical thickness were conducted with Freesurfer 6.0. We replicated previous findings showing an increased cortical thickness in early visual areas in congenitally blind compared to sighted participants. Individuals with a history of congenital cataracts showed an increased cortical thickness in the left primary visual cortex and additionally in a cluster in the left fusiform gyrus compared to sighted participants. We did not observe a correlation with age of surgery. These findings emphasize the critical role of visual experience for the structural development of the human cortex.

Title: Lynx1 sharpens orientation tuning of visual cortical neurons by dampening excitatory drive and intrinsic excitability

Authors: D. KATO[1,2,3], K. YAMAMURO[1,2,3], ***Y. GARKUN**[1,2,3], M. SADAHIRO[1,2,3], M. SAJO[1,2,3], G. C. R. ELLIS-DAVIES[2], H. MORISHITA[1,2,3];

Abstract: Orientation selectivity is one of the hallmark functional properties of visual cortical neurons that undergo protracted postnatal maturation. While cortical inhibition is implicated for early postnatal sharpening of orientation selectivity, little is known about the mechanisms regulating the later phase of its maturation. We examined the contribution of Lynx1, an

endogenous nicotinic signaling modulator that increases in expression following adolescence, to orientation selectivity. Using *in vivo* two photon Ca^{2+} imaging, we found that layer 2/3 (L2/3) primary visual cortex (V1) neurons in adult Lynx1 knock-out (KO) mice have reduced orientation tuning driven by excessive responses to non-preferred visual stimuli. Whole-cell patch-clamp slice recordings from L2/3 pyramidal neurons of adult Lynx1 KO mice revealed increased excitatory but unchanged inhibitory drive as well as increased intrinsic excitability. Furthermore, conditional knock-out of Lynx1 selectively in the adult V1 neurons after maturation of cortical circuitry was sufficient to reduce orientation tuning, indicating that the functional properties of the adult V1 are actively regulated by the presence of Lynx1. Our study implicates Lynx1 as a key regulator that sharpens orientation tuning at the late phase of maturation by dampening excessive excitatory inputs and intrinsic excitability.

Title: Changes in cortical responses caused by learning novel optogenetic stimuli

Authors: *P. K. LAFOSSE[1], S. P. DUFFY[2], L. N. RYAN[3], A. J. LI[2], M. H. HISTED[4]; [1]NIMH, [2]Natl. Inst. of Mental Hlth., NIH, Bethesda, MD; [3]Neurosci., New York Univ., New York, NY; [4]Natl. Inst. of Mental Hlth., NIH / NIMH, Bethesda, MD

Abstract: Repeated experience with a sensory stimulus can cause perceptual learning (Dosher and Lu, 2017), with cerebral cortical responses changing as behavioral improvement occurs. However, since sensory stimuli change the activity of neurons in many different brain areas, it has been unclear whether learning-related changes originate in the cortex. Here, to determine whether learning-related changes happen directly in local cortical circuits or if all changes occur in downstream areas, we take advantage of the fact animals can learn to base their behavior on non-natural ("off-manifold") activity patterns evoked by direct stimulation. We trained mice to detect and report the presence of neural activity evoked by optogenetic stimulation (ChrimsonR in excitatory neurons of primary visual cortex, V1), and found large behavioral improvements as animals learned to detect this stimulus. Animals were first trained to detect a visual stimulus of varying contrast. An optogenetic stimulus was then paired with each visual stimulus. When

performance increased for the lowest contrast visual stimulus, the visual stimulus was turned off and animals performed the task based on the optogenetic stimulus alone. As animals gained experience with the optogenetic stimulus presented alone, animals' reaction times decreased (-15.4±3.8 ms, per training session at fixed stimulation intensity, median±SEM, $p<0.01$, N=9 mice), and detection performance improved, increasing stimulus sensitivity by over an order of magnitude. We imaged calcium responses in V1 neurons before and after learning (before the optogenetic stimulus is presented and after animals' detection performance for the optogenetic stimulus improved) and found changes in local cortical activity at the site of stimulation, but not at a distinct, unstimulated site. Optogenetic learning decreased visual selectivity for direction and orientation, but overall neural responses became larger. Repeated stimulation of V1 neurons without training did not induce changes in selectivity or responsivity. These data suggest local cortical circuitry adapts to support learning of an optogenetic stimulus whereby neuronal tuning is degraded, while neural responses are enhanced.

Title: Cortical plasticity induced by conversion of synaptic eligibility traces *in vivo*

Authors: *S. Z. HONG[1], A. KIRKWOOD[2];
[2]Mind Brain Inst., [1]Johns Hopkins Univ., Baltimore, MD

Abstract: Our brain has the ability to learn about rewarding sensory stimuli through synaptic modifications of the associated circuits (reward-based learning). These changes depend on the sensory stimuli and the associated reward which is typically delayed. This temporal difference creates a conundrum, the so called "distal reward problem": How does the brain know which synapses are responsible for the reward among those that were active during the waiting period? A theoretical solution is 'synaptic eligibility traces,' silent and transient synaptic tags that can be converted into long-term synaptic strength changes by reward-linked neuromodulators. Previously in visual cortical slice preparation, we showed distinct synaptic eligibility traces for long-term potentiation (LTP) and depression (LTD), which are transformed by retrograde norepinephrine and serotonin signals, respectively. In the present work, we show evidence demonstrating the functional role of synaptic eligibility traces in the plasticity of visual responses

in vivo using whole cell patch clamp recording and optical imaging of the intrinsic cortical signal. First, optogenetic activation of norepinephrine or serotonin projections in a temporally retrograde manner induced rapid and selective potentiation or depression of the associated visual response, respectively. Secondly, interfering with the conversion of synaptic eligibility traces prevented the rapid change of visual response by neuromodulators. Furthermore, we tested these ideas in a more "natural" setting, and found that preventing the conversion of eligibility traces also prevented ocular dominance changes induced by monocular deprivation. These results suggest that the conversion of synaptic eligibility traces by neuromodulators has a functional role in visual cortical plasticity via reward based learning mechanisms.

Title: Circuit-specific changes in the visual cortical excitation/inhibition ratio across the light/dark cycle

Authors: *M. C. D. BRIDI[1], F.-J. ZONG[4], X.-T. ZHANG[4], D. SEVERIN[2], K.-W. HE[5], A. KIRKWOOD[3];
[2]Zanvyl Krieger Mind/Brain Inst., [3]Mind Brain Inst., [1]Johns Hopkins Univ., Baltimore, MD; [4]Shanghai Insititute of Organic Chemistry, Chinese Acad. of Sci., Shanghai, China; [5]IRCBC, Chinese Acad. of Sci., Shanghai, China

Abstract: Maintenance of the balance between synaptic excitation and inhibition (E/I balance) within a narrow window is thought to be crucial for cortical processing. However, changes in excitatory synaptic transmission have been reported to occur over the course of the sleep/wake cycle. Therefore, we tested whether compensatory changes in synaptic inhibition occur to maintain a stable E/I balance. We performed whole-cell patch clamp recording in mouse primary visual cortical (V1) slices obtained at different times of day. We found that in layer 2/3 pyramidal cells, spontaneous inhibitory postsynaptic currents (sIPSCs) change over the 24h light/dark cycle in a sleep-dependent manner. However, the direction of this change is the opposite of synaptic excitation, resulting in large fluctuations in the E/I balance. We next examined whether these changes were global or pathway-specific. We evoked postsynaptic responses by stimulating layer 4 (vertical pathway) or layer 2/3 (lateral pathway) and recorded

from pyramidal cells in layer 2/3. Excitatory and inhibitory responses were isolated by holding the cell in voltage clamp configuration at the reversal potential for $GABA_A$ or AMPA receptors, respectively, and the ratio between excitatory and inhibitory responses was calculated. We found that the E/I ratio fluctuated over the 24h light/dark cycle in the lateral, but not vertical, pathway. We next asked whether these synaptic changes have functional consequences for circuit output. To this end, we stimulated the lateral pathway at a range of intensities to identify the threshold for action potential generation while holding layer 2/3 cells in cell-attached configuration. We then broke the membrane seal and measured AMPA receptor currents in whole-cell voltage clamp configuration while stimulating at action potential threshold. At times of day when the E/I ratio was low, more AMPA receptor current was required to reach action potential threshold than at times of day when the E/I ratio was high. Consistent with this finding, there were no changes observed in intrinsic excitability. These observations demonstrate that 1) the cortical E/I balance is dynamic, 2) excitatory and inhibitory synaptic changes over the 24h day are circuit-specific, and 3) these changes alter circuit output, suggesting that time of day may impact sensory processing.

Abstract: Neuronal plasticity is fundamental for our brain's ability to adapt to changes in the environment but dramatically reduces after critical periods (CP) of early postnatal life. We have shown previously that the antidepressant fluoxetine induces juvenile-like plasticity (iPlasticity) in adulthood when combined with training, such as monocular deprivation during shift in ocular dominance (OD). Using the shift in OD paradigm, we question which networks and neuronal subpopulations are involved in iPlasticity in the visual cortex (VC). TrkB neurotrophin receptors are regulators of plasticity and activated by fluoxetine. They are highly expressed in parvalbumin (PV) interneurons, which seem to negatively regulate CP and OD plasticity in the VC upon maturation. Here, we first show that chronic treatment with fluoxetine reopens OD plasticity in wild-type mice but not in heterozygous PV-specific TrkB knockout mice. Then, to specifically activate TrkB-induced plasticity in PV cells, we used optically inducible TrkB (optoTrkB) constructs expressed only in PV neurons. Blue LED stimulation of optoTrkB expressed in PV neurons in the primary VC induces shift in OD in light-dependent manner and results in increased FosB intensity in optoTrkB expressing PV cells, suggesting the induction of downstream signaling and gene expression. Acute optoTrkB activation in PV cells permits long-term potentiation (LTP) in layer II/III of the VC after TBS stimulation, which is accompanied by rapid decreases in intrinsic excitability of and excitatory drive onto PV cells, resulting in disinhibition of pyramidal cells through decreased activation and output of PV cells, known to be required for OD plasticity. Furthermore, we observed a reduction in the number of perineuronal nets (PNN) surrounding PV cells and a decrease in PV and PNN intensities, suggesting dematuration and a shift towards a plastic PV network configuration state. Our data demonstrate that acute activation of optoTrkB is sufficient to trigger intrinsic changes in PV cells, accompanied by shifts in excitatory/inhibitory transmission to allow VC plasticity. These results show that TrkB activation in PV interneurons is a key regulator in OD plasticity thus offering a novel plastic mechanism for intracortical inhibition in the VC.

Title: Transplanted cells are essential for the induction but not the expression of cortical plasticity

Authors: *M. HOSEINI, B. RAKELA, Q. FLORES-RAMIREZ, A. HASENSTAUB, A. ALVAREZ-BUYLLA, M. STRYKER;
Univ. of California, San Francisco, CA

Abstract: Normal brain development is marked by temporally restricted windows of heightened experience-dependent plasticity known as critical periods (CPs). During a CP in primary visual cortex (V1)—postnatal day 25-35 in mouse—changes in neuronal circuitry facilitate the matching of left eye and right eye receptive fields in V1 binocular neurons. Occlusion of vision of either eye over this time, referred to as monocular deprivation, prevents binocular matching and results in structural and functional changes that reduce neural responses to the deprived eye and increase them to the eye that remains open[1].
Local inhibitory interneurons in V1 play a crucial role in opening the CP for ocular dominance (OD) plasticity, which begins ~35 days after these neurons are generated in the medial ganglionic eminence (MGE). Once the CP has closed, V1 circuits are thought to remain stable throughout life. However, transplantation of newly generated parvalbumin or somatostatin interneurons from the MGE of a donor embryo into the V1 of a postnatal host opens a second brief CP ~35 days after transplantation[2].
The precise contribution of inhibitory interneurons to OD plasticity is not known. While inhibitory neuron activity is crucial for inducing the CP[3], the expression of the plasticity following MD no longer depends on inhibition[4]. Here, we investigated whether MGE transplants produce a second CP of OD plasticity by stimulating changes in host circuitry or, alternatively, by constructing a separate parallel circuit within the host tissue to inhibit deprived-eye responses and/or disinhibit non-deprived-eye responses. We transplanted inhibitory interneurons expressing either archaerhodopsin-3 or channelrhodopsin-2 that allowed us to silence or activate the transplanted interneurons after plasticity is induced by 4-5 days of MD during the second CP. Our results indicate that an OD shift induced by brief MD persists under conditions of either reduced or enhanced transplant-derived inhibition. While the manipulating of the activity of transplanted interneurons after plasticity has been induced alters the ODs of some individual neurons, it does not change the overall OD of the population. Our findings reveal that transplanted interneurons are not responsible for the expression of OD plasticity but rather facilitate its induction in the host circuitry.

Title: Development of immune and inflammatory proteins in human visual cortex: Biological processes and cell types

Authors: *K. ARBABI, E. JEYANESAN, K. M. MURPHY;
McMaster Univ., Hamilton, ON, Canada

Abstract: Many types of immune and inflammatory proteins are expressed in the healthy human brain, where they modulate neural development and function. In addition to their well-known immunological functions, these proteins have been implicated in circuit refinement, synaptic transmission, plasticity and homeostatic synaptic scaling. Furthermore, abnormal levels of inflammatory proteins are characteristic of numerous pathological states, including neuropsychiatric disorders (i.e. bipolar disorder). Despite recent advances, the large majority of immune proteins have not been studied for their presence and function in the brain. Here we studied lifespan changes in expression of a large collection of immune and inflammatory proteins in human visual cortex and characterized the age-related changes in the representation of cell types and biological processes. We quantified expression of immune and inflammatory markers in post-mortem tissue samples from the human visual cortex in cases ranging in age from 20 days to 80 years (n=30, female=12). None of the cases had a neurological or psychiatric disease. We measured the expression of 200 inflammatory proteins using a slide-based quantitative analysis of protein concentration (RayBiotech Quantibody 4000 array), 72 of which were reliably measured. The individual proteins followed varied developmental trajectories. We used Robust Sparse K-Means (RSKC) clustering and PCA (Balsor et al. 2019 https://www.biorxiv.org/content/10.1101/554378v1) to analyze the high-dimensional patterns in these data and found an age-related progression of clusters that we analyzed to determine their content. We used an online transcriptomics database to identify proteins with high fidelity for the four major CNS cell types (microglia, astrocytes, neurons, and oligodendrocytes) and found that proteins with high-fidelity for neurons decreased across the lifespan. In contrast, proteins with high-fidelity for oligodendrocytes were over-represented in older adults, consistent with increased turnover and remodeling of myelin in aging. We used the Gene Ontology (GO) database to identify the biological functions of over-represented proteins in each cluster. The younger clusters were dominated by processes involving inflammatory response, chemotaxis, protein phosphorylation, phosphorous metabolism, and intracellular signalling. The oldest cluster

was dominated by positive regulation of protein metabolic processes but also negative regulation of cell death. These findings describe the changing lifespan landscape of cell-types and biological functions linked with immune and inflammatory proteins in the human cortex.

Title: Development of immune and inflammatory proteins in the human visual cortex: Relationship to glutamatergic and GABAergic proteins

Authors: *E. JEYANESAN, J. L. BALSOR, K. ARBABI, K. M. MURPHY;
McMaster Univ., Hamilton, ON, Canada

Abstract: Recent studies of the human cortex are charting developmental changes for proteins that regulate plasticity, however, less is known about the development of immune and inflammatory proteins. Those proteins are found in the healthy brain where they modulate a range of complex neural processes. Animal studies have shown that specific immune and inflammatory proteins are involved in plasticity, but little is known about their roles in neural development. Here we explore this question by characterizing developmental changes for a large collection of immune and inflammatory proteins in human visual cortex. We compared those patterns with glutamatergic and GABAergic proteins that have well-known plasticity functions and used this information to find candidate age- and plasticity-related processes for the immune and inflammatory proteins. We quantified expression of immune, inflammatory and synaptic proteins in post-mortem samples from the human visual cortex (Age: 20 days to 80 years, n=30, female=12). We measured 200 immune and inflammatory proteins using a slide-based ELISA (RayBiotech Quantibody 4000 array), 72 proteins were reliably quantified. Immunoblotting was used to quantify expression of 23 glutamatergic, GABAergic and other neural proteins. The proteins had a range of trajectories, some increased, others decreased, did not change, or had one or more peaks across the lifespan. We used a data-driven approach to analyzing these data (Balsor et al. 2019 https://www.biorxiv.org/content/10.1101/554378v1). Briefly, Robust and Sparse k-means clustering (RSKC) was used to analyze the immune and synaptic proteins. Next, the median age of samples in each cluster was calculated, and both datasets had a progression of cluster-age from neonates through infants, childhood, teens, young adults to older adults. Currently, we are analyzing the content of the clusters to determine which proteins are over- or

under-represented. We are also using PCA and the protein reweightings from RSKC to identify high-dimensional features in the data that are then combined to construct immune- and synaptic-phenotypes. Finally, we are determining similarities between the patterns of the 72 immune and 23 synaptic proteins by calculating a correlation matrix. These analyses will identify groups of immune proteins that follow the developmental trajectories of well-known plasticity mechanisms and form age-specific clusters that may provide new insights about the role of immune proteins in the functioning of the human cortex.

Title: Reorganization of functional streams in cerebral compared to ocular visual impairment

Authors: *E. S. BAILIN[1], I. DIEZ[2], C. M. BAUER[3], J. SEPULCRE[2], L. B. MERABET[4]; [1]Mass. Eye and Ear -- Harvard Med. Sch., Boston, MA; [2]Massachusetts Gen. Hosp., Boston, MA; [3]Harvard Med. School, Massachusetts Eye and Ear, Boston, MA; [4]MEEI- SERI Harvard Med. Sch., Boston, MA

Abstract: Background: Ocular blindness is associated with dramatic structural and functional neuroplastic changes in the brain. This includes evidence of functional connectivity changes associated with the functional recruitment of occipital cortical areas for the processing of nonvisual sensory information. However, how these network changes manifest in the setting of perinatal neurological injury such as cerebral/cortical visual impairment (CVI) remain unknown. In this study, we employed a novel graph theory approach of resting state functional connectivity (rsfc) MRI data called Stepwise Functional Connectivity (SFC) to explore the organization of visual processing streams and large-scale functional networks in individuals with CVI compared to ocular visual impaired (OVI) and neurotypical sighted controls. Methods: rsfMRI data was collected using a 3T Philips Achieva scanner with a 7 minute single shot EPI sequence (TE 30 ms, TR 3000 ms) sensitive to blood-oxygen-level-dependent (BOLD) contrast. A cohort of individuals with CVI (n=5), OVI (n=12), and controls (n=26) were instructed to stay awake with their eyes closed and allow their minds to "wander". Results: In controls, SFC analysis revealed

that the occipital pole was well segregated and the visual cortex's direct connectivity (step 1) followed along the dorsal and ventral medial streams. Subsequent steps revealed that visual cortex connectivity reached frontal areas and major cortical hubs of the brain. OVI individuals showed similar patterns of occipital connectivity however, increased connections within multimodal integration areas such as the superior parietal cortex were observed. In contrast, visual cortex connectivity in CVI subjects did not follow normal connectivity transitions, showing abnormal patterns of connectivity to other primary cortices (including auditory and motor) without a clear reach to cortical hubs. Conclusions: By delineating between how networks segregate and integrate within the brain, SFC analysis provides for more comprehensive characterization of visual connectivity organization and reorganization related to information transfer in cerebral compared to ocular based visual impairment.

Title: Layer 4 gates the critical period for visual plasticity through nogo receptor 1

Authors: M. G. FRANTZ[1], T. IKRAR[2], G. SOKHADZE[3], X. XU[5], ***A. W. MCGEE**[4]; [1]The Saban Res. Inst., USC, Los Angeles, CA; [2]Anat. & Neurobiology, Sch. of Med., Univ. of California, Irvine, Irvine, CA; [3]Anatom. Sci. & Neurobio., [4]Anatom. Sci. and Neurobio., Univ. of Louisville, Louisville, KY; [5]Anat. and Neurobio., Univ. California, Irvine, Irvine, CA

Abstract: Here we investigated the regulation and coordination of ocular dominance (OD) plasticity within the laminar circuitry of primary visual cortex. We performed a genetic dissection of the expression requirements for *nogo receptor 1 (ngr1)*, a gene required to close the developmental critical period, for sensitivity to 4-day (d) monocular deprivation (MD). Deleting *ngr1* in layer (L) 4, but not L2/3, L5, or L6, sustained critical-period OD plasticity in adult mice. Disinhibition mediated by reduced intracortical excitatory synaptic drive onto parvalbumin-expressing (PV) interneurons accompanied OD plasticity. Interestingly, after only 2 days of MD, OD plasticity was more extensive in L4 than L2/3 or L5 in both adult mice lacking *ngr1* selectively in L4, as well as juvenile wild-type mice. We propose that developmental OD

plasticity is predominantly feed-forward, and NgR1 closes the critical period by limiting neuronal and circuit compensation for reduced sensory input.

Title: Accelerating looming stimuli change the response timing of a collision-detection neuron

Authors: ***R. B. DEWELL**, G. K. KORDESTANI, F. GABBIANI;
Baylor Col. of Med., Houston, TX

Abstract: Visually-guided collision avoidance and escape is critical to the survival of many animals, and a wide range of animals from insects to primates have developed dedicated neurons for the detection of impending collisions. These neurons respond most strongly to objects approaching at constant velocity on a collision trajectory or their two-dimensional analogs called looming stimuli. The most common type of looming-sensitive neurons, η-type looming neurons, produce peak responses a fixed delay after a looming stimulus has reached a threshold angular size. Research into the neural computations underlying this relationship found η neurons' activity to be described by the product of the looming stimulus angular speed and the negative exponential of its angular size. However, another possible computation, denoted κ, in which the activity is determined by the product of the angular size and its negative exponential would also produce a peak response a fixed delay after the stimulus surpassed an angular threshold. The predictions for the timing of peak response made by the η and κ equations differ for non-constant velocity approaches. A well-studied looming-sensitive neuron in grasshoppers has long served as a model for understanding the neural computations underlying collision avoidance behaviors. We recorded the activity of this neuron, the lobula giant movement detector (LGMD) through its downstream relay while presenting looming stimuli of constant, increasing, or decreasing velocity to test which equation best described the response timing. We found that stimuli with positive acceleration produced later peak responses nearer to the time of collision, while stimuli with negative acceleration produced peak responses earlier before expected collision. These findings are consistent with the predictions made by the η equation. As predators could approach with changing velocity, exploring how the acceleration profile influences the neural response helps us better understand escape behavior and the neural computations underlying it.

Title: A biophysical model for visual feature integration during looming detection

Authors: S. J. O'ROURKE[1], D. P. GOODMAN[1], H. JANG[1], C. R. VON REYN[2,1], ***J. AUSBORN**[2];
[1]Sch. of Biomed. Engineering, Sci. and Hlth. Systems, Drexel Univ., Philadelphia, PA;
[2]Neurobio. & Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The early visual system distills visual stimuli into parallel visual features. How individual downstream neurons then integrate these features to form behaviorally relevant representations remains poorly understood. Here, we leverage the *Drosophila melanogaster* optic glomeruli, an area of the fly brain that provides unprecedented access to visual feature encoding and visual feature integrating cell types to study how a visual feature integrating neuron, the *Drosophila* giant fiber (GF), integrates separately processed visual features of a looming stimulus. Our previous work shows that the response of the GF, to drive timely escapes from rapidly approaching objects, results mainly from the summation of inputs from two cell types, LPLC2 and LC4. Both cell types project from the optic lobe (fly retina) to terminate on GF dendrites in the optic glomeruli of the central brain. LPLC2 and LC4 may each represent a different classical model for looming detection (eta and rho) encoding angular size and angular velocity of approaching objects, respectively. Many mathematical models have been derived to describe how looming responses could be formed via downstream integration of size and speed. While these descriptive mathematical models often faithfully describe the computational output of the circuits, we know little on how they could be biologically implemented. In the few cases where biophysical models have been developed, most lack knowledge of and access to the inputs to the looming integrators, and few have investigated the intrinsic properties of each cell type. Here, we use electrophysiology in tethered, behaving animals, genetic manipulations of GF ion channel expression and biophysical models of the GF to investigate the mechanisms that enable different looming stimulus features to be integrated in the GF to appropriately select and time an escape behavior. We investigate GF intrinsic properties using electrophysiology and computational modeling and identify ion channels that contribute to GF active conductances

using RNAi. We use multicompartment models to predict channel contributions to visual feature integration. These data will enhance our understanding of the neural algorithms for generating higher order representations from extracted visual features.

Title: Dendritic mechanisms underlying motion detection in starburst amacrine cells

Authors: *H. E. ACARON LEDESMA[1], C. CHAN[3], S. WANG[3], M. Z. LIN[4], W. WEI[2]; [1]Biophysical Sci., [2]Univ. of Chicago, Chicago, IL; [4]Neurobio., [3]Stanford Univ., Stanford, CA

Abstract: Dendritic computations play critical roles in shaping neuronal outputs and circuit functions. This is exemplified in the retinal direction-selective circuit, where starburst amacrine cells (SACs) provide directionally tuned inhibition onto direction-selective ganglion cells (DSGCs). The dendritic sectors of SACs are highly compartmentalized, each of which is strongly activated by motion in its centrifugal (outward) direction. The distal region of the SAC sector releases GABA selectively to a DSGC subtype that prefers the centripetal (inward) direction of the SAC sector, and thereby provides strong null-direction inhibition of the DSGC. The compartment-specific direction selectivity of SAC dendrites requires a sophisticated dendritic mechanism that not only converts the non-directional synaptic inputs into directionally tuned outputs during visual motion stimuli, but also establishes sufficient electrotonic isolation between sectors to maintain the independent directional tuning of each sector. Previous work from our lab has identified metabotropic glutamate receptor II (mGluR2) as an important regulator of dendritic compartmentalization. mGluR2 activation inhibits voltage-gated calcium channels on the SAC, and prevents activation of each sector in its nonpreferred centripetal direction but not in the centrifugal direction. In addition, voltage-gated K^+ (K_v) channels and passive dendritic properties have also been implicated in SAC dendritic processing. However, how these dendritic mechanisms together impact motion-evoked synaptic integration is still poorly understood. Here, we use electrophysiological recordings and subcellular functional imaging to explore the concerted action of multiple dendritic mechanisms underlying SAC dendritic computation. Our data suggest a synergistic interaction of mGluR2 signaling and K_v channels in the perisomatic compartment of the SAC in regulating sector-specific dendritic activation and synaptic release.

Title: Occlusion responses lead to fine spatial discrimination despite aberrant velocity information in direction-selective ganglion cells

Authors: ***J. DING**, A. CHEN, W. WEI, S. PALMER;
Univ. of Chicago, Chicago, IL

Abstract: How neural systems infer object trajectories in complex environments where signals can be interrupted or conflated with other sources is an essential question in sensory processing, yet little is known about the circuit mechanisms underlying these computations. The natural visual world is full of solid objects that occlude each other; here we investigate how occlusion impacts motion processing. We focus on the responses of retinal direction-selective ganglion cells (DSGCs), which fire maximally to visual stimuli moving in their preferred direction and are almost completely inhibited in their null direction. We created a visual stimulus in which a moving bar disappears behind an occluder centered on the receptive field of the DSGC. The occluder is larger than the total dendritic span of the DSGC. With electrophysiological recordings, we show that these cells fire an unexpected burst of spikes to a bar exiting the occlusion area and moving in the cell's null direction. One might expect this aberrant null direction response to degrade the fidelity of stimulus estimation. However, while the spiking of the cell to its non-preferred direction certainly hampers velocity estimation, it provides extra information about the bar's position, as assessed in a population model through maximum likelihood decoding of the stimulus position. This model incorporates biologically relevant parameters such as the distribution of inter-soma spacing and relevant trial-to-trial and cell-to-cell variability. Together, these experimental and modeling results reveal how complex features such as interrupted motion are encoded by retinal circuitry and may facilitate downstream readout of important stimulus features.

Title: Receptive field properties of the developing ferret lateral geniculate nucleus

Authors: *A. K. STACY[1], N. A. SCHNEIDER[1], D. A. BRESSLER[1], L. S. HAYASHI[1], S. D. VAN HOOSER[2];
[2]Biol., [1]Brandeis Univ., Waltham, MA

Abstract: Visual experience is critical for normal development of particular receptive field (RF) properties in primary visual cortex (V1). More specifically, visual experience is necessary for the development of direction selectivity in V1 of the ferret, while orientation selectivity is already present in ferret V1 at the onset of visual experience. However, little is known about receptive field properties of the lateral geniculate nucleus (LGN) inputs to V1 at the onset of visual experience in terms of orientation and direction selectivity, latency, and sustainedness/transience. Moreover, we do not know *how* visual experience affects the development of these RF properties. In order to address these gaps in knowledge, we performed multichannel, *in vivo* recordings of LGN cells in visually naïve ferrets, and made measurements before and after exposure to 6 hours of a moving sinusoidal grating stimulus known to induce direction selectivity in ferret V1. In our preliminary observations, most LGN cells are not significantly tuned for orientation or direction at the onset of visual experience, or following exposure to the motion stimulus, suggesting that individual LGN cells are not playing a large role in the increase of direction selectivity in V1 with visual experience. This indicates that direction selectivity must be computed at a later stage in the visual pathway, providing insight into the visual processing of motion detection.

Title: Development of direction selectivity in the ferret motion pathway and effects of stimulation

Authors: *A. A. LEMPEL[1], A. S. KAVUTURU[1], K. J. NIELSEN[2];
[2]Neurosci., [1]Johns Hopkins Univ., Baltimore, MD

Abstract: The ferret has become a major animal model for visual development due to its early parturition. In addition, motion processing in early visual structures of the ferret parallels that in primates, with direction-selective signals first found at the level of primary visual cortex (V1). Previous studies have therefore taken advantage of the ferret to investigate the development of V1 motion processing. These experiments demonstrate development of V1 direction selectivity during the first week after the onset of visual experience, which begins with eye opening around postnatal day 30. In addition, previous experiments also suggest a role of visual experience in the development of V1 direction selectivity. Recently, we have established the ferret as a model for studying the development of motion processing in cortical areas beyond V1. In particular, our work suggests that visual area PSS is a higher-order motion area comparable to area MT in the primate motion pathway. In this study, we make use of this finding to study the development of direction selectivity across multiple motion pathway stages. In a first set of experiments, we performed single unit recordings to determine V1 and PSS direction selectivity at different ages. In contrast to a strictly hierarchical development, our data show emergence of V1 and PSS direction selectivity during the same time period after eye opening. To more directly test the impact of visual experience on the development of direction selectivity in V1 and PSS, we then exposed visually naïve ferrets to drifting gratings for up to 8 hours while recording V1 and PSS responses. Prolonged exposure to drifting gratings indeed resulted in the emergence of V1 and PSS direction selectivity. In contrast, exposure to static stimuli did not induce the emergence of direction selectivity in either area. Finally, inhibition has been suggested to play an important role in shaping direction selectivity in ferret V1. We therefore studied how visual experience might impact the development of inhibitory circuits in V1 and PSS. To this end, we analyzed the laminar distribution of V1 and PSS parvalbumin (PV) expression in animals that had been exposed to moving gratings, static gratings, or were visually naïve. Intriguingly, this analysis revealed that exposure to moving stimuli resulted in early maturation of PV expression in both V1 and PSS. In conclusion, our results point to important parallels in how direction selectivity

develops in early and later stages of the motion pathway, including similar developmental timelines, impact of visual experience, and possible contributions of inhibitory circuit development.

Title: Erp evidence for persistence of object-based selection over unpredictable changes in object attributes

Authors: E. N. CATAK[1,2], *H. KAFALIGONUL[1,2], M. OZKAN[3], G. R. STONER[1,4]; [1]Natl. Magnetic Resonance Res. Ctr. (UMRAM), [2]Interdisciplinary Neurosci. Program, Bilkent Univ., Ankara, Turkey; [3]Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH; [4]Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: There is growing evidence that attention directed to one attribute of an object enhances the processing of other attributes of that object. The transparent-motion design introduced by Valdes-Sosa et al. (2000) has been adapted to study both perceptual mechanisms (e.g., Mitchell et al. 2003) and ERP correlates (e.g., Khoe et al. 2005) of such *object-based attention*. In this paradigm and its variants, subjects judge brief translations of one of two superimposed dot fields. It has been found that translations of dot fields that are cued (endogenously and/or exogenously) are judged more accurately than translations of the other field. By introducing motion direction and color swaps of the dots at the onset of translation, Stoner and Blanc (2010) discovered that the cueing advantage was specific to the individual cued dots. Their findings implicated early visual areas (e.g., V1) with receptive fields small enough to discriminate between the spatially intermixed dots. To explore the cortical bases of these behavioral effects, we designed an EEG experiment based on the Stoner and Blanc paradigm (i.e., delayed-onset cueing, with and without motion and/or color swaps). The behavioral results (N=14) confirmed that the cueing effect was specific to the cued dots though the cueing effect was significantly reduced by motion swaps. A cluster-based permutation analysis of the ERPs revealed an early (200-240 ms) spatiotemporal cluster ($p=0.054$) and a later (250-350 ms) cluster ($p=0.009$). Both clusters were centered over occipital and parieto-occipital scalp sites. To determine whether the clusters identified by this analysis were modulated by cueing and/or

swapping, we performed a two-way repeated-measures ANOVA with cueing (cued vs. uncued) and swapping (no-swap, motion, color, motion and color) as factors on the averaged ERP amplitudes. We found a significant effect of cueing for both time-ranges. For the early 200-240 ms time-range, we found a significant cueing effect ($p=0.007$), as well as an effect of swapping ($p=0.039$) such that swapping attributes decreased the average ERP amplitudes. For the late (250-350) time-range, we found robust modulation by cueing ($p<0.001$) and that swapping had no significant effect. While our ERP analyses did not reveal the involvement of early stages of visual processing, our findings demonstrate that the cueing effect, even in the presence of motion and color swaps, is correlated with modulation of later processes.

Title: Posterior entopallium lesions may produce a spatial integration deficit that affects pigeons' discrimination of human behavior

Authors: M. A. J. QADRI[1], ***S. L. KELLOGG**[2], G. ROTHMAN[1], H. ADAMSON[4], M. H. TRAN[3], A. M. KELLER[1], D. I. BROOKS[1], T. SHIMIZU[3], R. G. COOK[1];
[1]Psychology, Tufts Univ., Medford, MA; [3]Psychology, [2]Univ. of South Florida, Tampa, FL; [4]Max Planck Inst. for Human Cognitive and Brain, Leipzig, Germany

Abstract: The mammalian visual system demonstrates a greater reliance on thalamofugal processing over tectofugal processing, though the avian visual system shows the reverse. While separate processing streams and their functions have been identified and examined extensively in mammals, such segregation has received less attention in the visual system of birds. Previous research implicates the avian entopallium in tasks of motion and shape perception. Lesions of the anterior entopallium have been shown to impact form processing, while lesions of the posterior entopallium have impacted motion processing. To further explore this functional segregation using object-based stimuli, six of eight pigeons (Columba livia) were successfully trained on an action recognition task that required the pigeons to conditionally respond based on whether a digital human actor was static or moving and whether the actor's behavior demonstrated a martial arts or Indian dance sequence. These pigeons were then given bilateral electrolytic lesions targeting either the anterior portion of the entopallium or posterior portion of the entopallium. After recovery, these pigeons' performance on the visual action recognition task was assayed and revealed a detriment only in the case of the posterior entopallium lesion on motion processing. Subsequent post-lesion acquisitions suggested that the posterior portion of

the entopallium contributed to spatial processing while the anterior portion of the entopallium contributed to temporal processing. While the spatial processing deficits seemed to persist over the subsequent courses of training and testing, the temporal processing deficits showed initial decrement and rapid recovery. These data suggest that the posterior entopallium may be critical for processing the spatial aspects of object or agent motion, and that the anterior entopallium may be relevant for temporal processing. Future studies should further evaluate the temporal and spatial processing of these separate visual streams.

Title: Surround suppression in deep models of complex motion processing

Authors: *O. SADAT REZAI, **B. P. TRIPP**;
Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Inhibitory surrounds are ubiquitous in the visual cortex, and thought to be important both for calculating higher-order fields and for suppressing goal-irrelevant information. Spatial suppression measures strongly correlate with IQ in humans, hinting at a broadly important role of surrounds in neural computation, but the specific contributions of surrounds to perceptual decisions are unclear. Computational models have provided insight, but they have focused on simple information processing and/or idealized visual scenes. To fill this gap, we focused on the role of surrounds in models of naturalistic processing of naturalistic scenes. We began with a detailed model of activity in primate middle temporal area (MT), because details of the MT representation of visual motion are closely related to surround suppression of motion perception. We used the MT activity model as input to deep networks that performed naturalistic functions, specifically self-motion estimation (visual odometry) and gesture recognition. In each case, adding inhibitory surrounds to the MT model improved performance moderately. It is somewhat surprising that the effect was similar in each case, because gesture recognition involves complex motion discontinuities, while odometry involves large self-induced motions, which surrounds have been proposed to cancel out. We then compared the learned structure of direction-selective and non-selective components of the surround to data from the MT literature. We found that the

learned surrounds were distinct. Whereas non-selective surrounds are more distant from the excitatory center in MT, this difference did not appear in the task-optimized model surrounds. However, performance did not degrade when we manually incorporated biologically realistic surrounds. This suggests that the particular spatial structure of biological surrounds may belong to a larger manifold of structures that are similarly effective for these naturalistic tasks.

Title: Representation of multiple strokes apparent motion in awake monkey V1

Authors: *K. BLAIZE[1], S. CHEMLA[2], A. REYNAUD[3], M. DI VOLO[4], A. DESTEXHE[5,6], F. Y. CHAVANE[2];

Abstract: The apparent motion illusion is evoked when stationary stimuli are successively flashed in spatially separated positions. For large spatial and temporal separations, the so-called long-range apparent motion, we still have a poor understanding of how the visual system integrate and represent motion information. In a recent work, we used Voltage-Sensitive Dye Imaging (VSDI) in primary visual cortex (V1) of the awake monkey to image the cortical representation of two-stroke long-range apparent motion (Chemla et al 2019). We revealed that intra-cortical connections are crucial to shape the representation of illusory motion within V1 retinotopic map and keep track of the stimulus along the motion trajectory. More precisely, we showed that the two-stroke apparent motion (AM) illusion induce multiple wave interactions, generating a precise encoding of the stimulus velocity that is shaped by a suppressive wave propagating in a direction opposite to that of the AM stimulation. Using a neural field model, we showed that this suppressive wave is the expected emergent property of a dynamic recurrent gain control fed by the intra-cortical network. In the present work, we wanted to extend this study to apparent motion stimuli composed of multiple strokes in the same or opposite directions. Using

VSDI in the awake monkey we measured either a reinforcement of V1 activation when the stimuli were in the prolongation of the initial two-stroke AM, or a strong suppression when the third stimulus was presented in a direction opposite to the initial AM trajectory. We used our previously developed model (Zerlaut et al 2018, Chemla et al 2019) to test whether such results are expected by the dynamic recurrent gain control hypothesis. To conclude, these results show that the intra-cortical circuitry implement a gradual encoding of the illusory stimulus taking into account the spatio-temporal contiguity. Our understanding of the low-level processing involved in motion representation are a crucial step to guide further experiments that will link the V1 neuronal dynamics with the visual perception of motion.

Title: Predicting the future from the past in visual object motion: Optimal representations of mixed stochastic/deterministic trajectories

Authors: *V. SACHDEVA[1], A. WALCZAK[3], T. MORA[4], S. E. PALMER[2];
[2]Organismal Biol. and Anat., [1]Univ. of Chicago, Chicago, IL; [3]Ecole Normale Superieure, Paris, France; [4]Lab. de Physique Statistique, Ecole Normale Supérieure, Paris, France

Abstract: Making predictions about the future state of the external world confers benefits to biological systems that can translate to increased fitness. However, physical constraints, such as limited memory and finite neural population sizes, combined with energetic constraints, prevent the brain from constructing a representation that retains perfect knowledge of the past. Hence, any learned or evolved predictive encoding strategy must both compress the information of the current and past stimulus, yet still represent the future as faithfully as possible. For some classes of stimulus statistics, the optimal tradeoff can be computed directly. The retina has been shown to construct a representation that approaches this theoretical bound on the future information for a stimulus evolving with the dynamics of a stochastically driven, overdamped harmonic oscillator. This suggests that the retina has evolved to solve the so-called information bottleneck problem for this physical model with a particular set of motion parameters. Here, we compute the optimal predictive strategy for a variety of motion models, including those where there is a long-tailed correlation structure in the noise. We demonstrate that the encoding strategy that enables optimal prediction changes as a function of the damping coefficient. For overdamped harmonic motion, prediction requires high precision in measurements of the past object position.

For underdamped harmonic motion, oscillatory motion is produced, resulting in a need for predictive strategies that make precise measurements of both position and velocity simultaneously. This is especially true at prediction timescales comparable to the periodicity of the harmonic oscillator. We note that the presence of long-tailed correlations in the stimulus result in optimal predictive strategies requiring integration over a range of past measurements of the stimulus, and we can compute the optimal memory kernel for these dynamics. We also consider the conditions under which a particular predictive strategy can be generalized to a wider family of models while maintaining minimal performance loss, and which predictive strategies are highly tuned to specific types of motion. These representations can be compared to experimental measurements of predictive information in the brain, determining what types of motion the brain might have evolved to optimally predict.

Title: MSTd-like response properties emerge from evolving STDP and homeostatic parameters in a spiking neural network model of MT and MSTd

Authors: *K. CHEN[1], M. BEYELER[2], J. L. KRICHMAR[1];
[1]Univ. of California, Irvine, Irvine, CA; [2]Univ. of Washington, Seattle, WA

Abstract: Receiving direct input from the medial temporal (MT) area, the dorsal part of the medial superior temporal (MSTd) area is believed to play a key role in visual motion processing. A previous study demonstrated that several neurophysiological response properties of MSTd, such as 3D translation and rotation selectivity, emerge from applying a dimensionality reduction technique known as Nonnegative Matrix Factorization (NMF) to MT-like activity patterns. It was hypothesized that spike-timing dependent plasticity and homeostatic synaptic scaling (STDP-H) in Spiking Neural Networks (SNNs) performs a similar function as NMF. To test this hypothesis, we implemented a SNN model of macaque MT/MSTd, utilizing an evolutionary algorithm to optimize the parameters of STDP-H. Performance was measured by how well the SNN reconstructed flow pattern stimuli. In the network, each MT neuron was tuned to a speed of 1m/s and one of 8 different directions of movements, and had a receptive field of 1 pixel radius, subtending ~3° of visual angle**.** During training, simulated flow fields were fed into the network and STDP-H updated the connection weights between groups. By multiplying the MT to MSTd

connection weights and MSTd activations, we were able to reconstruct MT activity patterns (the reconstructed MT and the input MT neuronal firing rates have a correlation of 0.68±0.11), and recover the flow field stimuli with high fidelity. The MSTd neurons appeared to have 3D translation and rotation selectivity resembling neurophysiological data, and each neuron spanned only a subregion of the visual field, preferring a mixture of translational and rotational flow components. The model accurately captured the 3D visual response properties of MSTd and indicated that STDP-H is indeed performing a form of dimensionality reduction.

Title: Motion induced blindness increases with distance from moving background

Authors: ***S. SALEKI**, N. HELLER, P. CAVANAGH, P. U. TSE;
Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: A stationary target positioned among moving objects can fade in and out of perception (Motion Induced Blindness, MIB, Bonneh, Cooperman, & Sagi, 2001). We used a version of the stimulus with only two linear arrays of moving spots rather than a full background and varied the spacing between the linear arrays and the test target to see if MIB was influenced by spacing to the moving background elements. Participants fixated a dot in the lower half of the screen and viewed two horizontal, linear moving arrays of gabor patches (each array consisting of 14 gabors spanning display) positioned above the fixation point. During each trial, the arrays had 2 or 4 visual degrees displacement between them and a single target dot was presented halfway between the two arrays. In each trial, the internal texture of the gabors was either moving faster than the gabor (congruent), moving with the gabor (static), or moving more slowly than the gabor (incongruent). These different internal motions changed the apparent speed of the linear motion. Participants reported the moment of disappearance and reappearance of the target object over trials that lasted 20s each. The duration of disappearance was longer (more MIB) for the larger spacing between the moving arrays. Moreover, disappearance was longer for the incongruent internal gabor motion condition compared to the static or congruent internal motion conditions. Here, we showed that MIB occurs when a yellow stationary dot is positioned between only two linear arrays of moving gabor patches on a gray background and increases with distance from the background motion, and with the perceptually slower motion.

Title: Functional links between motion-onset visual evoked potentials and perception

Authors: *M. OZKAN[1], G. R. STONER[2,3], H. KAFALIGONUL[3,4];
[1]Psychological and Brain Sci., Dartmouth Col., Hanover, NH; [2]Salk Inst. for Biol. Studies, La Jolla, CA; [3]Natl. Magnetic Resonance Res. Ctr. (UMRAM), Ankara, Turkey; [4]Interdisciplinary Neurosci. Program, Bilkent Univ., Ankara, Turkey

Abstract: An important question in visual neuroscience is how low-frequency cortical activity and population responses are related to different aspects of motion. Previous studies have shown that visual evoked potentials (VEPs) around 160-200 ms (N2 component) after the onset of motion are driven by coherent motion perception (Kuba, et al., 2006; Niedeggen and Wist, 1998). Although this motion specific N2 component has been associated with the activity of

human area MT+ (Nakamura and Ohtsuka, 1999), it is still not clear how local information is integrated in the subdivisions of MT+ and how the N2 peak activity relates to behavioral performance. To shed light on these important issues, we focused on the relationship between the N2 component amplitude and coherence thresholds. Our EEG experiment included 3 types of random-dot motion (translational, rotational and radial) with coherence levels ranging from 5% to 80%. To control the coherence level and determine the position of every dot in each random-dot frame, we used the white noise motion algorithm developed by Britten et al. (1992). Observers engaged in a 2AFC (two-alternative forced-choice) direction discrimination task. In accordance with previous studies (e.g., Patzwahl and Zanker, 1999), N2 amplitude significantly increased as the coherence level was increased. Our results also indicated a significant two-way interaction (coherence level x motion type) such that radial motion produced overall larger amplitudes. More important, the average N2 amplitudes were significantly correlated with the individual thresholds (i.e., coherence level corresponding to 75% correct responses) for translational motion. This correlation was absent in the radial and the rotational motion types. However, these motion types elicited less between-subject variance in sensitivity as compared to the translational motion (*SDs* for the radial, rotational, and translational thresholds: 1.7%, 3.3%, and 14.4%, respectively). Thus, the relationship between the sensitivity to these motion types and the overall N2 amplitude still remains open to further investigation. Taken together, our results suggest that the N2 component is significantly dependent on the physical coherence level of the different motion types studied here, and the overall N2 amplitude is correlated with participants' sensitivity to translational motion.

Title: Multistable heterogeneous flicker has neural, functional and aesthetic effects

Authors: ***M. GRABOWECKY**, M. MENCELOGLU, S. SUZUKI;
Psychology, Northwestern Univ., Evanston, IL

Abstract: Spatially heterogeneous flicker is ubiquitous in natural dynamics. Phenomena such as falling rain, flames, waving grass, shimmering, falling and wavy water surfaces, rustling leaves, and so on are also typically pleasant to observe. One way in which spatially heterogeneous flicker is special is that it is multistable, allowing sensory activation that provides a good fit to momentary biases of the visual system. This activation may result in the perception of spontaneous motion and the calibration of motion detectors. In this sense, heterogeneous flicker

may provide particularly “natural” signals to the visual system, engaging fluent processes with minimal engagement of top-down control. In two exploratory experiments we used EEG to investigate this possibility, presenting observers with 16-element displays that varied in the number of independently flickering regions, and thus also varying in the amount of perceptual multistability. Consistent with our hypothesis, increasing multistable flicker (relative to control flicker with matching local and global temporal statistics) commensurately reduced posterior EEG beta power. This beta-band activity has been implicated in long-range neural interactions that are associated with top-down influences that impose constraints on sensory signals and potentially perceptual interpretations. Further, the degree of multistability, the amount of beta-power reduction, and the aesthetic rating of the presented flicker were closely associated (Fisher-Z transformed correlation coefficient r_Z, Expt. 1 r_Z *mean* = 0.490, r_Z *sem* = 0.117, t_{17} = 4.186, p=0.00062; Expt.2 t r_Z *mean* = 0.401, r_Z *sem* = 0.098, t_{17} = 4.089, p=0.00077). Thus spatially heterogeneous, multistable flicker reduced posterior EEG beta power relative to spatially homogeneous flicker controls that were matched in terms of the dynamics of local luminance changes, luminance changes at any location, and spatially averaged luminance changes. These results are consistent with the idea that the pleasantness of spatially heterogeneous flicker in nature may derive from its multistability that affords fluent and self-calibrating visual processing. The resulting sensory recalibration may be an underlying mechanism of observed restorative effects of exposure to nature.

Title: Dynamic scaling of motion in natural scenes

Authors: *J. M. SALISBURY, S. E. PALMER;
Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: Some of the most important tasks of visual and motor systems involve estimating the motion of objects and tracking them over time. Such systems evolved to meet the behavioral needs of the organism in its natural environment, and should therefore be adapted to the statistics of motion it is likely to encounter. Experimental neuroscientists, working in systems ranging from the retina to the pursuit eye movement system, have begun to explore this relationship

using stochastically moving stimuli; however, it is not at all clear what properties make motion naturalistic. By tracking the movement of individual points in videos of natural scenes using a simple optical flow-based algorithm, we begin to identify common properties of natural motion trajectories. As expected, objects in natural scenes move in a persistent fashion, with velocity correlations lasting hundreds of milliseconds depending on the composition of the particular scene. This can be attributed to the significant mass--and therefore inertia--of the objects we record. More subtly, we find that the observed velocity distributions are highly non-Gaussian and can be modeled as a scale mixture of Gaussians, a property that velocity in natural scenes shares with, for example, wavelet coefficients describing natural images and sounds. Extending this model to the time domain leads to a dynamic scale mixture model, consisting of a Gaussian process with relatively fast dynamics (here, a two-dimensional velocity vector evolving over time) multiplied by a positive scalar quantity with slower dynamics. Dynamic scaling of (angular) velocity arises naturally as a consequence of changes in object distance from the camera, and may approximate the effects of changes in other parameters governing the motion in a given scene. The dynamic scale mixture model allows us to estimate the scale process using maximum a posteriori estimation, decomposing the stimulus into a product of approximately Gaussian- and gamma-distributed components. This modeling and estimation framework may have implications for the neurobiology of sensory and motor systems, which need to cope with these fluctuations in scale in order to represent motion efficiently and drive fast and accurate behavior.

Title: Size matters (sometimes): Increasing stimulus size impairs motion perception for gratings, but not random-dot patterns

Authors: *B. WILD[1], A.-K. KENKEL[1], S. TREUE[2];
[1]German Primate Ctr. (DPZ), Goettingen, Germany; [2]German Primate Ctr., Goettingen, Germany

Abstract: Modern accounts of motion processing in the primate brain emphasize a hierarchy of different regions involved, especially primary visual cortex (V1) and the middle temporal area (MT). Different experimental approaches suggest that MT is both necessary and sufficient for motion perception. A recent study (Liu & Pack, 2017, *Neuron, 95*, 436-446), however, shows that monkeys can perceive the motion of a drifting sinusoidal grating after MT has been inactivated. After pro-longed training with random-dot patterns (RDPs), however, inactivating MT impairs performance for both gratings and RDPs, suggesting that the training with RDPs shifts the readout of motion information from other brain areas (e.g., V1) to MT. This hypothesis receives further support from behavioral findings: testing motion perception with gratings of different sizes shows that performance decreases once the stimulus size exceeds a critical value, presumably because bigger stimuli stimulate the suppressive surround of neuronal receptive fields (Tadin et al., 2003, *Nature, 424*, 312-315). In Liu & Pack's study, the optimal stimulus size, for which performance reaches its peak, increased after training with RDPs, providing further evidence that read-out had shifted to an area with larger receptive fields (e.g., from V1 to MT). We investigated this phenomenon in more detail in human subjects. 15 observers discriminated the motion of drifting gratings and RDPs of different sizes and contrast levels. We find the previously described impairment in performance with increasing stimulus size for gratings, but not for RDPs. Other than in the study by Tadin et al. (2003), these effects were independent of stimulus contrast. A possible explanation for these results is that the perception of gratings, but not RDPs, depends heavily on neurons with a clear center-surround structure. An alternative explanation would be that the size-effect in gratings is not caused by inhibitory subregions of visual neurons but is related to the stimulus and task-design: detecting the motion of a drifting grating might be easier if one can see the grating's edge, where individual dark or bright cycles appear or disappear as they drift into or out of the aperture. The grating's edges become less visible with increasing stimulus size when a subject fixates the grating's center. In RDPs, on the other hand, motion can be detected based on a single dot, independent of stimulus size. Our data document a highly flexibel network for visual motion processing, where alternative processing paths and/or adaptive local neuronal networks contribute to enable perceptual performance.

Title: Complex properties of visual motion during natural locomotion

Authors: *K. MULLER[1], J. S. MATTHIS[2], M. M. HAYHOE[3];
[1]Univ. of Texas At Austin Inst. For Neuros, Austin, TX; [2]Ctr. for Perceptual Systems, [3]Univ. of Texas at Austin, Austin, TX

Abstract: Properties of neural processing often reflect the statistics of natural images. For example, disparity tuning distributions in V1 reflect disparities encountered during a range of naturalistic tasks (Liu et al, 2008). Therefore we might expect that the tuning for visual motion reflects the statistics of the retinal motion signal experienced by observers during natural locomotion. However, the precise nature of these statistics has not been explored. We measured these motion patterns using a Pupil Labs mobile eye tracker to record eye position, and high-resolution scene video. Subjects' gaze patterns reveal a series of fixations, stabilizing the image through the vestibular ocular reflex. We estimated retinal motion input by first computing visual motion relative to the head-fixed camera using the DeepFlow optical flow estimation algorithm on the scene video (Weinzaepfel et al 2013), and then transforming it into the retinal coordinate frame and removing the motion transients generated by saccades. The resulting motion statistics are complex and shaped by the direction of gaze, the motion of the body, and environmental geometry. The overall distribution of speeds is skewed slow, with over half the distribution being less than 6 degrees per second. Due to the distortion introduced by the tilted ground plane, there are upward and downward directional biases in motion direction. Additionally, average speeds increase with retinal eccentricity, in all polar directions. Inspection of the first four components of retinal flow obtained through PCA reveal interpretable components of rotation, expansion, and translation in two directions. The distribution of scores for rotation is bimodal, generated by gaze locations both to the left and right of the body's instantaneous momentum as a result of body sway and turns. Likewise the expansion component distribution is bimodal, due to the gait-linked modulation of head velocity, leading to differing amounts of expansion and contraction relative to an expansive mean flow field. These different components have behavioral drivers, for example angle off of path is related to degree of rotation in the corresponding direction. While a number of studies have attempted to link neural responses in MSTd to self-motion, the complexity of the natural optic flow patterns which depend on both gaze and gait makes it hard to interpret the cells' precise role in coding self-motion. Thus investigation of neural responses to natural optic flow patterns may provide new insights into the neural coding of self-motion.

Title: Localized intracranial visual motion response drives fast BCI spelling

Authors: *D. LIU[1], X. XU[2], D. LI[1], J. LI[1], Z. LING[2], B. HONG[1];
[1]Tsinghua Univ., Beijing, China; [2]PLA Gen. Hosp., Beijing, China

Abstract: Currently, scalp EEG based brain-computer interface (BCI) is still the mainstream of BCI spelling system, with remarkable accuracy and speed on normal subjects (X. Chen et al., 2015). However, incapable of providing signal with consistent good quality over long-term use, BCI based on scalp EEG can hardly gain its position in clinical applications. Meanwhile, recent studies have shown that intracranial EEG (iEEG) based BCIs were able to achieve long-term stability (Jarosiewicz et al., 2015). However, for a practical intracranial BCI, minimizing the invasiveness of the electrode implantation while maintaining the performance is crucial. In this study, we used only three adjacent channels which matched most with the fMRI defined visual motion middle temporal (MT) region on one single Stereo-Electroencephalography (SEEG) electrode to implement an online BCI for fast typing. When subjects attended the virtual button containing moving bars, prominent responses were elicited by visual motion stimuli at the electrodes within the fMRI defined MT region, which were composed of motion-onset visual evoked potentials (mVEPs) around 200 ms post-stimulus and a power increase at the high gamma (70-100 Hz) frequency range (Zhang et al., 2013). In the online BCI experiment with four surgical epilepsy patients, combining both features and using a posterior probability based stopping strategy, the system achieved highest information transfer rate (ITR) of 61 bits/min, which was equivalent to 12 characters per minute. Our findings demonstrate the feasibility of implementing a minimally invasive intracranial BCI with the help of precise localization of visual motion area.

Abstract: The coleoid cephalopods can switch body patterns with unparalleled speed for camouflage and communication. While there are numerous studies on the physiology of the chromatophore system, the temporal dynamics of rapid chromatophore activation and coordination underlying body patterning are still mostly unknown. One way to study the complete sensorimotor transformation is by using an intact, living animal. The camouflage control system can be investigated by using a sudden, brief, and intense visual stimulus such as a flash of light to activate the startle reflex. The visual information from the sudden stimulus triggers the optic lobes to send signals to the central nervous system and, in turn, activate the giant axons controlling the chromatophore radial muscles. We used eight squid in this exploratory study to measure the coordination of chromatophore activity at the single organ level by using a light-flash stimulus to trigger body pattern changes. Two cameras captured images of the whole animal as well as close-ups of specific body regions (fin, mantle, head, and arms). The change-point analysis identified 4065 chromatophores from 185 trials with significant chromatophore surface area changes triggered by the stimulus. We measured the temporal dynamics of chromatophore responses as the magnitude of surface area changes, latency, and duration. Our findings indicate the latency of the response was at 50 milliseconds (+/- 16.67 milliseconds) on average, for both types of responses (expansion and retraction) and across all body regions. While the chromatophore surface area increased 155.06% on average during expansions, the retractions only caused a change of 40.46%. Further differences were observed between body regions; while the chromatophores on the mantle, head, and arms had surface area changes of 159% and 168%, respectively, the fin had a change of 116%. Our study is the first which characterizes the immediate temporal dynamics of individual chromatophore organ responses to a visual stimulus in an intact, living cephalopod. Collectively, the contributions of the methods and results described here will be valuable to help understand how cephalopods can employ hundreds of thousands of chromatophore organs in milliseconds to achieve rapid, dynamic camouflage.

Ctr., Farmington, CT

Abstract: How interneurons process sensory inputs to generate appropriate motor responses is a fundamental question in neuroscience. In *C. elegans* the interneuron AIY has an important role in a navigational behavior called thermotaxis, where the nematode detects temperature and decides which direction to move based on previous experience. Paralyzed worm preparations have been useful in understanding how AIY responds to thermal stimuli, but it is difficult to determine the behavioral relevance of this activity without simultaneously monitoring behavior. Our goal is to define calcium activity patterns in AIY during thermotaxis behavior in freely moving *C. elegans*. By specifically labeling AIY with the GCaMP6 indicator we can detect and measure calcium signals, while tracking the worm as it navigates a thermal gradient. With this tool we are able to dissect compartmentalized calcium activity with subcellular resolution in the AIY neurite and correlate activity patterns with precise thermosensory experience. Combining this approach with molecular genetics allows us to characterize how temperature preference is encoded at the synaptic level within the AFD-AIY synapse. We also correlate neural activity with body posture, velocity, dorsal-ventral flexions and direction over a thermal gradient to characterize the role of interneuron AIY in specific locomotor decisions during thermotaxis. With this approach we are investigating how mutants with defects in thermotaxis behavior affect AIY thermal responses. Our findings will contribute useful insight into how processing of thermal stimuli across a single synapse produces thermotaxis behavior.

Abstract: The lamprey lateral pallium (LPal), an area corresponding to cortex of mammals, has a three-layered laminated cytoarchitecture with a molecular layer and outer and inner cellular layers. GABAergic interneurons represent 22% of the total number of cells. Pyramidal tract-like (PT-type), intertelencephalic (IT-type) and thalamo-recipient cells (layer 4 equivalent) are located in the cellular layer and extend their dendrites towards the molecular layer (Suryanarayana et al., 2017). The LPal is also conserved in terms of efferent connectivity. Glutamatergic and monosynaptic projection neurons target all major motor centers in the midbrain, brainstem and rostral spinal cord (Ocaña et al., 2015). With respect to sensory mapping, primary visual input, relayed via thalamus, is represented in the dorsomedial LPal in a retinotopic fashion. Distinct neuronal subpopulations are activated by stimulation of different parts of retina. Whole-cell recordings during optic nerve/chiasm stimulation revealed EPSPs followed by inhibition. Thalamic neurons prelabelled from the LPal visual areas send their dendrites into the optic tract and stimulation of the optic tract elicited EPSPs and action potentials during whole-cell recordings in these neurons. Somatosensory information from the dorsal column nuclei is also relayed via thalamus, and represented in a ventromedial area in LPal, distinct from the visual areas. Thalamic neurons projecting to the somatosensory areas of LPal form a subpopulation distinct from those projecting to visual areas. Stimulation of the

dorsal column and the trigeminal nerve elicited field potentials in adjacent areas. The thalamus is a major relay of sensory input to LPal. This study reveals the presence of distinct modality specific sensory and motor areas in the phylogenetically oldest group of vertebrates. Our overarching conclusion is that basic aspects of sensory-motor organisation in the forebrain had evolved when cyclostomes diverged from the lineage leading up to mammals.
