Abstract: Experience strongly influences behavior, but little is known about how experience-dependent changes in neural activity are implemented at a network level to improve behavioral performance. Here, we use prey capture behavior in larval zebrafish as a model to study the role of experience in improving behavioral outcome. In larval zebrafish, prey capture is a complex behavior consisting of a stereotyped sequence of events: 1) ocular convergence, 2) approach and orientation towards the prey with J-bends of the tail, and 3) strike and engulfment of the prey. Earlier results in the lab have shown that prior experience with live prey increases capture success. Simultaneous behavior monitoring and wide-field calcium imaging in head-restrained animals showed that experienced fish exhibited greater activity in the forebrain during eye convergence. Moreover, Granger Causality analysis demonstrated a strengthened functional link from the optic tectum to the telencephalon during eye convergence in experienced fish. These findings suggest that the forebrain may play a role in modulating prey capture. The forebrain in zebrafish contains the telencephalon, which is homologous to the hippocampus and amygdala of other vertebrates, and the habenula, which is conserved across vertebrates and is involved in reward and avoidance learning. We find that pharmacogenetic and optogenetic disruption of the zebrafish forebrain compromises prey capture behavior. This supports the hypothesis that the forebrain operates as an experience-dependent switch that enhances the impact of information transfer from visual to motor-related areas during prey capture.

Title: Sensorimotor processing in the zebrafish dorsal raphe nucleus

Authors: *T. KAWASHIMA, Z. WEI, A. S. ABDELFATTAH, J. S. MARVIN, L. L. LOOGER, L. D. LAVIS, E. R. SCHREITER, M. B. AHRENS;

Abstract: The serotonergic system affects brain-wide neural systems in motor learning, passive coping, and other behaviors. Underlying this widespread modulation of neural function are fast computations in the dorsal raphe nucleus, of which very little is known. To gain mechanistic insight into such millisecond-timescale computation, we measured the subthreshold membrane potential and spiking of serotonergic neurons during motor learning tasks in zebrafish by using a chemigenetic voltage indicator Voltron[1] and an advanced imaging processing pipeline[2]. We also measured glutamatergic and GABAergic input into serotonergic neurons using neurotransmitter indicators iGluSnFR[3] and iGABASnFR[4]. Consistent with previous observations[5], serotonergic neurons responded to visual sensory signals during swim bouts with action potentials. Although the spiking dynamics contained little information about motor variables, surprisingly, right after swim bout initiation, the subthreshold voltage of serotonergic neurons showed strong hyperpolarization which depended on motor vigor. This hyperpolarization occurred during simultaneous GABAergic and glutamatergic inputs into serotonergic neurons during swimming. Post-swim release from inhibition was accompanied by the release of glutamate onto serotonergic dendrites encoding visual feedback from swimming, which may contribute to motor learning. These results show that sensorimotor computations in the raphe nucleus are implemented by a temporally-precise, behavior-locked sequence of inhibition and excitation that together allow serotonergic neurons to encode the consequences of actions.

Title: Alpha7 nicotinic acetylcholine receptors in bipolar cells play a role in the optomotor response in mice

Authors: *C. C. KOEHLER, J. GOPE, C. B. HELLMER, L. M. HALL, T. ICHINOSE; Ophthalmology, Anatom. and Visual Sci., Wayne State Univ. Sch. of Med., Detroit, MI

Abstract: The underlying mechanism of motion detection in the retina remains contested. Certain third-order neurons, starburst amacrine cells (SACs) and direction-selective ganglion cells, contribute to retinal direction selectivity and are considered key parts of the motion detection mechanism. Bipolar cells however, have largely been excluded. We recently found that specific types of bipolar cells express α7 nicotinic acetylcholine receptors (α7 nAChRs). Since SACs are the only retinal neurons that release acetylcholine, it is likely these bipolar cells play a role in motion detection. We knocked out α7 nAChRs in type 7 bipolar cells and tested the ability of these mice to detect motion by measuring their optomotor response (OMR).
We generated transgenic mice in which α7 nAChRs were eliminated from type 7 bipolar cells using Cre-loxP technology and Cre-DOG (dependent on GFP). We first generated mice that carry a floxed Chrna7 (α7 nAChR gene) locus (homozygous) and express GFP in only type 7 bipolar cells (Gus-GFP). We injected adeno associated virus (AAV) which packaged Cre-DOG into the intra-vitreal space of male and female target mice 4 to 7 weeks old. C57BL/6J mice, transgenic mice lacking Chrna7-loxP or Gus-GFP, and non-injected mutants were used as controls. OMRs were measured and contrast sensitivity was assessed. A looming test was run and pupillary light reflexes were examined to demonstrate the preservation of visual response in mutant mice.
Two months after AAV injection, OMR and light reflex were measured. α7 nAChR knockout mice (n=10 eyes) had a significantly lower contrast sensitivity ($p<0.01$) than control mice, including C57 mice (n=23), non-injected transgenic mice (n=11), and injected mice lacking either Chrna7-loxP (n=14) or Gus-GFP (n=8). In contrast, no significant difference was found among control mice. α7 nAChR knockout mice demonstrated no significant change in response

to looming stimuli after injection ($p>0.5$). All transgenic mice retained normal pupil light response.
Mice in which α7 nAChRs were knocked out of type 7 bipolar cells demonstrated significantly decreased optomotor response measurements. We conclude that α7 nAChRs in type 7 bipolar cells likely play a key role in tuning the motion detection pathway through bipolar cell outputs.

Title: Improvement of visual discrimination during active behavior requires precise sensorimotor contingencies

Authors: *M. CONCHA-MIRANDA[1,2], J. RIOS[1,2], J. BOU[1,2], J. VALDÉS[1,2], P. MALDONADO[1,2];

Abstract: Active sensing refers to the process by which animals perceive their environment through self-initiated motor acts. During active sensing, movements elicit changes on the sensory organs that are temporarily locked to the initiation of the action. To the date, it has been shown that motor acts can modulate sensory processing in different modalities, and through a variety of actions. But, is the brain able to take advantage of the precise time-locking that occurs during active sensing? We conjecture that if stimuli presentation is evoked by a self-initiated motor act sensory discrimination would improve and that this improvement requires precise time coordination between the motor act and the sensory stimulation produced. We studied this phenomenon by training rats to locate the position of a brief light stimulus, either when it was elicited by a warning light [passive condition (PC)] or when it was generated by a lever press [active condition (AC)]. We found that during the AC rats had a significantly higher percentage of correct responses when compared with the PC. Furthermore, reaction times and omissions were reduced during AC. To test if this improvement required precise coordination between action and the corresponding sensory stimulation, rats were subjected to a variation of the AC were the stimulus was uncoupled from the motor act, by introducing a random delay after the lever press. For the latter condition, the probability of detecting the side of the light stimulus was

negatively correlated with the time lag between the motor act and the evoked light. We also found differential modulation of functional connectivity between motor and sensory areas during these three tasks. These experiments shows that the mechanism that underlies sensory improvement during active behaviors have a constrained time dynamic, where the peak performances occur during the motor act, decreasing proportionally to the lag between the motor act and the stimulus presentation. This result is consistent with the evidence already found in humans, of a precise time dynamic of the improvement of sensory acuity after a motor act and reveals an equivalent process in rodents. Our results support the idea that perception and action are precisely coordinated in the brain.

Title: Behavioral responses evoked by novel motion stimuli change over development and correlate with immediate early gene expression patterns in the midbrain and cortex

Authors: *K. M. ALLEN, N. M. PROCACCI, J. L. HOY;
Univ. of Nevada, Reno, Reno, NV

Abstract: Orienting responses evoked by visual motion are present early in life. Successfully honing these responses during development ultimately shapes both complex visuomotor behavior and the regulation of spatial attention in the adult. However, the mechanisms underlying the development of motion processing and spatial orienting behaviors in the mammalian brain are unclear. Similar to a wide range of experimental models, adult mice exhibit distinct orienting responses to specific features of visual motion. This presents an opportunity to study the cellular and molecular mechanisms underlying the development of these basic visuomotor orienting responses in the mammalian brain. Here, we begin to address this goal by quantifying how juvenile mice respond to novel, naturalistic virtual stimuli that evoke approaches in adult mice. We demonstrate that adult mice display two behavioral responses to motion stimuli: approaching and freezing. While juvenile mice approach motion stimuli as often as adults, they rarely freeze. This behavioral difference corresponds to cellular activity measured by immediate early gene (IEG) activation in the periaqueductal gray (PAG) and specific layers of primary visual cortex

(V1). Ongoing experiments seek to understand whether the activity of either midbrain and/or cortical circuits are causal to developmental differences in responses to motion. Ultimately, this work will facilitate our understanding of the mechanisms underlying the development of spatial orientating behaviors in the mammalian brain.

Title: Experience alters the connectivity between hypothalamus and periaqueductal gray during critical periods of development in the mouse

Authors: *R. OLVERA[1], K. ALLEN[2], A. AYALA[3], J. L. HOY[4];
[1]Biol., Univ. of Nevada Reno, Reno, NV; [2]Univ. of Nevada, Reno, Cool, CA; [4]Biol., [3]Univ. of Nevada, Reno, Reno, NV

Abstract: The proper development of neural circuits that underlie responses to salient environmental stimuli is essential for an organism's survival. For example, visuomotor circuits that underlie the innate ability to rapidly obtain prey or flee threat are highly conserved across species. Innate behaviors should be evoked robustly, but also in the appropriate context; e.g. it is beneficial to become more sensitive to stimuli that signal food when hungry, while amplify avoidance responses and decrease sensitivity to food signals when sated. To respond to stimuli in a conditional manner, the brain couples internal states, such as hunger, to circuitry that robustly transforms sensory stimuli into seeking or avoidance behaviors. In more complex organisms, state-dependent modulation of sensory processing may depend on early experience. Here, we provide evidence that early life experience alters the structural connectivity between leptin (nutrient) sensing neurons in the ventromedial hypothalamus (VMH) and those that directly gate avoidance behaviors in the periaqueductal gray (PAG) in the adult. By studying a mouse model of prey capture and using a Cre transgenic approach, we identified a specific projection from VMH to dPAG that is selectively weakened in mice given prey capture experience as juveniles. The density of these projections did not change in adults exposed to the same experiences. Thus, this structural connectivity may be particularly flexible during sensitive periods of development in the mouse. Ongoing studies seek to understand how this structural change induced by juvenile experience influences behavioral responses to sensory stimuli as well as foraging behavior in the adult. We are also working to understand how this connectivity directly influences visually-

guided predation behavior in both adults and juveniles. This work will ultimately further our understanding of how developmental experience shapes the brain to conditionally transform visual stimuli into context-appropriate motor output.

Title: Long-range inhibition mediates decision making in the superior colliculus

Authors: *J. ESSIG, J. B. HUNT, G. FELSEN;
Dept. of Physiol. and Biophysics, U. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Fast and accurate decision making is required for generating purposeful behaviors in a complex environment. Despite numerous innovative experimental and theoretical approaches, how internal states and external stimuli are integrated by neural circuits to produce behavior continues to be elusive. The superior colliculus (SC) is at the center of sensorimotor decision making for survival-based orienting movements. Since the SC has been extensively characterized anatomically, physiologically and functionally across many species, it is poised to serve as a powerful model system to illuminate how activity in neural circuits give rise to behavior. Here, we examine how GABAergic neurons in the SC shape decisions. Mice were trained to select a left or right reward port based on a binary odor mixture and to wait for a ‘go tone’ before initiating a movement, thus giving us access to neural activity during the decision (i.e., the ‘delay epoch’). We first confirmed that SC output promotes contralateral choices by optogenetically exciting glutamatergic SC neurons during the delay epoch and by inhibiting the SC with muscimol. As expected, excitation elicited a contralateral choice bias and inhibition elicited an ipsilateral choice bias. Informed by anatomical and physiological data obtained from slice experiments, we initially hypothesized that GABAergic neurons inhibit adjacent SC motor output neurons (akin to common motifs in cortical circuits) and therefore predicted that these neurons would be most active before, and promote, ipsilateral choices. However, optogenetic identification and activation of GABAergic neurons revealed that they are active before contralateral choices, and driving their activity during the delay epoch elicited a contralateral choice bias. Histological analysis revealed GABAergic neurons projecting to various locations in the midbrain, including the opposite colliculus. We are currently testing if our results are

mediated by commissural GABAergic neurons by optogenetically silencing their terminals during the delay epoch. Together, our findings point to a functional role for long-range inhibitory interactions in the SC, which provide a substrate capable of mediating winner-take-all dynamics during decision making.

Abstract: Visual systems combine lower-level sensory signals (e.g. light intensity) to generate higher-order representations for guiding natural and voluntary behaviors. In *Drosophila*, it is thought that encoding of higher order visual features such as another fly or potential predator may be supported by ~20 classes of lobula visual projection neurons, which convey visual information from the optic lobe to the central brain. Using in-vivo two-photon imaging of these visual projection neurons in response to a wide range of visual stimuli, we show that they have diverse size and motion selectivity. We propose potential mechanisms that enable these neurons to have diverse feature representations and how they may be used to visually guide natural behaviors.

Title: Motor context-dependent dynamic neural processing for fine-scale control of locomotion

Authors: *T. FUJIWARA, T. CRUZ, E. CHIAPPE;
Champalimaud Fndn., Lisbon, Portugal

Abstract: Locomotion is a dynamic process that relies on an accurate estimate of self-motion to adjust to the unpredictable properties of the environment. Such a robust self-motion estimation is thought to depend on the integration of multiple sensory feedback, such as self-generated visual flow and motor-related mechanosensory signals. In addition, this integration must occur flexibly, i.e., depending on motor context, since the properties of sensory feedback depend on the structure of locomotion. However, the nature of such a dynamic multi-modal processing underlying locomotor performance remains poorly understood. Previously, we found that in *Drosophila melanogaster*, a class of progressive motion-sensitive visual cells, the HS cells integrate direction-selective motor-related and visual signals congruently to encode self-rotations during walking (Fujiwara et al., 2017). Here we found that a class of regressive motion-sensitive cells, the H2 cells, also integrates direction-selective, motor-related and visual signals congruently. Like HS cells, H2 cells are thought to contribute to course control. Further, we observed that at high forward walking speed, HS and H2 cells are modulated differentially, with an increase in overall activity in HS cells, and a decrease in direction selective responses in H2 cells. These modulations occur at a fine time scale, and reveal a flexible control of visuomotor interactions for an internal estimate of self-motion that depend on motor context (here defined as a function of forward speed). Furthermore, conditional unilateral silencing perturbations of neural activity, showed that HS activity contributes to locomotion control while H2 does not when the fly walks at high forward speed, further supporting the motor-context dependent contribution of these neurons to the control of locomotion. Therefore, our study reveals an underlying dynamic mechanism for fine-scale motor control that depends on the interaction of multi-modal sensory feedback with motor-related internal signals, and that guarantees flexible

control of the contribution of neural activity to behavior.

Title: A gradient of synaptic connectivity underlies directional control of fly escape

Authors: *M. Y. PEEK[1], S. NAMIKI[2], P. BREADS[1], J. POLSKY[1], S. ALGHAILANI[1], E. TENSHAW[1], W. R. WILLIAMSON[1], R. PAREKH[3], G. M. CARD[1];

Abstract: To investigate the neural basis of directional, visually-evoked behavior, we dissected the circuit mechanisms underlying the control of looming-evoked fly escapes. Utilizing a collection of cell type-specific lines, we identified a set of nine descending neurons that receive input from the same looming-speed-encoding visual projection cell type (LC4) as the giant fiber, a well-studied descending neuron controlling rapid escape. By annotating and analyzing these connections in an electron microscopy dataset, we discovered gradients in the number of synapses between the 55 retinotopically-arranged LC4 neurons, and four downstream descending neuron partners. The synaptic connectivity gradients are unique for each descending neuron cell type and anatomically suggest distinct regions of higher sensitivity to looming stimuli within the visual field. Furthermore, for two descending neurons, optogenetic activation generated shifts in body posture that result in directional escapes opposite to regions of predicted high sensitivity, indicating that these descending neurons map the approach direction of looming stimuli to appropriate directional escape motor programs by a synaptic count mechanism that weighs the sensitivity to looming features across the visual field.

Title: Action selection and feature detection in neuronal circuits for escape and landing in *drosophila*

Authors: *J. M. ACHE[1], S. NAMIKI[1], C. R. VON REYN[2], M. SUMATHIPALA[1], P. BREADS[1], E. ROGERS[1], K. M. BRANSON[1], G. M. CARD[1];
[1]HHMI/Janelia Res. Campus, Ashburn, VA; [2]Sch. of Biomed. Engineering, Sci. and Hlth. Systems, Drexel Univ., Philadelphia, PA

Abstract: To survive, animals must detect and respond to sensory cues in a context-specific manner. Even innate sensorimotor responses are flexible, such that an identical cue can elicit different actions in different situations. How the brain achieves this context-dependent flexibility is unclear. In *Drosophila*, visual looming stimuli elicit an escape takeoff when the fly is standing, but a landing response during flight. To unravel the mechanisms enabling this flexibility, we dissect the neuronal circuits for escape and landing by combining *in-vivo* electrophysiology, neurogenetics, and EM circuit reconstruction.
First, we show that a population of visual projection neurons anatomically specialized to detect looming (LPLC2) mediate the size of visual looming objects to the giant fiber (GF) escape neuron. We establish LPLC2 as necessary for GF-mediated escape, and find LPLC2 and a second population of visual projection neurons (LC4) directly presynaptic to the GF via EM reconstruction. Critically, LPLC2 silencing eliminates the size component of the GF looming response, leaving only the velocity component, whereas LC4 silencing eliminates the velocity component but leaves the size component intact. Selection and timing of the GF-driven escape response is therefore determined by the summation of inputs from two populations of visual feature-detecting neurons.
To understand how the selection of escape or landing is achieved, we conducted an optogenetic activation screen of 130 descending neuron (DN) lines and identified two DN types whose activation drove landing responses. Silencing either DN significantly reduced visually-evoked landing responses, suggesting they are intrinsically important to the control of landing. *In-vivo* patch-clamp recordings revealed that the landing DNs encode visual stimuli and control leg extensions in a graded fashion while the fly is flying. Critically, their visual responses are severely attenuated when the fly is not flying. This gating occurs by separate mechanisms (neuromodulation and motor feedback) in the two landing DN types. Thus, landing DNs are

gated out when the fly is not flying, such that landing responses cannot be elicited by a looming stimulus. The GF visual responses, in contrast, do not require flight, which enables escape takeoff in standing flies.
Our findings show that sensorimotor flexibility is achieved by state-dependent coupling of sensory networks of the brain to motor networks in the ventral nerve cord.

Title: Development of ecologically-relevant visual stimuli for study of *Drosophila* behavioral response phenotypes

Authors: *C. MORROW, T. ORAM, P. BREADS, G. CARD;
HHMI Janelia Res. Campus, Ashburn, VA

Abstract: In the wild, *Drosophila melanogaster* live in visually complex surroundings in which they must identify approaching conspecifics and predators, and differentiate them from environmental clutter, to select the appropriate behavioral response. While the mechanisms by which many neurons in the early visual pathway encode ethologically relevant object features, such as looming motion, have been recently elucidated, it remains unclear how these visual features are integrated to build perceptions of complex visual objects. We utilized the recently-developed FlyPEZ platform, which provides a means to study behavioral responses to visual stimuli with high-throughput and high spatiotemporal resolution, to display a variety of stimuli based on objects *Drosophila melanogaster* would encounter in the wild. In some cases, these stimuli are developed through 3D kinematic modeling of conspecific or predator behaviors, which are then mapped to the observing animal's visual field. These modeled behaviors are digitized and can be presented to animals on the FlyPEZ to identify behavioral phenotypes associated with the animal's response. By observing the differences in behavioral response phenotypes, and identifying the neurons involved in the behaviors, we can gain an understanding of the mechanisms by which flies differentiate between these stimuli.

Title: Should I stay or should I go?: Mechanisms of survival decisions in *Drosophila*

Authors: *T. B. ORAM, J. M. ACHE, G. M. CARD;
HHMI Janelia Res. Campus, Ashburn, VA

Abstract: In nature, animals simultaneously face both homeostatic and acute challenges to their survival. For example, a hungry fruit fly requires food to replenish energy and nutrient stores, but feeding on a fallen apple exposes it to the threat of predation. If a predator attacks, the fly must then choose whether to stay on the apple and risk being eaten, or fly away and risk starvation. The fly's survival thus depends on its ability to integrate environmental stimuli and representations of internal state to produce a rapid response. Here, we studied the neural mechanisms of conflicting-threat resolution in the context of hungry flies responding to predator-mimicking looming stimuli. In response to these stimuli, one appropriate escape behavior in flies is a takeoff (TO). TO sequences can be classified as either a fast, unstable short-duration takeoff (short mode) or a slow, stable long-duration takeoff (long mode). When a fly perceives a looming stimulus, it must decide whether to take off, and if speed or stability is more critical. The *Drosophila* Giant Fiber (GF) descending neuron is necessary and sufficient for short mode takeoff; alternate descending pathways are implicated in control of long mode takeoff. To determine whether hunger state affected a fly's decision to take off, we presented starved flies with the choice of staying on a food-bearing platform or escaping from a looming stimulus. We found that, compared to sated flies presented with the same choice, starved flies rarely chose to leave a food source when confronted with a looming stimulus (sated, with food: 29% TO; starved, with food: 9% TO). Moreover, the presence of food did not significantly affect sated flies' decision to take off (sated, no food: 35% TO). We also found that starvation changed the likelihood a fly would elect a short mode versus a long mode takeoff (starved: 29% short mode; sated: 14% short mode). This suggests that hunger state modulates a fly's decisions of both whether and how to take off. Finally, when we inhibited GF activity in starved flies using a GF-specific split-GAL4 driver to selectively express Kir2.1 channels (GF x Kir2.1), the takeoff percentage in response to looming stimuli decreased from that of starved wild-type flies in which GF activity is intact (WT, starved: 25% TO; GF x Kir, starved: 5% TO). The TO percentage was unaffected by inhibition of GF activity in sated flies (WT, sated: 39% TO; GF x Kir, sated: 36% TO), suggesting that starvation selectively inhibits the non-GF descending pathways

coordinating long mode takeoff. Thus, hunger state and immediate food cues regulate survival decisions through the differential, context-dependent modulation of descending escape pathways.

Title: Tracing all presynaptic inputs to the Giant Fiber descending neuron of *Drosophila melanogaster* in an electron microscopy dataset

Authors: R. PAREKH[1], E. TENSHAW[1], J. POLSKY[1], S. ALGHAILANI[1], J. S. LAURITZEN[1], D. BOCK[2], *G. M. CARD[1];
[1]HHMI Janelia Res. Campus, Ashburn, VA; [2]Univ. of Vermont, Burlington, VT

Abstract: In the fly, *Drosophila melanogaster*, visual looming stimuli that mimic an approaching predator prompt the fly to take evasive action. Among other possible escape maneuvers (freezing, turning, etc.), the fly chooses between a short-duration takeoff, which is fast but unsteady, and a long-duration takeoff that risks capture but is more controlled. We previously showed that the timing of a single spike in the Giant Fiber (GF) descending neuron, relative to activity in other descending neurons, determines whether the takeoff executed is short or long. Several inputs to the GF are already known, including Johnston's Organ neurons, the Giant Commissural neurons, and two visual projection neuron types that determine GF spike timing in response to looming stimuli. However, in addition to immediate visual cues, other sensory and contextual information may be integrated by the GF, affecting its spike timing. Thus to understand how spike timing in the GF is determined, ideally one would identify all of its inputs. Using a serial section TEM (ssTEM) dataset of the female adult *Drosophila* brain and CATMAID manual annotation software, we identified the single GF neuron in each hemisphere, traced GF dendrites to completion, and traced each unbranched GF axon to its EM volume exit at the neck connective. We tagged every postsynaptic site on the right GF. From these marked synapses, we manually traced the major neurites of each presynaptic neuron. We found 694 neurons presynaptic to the right GF. Of these, 297 were identified based on known morphology (108 JO neurons, 107 LPLC2, 55 LC4, 24 descending neurons, 3 interneurons of the giant commissure). We grouped the remaining 397 neurons into over 100 types using criteria such as morphology, fiber bundle, soma location, synapse location, neuropils innervated, and associated sensory modality. We uncovered innervation patterns in the input neurons including GF branch-

specificity, sensory modality preferences, and synapse count differences within a cell type onto the two GFs. Our traced presynaptic neurons comprise a library of GF input neuron skeletons that can be compared to light microscopy images of GAL4-line expression patterns to facilitate future experiments assessing the contribution of each input type to GF responses and escape behavior in behavioral and electrophysiological experiments with transgenic flies. This work forms the first comprehensive report of all inputs to the GF from EM data. Given the role of GFs in rapid sensory-motor responses, having a complete collection of identified upstream partners will help in understanding the complex circuit underlying motor behavior involving the GFs.

Title: Investigating the functional organization of cerebellotectal projections in orienting behavior

Authors: *T. YAMAUCHI, T. DOYKOS, A. PERSON, G. FELSEN;
Dept. of Physiol. and Biophysics, Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Well executed orienting behavior is fundamental to an animal's ability to select and acquire targets of interest. This class of behaviors is controlled by a network of several interconnected brain regions, but how activity is coordinated across these regions at the level of neural circuitry is not understood. The cerebellum (Cb), important for motor control, and the superior colliculus (SC), important for target selection and the resulting orienting movement, are key hubs of this network and may play complementary roles in orienting behavior. Anterograde tracing methods across multiple species have consistently shown monosynaptic projections from major Cb output structures, the cerebellar nuclei (CbN), to motor regions of the SC, intermediate and deep layers (int/dpSC). However, the cell type specificity and rudimentary function of these cerebellotectal projections have yet to be examined. Using pseudotyped G-deleted rabies-mediated retrograde tracing methods in Gad2 -cre and VGlut2-cre mice, we assessed the innervation patterns of individual CbNs to excitatory (eSCN) and inhibitory (iSCN) SC neurons. We found the major source of cerebellotectal projections were provided by lateral (LN) and

interposed (IN) nuclei, whereas the medial nucleus (MN) provided fewer projections overall. All CbNs demonstrated stronger projections to eSCNs relative to iSCNs across int/dp SC. While MN specifically targeted rostral eSCNs, LN and IN contacted both rostral and caudal eSCNs with a stronger projection to rostral eSCNs relative to caudal eSCNs. To interrogate the basic function of CbN input to SC, we recorded SC activity in anesthetized mice while stimulating ChR2-mCherry expressing neurons in the IN. Optogenetic activation of IN revealed short-latency drive of rostral and caudal SC neurons. Consistent with our retrograde tracing, histological analysis of these mice revealed synaptic terminals expressing mCherry throughout int/dpSC showing robust labeling in rostral SC. Together, these data provide insights into the functional organization of cerebellotectal circuitry and allow for the examination of how Cb drive to the SC may influence target selection and motor plans.

Title: Hippocampus and MST cortex integrate self-movement and location in driving monkeys

Authors: *C. J. D. DUFFY[1], **W. K. PAGE**[2];
[1]Neurol., Penn State Hlth., Hershey, PA; [2]Neurol., Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: INTRODUCTION: MST cortex is thought to play a critical role in the processing of self-movement, and the hippocampus is thought to support location sensitivity for cognitive mapping. Here we test whether monkey MST and hippocampus show such distinct roles during active driving by awake monkeys. METHODS: We trained a monkey to steer a room-sized, rail-mounted sled between a randomly selected series of targets drawn from eight locations distributed around the room. Successive steering target locations were designated on a small computer screen to guide the monkey's joystick steering between locations. Single neuron responses (SNRs) and local field potentials (LFPs) were recorded from MST cortex and the ipsilateral hippocampus as the monkey drove to successive goal locations.
RESULTS: Hippocampal and MST LFP spectra showed similar sensitivities to room position and self-movement speed and direction. Likewise, SNRs in hippocampus and MST showed location and movement sensitivities with single neurons in both areas showing a wide range of preferred location and movement sensitivities. Re-analyzing LFP and SNR activity with reference to the current target location revealed that both hippocampus and MST mainly represented the monkeys' current goal location and best direction from its current location to the goal location.

CONCLUSIONS: Our findings suggest that hippocampus and MST cortex share a great many response properties related to navigation. In particular, during active driving to designated locations, both hippocampus and MST are sensitive to where the monkey is driving to in each driving trial.

Title: Retinal optic flow and the visual control of locomotion in real-world terrain

Authors: *J. S. MATTHIS[1], K. S. MULLER[2], M. M. HAYHOE[3];
[1]Biol., Northeastern Univ., Boston, MA; [2]Ctr. for Perceptual Systems, [3]Univ. of Texas at Austin, Austin, TX

Abstract: A long history of research on the visual control of locomotion has explored the role of optic flow in the regulation and guidance of human walking. It was generally agreed that the head-centered Focus of Expansion (FoE) lies in a stable location in the walker's direction of travel, and that humans use this feature to control heading. We used optic flow estimation algorithms to measure head-centered optic flow recorded from the head-mounted camera of a mobile eye tracker of subjects walking in real-world environments. Contrary to the traditional view, we found natural head oscillations during locomotion cause the FoE to move constantly at high velocities within the walker's field of view. Thus strategies that suggest the FoE is used for heading could not be implemented on the basis of naturally occurring optic flow. In contrast, we found that retinal optic flow contains information that may be used for the control of locomotion. Fixation nulls motion at the fovea, resulting in regular patterns of outward flow across the retina that encode information about the walker's movement relative to the fixated location. Analyzing retinal flow fields using the curl and divergence operators from vector calculus reveals features that are directly applicable for the control of locomotion. For instance, the sign of retinal curl (which corresponds clockwise/counter clockwise rotation) indicates whether the walker will pass to the left or right of the point they are fixating. In addition, the walkers' instantaneous, world-centered velocity vector may be derived directly from the divergence across the retinal flow field. These features provide a much richer and more stable source of information for the control of locomotion than the FoE. Furthermore, this information can be extracted directly from

retinotopic visual motion, so a coordinate transform into head-centered coordinates is unnecessary.

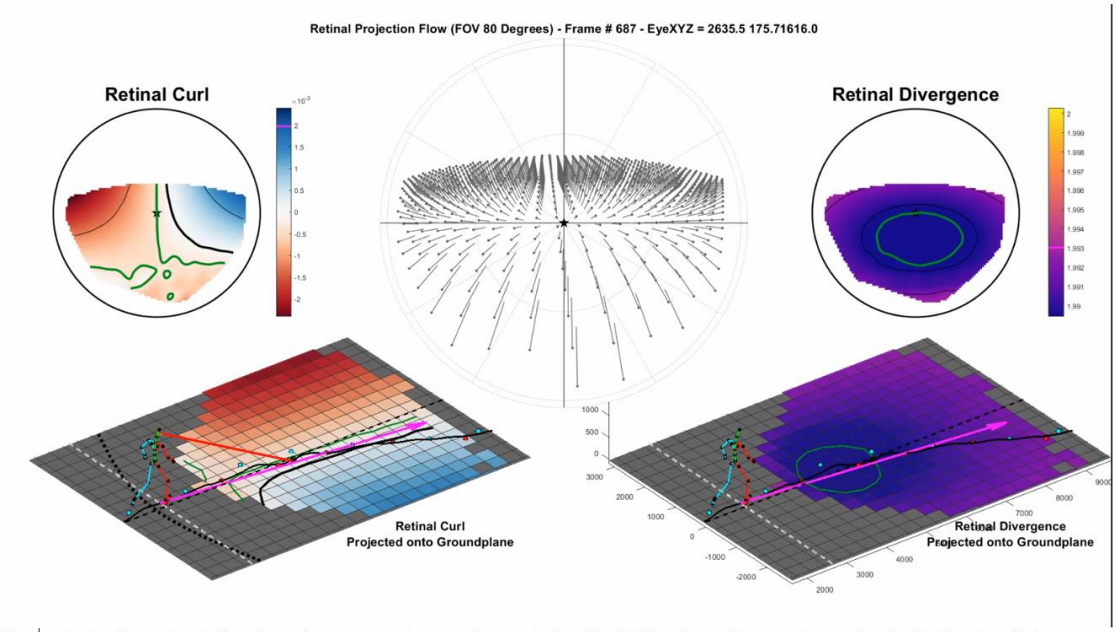

Fig1 - Optic flow simulation based on an eye tracker integrated with full-body motion capture of an individual walking over real world terrain. Middle circular panel shows simulated optic flow based on fixation location and body movement. Left and right circular panels panel shows the results of applying the curl and divergence operators to the retinal flow field in the middle panel. Left and right bottom panels show the projection of the curl (left) and divergence right) onto a flat groundplane. The pink arrow shows the walker's instantaneous velocity vector (scaled for visibility), which always bisects the foveal isoline of the retinal divergence field (green circle).

Title: The stronger EEG signature of motor preparation for real objects versus images is modulated by graspability

Authors: G. T. FAIRCHILD[1], F. MARINI[2], J. C. SNOW[1];
[1]Psychology, Univ. of Nevada Reno Dept. of Psychology, Reno, NV; [2]Swartz Ctr. for Computat. Neurosci., UCSD, San Diego, CA

Abstract: The human brain evolved for a world of real, physical, three-dimensional (3-D) objects, yet the vast majority of scientific studies of visual cognition have relied on impoverished stimuli presented as two-dimensional (2-D) images - stimuli that do not afford manual interaction. We recently investigated how the action affordances provided by real objects affect cortical brain dynamics by recording electroencephalography (EEG) while observers viewed real-world objects or closely matched 2-D images of the same items. Real objects elicited stronger event-related μ-band (8-13 Hz) desynchronization, attesting to greater automatic motor preparation. This larger μ desynchronization for real objects vs. images persisted both throughout the 800-ms window of stimulus presentation, and ~700 ms beyond stimulus offset. In the current study, we extended this work by examining whether similar patterns of μ desynchronization were apparent when the same stimuli were presented unoccluded (as in our previous study), or behind a clear acrylic glass barrier that eliminated the potential for manual interaction with the (real) objects. Without the barrier, we replicated our previous finding of stronger μ desynchronization for real objects than images both during and after stimulus presentation. Importantly, the barrier attenuated the difference in μ desynchronization between real objects and images during the period of stimulus presentation, while later μ desynchronization differences between stimulus formats after stimulus offset were relatively unaffected. These results suggest that a physical barrier that limits the potential for in-the-moment manual interaction with a real object attenuates the early (but not later) differential in cortical motor preparation signals for real objects vs. images. The early versus late μ desynchronization differences between real objects and images may reflect different underlying cortical processes related to graspability -an early process that is influenced by immediate actionability and a later process that reflects the inherent graspability of real objects.

Title: The impact of perceptual, cognitive and motor demands on the fidelity of internal time estimates

Authors: *A. AKKAD[1], T. V. PARKS[1], A. C. FERGUSON[2], M. JAZAYERI[1,2];
[1]McGovern Inst. for Brain Res., Cambridge, MA; [2]Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Perceptual, cognitive and motor aspects of interval timing are often examined in isolation. For example, sensory anticipation tasks have focused on the perceptual aspects of timing, whereas studies in the motor system have focused on the motor aspects. Natural behavior, however, depends on a confluence of multiple aspects of interval timing. For example, the performance of a musician or an athlete depends critically on the ability to estimate time intervals using multiple temporal cues, retain information about time intervals over delays, and plan multiple movements in accordance with different temporal contingencies. Here, we developed a novel composite timing task for monkeys to investigate the mechanisms by which the nervous system integrates the perceptual, cognitive and motor aspects of interval timing. The task consists of 5 epochs: 1) Fixation: monkeys fixate a central spot and a peripheral saccadic target is presented. 2) Entrainment: monkeys see a visual metronome; i.e., a ring that alternates its position once or twice between the target and fixation points. The tempo is sampled from a prior distribution ranging between 659 and 1139 ms. 3) Memory: monkeys continue fixating during a variable delay period. 4) Production: monkeys shift their gaze toward the target immediately after a 'go' cue, and make alternating saccades afterwards between the target and fixation points aiming to reproduce the tempo of the visual metronome in the entrainment epoch. 5) Feedback: monkeys receive reward whose magnitude was adjusted based on the magnitude of error.

Monkeys' behavior exhibited four important characteristics. First, produced intervals exhibited a characteristic bias toward the mean of the sample distribution, indicating that animals relied on their prior knowledge to optimize their responses. Second, performance improved when the entrainment period consisted of two compared to one alternation. This improvement was manifested by a decrease in both bias and variance. Third, performance was weakly affected by the delay period suggesting that animals maintained a reasonably stable memory of the estimated interval. Fourth, performance during the production epoch deteriorated when animals produced the desired interval twice compared to once; i.e, the second produced interval was more variable and more biased relative to the first. These results provide a rich dataset for understanding the perceptual, cognitive and motor factors that influence the fidelity of temporal information in the nervous system. Electrophysiological experiments are underway to probe the underlying neural mechanisms.

Title: Information dynamics in embodied multifunctional recurrent neural networks

Authors: *M. CANDADAI, E. J. IZQUIERDO;
Program in Cognitive Sci., Indiana Univ., Bloomington, IN

Abstract: Understanding how information about external stimuli is transformed into behavior by the nervous system is one of the central goals of neuroscience. This involves characterizing in detail the flow of information through a complete brain-body-environment system: from the task-relevant environmental information, to the sensory stimulus, through the sensory neurons, interneurons, motoneurons, all the way to action. There are a number of experimental challenges to this endeavor, which include access to all variables of interest in the brain-body-environment system over many repeated trials and under different conditions. To address these shortcomings, we adopt a complementary computational modeling approach. We utilize optimization techniques to generate an ensemble of recurrent dynamical neural network models, embodied, and situated in environments, where they perform the behaviors of interest. All relevant variables are simultaneously recorded, and this data is then analyzed using information theory to understand their operation. Specifically, we apply a set of information theoretic tools that are based on a multivariate generalization of mutual information, which extends Shannon's traditional concepts in key important ways: We unroll information over time and across different trials and tasks; and we consider how information is spread across different variables in the system, thereby measuring redundant, unique, and synergistic information. We use these tools to understand the flow of information in neural circuits at three levels: task-relevant information; sensorimotor information; and neural information. In the current work, we report on the analysis of neural circuits trained to perform multiple visually-guided tasks, including object categorization and affordance perception. Results reveal key insights into the principles of operation of multifunctional neural circuits. First, task-relevant information is represented in a distributed and spatiotemporally dynamic manner within the circuit. Second, synergistic information about sensory stimuli and motor actions reveals neurons that are performing crucial computations in the circuit. Third, the transfer of information within the circuit tends to form task-dependent effective networks. Altogether, our work demonstrates how the tools of multivariate information theory can be used to characterize the information flow throughout a complete sensorimotor circuit and the unique insights that such analyses can provide. Ultimately,

the principles derived from our analysis can be used to drive new experiments and the theoretical framework can be used to analyze existing data.

Title: Complex social behaviors in larva and juvenile zebrafish are controlled by simple visual cues and are affected by single gene mutations

Authors: *R. HARPAZ, A. C. ASPIRAS, A. BAHL, M. C. FISHMAN, F. ENGERT; Harvard Univ., Cambridge, MA

Abstract: Dysfunctional social behavior can be detrimental to the survival of individuals in most animal species. Despite its importance, the links between genes, neural circuits and adaptive social behavior are largely unknown. The zebrafish model system, provides a unique opportunity to study the genetic and neural basis of social behavior.
Here, we aimed to characterize collective social behavior in larva and juvenile fish, infer how visual social cues drive swimming responses and their underlying genetic control. We analyzed group swimming behavior (5-10 fish) of wildtype larva and juvenile fish and compared it to groups of fish carrying single mutations in genes associated with autism and schizophrenia. We found that from age 7 to 21 days fish transition from swimming in highly dispersed spatial distributions to tight groups. Mutations in the *immp2l* gene, and in the *homer1b* gene resulted in a significant increase in group cohesion already at age 7-days that persisted over development.
To extract the visual cues that drive fish movement decisions in a group we reconstructed the visual scene of each fish during movement decisions. We found that the visual angle subtended by neighbors on each eye strongly modulated the turning direction and bout rate of the fish. In mutant fish, we found clear alterations in responses to these visual cues, matching the observed increase in group cohesion. Presenting free swimming fish with simple fictive social stimuli to each eye, mimicking the visual occupancy experienced when swimming in a group, elicited similar swimming responses. Finally, we used the identified responses to visual cues to inform mathematical models of fish social interactions. Simulating group swimming behavior using these models we show that the identified social interactions are sufficient to explain behavioral findings for both wildtype and mutant fish over development.
Our results link complex collective behaviors to simple social cues already at 7-day old larva

zebrafish and show that single gene mutations can alter these innate behaviors. Next, these findings will allow us to explore the neural circuits underlying social and collective behavior using optical imaging to acquire whole-brain activity recordings while larva fish engage in fictive social interactions. Comparisons between wildtype and mutant fish with altered social responses will potentially help identify the crucial circuit elements affected by these mutations and their relation to maladaptive social behavior.

Title: Effects of motor timing training on golf swing motion in Parkinson's disease

Authors: *J. KIM[1], Z. LEMKE[1], A. L. RIDGEL[1,2];
[1]Exercise Physiology., Kent State Univ., Kent, OH; [2]KSU Brain Hlth. Res. Inst., Kent, OH

Abstract: Individuals with Parkinson's disease often show deficits in motor timing, specifically during tasks that require rhythmic motor patterns such as gait and finger tapping. However, it is not clear if rehabilitation training that focuses on improving motor timing can improve rhythmicity during coordinated movements. In this study, we utilized a computer-based rehabilitation tool, called Interactive Metronome (IM), which trains individuals to improve motor timing by reacting to an auditory or visual reference cue. Changes in motor timing and coordination were measured using a golf swing motion. The purpose of this study was to examine if IM training with golf swing motion improves motor timing in Parkinson's disease. Participants completed 12 IM sessions, three times weekly training for 4 weeks. The aim of each session was to perform the golf swing motion to match the audible beat. Visual feedback was given to the participants to encourage them to hit the 'target zone' (±15 ms) during the golf swing. Motor timing was assessed using the Long Form Assessment (LFA) which evaluated timing and accuracy during fourteen movement tasks of the hands and feet. A wireless kinematic sensor system was utilized to measure movement acceleration and pitch during the backswing and down swing. Paired t-test were used to compare pre- and post-intervention measures. There was no significant difference in motor timing as measured with LFA, but the motor timing improved after the intervention (pre: 131±76.4 vs post: 54.5±0.7 ms). There was a significant difference between pre-post training in the thigh pitch on the back swing (X pitch) [t=2.766, p=.012] and the down swing (Y pitch) [t=2.93, p=.009]. Although there was no significant difference, acceleration of the pelvis during the back swing improved from 8.5±8.7 to 4.1±2.8

sec. These results suggest that IM training can improve motor timing and acceleration during the golf swing in Parkinson's disease. In light of these findings, future studies will also examine if MT training promotes improved motor timing and golf swing mechanics in individuals who show impaired range of motion.

Title: Different speeds and retention periods for motor adaptation to different types of unexpected impedances for target reaching by intact human subjects

Authors: *K. OH[1,2], W. Z. RYMER[2,1];
[1]Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [2]Shirley Ryan AbilityLab, Chicago, IL

Abstract: Impedance-based training has been widely used to enhance recovery of motor performance in patients with neurological disorders. Using an internal model formulated in the cerebellum, humans can estimate load magnitude and load characteristics imposed on their limbs, correct deviations from the planned movements, and plan revised movement trajectories. Even for unexpected changes in load, intact subjects can successfully adapt within a few trials, and could can show that movements converge to a specific trajectory. Nevertheless, how swiftly humans can adapt to different types of mechanical impedances and which type of adaptation lasts longer still remain unclear.
In this study, we compared adaptation speed and retention period for motor adaptation between different types of mechanical impedances imposed on via a haptic device during outward reaching in the horizontal pane. We added a rotational spring (1 N-m/rad) referenced to the elbow joint, a mass (5 kg), or a damper (10 N-s/m) each implemented by using the HapticMaster multi degree of freedom robot. Four intact subjects participated in this experiment.
A randomly chosen impedance was introduced unexpectedly after 20 trials with a baseline impedance, and an average of movement velocity profiles from last three trials among 10 trials was used to represent a fully adapted velocity profile. The minimum number of trials required for adaptation to reduce a deviation from the fully adapted velocity profile to 15% was then calculated. After testing all three types of impedances, the second phase with the same protocol

was conducted to check if the previous experience could help subjects adapt more promptly. For a given inertial load, our subjects showed relatively smaller number of trials for adaptation (2.3 trials) as compared to the spring (5.3 trials) and the damper (4.7 trials). Interestingly, even after 15 minutes of the first phase and 5 minutes of rest, only spring condition showed the decreased number of trials for adaptation from 5.3 to 2.3 in the second phase.
The results imply that both the time required for formulating and updating an internal model for a given load and correcting movements and the retention period for the adaptation may vary with different types of mechanical impedances. Our study may be utilized to identify time-efficient protocols to quickly modify a movement trajectory with relatively long-lasting effects. We still need to analyze if different speeds of motor adaptation correlate with different exposure rates of each type of impedance in daily life, or with magnitude of impedance, or other factors.

Title: Visualizing high-dimensional motion and muscle signals

Authors: *F. RIZZOGLIO[1,2,3], A. A. PORTNOVA[2,3], D. DE SANTIS[2,3], E. ROMBOKAS[4], M. CASADIO[1], F. A. MUSSA-IVALDI[2,3];
[1]DIBRIS, Univ. of Genova, Genova, Italy; [2]Northwestern Univ., Chicago, IL; [3]Shirley Ryan Ability Lab., Chicago, IL; [4]Univ. of Washington, Seattle, WA

Abstract: Body Machine Interfaces (BoMIs) convert high-dimensional body signals into low-dimensional control commands that allow their users to operate external devices. To this end, nonlinear methods for dimensionality reduction, such as Autoencoder (AE) networks, are used to learn a mapping that embeds the low-dimensional latent space as a manifold *M* into the high-dimensional data (body space, *y*) so that it captures the probability density of *y*. However, interpreting these methods is difficult because of their nonlinear character compounded with the problem of visualizing data distributions in high dimensions. We applied cartographic algorithms, used for representing higher-dimensional maps in 2D, to visualize the nonlinear latent space of electromyographic (EMG) and kinematic data from individuals performing a variety of body and hand movements. To construct a coordinate chart, we superimposed a grid

over the 2D latent manifold obtained after training a nonlinear AE on input data. The AE decoder was applied to the grid to obtain its embedding *M*. First, Euclidean distances within local neighborhoods of *M* were measured. Then, a matrix (*R*) of global distances was determined by computing the geodesic between each pair of intersection points in *M*. Finally, the original grid was redrawn by displacing all the intersection points so as to match the corresponding distances in high dimension (as specified in *R*). Hence, Euclidean distances between points lying on the distorted grid reflect those between body space data lying on the manifold *M*. Visualization of the latent space was modeled by the nonlinear AE with 2 coding units (CUs) in the latent manifold. Movement/EMG data were fed into the AE encoder to obtain corresponding points in the 2D coordinate chart. This visualization applied to the muscle and kinematic data allowed us to observe distortions in the latent grid of a nonlinear AE as well as to establish the separability of different tasks, muscle synergies, and movements in the latent space. We expect that this technique can be also used to assess learning, for example, by studying how distortions evolve during a learning process. In addition, we aim to understand how visualization of the latent space can aid the user in improving the performance of their controller.

Title: Hybrid EMG-IMU BOdy-Machine Interfaces for promoting voluntary control of muscles after spinal cord injury

Authors: *D. DE SANTIS[1,2], M. T. PERLMAN[1], F. MUSSA-IVALDI[1];
[1]Northwestern Univ., Chicago, IL; [2]Inst. Italiano di Tecnologia, Genova, Italy

Abstract: High-level injuries to the spinal cord (SCI) compromise function of the upper limb and result in severe deterioration of the quality of life. Studies have shown that learning novel motor skills triggers a process of remodeling at different levels of the Central Nervous System. In particular, there is evidence that corticospinal plasticity is very localized to the muscles engaged in leaning the skill. Hence, the question arises of how to involve in skilled activities muscles for which residual voluntary control is limited by SCI.

Body-machine interfaces (BoMIs) allow their users to perform skillful tasks via artificially re-mapping available movements after SCI into a suitable control space. They are effective in promoting continued practice, improving upper body strength and help restoring independence. However, one of the major drawbacks of movement-based BoMIs is the lack of control over which muscles contribute to the observed motions. Here we present a novel approach for engaging targeted muscles into skilled activities while operating a movement-based BoMI. EMG signals from muscles of interest are collected while the user learns to operate a IMU-based BoMI. After an initial phase of familiarization with the IMU-BoMI, we evaluate the cross-correlation between a target EMG channel and all IMU signal pairs. The target muscle is then remapped onto the IMU signal with the highest correlation and minimum delay among the possible combinations. Moreover, the degree to which a certain muscle contributes to the selected input of the BoMI is modulated by a weighting factor that scales the contribution of the IMU signal and its EMG-derived reconstruction.
Following this approach, the IMU-BoMI is transformed into a Hybrid EMG-IMU BoMI in its input space, while the mapping from body-motion to control signals itself is left unaffected.
In order to evaluate the efficacy of our method in increasing the activity of targeted muscles (Biceps or Triceps brachii), we asked unimpaired volunteers to practice a reaching task with the BoMI using their upper arms and forearms for one session of about 1 hour. Preliminary results show that manipulation of the weighting factor is effective increasing the contribution of the targeted muscle over its antagonist through time.

Title: 2-dimensional cursor control via EMG from upper cervically-innervated muscles can be learned rapidly via deep learning driven game play

Authors: *R. J. COTTON;
Physical Med. and Rehabil., Shirley Ryan Abilitylab & Northwestern, Chicago, IL

Abstract: Accessing a smartphone is an important part of modern life, but for many people with quadriplegia this can be a significant challenge. Decoding neural population activity is a promising research direction, although requires invasive recordings from the brain. Decoding more easily accessible signals, such as electromyography (EMG) from muscles remaining under

volitional control is another option. However, it also has significant challenges including system performance, refinement for intact muscles, calibration, and portability. Here I describe work to reduce these barriers.
The control system was implemented with wearable sensors using a smartphone application. Specifically, a miniature battery-powered, Bluetooth-enabled, 8-channel differential biopotential amplifier was developed for surface EMG acquisition. The sensor connects to an accompanying Android application for data recording and real-time processing. Multichannel EMG activity was mapped to control signals using a neural network. First a latent space representation is learned from spontaneous movement to find the lower dimensional manifold capturing the spatiotemporal EMG activity. Following this, subjects play a game on the smartphone where they attempt to follow a cursor. This provides a supervised learning signal to train additional output layers that map from the latent space to the control signals. The EMG activity and target location collected during training is streamed from the smartphone to a GPU-powered server allowing real-time training of the network and feedback to the subject. Finally, the optimized network can run the control inference in real time on the phone. The system was demonstrated on a neurologically intact test subject by recording from muscles available in many quadriplegic patients (trapezius, rhomboids, deltoids, sternocleidomastoid).
One advantage of this neural network driven supervised learning is that the movements of the subject do not have to be predetermined and the user can select motions that feel easy or natural. This may benefit people with disabilities who each have unique impairments. In addition, the game-based training procedure with real-time feedback allows the user to quickly see which movements are effective and which are less effective as the network learns the EMG patterns. This addresses some challenges for quadriplegic patients to control a phone via EMG: it uses wireless and portable hardware with a training approach that allows more natural movements and can be rapidly trained.

Abstract: Proprioceptive deficits are frequently associated with neuromotor impairments that strongly affect daily-life activities, interfering with motor control, learning, and recovery. Despite this, these deficits are poorly understood, less investigated and treated than motor impairments.
Here we aim to assess proprioceptive deficits through the observation of position and force control performance during bimanual tasks, because most daily-life activities require coordinating the motion and the force produced by both hands. Moreover, several neurological diseases induce coordination problems and often affect the two arms differently. In our study participants had to (1) reach a target position with both their hands while holding objects with equal or different weights and (2) exert an isometric force, pushing equally with the two arms in the upward direction, while their hands were maintained in a fixed position at the same or at different heights. Our primary outcome was the difference between the two hands at the end of each trial, in terms of position (task 1), or force (task 2). First, we tested a population of unimpaired subjects and then we provided a first proof of concept that this set-up could be used also for people with Multiple Sclerosis (MS) with a low to moderate level of impairment.
As for the unimpaired participants (20 subjects for task 1; 25 for task 2), we found that the difference in hand positions was greater when the two hands held different weights; instead, the ability to exert forces was influenced by the position of the left hand, regardless of the right hand position and without effects of symmetric or asymmetric arm configurations.
As for MS participants (7 people with MS and different levels of impairment and 7 matched controls) we found that the ability to exert symmetric forces with the two hands was significantly altered in all subjects with respect to healthy controls, independently of the hand configuration. Conversely, their ability to control the position decreased only for subjects with higher level of impairment. These findings, if confirmed on a wider population, could be relevant for the early detection of the disease onset, and to assess how the proprioception and motor control changes in the progress of the disease.
The next step is to modify the device for providing different somatosensory feedback and investigating the influence on performance and training outcomes.

Title: Motor learning of novel dynamic environments for robotic rehabilitation using an exoskeleton

Authors: *C. PIERELLA[1], S. GUELFI[2], N. ROSSIGNOL[1], M. CASADIO[2], S. MICERA[1]; [1]Ecole Polytechnique Federale De Lausanne (EPFL), Lausanne, Switzerland; [2]Univ. of Genova, Genova, Italy

Abstract: Stroke is one of the most prevalent causes of impairment in many countries and its incidence continues to rise. The possibility to modify the usually pathological patterns of upper-limb coordination in stroke survivors remains a central issue and an open question for neurorehabilitation. Current therapies for rehabilitation perform assisting movements to help the patient recover some smoothness and regain some control of the impaired limb. Recent works provide evidence that error-enhancing strategies of rehabilitation might prove beneficial for a more efficient recovery. In particular, exposing the patient to a new dynamic environment, i.e. force field while working with a planar robot, is indeed expected to activate motor learning strategies that promote neuromotor adaptation and reorganization. This work exploit the potential of exoskeletons to address the problem of understanding the way the human central nervous system deals with natural upper-limb redundancy for common activities, motor learning and coordination in novel environments. We recruited healthy subjects and, while most studies focused on 2D force fields at the end-effector (EE) of the device, we investigated the possible differences when subjects had to adapt to a 3D force field either at the EE of the exoskeleton or at one of the 2 joints, elbow or shoulder. Subjects worked with ALEx, an upper limb exoskeleton, and were asked to perform a center-out reaching task. Kinematic and muscular activity was recorded during the full training. Results show that all the subjects, with training, were able to adapt to the perturbation introduce by the force field. Moreover the force field applied at the EE and the ones applied at the joints generated different compensatory movement and motor strategies of adaptation at the kinematic and muscular level. This is a first step into gaining a deeper insight on the control mechanisms in healthy subjects and then transfers them to understand and predict behavior of stroke subjects and their recovery. Future perspective will translate this knowledge into robot-based subject-specific rehabilitative approaches suited to tackle the problem of motor coordination in stroke.

Abstract: Aging increases the probability of falling in healthy subjects. Risks of falling are associated with balance deficits and with the inability to counteract unexpected perturbations or instability of the support surface. Currently, there are protocols and devices that allow studying postural control under static and dynamic conditions by using robotic force platforms. Our goal is to define a set of different exercises and parameters that allow quantifying balance deficits and detecting their onset. We tested 160 healthy subjects with ages ranging from 20 to 90. Participants performed both static and dynamic exercises with the Hunova device (Movendo srl, Genoa): in the static test, they stood on a fixed platform both with eyes open and closed. Then they performed two dynamic tests with eyes open. In the first test the platform moved in proportion to the body sway, hence subjects were actively controlling the platform motion. In the second test, the platform tilted in a preprogrammed way around a central pivot, hence the subjects had to compensate the platform motion. During all these tests, the Hunova measured the inclination of the platform and the displacement of the center of pressure, while the trunk movements were recorded with an inertial measurement sensor placed on the sternum. For a comprehensive evaluation of task performance, we computed parameters from both the center of pressure and the trunk oscillations. Then, with advanced classification algorithms we defined the combination of parameters that better discriminates postural performance in subjects with

different ages and that allows detecting the onset of balance deficits. Our protocol was well tolerated by all subjects, independent of their age. Hence, this study can be a starting point for the definition of rehabilitative protocols aiming at preventing falls in older adults, by detecting the onset of balance problems and specifically targeting the skills that firstly deteriorate with age.

Title: A dysfunctional consequence of visuo-motor adaptation

Authors: I. PLENZIO[1,2], K. OH[3,4], F. RIZZOGLIO[1,3,4], I. NISKY[5], E. H. WALKER[3], R. A. SCHEIDT[2,3], M. CASADIO[1], ***F. A. MUSSA-IVALDI**[3,4];

Abstract: The brain determines positions and movements of body parts from inputs arising at least from two different systems: visual and proprioceptive. Interactions between the two sensory modalities have been described in experiments inducing conflict between vision and proprioception during some motor tasks. The dominance of vision over proprioception has been widely reported in the literature and it has been showed that incorrect visual feedback on the position of the hand can bias the perception of hand location.
In this study, we investigated the visuo-proprioceptive conflict when applying contact forces, by developing a new experimental protocol and finding a model capable of predicting the effect of a rotation of the visual field on the estimate of hand position through the control of a contact force. During the experiment, users performed reaching task while holding the end effector of a planar manipulandum. At the end of each reaching movement the end effector was locked, and subjects

were instructed to reproduce, in direction and magnitude, a specified force that they learned during a previous training phase. Subjects wore a virtual-reality headset, preventing them to observe the actual configuration of their arm. We then imposed a rotation of the visual field and allowed subjects to adapt by performing repeated movements. At the end of adaptation, subjects learned to compensate the rotation by moving the hand to a position that differed from the one presented in the display. We observed how this difference affected the contact force that they produced. We considered two different hypotheses: 1) The brain relies on the (unrotated) proprioceptive estimate of hand position to apply the correct force at the end of the reach, resulting in no effect of visual rotation on force error (Proprioception Dominance); 2) The brain relies on the visual estimate of hand position to produce the desired force and generates the same torques it would have applied if the hand were actually in the displayed location (Vision Dominance). Results obtained from a cohort of 11 unimpaired subjects show an overall superiority of the vision dominance model with respect to its competitor. As subjects adapted the hand motion to match the visual display, they effectively learned to discount the truthful proprioceptive information about the configuration of their arm and as a consequence a consistent systematic error emerged in the applied force and amplitude of the applied force vectors with respect to the planned values. We conclude that the dominance of vision over proprioception in the production of free hand movements carries a penalty for force control, a critical component of skillful manipulation.

Title: Proxy process models enable identification of the time course of motor learning from sparse observations

Authors: ***P. N. PARMAR**[1,2], J. L. PATTON[1,2];
[1]Arms + Hands Lab., Shirley Ryan Ability Lab., Chicago, IL; [2]Bioengineering, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Enhanced neurorehabilitation using robotic and virtual-reality technologies require a computational framework that can readily assess the time course of motor learning in order to

recommend the best conditions for training. Error-feedback plays an important role in the acquisition of motor skills for goal-directed movements by facilitating the learning of internal models. In this study, we investigated changes in movement errors during sparse and intermittent "catch" (no-vision) trials, which served as a "proxy" of the underlying process of internal model formations. We trained 15 healthy subjects to reach for visual targets under eight distinct visuomotor distortions, and we removed visual feedback (no-vision) intermittently. We tested their learning data from no-vision trials against our so-called *proxy process models*, which assumed linear, affine, and second-order model structures. In order to handle sparse (no-vision) observations, we allowed proxy process models to either update trial-to-trial, predicting across voids of sparse samples or update sample-to-sample, disregarding the trial gaps. We exhaustively cross-validated our models across subjects and across learning tasks. The results revealed that the second-order model with trial-to-trial update best predicted the proxy process of visuomotor learning.

Title: Effects of brief exposure to velocity-based perturbations on movement performance in stroke survivors

Authors: *Y. ABDEL MAJEED[1], S. AWADALLA[2], J. L. PATTON[3];
[1]Bioengineering, Univ. of Illinois At Chicago, Chicago, IL; [2]Sch. of Publ. Hlth., Univ. of Illinois at Chicago, Chicago, IL; [3]Sensory Motor Performance Prog, Rehab Inst. Chicago, Chicago, IL

Abstract: The first step towards improving clinical outcomes for stroke survivors is understanding the relationship between movement metrics and clinical performance. Our efforts to model change in clinical outcomes using movement data suggested that velocity- or speed-based training has the highest potential to improve clinical outcomes. First, we needed to find the most effective method of increasing patient speed. We devised a crossover paradigm in which each patient is exposed to three types of velocity-based forces: negative viscosity, positive viscosity, and breakthrough. The breakthrough condition involved positive viscosity up to the 70th percentile of a patient's speed during baseline, after which viscosity was removed as a 'reward' for reaching faster speeds. We evaluated the effects of each of these force types using changes in two primary metrics, maximum speed and maximum perpendicular distance, before

and after exposure to each force type. Here, we present the results of this exploration. We are using the most effective force type in this paradigm as the basis for a longer-term intervention, where our main outcome measure is patient performance on standard clinical assessments.

Title: Movement distribution variables that best predict clinical assessment in stroke

Authors: *Z. A. WRIGHT[1,2], J. L. PATTON[2,1], F. C. HUANG[2];
[1]Bioengineering, Univ. of Illinois at Chicago, Chicago, IL; [2]Arms + Hands Lab., Shirley Ryan AbilityLab, Chicago, IL

Abstract: We investigated probability distributions of several movement variables to find the best predictors of upper limb impairment during self-directed motor exploration. Our past work analyzed endpoint and joint kinematics (position, velocity, acceleration), which relate to some clinical descriptions of impairment that include, range of motion and interjoint synergies. However, motor impairments often manifest in terms of weak neural drive or changes in muscle force production, which are perhaps more directly attributed to kinetic variables (i.e. relating force and energy to motion; including endpoint force, joint torque and joint power). We hypothesized that kinetic variables would be most important for predicting individual differences in impairment level, measured using Fugl-Meyer scores (UEFM). Stroke survivors (n = 22) were asked to perform a motor exploration task with affected limb, moving at various speeds and directions, while trying not to repeat the same patterns. For each participant, we computed two-dimensional probability distributions (20 bins x 20 bins) of each variable (nine in total). Since there are a large number of bins (400 bins per variable), many of which are likely mutually correlated, we first applied principal component analysis across all distribution variables. We then performed multiple regression analysis (with LASSO regularization) using the reduced feature set (21 principal component scores) to predict UEFM scores. To evaluate model performance, we used the PRESS statistic which is a modified coefficient of determination (R2) calculation for leave-two-out cross-validation. With all variables included in our model (full model), the variance explained was 29.7 ± 11.3% (mean ± standard deviation R2). Next, we performed three separate runs of the PCA-LASSO method removing a single variable domain per run, and then compared the differences in predictive performance with respect to the results

of the full model. We found that model performance decreased the most when we removed endpoint kinematic variables (change in R2, -46.0%; mean ± standard deviation R2, -16.3 ± 10.4%) followed by joint kinematic variables (change in R2, -30.0%; mean ± standard deviation R2, -9.7 ± 11.2%). Removing kinetic variables modestly increased model predictions (change in R2, 10.3%; mean ± standard deviation R2, 40.0 ± 8.6%). Despite overall modest predictive performance, these results indicate that distributions of kinematic variables are most important for predicting clinical UEFM scores.

Title: Velocity error augmentation in learning a visual distortion task

Authors: *F. C. HUANG[1], J. L. PATTON[2], C. FRITSCHE[3];
[1]Shirley Ryan Abilitylab, Chicago, Illinois, IL; [2]Sensory Motor Performance Prog, Rehab Inst. Chicago, Chicago, IL; [3]Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland

Abstract: This study tested a novel form of assistance for motor skill training: Velocity Error Augmentation (VelEA). Our task paradigm considered error as the lateral deviation of the hand moving along a path between a start to a stop target. Our augmentation scheme makes use of robot rendered forces, designed to be proportional to only the components of velocity that point perpendicularly away from the straight line representing the ideal path. From a causality point of view, error in velocity precedes errors in position space. Hence, we hypothesized that augmentation of velocity error would, in particular, facilitate adaptation of planning, or feedforward aspect of control. As a secondary hypothesis, we expected that augmentation forces could help adaptation when visual feedback is not reliable. In order to test VelEA, we developed a 3-dimensional point-to-point reaching task using a 3-DOF robot and stereo feedback visual display. The protocol consisted of four phases: baseline, training, testing, and washout. As a novel visuomotor environment, we presented a 60-degree visual rotation during the training and testing phases. We tested twenty neurologically intact subjects, randomly assigned to two groups (force and control). During the training phase, the force group received forces based on velocity error augmentation, while the control group did not receive forces. Our results were striking in that while the direct effects of training with forces were strong, the results in learning were quite similar. Our analysis showed that both groups adapted to the novel environment and exhibited characteristic after-effects. The groups were comparable in pre/post change for maximum perpendicular error. However, the force group significantly reduced depth error (p=0.0008),

whereas the control group exhibited only marginally significant reductions (p=0.053). These preliminary results suggest that VelEA can benefit motor skill training in cases with limited visual feedback. It is also possible that the velocity-based forces in this study promoted increases in co-contraction, which diminished or masked the effects of learning. Another possibility is that the nervous system places a greater priority on spatial error than on higher-order movement variables. This study provides an important foundation for the study of velocity error augmentation. Further study is needed for how to better facilitate adaptation specifically such higher order variables with forces or other forms of augmentation.

Title: The integrative role of the M1 for the motor sequence learning

Authors: *Y. H. HAMANO[1], S. K. SUGAWARA[2,3], M. FUKUNAGA[2,3], N. SADATO[2,3]; [1]Natl. Inst. For Physiological Sci., Okazaki, Aichi, Japan; [2]Natl. Inst. for Physiological Sci., Okazaki, Aichi, Japan; [3]SOKENDAI, Hayama, Japan

Abstract: Primary motor cortex (M1) is known to be crucial in motor learning. Our previous study demonstrated that distinct motor engrams are formed depending on the training modes, specifically left anterior intraparietal sulcus with the speed pressure training (maximum mode, as quickly accurately and as possible) and bilateral dorsal premotor areas and M1 through visually cued training without speed pressure, (constant mode) (Hamano et al. 2019). It is unknown if the motor engrams generated by different learning procedures are integrated into the M1. Evaluation of the motor engram in M1 is difficult because their active states are hard to discriminate from the motor execution per se. As preparatory activity is known to reflect the parameters of the upcoming movement, we hypothesized that the retrieval of motor engrams generated by different learning modes is reflected as learning related increase in the preparatory activity of M1. To test this hypothesis, we evaluated the preparatory activity during the learning of sequential finger tapping with the non-dominant left hand using 7TMRI. The task was consisted of maximum mode and constant mode alternatively with the rest epoch right after each epoch of both modes for 30 minutes duration of time. Participants performed the sequential finger tapping task as quickly and as possible during the max mode, and as accurately as possible with the 2 Hz paced sequence specifying visual cue during the constant mode. At the beginning of each epoch, the

instruction message appeared for 2 secs to instruct participants to do either maximum or constant mode. We estimated the preparatory activity map related to each instruction. Then, we calculated the increased activities across the training in each mode. We found a training-related increase in preparatory activity in the network covering bilateral anterior intraparietal sulcus and inferior parietal lobule extending to right M1 during the maximum mode, and right M1 during the constant mode. Conjunction analysis showed the preparatory activity in right M1 commonly increased in both training modes. Present findings indicate that right M1, as the last effector of the motor output, integrates the distinct motor engrams generated by different training modes.

Title: Altered alpha and beta oscillations in parietal and occipital cortices in chronic jaw pain

Authors: *W.-E. WANG, R. HO, S. A. COOMBES;
Univ. of Florida, Gainesville, FL

Abstract: Motor- and pain-related processes separately induce a reduction in alpha and beta power over sensorimotor cortex. When movement and pain occur simultaneously, the effects on alpha and beta power are additive, but this has only been demonstrated in healthy adults when the pain eliciting stimulus and the movement are spatially and temporally overlapping but are independent of one another. Hence, very little is known about the cortical processes underlying motor-evoked pain. In the current study, we combined high-density electroencephalography with a paradigm in which motor-evoked pain was induced during a visually-guided jaw force task. Eighteen human participants with chronic jaw pain and sixteen control participants produced jaw force at 2% and 15% of their maximum voluntary contraction (MVC). We report 2 novel findings. First, compared to controls, task performance in the chronic jaw pain group was associated with an increase in motor-evoked jaw pain, an increase in motor variability, and an increase in motor error. Second, rather than being additive, motor-evoked pain attenuated the modulation of alpha and beta power, and this was most evident over parietal and occipital regions. Our findings provide the first evidence of the neural basis of motor-evoked jaw pain, and are in line with previous studies that link chronic pain with deficits in attention and visuomotor brain networks.

Abstract: Sensorimotor control of visually guided arm movements uses visual feedback to relate current limb position with a desired location. To compensate for long feedback delays, an internal prediction of movement is used to enable corrective movements. In persons with Multiple Sclerosis (PwMS) who have upper extremity dysfunction, a mismatch between the predicted and actual visual feedback delay during goal-directed movement has been reported. The goal of this research was to identify neurological correlates of the visual delay mismatch using electroencephalography (EEG) to characterize brain activity while subjects performed a reach and hold task.

Seven PwMS (5 male, 33-58 years) and 6 gender and age-matched controls (4 male, 32-60 years), all right handed, performed a reach and hold task using a 1-D passive wrist manipulandum while 64-channel EEG was recorded simultaneously. During the task, participants were asked to continually place a user-controlled cursor onto a target. The target would pseudorandomly move once every 3.0-5.5 seconds to a new position throughout ten, 50 second trials. Cross-correlation between the target displacement and the participant's response was used to estimate the visual feedback delay of each participant. The predicted visual delay was quantified using a submovement interval analysis of the velocity data. After typical EEG preprocessing, task related magnitude squared coherence (MSC) was calculated for all electrode pairs in the alpha [8 12] Hz and beta [14 30] Hz frequency ranges during target reach and stabilization to measure the synchronization between brain regions.

On average, PwMS had a larger mismatch between the predicted and actual visual feedback

delay. Compared with controls, PwMS had a decreased local MSC (average MSC of the adjacent electrodes) over parietal and motor regions for alpha frequencies and over motor regions for beta frequencies. In the alpha band, the visual delay mismatch in PwMS was well correlated with the MSC between contralateral parietal electrode (CP5) and ipsilateral parietal electrodes across subjects. More extensive correlations were seen in the beta band between occipital-parietal (O2:CP5), occipital-motor (O2:C3), and parietal-motor (CP5:C6) electrodes. These results suggest upper extremity dysfunction with visual delay mismatch is associated with a reduction in functional connectivity within sensory integration areas of the brain. Future studies will examine how the changes in cortical connectivity impact cerebellar-cortical processing of goal directed movements in PwMS.

Title: Associations of cortical thickness and surface area with dexterity measures in mild cognitive impairment

Authors: *S. A. CASTRO-CHAVIRA[1], O. VASYLENKO[2], T. R. VANGBERG[4], M. M. GORECKA[3], K. K. WATERLOO[1], C. RODRIGUEZ-ARANDA[1];

Abstract: Novel clinical research showed that manual dexterity deteriorates in Mild Cognitive Impairment (MCI). However, no experimental data corroborating this finding exists. Because cerebral atrophy is documented in MCI, the present study aims to explore the association between dexterity declines as measured by a detailed kinematic analysis and gray-matter cortical thickness and surface area in patients with MCI and healthy older controls. Both dominant and non-dominant hand abilities were investigated. Method: 16 right-handed MCI patients (mean age 70.4 y, 10 women) and 20 right-handed healthy elderly (mean age 70.4 y, 13 women) were tested with the Purdue Pegboard test and video recorded with Vicon Motus to calculate movement

times (MT) and kinematic parameters for reaching, grasping, transport and inserting. T1-weighted MR brain images, acquired on a 3T MR scanner, were processed using the FreeSurfer pipeline. The associations of cortical surface area and thickness with MTs and kinematics, including path length and linear velocity, were analyzed with the general linear model controlling for age and gender, and results were corrected for multiple comparisons. *Behavioral results*: A main effect of hand was observed across all dexterity measures. For MTs, group differences were found for reaching ($p<0.000$) and grasping ($p<0.01$), while interactions existed between hand and group ($p<0.01$) in reaching and transport. Mean linear velocity (MLinV) showed interactions on reaching ($p<0.001$) but no group differences. For path length, there were significant interactions during grasping ($p<0.001$) and inserting ($p<0.01$). For grasping, only path length differed between the groups ($p<0.001$). *MRI results*: No group differences were found on cortical thickness or surface area. However, we found an interaction between group and gender in the left lateral orbitofrontal cortex. A positive association existed between cortical thickness and MLinV during transport of pins on right hand in left frontal and parietal regions (11 clusters, $2.88<z<5.92$) and a positive correlation between cortical surface and MLinV for transport was found on left hand, which differed between MCI and controls in the right *pars triangularis*. This correlation had a steeper slope for controls. Conclusions: The MCI subjects had dexterity declines in terms of larger MTs for both hands and disproportionate path lengths for the left hand. Although groups did not differ on MLinV, this measure was the only one showing a correlation that differentiated the groups where larger cortical thickness corresponded to faster hand movements.

Title: Action planning emerges from competition between value and motor representations

Authors: *J. M. FINE, S. BOEGE, M. SANTELLO;
Arizona State Univ., Phoenix, AZ

Abstract: Individuals must often choose how to move among potential alternatives before a motor goal is specified. This is experimentally examined using a ‘go before you know’ task, wherein individuals start reaching towards multiple potential targets before a target is specified.

Initial movements are often aimed midway between targets when they are equally likely. Early theories posited this phenomenon occurred via dorsal pre-motor (PmD) areas representing multiple motor plans that compete for expression and are 'incidentally' averaged. Averaging can be biased by both differential target-reward or -spatial separation. These averaging effects indicate motor plans compete for expression in a value and sensorimotor space. An alternative explanation is that midway reaching results from goal-uncertainty, decisions are indifferent to sensorimotor contingencies, and only a single motor plan is represented. Herein, we tested a third alternative: initial reach decisions are driven by 'purposeful' (Bayesian) averaging of motor plans: initial reach plans emerge from an adjudication between control policies weighted by their expected utility denoted by target value and risk. We tested this in humans performing a "go before you know" reach task with two potential targets. We scaled relative monetary reward and risk of targets. By defining 'risk' as the target size scaled to individual's baseline motor variability, we could generate an expected utility of each target. Behaviorally, initial reach angles were strongly and linearly related to the relative expected utility (REU) of potential targets (R^2=0.85), even though targets were equally likely to be specified. REU effects on initial angles were independent of reaction time (r=0.05), delays in initiation were unrelated to motor plan expression. This indicates decisions involved an averaging competition process in both value and motor spaces. We examined source-based EEG of sensorimotor, frontal, and parietal cortices to estimate neural planning processes involved in this purposeful averaging. Supporting our hypothesis, PmD planning activity encoded both value and risk, and scaling of its activity (power) was contingent on the relative expected target utility, rather than a target with maximum utility. Our behavioral and neural results support a purposeful averaging mechanism in motor planning.

Title: Resting-state functional connectivity and ophthalmic changes associated with a spaceflight analogue environment

Authors: H. MCGREGOR[1], J. LEE[2], N. GADD[3], I. KOFMAN[3], Y. DEDIOS[3], J. BLOOMBERG[4], A. MULAVARA[3], *R. D. S. SEIDLER[5];

Abstract: Following spaceflight, astronauts exhibit functional remodeling of the brain, impairments in sensorimotor performance and, in approximately 30% of cases, ophthalmic abnormalities collectively known as Spaceflight Associated Neuro-ocular Syndrome (SANS). Astronauts are exposed to microgravity and elevated CO_2 levels onboard the International Space Station. It is unclear how microgravity and elevated CO_2 combine to affect the brain and behavior. We investigated this issue using 6º head-down tilt bed rest with elevated ambient CO_2 (HDTBR+CO_2) as a spaceflight analog. This bed rest intervention was the first of its kind to induce signs of SANS in a subset of the healthy subjects. Here we present differential profiles of brain and behavioral changes following bed rest for those subjects who developed signs of SANS compared to those who did not. We examined brain function in terms of resting-state functional connectivity. We assessed sensorimotor behavior using dynamic posturography to assess balance, and a rod and frame test to assess visual sensory bias. Eleven healthy subjects participated in this study. Subjects underwent a 14-day baseline phase followed by 30 consecutive days of HDTBR in 0.5% ambient CO_2. By the end of the HDTBR+CO_2 phase, 5 of the 11 subjects had developed optic disc edema, a sign of SANS. After bed rest, subjects underwent a 14-day recovery phase which involved physiotherapy. Resting-state fMRI and behavioral measures were each acquired twice during the baseline phase, twice during the HDTBR+CO_2 phase, and twice during the recovery phase. We found that those subjects who developed signs of SANS during HDTBR+CO_2 exhibited different functional connectivity patterns prior to bed rest compared to subjects who did not develop signs of SANS. Subjects who exhibited functional connectivity between the insula, motor, and memory brain areas at baseline were those who went on to develop signs on SANS during HDTBR+CO_2. Following bed rest, subjects who developed signs of SANS exhibited increased functional connectivity between primary visual and premotor cortices, as well as decreased functional connectivity between posterior cingulate and primary visual cortices. These connectivity changes are suggestive of bed rest-associated multisensory reweighting. Supported by NASA 80NSSC17K0021.

Title: Neural mechanisms of obstacle avoidance: Obstacle avoidance differs from planning and execution of collision-free trajectory

Authors: *J.-K. RYU[1,2], H. JOO[3], S. KIM[1,4], M. SEO[3], K.-M. LEE[5,3];
[1]Inst. for Cognitive Science, Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Dept. of Physical Educ., Dongguk Univ., Seoul, Korea, Republic of; [3]Interdisciplinary Program in Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of; [4]Neurosci. Res. Institute, Gachon Univ., Incheon, Korea, Republic of; [5]Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of

Abstract: Humans and animals can move safely and efficiently in very complex environments. The ability to avoid obstacles plays a vital role in successful movements in complex environments as well as the ability to approach the target. Although it is widely known that parietal cortex plays an important role in moving towards the target, much remains to be unknown about the neural mechanisms of obstacle avoidance.
The purpose of this study is to examine the neural mechanisms of obstacle avoidance and to show that obstacle avoidance cannot be explained by the planning and execution of collision-free paths, which is often referred to as waypoint passing.
Forty-eight healthy adults participated in the study and all procedures were performed with the approval of Seoul National University IRB. The participants used a joystick in the fMRI scanner to make the cursor displayed on the screen to arrive at the target point as accurately and quickly as possible. Experimental conditions consisted of four types: direct movement, obstacle avoidance, waypoint passing, and stopping. In the direct movement condition, participants moved the cursor to the target point as fast as possible. In the obstacle avoidance condition, participants moved the cursor to the target point avoiding collision with the obstacle. In the waypoint passing condition, the participants moved the cursor to the target point through the intermediate waypoint. In the stop condition, participants waited without moving the cursor. All conditions were presented in random order. The collected fMRI data were analyzed by SPM 8 software, and the neural activities related to obstacle avoidance were examined through the contrast between obstacle avoidance, waypoint passing, and direct movement conditions.
The analysis showed that the neural activity of the right superior parietal cortex was larger in the condition of avoiding obstacles than the condition of the waypoint passing. This neural activity did not appear to be significant in the stopping condition and the direct movement condition, and the activity of the right superior parietal cortex was confirmed to be a unique neural activity to avoid obstacles.
If obstacle avoidance is simply planning and executing collision-free trajectories, there should be no difference in the neural activity between obstacle avoidance condition and waypoint condition. However, we showed that the neural activity involved in obstacle avoidance was different from that of waypoint passing. Therefore, it was confirmed that avoidance of obstacles cannot be explained by simply planning and executing a collision-free trajectory.

Title: Functional neural changes in response to head-down tilt bedrest with elevated CO_2 during a sensorimotor dual task

Authors: *A. D. MAHADEVAN[1], K. E. HUPFELD[1], J. K. LEE[2], Y. E. DE DIOS[3], I. S. KOFMAN[3], N. E. GADD[3], J. J. BLOOMBERG[4], A. P. MULAVARA[3], R. D. SEIDLER[1]; [1]Dept. of Applied Physiol. and Kinesiology, Univ. of Florida, Gainesville, FL; [2]DLR (Deutsches Zentrum für Luft- und Raumfahrt e.V, Cologne, Germany; [3]KBRwyle, Houston, TX; [4]NASA Johnson Space Ctr., Houston, TX

Abstract: Spaceflight and microgravity cause well-characterized changes in sensory weighting processes, central fluid distribution, and musculoskeletal structure and it is important to assess how these changes affect our ability to integrate sensorimotor information. Ground-based spaceflight analogues incorporating 6° head-down tilt bedrest (HDBR) are often used to simulate microgravity and its associated physiological changes but, recently, it has been hypothesized that combining HDBR with elevated carbon dioxide (CO_2) might better mimic the conditions of a closed environment like the International Space Station. Dual task cost is a sensitive indicator of change in central motor function, and one that is affected by HDBR. Here, we examine how a 30-day HDBR intervention, including 0.5% ambient CO_2, changes human performance and functional brain activity during single and dual task conditions. The task involved three phases in which participants i) counted the number of times an oddball stimulus was presented among distractor stimuli; ii) tapped one of two buttons in response to a visual cue at a rate of 1 Hz; and iii) performed both tasks concurrently. 11 participants (6 males) underwent functional MRI (fMRI) during the task: twice prior to HDBR+CO_2, twice during HDBR+CO_2, and twice following HDBR+CO_2, allowing us to assess changes with HDBR+CO_2 as well as subsequent recovery. Behavioral measures included reaction time and tapping accuracy during both the tapping and dual conditions, as well as counting accuracy during the counting and dual conditions. fMRI data were evaluated at an uncorrected $p<.001$. These exploratory analyses revealed areas following varying patterns of change and recovery, with some regions displaying only an initial change with the intervention while other regions displayed a dose-dependent effect. Across all task conditions, changes were found in the precentral, postcentral, and superior frontal gyri, all areas associated with sensorimotor or cognitive functions. Patterns of activation

change as they correlate with behavioral change differed by task condition. The tapping condition showed better accuracy/shorter reaction time with more activation, but the dual task condition showed a more compensatory pattern. When compared to our previous HDBR investigation, we found that the increased ambient CO_2 may have altered patterns of activation change seen throughout the brain. Together, these findings provide information about the additional and/or interactive effects of CO_2 administration with HDBR and about how spaceflight conditions may impact the brain's ability to maintain function during sensorimotor interference.

Title: Spectral power fluctuations induced in electrocorticography during spontaneous upper-limb movements

Authors: *S. M. PETERSON, S. SINGH, R. P. N. RAO, B. W. BRUNTON;
Univ. of Washington, Seattle, WA

Abstract: Much of our knowledge of human motor movements have come from relatively short, controlled laboratory paradigms. However, it is unclear how well these results generalize to natural settings, where actions occur spontaneously and throughout the entire day. Therefore, we are motivated to study long-term electrocortical activity "in the wild," where movements are unconstrained by experimental paradigms. We analyzed electrocortical activity from 4 patients with intractable epilepsy using electrocorticography (ECoG) as they performed spontaneous wrist movements across 5 days of clinical recording. Wrist movements were identified by applying computer vision to continuous video recordings (Wang et al. 2018). To quantify movement-related electrocortical activity, we computed time-frequency power spectrograms at every contralateral surface electrode, averaged across over 500 spontaneous events. Based on previous ECoG findings performed in a controlled experimental setting (Miller et al. 2007), we expected movement events to decrease ECoG power at low-frequencies (8-32 Hz) and increase

power at high-frequencies (76-100 Hz), primarily in electrodes near sensorimotor cortex. Our results corroborated this expectation (Figure 1). In addition, high-frequency power fluctuations were localized to sensorimotor areas, while low-frequency power fluctuations were more widespread across the cortex. We found a consistent spectral power pattern that spatially overlapped between subjects and across days during spontaneous movements. Using this framework, we can explore how electrocortical power varies across days and in a greater number of subjects. Such an approach could enhance our understanding of how cortical activity relates to unconstrained, natural behavior outside of traditional experimental settings.

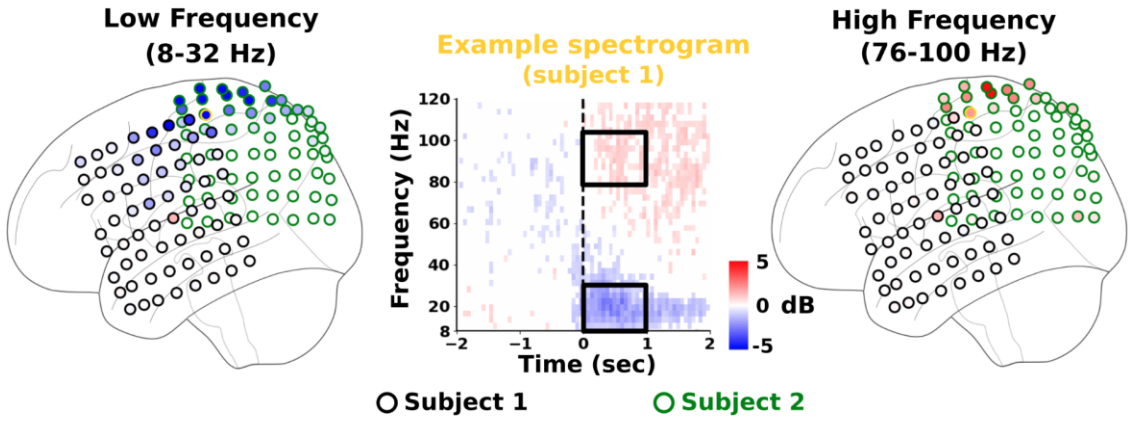

Figure 1: Electrocorticography (ECoG) spectral power during spontaneous wrist movements for 2 of the 4 subjects, with an example spectrogram showing how we averaged spectral power across frequency bands.

Title: Mobile brain imaging in cooperative and competitive tennis play

Authors: *T. C. HAUGE[1], A. K. STUDNICKI[2], R. D. SEIDLER[1], D. P. FERRIS[2];
[1]Applied Physiol. & Kinesiology, [2]Biomed. Engin., Univ. of Florida, Gainesville, FL

Abstract: Recent advances in EEG hardware and data analysis methods allow for examination of brain activity while participants freely move outside of the laboratory (e.g. Gramann et al., 2011; Nordin et al., 2019). Here, we leverage this technology to study the brain dynamics of cooperative and competitive interactions while participants play tennis. Previous functional MRI

work on the neural bases of cooperative versus competitive dyadic interactions show increased activation in the prefrontal and orbitofrontal cortex during cooperation as opposed to competition (Decety et al., 2004; Lee et al., 2018). Additional work in EEG shows increased mu suppression in sensorimotor regions in dyadic competitive interactions versus cooperative/perceptual interactions (Perry et al., 2011). We hypothesize that electrocortical activity will show increased theta and alpha spectral power in the medial prefrontal cortex and left medial orbitofrontal cortex during cooperative versus competitive play conditions. We also hypothesize that dorsolateral prefrontal cortex will exhibit increased synchronization during competition, and that there will be greater mu suppression at 8-13 Hz in the sensorimotor cortex during competition compared to cooperation. In this project, tennis participants are outfitted in mobile, high density dual-layer EEG equipment (BrainVision^{TM}), inertial measurement units (Cometa^{TM}) for upper limb kinematics during play, and instrumented insoles (novel^{TM}) to record force and stance data related to gameplay. All data streams are synchronized with a square wave pulse. Subjects play with a human player in both competitive and cooperative settings. We examine changes in power spectra across multiple frequency bands (theta, alpha, beta, and gamma) as well as differences in event related spectral perturbations time-locked to racquet-to-ball contact. The findings of this study contribute to the larger body of knowledge surrounding the link between the brain and the body during dynamic movements executed in a real-world environment. Moreover, results will explore the influence of dyadic interactions during real-time sport game play and how changing social contexts are expressed in neural dynamics during tennis.

Title: Task-evoked and spontaneous brain activity characterizes individual differences in a function dictating frequency-rhythmicity relationship

Authors: *K. UEHARA[1,2], H. TOGO[3], T. HANAKAWA[3];
[1]Div. of Neural Dynamics, Natl. Inst. for Physiological Sci., Okazaki, Japan; [2]Integrative Brain Imaging Ctr., [3]Dept. of Advanced Neuroimaging, Integrative Brain Imaging Ctr., Natl. Ctr. of Neurol. and Psychiatry, Kodaira-Shi, Japan

Abstract: When controlling a sequential movement such as keystrokes during piano playing, precise rhythmicity is required even though movement-frequency is increased. However, this ability has high individual variability that is likely to arise from neural systems. Yet, little is known about the neural substrates underlying individual differences in a frequency-rhythmicity (FR) function. To address this, we investigated relationships between task-evoked activity or spontaneous brain activity and an FR function during rhythmic movement.During task-fMRI, twenty-four healthy participants were asked to perform a finger tapping task with their right index finger at four different rates (0.25, 1, 2, 3 and 4 Hz) paced by auditory cues. Resting-state fMRI was acquired before the task-fMRI. As a measure of tapping rhythmicity, we calculated a coefficient of variation (CV) of the inter-tapping intervals in the 1-4 Hz conditions in each individual. To define individual differences in an FR function, CV values from 1 to 4 Hz were fitted by a linear regression model within each participant. The beta variable obtained from the liner regression model from each participant was treated as a parameter representing the FR function. After preprocessing of task-fMRI data, a first-level general liner model analysis included a parametric regressor modeling 5 different movement rates to capture brain activity correlated with the tapping rates. A correlation analysis between the FR function and task-related brain activity was then performed at the second level. The resting-state networks were examined based on regions of interests covered the whole brain. We then explored resting-state networks correlated with the FR function in a second-level.Task-related activity in the anterior cingulate cortex (ACC) and right middle frontal gyrus (MFG) was negatively correlated with the tapping frequencies, and, moreover, accounted for individual differences in the FR function. Individual differences in the FR function were also correlated with spontaneous activity fluctuation in the resting-state networks linking between the left ACC and right middle temporal gyrus (MTG) and between the right paracingulate gyrus and left MTG. Our findings suggest that individual differences in the FR function may be tagged with neural systems within task-evoked and spontaneous brain activities.

Title: The asymmetry of antagonistic muscle systems makes equilibrium joint postures dependent on muscle strength

Authors: *R. RAMADAN, G. SCHÖNER;
Ruhr-Universität Bochum, Bochum, Germany

Abstract: Central to Equilibrium Point thinking is that movement commands are spatial variables, the muscle threshold lengths, λ [Feldman, 1995]. When agonist and antagonist muscles are symmetrical, a joint reference configuration, R, can be computed from these threshold lengths. Realistic muscle systems, however, comprise muscles of different lengths, insertions, and strengths so that agonist and antagonist muscles are not symmetrical. The zero crossing of active joint torque then depends not only on muscle threshold lengths, but also on the levels of force generated by each muscle. Based on a neuro-muscular model of control, we simulated arm movements by obtaining time courses of muscle threshold lengths, λ(t), that minimized their change while bringing about movements of a prescribed direction, extent, and duration. From the simulated movements, we computed at each point in time, the virtual attractor position to which the arm would converge in the absence of external forces [Hodgson, 2000]. We compared such virtual attractor joint trajectories to the time courses of the joint reference trajectories, R(t). We found that virtual attractor trajectories were shifted from joint reference configurations such that stronger muscles were shorter. Significant structural differences between the two types of trajectories were consistent with threshold lengths, λ(t), reflecting constraints at the level of muscle force, including interaction and inertial torques.

Title: Inverting a model of neuro-muscular control to estimate central commands for fast reaching movements

Authors: C. HUMMERT, *G. SCHONER;
Inst. für Neuroinformatik, Ruhr-Universität Bochum, Bochum, Germany

Abstract: A longstanding debate surrounds the complexity of central commands for fast reaching movements. Early evidence for N-shaped virtual trajectories [2] suggested that central commands reflect biomechanical constraints. Simulations of a model that takes biomechanics, muscle dynamics, and neural reflex loops into account [1] provided evidence that monotonic ramp-like virtual trajectories may be sufficent central commands to overcome interaction torques and inertial coupling [1,3]. Direct estimation of the descending commands within such models may be a way to settle such questions.
We developed a two-step inverse dynamics approach, in which joint torques are first estimated from kinematic data in the conventional way, and then descending commands are estimated by inverting the model of muscle force generation under reflex control [1] under a number of

simplifying assumptions. We applied the method to a data set that samples workspace and movement time. Participants performed planar movements involving the shoulder and elbow joint. Two long (0.4m) and six shorter (0.25m) movements sampled workspace. Fast (400ms duration) and slow (800ms duration) conditions sampled movement speed. The estimated commands approximated a monotonic ramp from initial to end position for the slow movements, while commands for fast movements had a non-monotonic form, first overshooting and then returning to the target.

Title: Reconstruction of threshold muscle lengths underlying reaching movements

Authors: *L. ZHANG, G. SCHÖNER;
Ruhr Univ. Bochum, Bochum, Germany

Abstract: According to the Equilibrium Point Hypothesis, arm reaching movements may result from changes in a referent arm configuration that specifies the threshold lengths at which muscles begin to be activated. Muscle activation and force generation is driven by the deviation of the actual from the referent configuration. This study aims to reconstruct commanded threshold lengths underlying single-joint reaching movements, based on a referent control model that integrates biomechanical muscle properties. We first performed unloading experiments at 4 levels of initial load. To keep commanded muscle thresholds invariant, subjects were instructed not to intervene after the unloading of the pre-loaded wrist muscles. We recorded voluntary wrist movements at different speeds (fast, medium and slow) and reconstructed the time course of threshold muscle lengths by fitting the model to experimental kinematics and EMG patterns. Reconstructed threshold muscle lengths were non-monotonic (N-shaped) during fast movements but monotonic and similar to the joint trajectories during slow movements. The N-shaped commanded threshold lengths may reflect dynamical properties of the neuromuscular system

during fast movements. Possible influences of reciprocal inhibition and of other factors on the estimation of the time course of commanded threshold lengths are discussed.

Title: On the consistency of preferred movement speed

Authors: *R. J. COURTER, IV[1], A. A. AHMED[2];
[1]Integrative Physiol., Univ. of Colorado Boulder, Boulder, CO; [2]Mechanical Engin., Univ. of Colorado, Boulder, CO

Abstract: Understanding preferred movement speed is vital for characterizing overall health and for indicating underlying movement disorders. Preferred walking speed correlates with mortality in older adults, while diseases like Parkinson's exhibit movement slowing [1], [2]. Though preferred locomotion speeds are relatively well understood, preferred reaching speeds have not yet been well described [3]. We sought to develop a robust protocol to elicit preferred reaching speeds in an objective manner by minimizing external or instructional biases. We tested whether subjects converged to a preferred speed, and whether this speed was conserved across individuals. Subjects were required to make a series of 10cm reaches from a central starting circle to one of 8 radial targets. Each subject performed reaches under 5 prescribed durations (400, 550, 700, 850, and 1000ms) in randomized order. Initially, subjects were required to move to the target within the prescribed duration while "held" within constraints of +/-25ms. The time constraints on the duration slowly loosened, or "released," unbeknownst to the subject, allowing reaches to be performed slower or faster as desired. The speed at which a subject tended to converge was considered their preferred speed. These speeds were compared to pre and post unconstrained, baseline reaches. Using a linear mixed effects model, we found a main effect of time ($p << 0.001$) and condition ($p << 0.001$). There were no between subject differences in preferred reaching speeds ($p > 0.05$). There was a significant time-condition interaction ($p << 0.001$), indicating that subjects increased or decreased peak velocity at different rates dependent upon the prescribed duration. Preferred reach duration lies somewhere between 550 and 700ms. Unconstrained reaches showed high variability in speeds within and between subjects, suggesting that unconstrained reaches may not be an adequate metric for preference. Results indicate that young adults have similar preferred speed when making 10cm reaches, around

0.276m/s, and tend to exhibit elasticity in returning to this preference, supporting our initial hypotheses. Understanding the preferred reaching speeds is a vital metric for understanding how the CNS executes motor control, and how movements alter with age or disease.

Title: Effect of travel effort on movement vigor during foraging

Authors: *S. SUKUMAR[1], R. SHADMEHR[2], A. A. AHMED[3];
[1]Dept. of Computer Sci., Univ. of Colorado Boulder, Boulder, CO; [2]Dept Biomed. Eng, Johns Hopkins Univ. Dept. of Biomed. Engin., Baltimore, MD; [3]Departments of Mechanical Engin. and Integrative Physiol., Univ. of Colorado, Boulder, CO

Abstract: During foraging, animals stay at a site and harvest reward, and then travel to the next reward site with a certain vigor. This behavior entails decision-making regarding how long to stay and harvest, and motor-control regarding how fast to travel to the next reward opportunity. Previous work has generally focused on the decision-making problem, producing the Marginal Value Theorem (MVT) [1]. However, the question of how the brain determines vigor of movements remains poorly understood. In a previous study [2], we extended MVT [1] to predict how travel vigor should vary as a function of the experience of the animal. That theory predicted that experience of low reward rates should result in slower movements between reward sites. Here, we tested some of the predictions of this theory in humans during a task that entailed reaching between reward patches.
We designed an arm reaching experiment that emulated a patch-foraging task. Seated subjects (n=6) performed horizontal planar arm reaches to travel between “patches” of reward. Once in a patch, reward was dispensed at a hyperbolically depleting rate. Subjects were free to leave a patch in favor of the newly replenished one at any time. Travel effort between patches was modulated by simulating added mass (m) via forces generated by the robot. Subjects performed foraging in two environments each with 200 trials, one with high travel effort (m = 3.5 kg) and one with a low travel effort (m = 0 kg). The order of the experienced environments was

randomized across subjects. 40 trials in each environment were deemed 'probe' trials with intermediate travel effort (m = 2kg). Vigor of reaches was quantified via peak velocity and movement duration.
We observed that people reduced the vigor of their reaches in response to higher effort. Vigor was higher in the low effort trials (m=0kg) compared to probe trials (m=2kg, $p<<0.001$), and was correspondingly lower in the high effort trials (m=3.5kg, $p<<0.001$), as predicted by the MVT model. However, the theory additionally predicted that vigor associated with identical travel effort, would also be modulated by the travel effort in the environment. Contrary to model predictions, there was no significant difference in vigor between probe trials (m=2kg) in the two environments ($p>0.1$). Our findings therefore suggest that travel effort modulates the utility rate of the environment differently than assumed by the MVT framework.

Title: Distinct neural signals in speech preparation differentially modulate auditory responses

Authors: *S. LI[1,2], H. ZHU[2,3], X. TIAN[2,3];
[1]East China Normal Univ., Shanghai, China; [2]NYU-ECNU Inst. of Brain and Cognitive Sci., Shanghai, China; [3]New York Univ. Shanghai, Shanghai, China

Abstract: Actions influence sensory processing in a complex way to shape behavior. For example, it has been hypothesized that during action, a copy of motor signals -- termed corollary discharge or efference copy -- can be transmitted to sensory regions and modulate perception (motor-to-sensory transformation). Such mechanisms have been evident among animal species

and are extended to human speech production and control. Previous speech studies focus on the interaction between production and perception during articulation. However, the functional specificity of motor signals along the entire course of speaking, including intention, preparation, and execution, is far from clear. Theories have been proposed that corollary discharge and efference copy are two separate forms and generated at different stages of actions. Specific in speech, we hypothesized that the content in the motor signals available at distinct preparation stages determined the nature of signals (corollary discharge vs. efference copy) and constrained its modulatory functions on sensory processing. We tested this hypothesis in 3 experiments by recording electroencephalography (EEG) in a novel preparation-perception-delayed-vocalization paradigm. In Experiment 1, participants (total of 16, 5 males, mean age of 23.1) prepared to vocalize a syllable according to visual cues that were either symbols (general preparation, GP) or syllables in red (specific preparation, SP). When a syllable in green appeared, participants rapidly pronounced it. During each preparation stage, a 1k Hz pure tone or a syllable sound was presented to probe the modulatory function of preparatory signals. We found that SP enhanced the neural responses to the prepared syllables around 100ms after sound onset (presumably efference copy). In Experiment 2 (19 participants, 5 males, mean age of 23.9) where only GP condition was included and trials without auditory stimuli were added, we found neural suppression (presumably corollary discharge). In both experiments, the modulation effects were absent in the responses to tones that were hard to produce with human articulators and irrelevant to the task, suggesting the signals available during preparation and their functions are motor and action specific. In Experiment 3 (17 participants, 4 males, mean age of 23.9), the attentional modulation were different from motor preparatory modulation in the first experiment, and hence we ruled out the confound. These consistent results suggest that before action execution distinct motor signals can be generated in the motor-to-sensory transformation and integrated with sensory input to modulate perception.

Title: The effect of spatial and verbal working memory on different inputs to the corticospinal neuron

Authors: M. W. LENIZKY, *S. K. MEEHAN;
Kinesiology, Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Volitional allocation of cognitive resources modulates afferent input projected on to corticospinal neurons. Short-latency afferent inhibition provides a method to probe the modulatory effects of somatosensory afference upon corticospinal output. Short-latency afferent inhibition involves preceding a monophasic transcranial magnetic stimulus with electrical stimulation of the corresponding peripheral nerve. Manipulating the monophasic current direction of the transcranial magnetic stimulus provides a method to probe the modulatory effect of somatosensory afference to specific corticospinal inputs. For example, we previously demonstrated that non-spatial attention selectively modulated somatosensory projections of corticospinal inputs sensitive to the anterior-posterior (AP) stimulating current whereas verbal working memory demands modulated somatosensory influence over inputs sensitive to both posterior-anterior (PA) and AP stimulating current. The present study determined whether spatial working memory load selectively influences somatosensory afference to PA- and AP-sensitive corticospinal inputs. Participants completed two similar sessions during which short-latency afferent inhibition was elicited, using PA or AP monophasic current, during the maintenance period of a modified Sternberg short-term memory task. Session 1 - Spatial memory task: Participant were required to encode a spatial display and maintain the spatial array in working memory to determine whether a probe matched or did not match the original display. The spatial array consisted of either two or six dots arrayed around a central fixation cross. Session 2 - Verbal memory task: Participants were required to encode and maintain a set of letters arranged in a concentric circle around a central fixation cross. The probe consistent of a single letter and participants indicated whether the probe was part of the initial set of letters. The verbal set consisted of either two or six letters. Preliminary results suggest that increasing spatial set size selectively reduced AP short-latency afferent inhibition, whereas increasing verbal working memory set size decreased both PA and AP short-latency afferent inhibition. The present results suggest that spatial and verbal working memory influence different inputs to the corticospinal neuron. The different inputs may provide distinct pathways by which declarative strategies can shape procedural motor control.

Title: Intracranial evidence for retrieval of movement goals by the hippocampus

Authors: *D. M. HUBERDEAU[1,2], C. F. A. BENJAMIN[3,4], D. D. SPENCER[3], J. L. GERRARD[3], G. MCCARTHY[1,2], N. B. TURK-BROWNE[2,1];
[2]Psychology, [1]Yale Univ., New Haven, CT; [3]Dept. of Neurosurg., [4]Psychology, Yale Sch. of Med., New Haven, CT

Abstract: Motor skills rely on the accurate selection of movement. For example, a baseball batter must produce the correct swing at just the right moment. The information indicating what movement is required is often encoded in arbitrary sensory cues (e.g., angle of pitcher's arm, spin of ball laces), whose interpretation requires memory recall. There is ample evidence that neural activity in the neocortex, especially primary motor cortex (M1) and dorsal premotor cortex (PMd), during the pre-movement period represents information pertaining to the upcoming movement. How are pre-movement representations of movement goals instantiated in these cortical areas when elicited by sensory cues with no direct affordances? We hypothesized that the hippocampus facilitates preparation of movement in M1 and PMd through a predictive coding mechanism when the goals of that movement rely on recall of learned arbitrary visuomotor associations (VMAs). Prior studies have found that the hippocampus is necessary in order to learn arbitrary VMAs and that neural activity in the hippocampus changes as VMAs are learned. To test this hypothesis, we conducted a VMA task in eight human participants who were undergoing intracranial monitoring during pre-surgical evaluation for treatment of otherwise intractable epilepsy. Each participant had one or more depth electrodes implanted into their medial temporal lobe (MTL), with at least one contact in the hippocampus as well as in MTL cortical areas. Many also had electrodes on the cortical surface. The VMA task required participants to make reaching movements with their upper limb using a digitizing joystick to one of four possible target locations presented on a computer screen. Prior to some of these reaches, a cue indicating the location of the upcoming target was presented. Cues took the form of either the pre-presentation of the target itself or the presentation of an arbitrary symbol. Participants memorized the target location that each arbitrary symbol indicated prior to the experiment. Trials without any cue were also included. We found that the hippocampus responded selectively at the time of the cue when movement goal information was specified through a symbol requiring recall, compared to directly by a target or in cases without a cue. In comparison, at the time of the movement and the ultimate appearance of the target, the hippocampus responded similarly across conditions. Electrodes in the neocortex did not show this differential response to the presentation of the symbolic cue. These results are consistent with a model for the hippocampus as recalling movement goals signified by sensory cues, indicating a role for memory systems in motor skill.

Title: Supplementary motor area activity during finger tapping with and without the pacing tone in young adults with developmental dyslexia

Authors: *A. L. SMILEY-OYEN, M. E. HARTMAN, M. L. STEPHENSON, M. A. MCDONOUGH;
Kinesiology, Iowa State Univ., Ames, IA

Abstract: Developmental dyslexia (DD) is generally viewed as a disorder involving phonetics, with the underlying cause that of poorly processing sound. Many people with DD also exhibit difficulties with the temporal aspect of movement sequencing. It is well established that the pre-supplementary motor area (SMA) and SMA, involved in motor planning and execution of movement sequences, are also a part of the broad network for sound processing. One position is that the preSMA/SMA serves as part of a larger cortical-subcortical *temporal processing network* that underlies processing sound (Kotz et al., 2010, Schwartz et al., 2012; Schwartz et al., 2011). Therefore, when rhythmic movement (repetitive finger tapping) is performed in concert with rhythmic sound, the synchrony or desynchrony (variability) of this behavior and the activation pattern of the preSMA/SMA may provide insight into this temporal processing network in young adults with DD. **PURPOSE.** The purpose of this study was to examine EEG activity over the preSMA/SMA during finger tapping with and without a pacing tone in young adults with and without DD. It has been found that children with DD exhibit a dominance of theta band activity (4-7 Hz) at rest (Papagiannopoulou & Lagopoulos, 2016), which was interpreted as abnormal hypoarousal mechanisms, and sustained theta activity during linguistic tasks (Spironelli et al., 2008). We hypothesized that theta band activity would be greater in young adults with DD during rest and during finger tapping with or without a tone, and that theta would further increase in DD when tapping off beat. Furthermore, we hypothesized that intertap interval (ITI) variability would be greater in the DD group. **METHOD.** Participants were age- and gender-matched, and all were right-handed. They engaged in the following conditions: sitting quietly at rest with eyes closed (rest), sitting quietly at rest with eyes open (baseline), tapping with their right-hand index finger in synchrony with and without a tone at 70 bpm, doing the same at 140 bmp, and tapping off beat at 70 bpm with and without the tone. Analyses focused on EEG collected from electrode Cz (area over the preSMA/SMA). **RESULTS.** The power spectrum pattern of results supported our hypotheses. Theta activity at Cz was higher in those with DD during tapping at both rates, with or without the tone and tapping off the beat. Also, ITI variability was greater in the DD group. We interpret these data as support for the position that

movement sequencing is more difficult for young adults with DD and that the study of the preSMA/SMA is a productive approach to better understand linkage between movement sequencing and sound processing.

Title: Realignment in visuo-proprioceptive estimates of hand position: Somatotopic specificity and the role of sensory cortices

Authors: *C. R. SEIGEL, J. L. MIRDAMADI, S. D. HUSCH, K. D. MORGAN, H. J. BLOCK;
Indiana Univ. Bloomington, Bloomington, IN

Abstract: Spatial realignment of visual and proprioceptive hand position estimates can occur in response to a perturbation. E.g., viewing the hand underwater while washing dishes: water refracts light, shifting the visual estimate of the hand away from the proprioceptive estimate. The brain compensates for this misalignment by realigning visual and proprioceptive estimates of the hand. Such perceptual learning presumably affects the hand perception used in motor planning, raising the question of whether multisensory integration and motor control share a common sensorimotor map. Our recent experiments support this hypothesis. Using transcranial magnetic stimulation (TMS), we detected excitability changes in the primary motor cortex (M1) index finger representation after subjects experienced misaligned, but not veridical, visuo-proprioceptive information about the index finger (N=29). The effects were somatotopically focal: Strongly apparent in the index finger representation (β=-0.99 for proprioceptive and 0.42 for visual realignment, $p<0.05$), weakly apparent in the pinky finger representation (β=-0.96 and -0.19, NS), and absent in the forearm and biceps representations. A behavioral experiment (N=13) further supports this interpretation: We asked subjects to indicate their proprioceptive estimate of the knuckle, wrist, and elbow, in addition to the misaligned fingertip. Proprioceptive realignment in the knuckle was similar to the fingertip, but realignment in the wrist and elbow estimates were significantly less ($p<0.05$). This suggests the effects of misaligned visual information at the fingertip are somatotopically focal.

Interestingly, subjects who realigned proprioception more than vision had decreased M1 excitability in the index finger representation, while subjects who realigned vision more than proprioception had increased M1 excitability. This suggests a modality-specific neural mechanism, such as modulation of somatosensory cortex or dorsal stream visual areas that impact M1. Indeed, short latency afferent inhibition (SAI) changes were significantly correlated with the magnitude of subjects' proprioceptive realignment (β=-1.84, $p<0.01$), suggesting changes in somatosensory inputs to M1 were involved (N=21). We will next use a paired pulse TMS technique to assess whether changes in visual pathways to M1 are associated with subjects' visual realignment. Taken together, these results suggest visuo-proprioceptive realignment is associated with somatotopically focal physiological changes in the sensory and motor systems, consistent with a common sensorimotor map for multisensory and motor control.

Title: Non-invasive transvertebral magnetic stimulation discloses residual motor function of sublesional spinal circuitry in humans with spinal cord injury

Authors: *T. TAZOE[1], M. SUZUKI[1], M. KANESHIGE[1], K. IWATSUKI[2], Y. NISHIMURA[1]; [1]Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan; [2]Senbokujinnai Hosp., Sakai city, Japan

Abstract: The interruption of supraspinal descending motor drives due to spinal cord injury (SCI) results in the paralysis of all muscles innerved by the sublesional spinal motoneurons. However, most of motoneurons spared from actual damages preserve their function. In humans, it is hard to examine residual function in sublesional spared motoneuronal circuitry. To address this issue, we used non-invasive magnetic stimulation delivering to the sublesional lumbar spinal cord in individuals with and without spinal cord injury. Single pulses transvertebral magnetic stimulation (TVMS) were given to 18 intervertebral pointes from T11 to L5 with three cascades. We mapped the peak-to-peak amplitude of stimulus-evoked responses in the bilateral leg muscles; iliopsoas, gluteus maxima, quadriceps, biceps femoris, tibialis anterior, soleus. In 13 intact participants, we acquired spinal motor maps with a rostro-caudal configuration in which proximo-distal leg muscles were represented. In 8 participants with SCI, the neurological level of

injury (NLI) was clinically diagnosed as C8 in 1 participant, T2-T12 in 6 participants, and L1 in another 1 participant. Six SCI participants exhibited that TVMS illustrated the preserved motor maps in the paralyzed leg muscles. In rest of 2 SCI participants, TVMS failed to elicit clear evoked-muscle responses in any leg muscles. The presence of TVMS-induced responses was not relevant with the completeness or level of injury. Our results indicated that the motor function was occasionally preserved in the sublesional spinal motoneuronal circuitry. TVMS is a useful diagnosis approach to discloses residual spinal motorneuronal circuitry.

Title: Does fMRI reveal different brain response in persons with anterior cruciate ligament reconstruction compared to controls during a novel knee proprioception test?

Authors: *A. STRONG[1], H. GRIP[2], C.-J. BORAXBEKK[3], C. K. HÄGER[1];
[1]Dept. of Community Med. and Rehabilitation, Physiotherapy, [2]Dept. of Radiation Sciences, Biomed. Engin., Umeå Univ., Umeå, Sweden; [3]Danish Res. Ctr. for Magnetic Resonance, Copenhagen Univ. Hosp. Hvidovre, Copenhagen, Denmark

Abstract: Injury to the anterior cruciate ligament (ACL) of the knee is common, particularly during sporting activities, and causes damage to and/or loss of its proprioceptors. Knee proprioception, believed important in prevention of and recovery from injury to the joint, appears worse among those who have suffered an ACL injury compared to asymptomatic persons. Further, studies showing different brain response in persons post-ACL reconstruction during simple knee flexion/extension movements indicate neuroplasticity due to the injury and/or subsequent surgical reconstruction. However, brain response post-ACL reconstruction during knee proprioception tests has yet to be established, partly due to methodological constraints. We therefore aimed to develop a novel knee proprioception test suitable for simultaneous functional magnetic resonance imaging (fMRI) and implement the test in order to map proprioception-related brain response post-ACL reconstruction. 21 persons who had received ACL reconstruction (ACLR) 7 months to 5 years previously and 21 age-, sex-, and activity level-matched controls (CTRL) performed our novel knee joint position sense (JPS) test firstly in a

movement laboratory and secondly during simultaneous fMRI. Three-dimensional motion capture systems, also integrated in the MR environment, recorded knee angles to provide test instructions and knee JPS outcome measures. The order of leg and two target angles (40 and 65 degrees knee flexion) was randomised. Blood oxygen level-dependent (BOLD) contrast imaging was used to assess brain response during the knee JPS test. Preliminary analyses show overactivation in frontal and motor areas of ACLR compared to controls when attempting to reproduce the knee joint angles. Our study confirms the successful development and implementation of a novel knee proprioception test for simultaneous fMRI to investigate knee proprioception-related brain response. The preliminary results build on previous studies indicating neuroplasticity among persons with a reconstructed ACL and provide added evidence regarding specific brain regions utilised for knee proprioception. This understanding may help to inform targeted rehabilitation strategies for improved outcomes. Ongoing analyses will provide further information regarding brain response among our groups as well as assess the ability of both groups to reproduce the knee joint angles.

Title: Neurophysiology of motor skill learning in chronic stroke

Authors: *R. MOONEY[1,2], J. CIRILLO[1,2], C. M. STINEAR[3,2], W. D. BYBLOW[1,2];
[1]Dept. of Exercise Sci., [2]Ctr. for Brain Res., [3]Dept. of Med., Univ. of Auckland, Auckland, New Zealand

Abstract: Despite early motor recovery, many stroke survivors are left with residual upper limb impairment at the chronic stage. Motor learning is relevant in chronic stroke for acquiring and improving the execution of compensatory strategies to motor control deficits. However, the neurophysiological mechanisms underlying motor skill acquisition with the affected upper limb after stroke have received little systematic investigation. The aim of this study was to assess the modulation of corticomotor excitability and inhibition within ipsilesional primary motor cortex (M1) during motor skill learning in chronic stroke. Ten people with chronic stroke and twelve neurologically healthy age-matched controls trained with their paretic and nondominant hand respectively on a sequential visual isometric wrist extension task. Each participant's speed-accuracy function was determined to quantify skill before, immediately after, 24 hours and 7 days post-training. Threshold hunting paired-pulse transcranial magnetic stimulation protocols were used to examine corticomotor excitability, short- and long-interval intracortical inhibition

and short-interval intracortical facilitation before and immediately after training. Both groups exhibited successful skill acquisition and retention, but absolute skill level was lower in chronic stroke participants compared with controls. In contrast to controls, ipsilesional corticomotor excitability was not modulated after skill acquisition, which may in part be attributed to heightened long-interval intracortical inhibition within ipsilesional M1. Short-interval intracortical inhibition within M1 decreased after training in both groups. Long-interval intracortical inhibition and short-interval intracortical facilitation were not modulated. Our findings indicate neurophysiological mechanisms within M1 relevant for motor learning after stroke, which could inform adjuvants aimed at augmenting motor recovery in neurorehabilitation contexts.

Abstract: The preparation of movements, even the simplest ones, involves drastic changes of neural activity in the motor system well before action initiation (Gao et al., 2018). A recent behavioral study showed that training on a specific motor task can reduce reaction times (RT) for the trained movement, and that this reduction is due to faster motor processing during the preparatory period (Mawase et al., 2018). This finding suggests that motor training reduces RTs by modulating preparatory activity in the motor system. Here, we tested this hypothesis in humans by examining the neural correlates of this training-related reduction in RTs. To do so, we assessed preparatory activity in the motor cortex at different stages of training while subjects performed a RT task. 14 subjects performed 10 blocks of 40 trials of an instructed-delay choice RT task which required them to prepare left of right index finger movements according to a preparatory cue and to withhold their response until an imperative signal was displayed. Subject were told to respond as fast as possible to gain points while avoiding errors (e.g. responding too

early or too late or responding with the wrong hand) that would penalize their score. In order to probe corticospinal excitability, double-coil TMS was applied over the right and the left primary motor cortex to elicit near-simultaneous motor-evoked potentials (MEPs) in the left and the right hand, respectively (Vassiliadis et al., 2018). MEPs recorded during the preparatory period (i.e. between the preparatory cue and the imperative signal; MEP_{Prep}) were expressed in percentage of MEPs acquired at rest (i.e. between 2 trials; $MEP_{Baseline}$). We compared RTs, errors and MEPs from both hands in the early ($Training_{early}$) and late stages of training ($Training_{late}$). In a second-level analysis, we correlated MEPs to bins of 10 consecutive percentile windows of RT (i.e., 0 to 10^{th}, 10^{th} to 20^{th} . . . 90^{th} to 100^{th}). At the behavioral level, RTs were reduced at $Training_{late}$ compared to $Training_{early}$ in both hands despite no significant changes in the number of errors. At the neural level, MEP_{Prep} were systematically suppressed compared to $MEP_{Baseline}$; a process that has been previously referred to as preparatory inhibition (Duque et al., 2017). Most importantly, this preparatory activity was modulated by the amount of training performed: MEP_{Prep} were more suppressed at $Trainning_{late}$ than at $Training_{early}$. Moreover, we found that there was a strong correlation between MEP_{Prep} and the subsequent RT: the smaller the MEP_{Prep}, the faster the RT. Overall, our results suggest that training involves a modulation of preparatory activity in the motor system that subserves RT reduction.

Title: Motor imagery increments the cortico-motoneuronal excitation mediated via presumed cervical interneurons in humans

Authors: *S. IRIE[1], T. NAKAJIMA[1], S. SUZUKI[1,2], R. ARIYASU[1], T. KOMIYAMA[3], Y. OHKI[1];
[1]Dept. of Integrative Physiol., Kyorin Univ. Sch. of Medicine,, Mitaka, Tokyo, Japan; [2]Sch. of Rehabil. Sci., Hlth. Sci. Univ. of Hokkaido, Tobetsu, Hokkaido, Japan; [3]Fac. of Educ., Chiba Univ., Chiba City, Japan

Abstract: Motor imagery is known to affect the reacquisition of motor functions after damages to the central nervous systems. However, it is unclear if motor imagery influences the corticospinal (CST) excitation mediated via cervical interneurons (INs), which may be important for functional motor recovery in animals and humans. To investigate this, we examined the spatial facilitation of motor-evoked potentials (MEPs) induced by combined stimulation (CS) of the pyramidal tract and peripheral nerves in humans. Twenty-nine healthy volunteers and three patients with spinal cord disorders (one incomplete spinal cord injury and two myelopathy patients) were included to record electromyograms (EMGs) from the right biceps brachii (BB). Transcranial magnetic stimulation (TMS) to the left motor cortex and electrical stimulation of the right ulnar nerve at wrist (NERVE) were delivered separately or in combination with inter-stimulus interval of 6-15 ms (NERVE ahead). As for motor imagery tasks, subjects were instructed to imagine elbow flexion with maximum effort during the stimulation without actual movements. During both motor imagery and control tasks, CS facilitated MEPs in the surface EMG compared with simple mathematical summation of responses with TMS alone and NERVE alone. Interestingly, the CS-induced facilitation was significantly increased by motor imagery, depending on timing of NERVE and TMS (7.5-12 ms of ISIs). Single motor unit recording also revealed increased facilitation during motor imagery, which was observed in peaks of the peri-stimulus time histogram 1-2 ms later than the onset latency. The present findings suggest that motor imagery facilitates indirect CST excitations to arm motoneurons, which are mediated by the cervical IN systems (i.e., di- or oligosynaptic contribution). As for the experiments with patients of spinal disorders, also, the facilitation was markedly enhanced during motor imagery tasks. Thus, motor imagery could be a useful tool for reacquisition of movement using the cervical IN circuitry

Title: The role of interhemispheric inhibition during partial cancellation of bimanual motor actions

Authors: *H. MACDONALD, C. LAKSANAPHUK, A. DAY, N. JENKINSON;
Univ. of Birmingham, Birmingham, United Kingdom

Abstract: The rapid and unexpected cancellation of action is vital for controlling motor behaviour. Sometimes a subset of a motor action must be cancelled while the remaining elements

continue. This partial cancellation is difficult and responding elements are substantially slowed. A specific temporal pattern of corticomotor excitability is seen in the delayed responding element that reflects the anticipation, non-selective inhibition and subsequent initiation of the required response. The neural mechanisms underlying this complex pattern of excitability are not yet understood. The present study examined whether interhemispheric inhibitory mechanisms play a role in modulating excitability in this context. In two experiments, healthy younger adults received transcranial magnetic stimulation to both primary motor cortices while performing a bimanual anticipatory response inhibition task. Participants performed bimanual index finger abduction to intercept two rising bars with an on-screen target (Go trials) and were cued to cancel the response in a single hand on 20 % of trials (Unimanual Stop trials). During Go trials, a rise in corticomotor excitability (p < 0.001) and concomitant decrease in interhemispheric inhibition (IHI, p < 0.01) for both muscles preceded the prepared bimanual response. Following the stop signal on Unimanual Stop trials, there was a dissociation in IHI onto the responding versus cancelled hands; in experiment one, IHI increased onto the cancelled non-dominant hand, and was completely released for the responding dominant hand (p < 0.01). Experiment two confirmed an equivalent dissociation in IHI was also present, albeit at a later time point, when the non-dominant hand was the one responding (p < 0.05). This dissociation between hands indicates IHI enables uncoupling of the muscles comprising the anticipated bimanual response, and assists selective initiation of just the required unimanual element. Thus, IHI plays an integral role in partial cancellation of prepared bimanual action.

Title: Left-right asymmetry of motor cortex excitability and tsms-induced plasticity in essential tremor

Authors: C. AMMANN[1], D. URSO[1], J. A. PINEDA-PARDO[1], A. OLIVIERO[2], J. A. OBESO[1,3], ***G. FOFFANI**[1,2];
[1]CINAC, Univ. Hosp. HM Puerta del Sur, Madrid, Spain; [2]Hosp. Nacional de Parapléjicos, Toledo, Spain; [3]CIBERNED, Inst. de Salud Carlos III, Madrid, Spain

Abstract: Essential tremor (ET) typically manifests with mild asymmetry between the left and right upper limbs. Early studies with accelerometric measures in clinic-based samples reported a predominance of right-hand tremor (Biary and Koller, Arch Neurol 1985), whereas later investigations with clinical measures in community-based samples reported an opposite predominance of left-hand tremor (Louis et al., Arch Neurol 1998). However, the pathophysiological significance of this asymmetry and the possible predominance of one side remain unclear. To address this issue, here we studied 30 patients with essential tremor. The amplitude and frequency of postural tremor quantified with accelerometry did not show any left/right hand predominance, whereas action tremor assessed with clinical scales displayed a clear left-hand predominance. Transcranial magnetic stimulation (TMS) in a subset of patients revealed significant left-right differences in intracortical excitability, with less inhibition and more facilitation in the right compared to the left hemisphere. Diffusion MRI also showed significantly lower mean diffusivity in the right compared to left motor cortex. Finally, a 30-min session of unilateral transcranial static magnetic field stimulation (tSMS) of the motor cortex (NCT03780426) significantly reduced contralateral hand postural tremor and bilateral hand action tremor, but only when tSMS was applied to the right cortex. These results suggest that asymmetries in motor cortex excitability and plasticity may lateralize the clinical manifestation and the response to non-invasive brain stimulation in essential tremor.

Title: Augmented attention during physical training improves brain connectivity and motor function

Authors: *S. H. SALEH[1], M. GLASSEN[1], A. HOXHA[1], M. KWASNICA[1], D. ALLEXANDRE[1], G. H. YUE[2];

Abstract: Bimanual coordination deficit is common in individuals with sustained moderate to severe traumatic brain injury (TBI). Effective treatments require a large amount of physical training to recover normal motor function. Unfortunately, attention deficits and physical weakness limit the patients' ability to engage in intensive physical training. In this study, physical and mental practice were combined to achieve high engagement and intensity during training without inducing fatigue. The study compares an intervention combining physical practice and motor imagery (MP group) versus physical practice and action observation (PP group). Ten participants were enrolled in the study after signing an informed consent approved by the IRB. 5 participants (1F, 4M, 35±14 yrs. old) were enrolled in the MP group and 5 (5M, 45±12 yrs. old) in the PP group. Participants were trained in 3 one-hour sessions per week for 4 weeks. Outcome measures included assessment of maximum voluntary contraction (MVC) strength in wrist flexion and extension for both hands at each session, and fMRI-based neurophysiological measures of brain connectivity at rest before and after training. Resting fMRI data were preprocessed using conventional methods and analyzed using seed-based analysis. Regions of interests used to study Sensorimotor (SM), Dorsal Attention Network (DAN), and Ventral Attention Network (VAN) were bilateral 1) primary motor, 2) premotor, and 3) ventral frontal cortices. Group level analysis showed a median increase in MVC of 6%±28% IQR after training in the MP group and 20%±26% IQR in the PP group, but it did not show significant difference between groups. Resting state fMRI data showed pre to post significant decrease (FWE, $p<0.05$) in the extent of connectivity within the SM, DAN, and VAN networks, indicating more focal networks after training, and no difference between groups. The findings suggest that high-level of attention during physical training, whether achieved through motor imagery or action observation, engages the sensorimotor and attention networks, and strengthens their connectivity that might translate into better motor function. The study is ongoing and a larger sample size and analysis of other outcomes would allow us to draw more surefire conclusions.

Title: Oscillatory cortical dynamics predict successful motor preparation

Authors: B. POSTIGO-ALONSO[1], A. GALVAO-CARMONA[1], M. HOFMANN[2], A. KÜHN[3], ***W.-J. NEUMANN**[2];

Abstract: Background: Taking time to prepare voluntary movement can improve motor performance in dependence of required motor control capacity. In previous works, we have demonstrated that neuromodulation of supplementary motor cortex projections to STN decreases reaction times when movements were associated with higher cognitive demand. Aim: In the present study we aimed to identify cortical oscillatory correlates of successful motor preparation. Method: 20 right-handed healthy adults were assessed with 64-channel EEG while performing a visuomotor task consisting on navigating as fast as possible on a digitizing tablet to reach a target circle shown on the screen with a pen, whose axes representation was unperturbed (automatic mode) or inverted (controlled mode). Reaction time, movement time, trajectory error and peak velocity were decomposed using principal component analysis and a component associated with longer reaction- but shorter movement time and lower motor error was identified. Whole brain source extraction was conducted on a cortical mesh. Source activity was transferred to the frequency domain and spatio-temporal correlation maps with the motor control component were created. P-values were FDR corrected for multiple comparisons. Results: Correlation of oscillatory cortical activity peaked in the supplementary motor area ~500 ms before movement onset in the beta frequency range. Similarity of individual temporospatial activity patterns could significantly predict left out subjects through cross-validation. Conclusion: Our results confirm the implication of the supplementary motor area in preparation of motor commands under cognitive demand.

Title: Contribution of human primary motor cortex to force variability during precision grasping

Authors: *N. RAO[1], L. SKINNER[2], J. KASS[1], P. J. PARIKH[1];
[1]Hlth. and Human Performance, Univ. of Houston, Houston, TX; [2]Villanova Univ., Villanova, PA

Abstract: Variability in motor responses influences the ability to perform everyday motor tasks. Primate work has shown that behavioral variability can be partly explained by the neural activity within primary motor cortex (M1) and premotor cortex. Our recent work has found contribution of human corticospinal system to the variability in the application of digit force. However, in humans, the specific sources at the central level that contribute to behavioral variability are not well understood. In this study, we determined whether a transient and reversible lesion of human M1 alters the variability in grip force applied to an object using a precision grip. Healthy young adults (n=7) performed an isometric grip force task before and after the delivery of continuous theta burst stimulation (cTBS) over contralateral M1 or vertex (a control site). During the isometric grip force task, target forces equivalent to 5, 15, or 30% of subject's maximum grip force were displayed on a computer screen. During each trial, subjects were instructed to squeeze a grip device using index finger and thumb to reach a target force and then maintain the force for 8 sec. Following this, the screen was blocked, and subjects were instructed to continue to maintain the force for another 8 sec. We assessed neurophysiological changes following cTBS over M1 by assessing corticospinal excitability (CSE), short interval intracortical inhibition (SICI), and intracortical facilitation (ICF). We found that cTBS over M1 increased the moment-to-moment variability in the grip force applied to the object for 15% ($p=0.0006$) and 30% ($p=0.02$) of force, but not for 5% of force. These effects were found when the task was performed under the visual feedback condition, but not when the feedback was blocked. However, we did not observe any change in the magnitude of CSE, SICI, and ICF following cTBS over M1. Furthermore, cTBS over vertex did not change grip force variability. These findings suggest a critical role of M1 in visually-driven control of force mainly at higher magnitudes.

Title: The subthalamic nucleus as a potential neural driver of motor inhibition during action preparation?

Authors: *E. WILHELM[1,2], G. DEROSIERE[1], C. QUOILIN[1], A. JEANJEAN[2], J. DUQUE[1]; [1]Inst. of Neurosci., Brussels, Belgium; [2]Saint-Luc Univ. Hosp., Brussels, Belgium

Abstract: By applying transcranial magnetic stimulation (TMS) over the primary motor cortex (M1) during reaction time (RT) tasks, many studies have revealed a suppression of motor-evoked potentials (MEPs) during action preparation (*i.e.*, compared to a resting state) - a phenomenon referred to as *preparatory inhibition*. Intriguingly, little is known about the neural structures at the origin of this suppression. The subthalamic nucleus (STN) has a strong inhibitory influence on M1 and thus represents a plausible candidate for contributing to the generation of preparatory inhibition. Here, we investigated the functional contribution of the STN to preparatory inhibition by probing MEPs during action preparation in Parkinson's disease (PD) patients treated with deep brain stimulation (DBS). Right-handed PD patients and matched healthy subjects participated in the study. They performed an instructed-delay choice RT task, in which they had to select either left or right index finger responses based on the position of a preparatory cue, but had to wait until the onset of an imperative signal to release their movement. TMS was applied over both M1 using a double coil method, eliciting concurrent MEPs in right and left index finger muscles. Pulses were applied either at rest (during the inter-trial interval) or during the preparatory period (just before the imperative signal). The patients realized the task either OFF- or ON-DBS on two consecutive days (randomized order), allowing us to probe preparatory inhibition in PD patients, and to examine the impact of the perturbation of STN activity (ON-DBS) on preparatory inhibition. In line with past research, healthy subjects exhibited a substantial suppression of MEPs during action preparation (*i.e.*, compared to MEPs obtained at rest). This effect was evident for MEPs elicited in both the left and the right finger muscles and occurred regardless of whether the preparatory cue required a left or right hand response. In contrast, such an MEP suppression was less consistent in the PD patients. Intriguingly, in these patients, preparatory MEPs even displayed some facilitation in a number of conditions and this effect was stronger when the DBS was turned ON compared to when patients were tested in the OFF-DBS state. The latter observations suggest an alteration of preparatory inhibition in PD patients, especially when DBS perturbs the STN, probably releasing M1 from its inhibitory tone.

Title: The neural correlates of combining submaximal contraction with motor imagery in breast cancer survivors

Authors: *D. ALLEXANDRE, A. HOXHA, S. SELVAN, S. H. SALEH, G. H. YUE;
Ctr. for Mobility and Rehabil. Engin. Res., Kessler Fndn., West Orange, NJ

Abstract: Cancer and its treatment is often associated with long term side-effects of fatigue and physical weakness. Engaging in low intensity strength training has found to be beneficial in lessening the side effects. Similarly, motor imagery (MI) which engages the same motor network than the one controlling the actual motor task, can on its own improve motor performance and physical strength. This study examined the potential added benefit of combining MI with low intensity exercise in breast cancer survivors with physical weakness by investigating its neural correlates using an EEG source-space time-frequency analysis. 10 right handed breast cancer survivors performed a series of 30 mixed trials of the following three handgrip conditions held for 10s: (1) kinesthetic MI where they imagined performing handgrip at maximal voluntary force (MVF), (2) submaximal handgrip contractions (SC) at 20% MVF, and (3) SC at 20% MVC combined with kinesthetic motor imagery (MI) of handgrip contraction at MVF (SC+MI). EEG data were collected during the task using a 64 channel actiCAP EEG system (Brain Products) and all data were processed using EEGLAB toolbox. After standard preprocessing, Infomax ICA source separation was applied to the concatenated data of all participants and conditions to obtain group-level sources. This led to the selection of 13 artefact-free brain sources over the prefrontal cortex (PFC), Supplementary Motor Area (SMA), primary motor (M1) and sensory (S1) cortices, posterior cingulate cortex (PCC) and parietal cortex (PC). Time-frequency analysis was then performed to compare conditions using permutation-based statistics.SC+MI and SC showed significantly greater desynchronization (ERD) in the alpha (8-12Hz) and beta (12-25Hz) frequency bands than MI, consistently across all sources. Significantly greater ERD for SC+MI was only observed in the left PFC source in the alpha and theta (5-8Hz) band. Left PFC source showed also greater gamma (30-50Hz) band synchronization in MI vs SC+MI and SC. A single session of SC+MI only marginally increased brain activation compared to SC alone. The greater alpha and theta band activation for the left PFC source suggests increased attention to perform MI during handgrip contraction. Study participants were randomly assigned to either receive twenty 45-min sessions of SC or SC+MI handgrip strength training over 4 weeks. We are in the process of analyzing and investigating pre to post training strength gain and pre to post neuroplasticity changes using time-frequency and brain connectivity analysis.

Title: Modeling neural population dynamics informs and improves decoding of electrocorticographic signals

Authors: *K. LI[1], R. FLINT[2], M. W. SLUTZKY[2], C. PANDARINATH[1,3];
[1]The Wallace H. Coulter Dept. of Biomed. Engin., Emory University/Georgia Tech., Atlanta, GA; [2]Dept. of Neurology, Feinberg Sch. of Med., Northwestern Univ., Evanston, IL; [3]Dept. of Neurosurg., Emory Univ., Atlanta, GA

Abstract: Brain-machine Interfaces (BMIs) aim to assist people with paralysis due to injuries or neurodegenerative diseases by creating a connection between the brain and external assistive devices. One commonly-used interface for BMIs is electrocorticography (ECoG), which measures cortical surface potentials and provides substantial information about movement intention. ECoG covers large areas of the brain, thus providing access to broad cortical networks, but generally has lower signal quality than interfaces such as intracortical microelectrode arrays. A potential avenue to improve its performance comes from deep learning methods such as Latent Factor Analysis via Dynamical Systems (LFADS), which uncover structure from neural population activity that is consistent with a low-dimensional dynamical system. In previous applications to intracortical recordings from primary motor cortex, LFADS increased decoding accuracy by uncovering estimates of neural population dynamics on a single-trial, moment-by-moment basis. However, it was unclear whether it could similarly uncover structure and "de-noise" recordings with lower spatial resolution that sample from broad cortical networks, such as ECoG. In this study, we tested whether modeling neural population dynamics could uncover signatures of behavior from broad cortical activity and improve ECoG decoding performance. We applied LFADS to ECoG from seven human subjects who were being monitored as part of surgical treatment for epilepsy or brain tumors. Subjects performed a one-finger flexion task that incorporated movement and isometric force production. We compared our ability to decode

behavioral states (i.e. pre-movement, movement or force) before and after application of LFADS. The latent factors that described the underlying dynamical system showed clear differences between states, which improved the accuracy of a discrete classifier in correctly identifying states. Across subjects, median (+/-IQR) prediction accuracy prior to LFADS was 84%±8%, while prediction accuracy following LFADS increased to 90%±6%, a significant improvement (p=5x10-14; kruskal-wallis test). Our results show that lower-dimensional representations can parsimoniously describe the combined activity of widespread cortical networks spanning multiple regions. They also represent a new path for improving the performance of ECoG-based BMIs. Future work will test whether using "dynamic neural stitching" to combine data from multiple sessions could further improve ECoG decoding performance, and whether the improvements translate to more complicated behavioral tasks.

Title: Cortical silent period in task-irrelevant muscles is shortened during motor response preparation

Authors: *I. GOMEZ, I. GREENHOUSE;
Human Physiol., Univ. of Oregon, Eugene, OR

Abstract: Several transcranial magnetic stimulation (TMS) studies have observed decreased excitability during the preparation of movements that spreads to task-irrelevant muscles. Whether widespread changes in preparatory corticospinal excitability reflect the involvement of intracortical, subcortical, and/or spinal mechanisms remains an unanswered question. The duration of the cortical silent period (CSP) in the electromyogram (EMG) of a tonically active muscle following a single TMS pulse is believed to reflect GABA-b dependent intracortical inhibition. Here, we test the hypothesis that widespread changes in corticospinal excitability depend on GABA-b intracortical mechanisms by measuring the CSP in a task-irrelevant muscle during the preparation of movements. Seven healthy, right-handed subjects (2 females, 26 ± 5 y.o.) completed a unimanual delayed response task while maintaining a tonic contraction with the non-responding hand. Participants performed fifty trials using each hand with the hand order counterbalanced to account for laterality differences. EMG was recorded from both first dorsal interossei. Participants squeezed a ball between the index and thumb of the non-responding hand for the duration of the task and were trained to hold an isometric contraction at 25% of the maximum voluntary. Each trial consisted of a baseline fixation cue (200ms), a preparatory cue

(900ms) and an imperative stimulus (500ms). Participants made lateral index finger button presses in response to the imperative stimuli. Six catch trials, during which no imperative stimulus appeared, were included for each hand to discourage premature responding. TMS was administered at 115% resting motor threshold over M1 contralateral to the non-responding hand. Motor-evoked potentials (MEP) and CSP's were elicited in the contracted hand at one of two time points per trial: either at fixation onset (baseline) or 100ms before the imperative cue (delay). CSP duration was significantly shorter during the preparatory period compared to baseline for both left-hand (baseline = 82 ± 9.6ms, delay = 63 ± 9.2ms, p = .004) and right-hand (baseline = 117 ± 6.2ms, delay = 103 ± 2.2ms, p = .001) responses. MEP amplitudes did not differ between the preparatory period and baseline for either the left-hand (baseline = 6.32 ± 1.6mV, delay = 6.38 ± 1.4mV, p = .75) or right-hand (baseline = 7.66 ± 0.8mV, delay = 7.63 ± 0.8mV, p = .9) responses. Reaction times were similar between hands (left = 329 ± 40ms, right = 304 ± 27ms, p = .12). The significant reduction in CSP duration during the delay period may reflect a release of inhibition in ipsilateral motor cortex to facilitate execution of goal-oriented movement.

Abstract: Upper limb movements are primarily controlled by the motor cortex in the contralateral hemisphere. However, the decoding success of unilateral movement from electrocorticography (ECoG) or single unit activity is surprisingly similar for contralateral and ipsilateral motor cortex (Ganguly, 2009). While this observation offers a promising neuroprosthetic alternative approach for patients with hemiparesis, the functional relevance of

ipsilateral motor representations remains unclear. Decoding motor kinematics from ECoG often entails multiple neural features from electrodes that span several centimeters of cortex comprising different cortical areas. The goal of this study is to gain a better understanding of how and where kinematics are encoded, and how these neural representations compare in the contralateral and ipsilateral hemisphere. We collected data from four individuals undergoing intracranial monitoring, who performed an instructed-delay reaching task using either the hand ipsilateral or contralateral to the ECoG electrodes. We built a cross-validated encoding model to predict ECoG data from continuous kinematic features of the patient's movements while they performed the task. Specifically we used continuous kinematic features to predict the activity of eight different neural features: 1) the local motor potential (LMP) and 2) the analytic amplitude of seven time-frequency bands (delta (1-4Hz), theta (4-8Hz), mu (8-12Hz), low beta (12-20Hz), high beta (20-30Hz), gamma (30-60) and high frequency broadband (HFB; 65-150Hz)). We used two different kinematic feature sets to predict the neural activity. The first represents the patient's movements in a cartesian coordinate space ($Position_X$, $Position_y$, $Position_z$) and the second in a spherical coordinate space (Magnitude, azimuthal angle, bipolar angle). We found that kinematic features represented in a spherical coordinate frame better predicts held-out ECoG activity across electrodes. The neural features that were best predicted by the spherical kinematic model were the LMP and high frequency bands. To better understand the role of the ipsilateral hemisphere in motor control we trained the spherical kinematic model from reaches when the hand ipsilateral to the ECoG electrodes was moving and predicted the neural activity when the hand contralateral to the ECoG electrodes was moving. We find neural features that can generalize across the two hands and neural features that cannot generalize across the two hands, suggesting that some neural features are encoding information that is effector independent and some neural features are encoding information that is effector dependent.

Title: Evidence for sequential recruitment of contralateral PPC and motor regions for rapid online control

Authors: *P.-M. BERNIER[1], D. GAUDREAULT[1], F. R. SARLEGNA[2];
[1]Univ. De Sherbrooke, Sherbrooke, QC, Canada; [2]CNRS and Aix-Marseille Univ., Marseille, France

Abstract: Upon a perturbation of hand visual feedback during movement, humans are able to rapidly correct their movement during its execution. Regions of the parieto-frontal network, including the posterior parietal cortex (PPC), premotor cortex (PMC) and primary motor cortex (M1) are involved in this process (Mulliken et al., 2008, Shadmehr and Krakauer, 2008, Archambault et al., 2011). However, it is still unclear how these regions coordinate their activities during online control. Here, we study the time-course of recruitment of these regions and ask whether PPC activity precedes PMC/M1 activity during rapid online corrections. Electroencephalography (EEG) was recorded while participants (n=19) performed a rapid arm reaching task with their right hand toward visual targets (MT ~ 600ms). Hand visual feedback was provided during the movement (only between 100ms and 200ms) with a cursor that could be either spatially congruent with the hand position (Congruent condition; CONG), shifted left or right from the hand position by 1.5cm (Incongruent 1.5 condition; INC-1.5), or shifted left or right by 3cm (Incongruent 3 condition; INC-3). Kinematic analyses revealed that subjects did compensate for the cursor shifts during movement, as evidenced by significant differences in X-accuracy at movement endpoint across conditions ($p<0.01$). The onset of correction, defined as the first time-point where the trajectory in each incongruent condition went beyond the 99% confidence interval of the congruent trials, revealed that participants were slightly but significantly faster to initiate online corrections in the INC-3 condition (300ms) than in the in the INC-1.5 condition (320ms) ($p<0.05$). To track the time-course of online corrections within the parieto-frontal network, the ERPs associated with the incongruent conditions were compared to those of the congruent condition, which served as a baseline. Data were time-locked to the onset of the movement. Cluster-based permutation tests were used. For the Inc-3 vs Cong contrast, results revealed an early significant cluster ($p<0.01$) over the left-central parietal regions from 203 to 243ms (peak differential activity at 237ms). Slightly later, another significant cluster ($p<0.01$) was observed over the left motor regions between 270 and 323ms (peak differential activity at 290ms). No significant cluster was found in the Inc-1.5 vs Cong contrast. We suggest that the sequential recruitment of the PPC and motor regions reflects two processes: the PPC would first be involved in updating the state of the limb in real time, while motor regions would then implement a corrective motor command.

Title: Corticospinal correlates of urgent motor decisions

Authors: *G. DEROSIERE[1], D. THURA[2], P. CISEK[3], J. DUQUE[1];
[1]Inst. of Neurosci., Catholic Univ. of Louvain, Brussels, Belgium; [2]Impact team, Inserm U1028, Lyon Neurosci. Res. Ctr., Lyon, France; [3]Univ. of Montreal, Montreal, QC, Canada

Abstract: Making motor decisions often requires balancing the desire to take time to choose accurately with the urge to act. During a speeded decision, the urge to act increases as time passes but the overall level of urgency also varies depending on the context. Recent work suggests that urgency operates as a gain modulator of task-related activity: when decisions between reaching movements are made under time pressure, activity in motor areas involved in arm movements is amplified. An open question relates to the generalization of this gain modulation in the motor system. Here, we investigated the impact of urgency on corticospinal excitability in different task-related and task-unrelated motor representations in humans, by applying transcranial magnetic stimulation (TMS) over the primary motor cortex. Subjects performed a decision-making task. In each trial, 15 tokens jumped one-by-one every 200 ms from a central circle to one of two lateral target circles; participants had to guess which target circle would ultimately receive the majority of the tokens, and to report their decision on a keyboard with either the left or the right index finger. Importantly, the reward provided for correct choices was proportional to the number of tokens remaining in the central circle at the time of the response. Because this number decreased over time, the urge to act grew accordingly. Further, we manipulated the overall level of urgency in two contexts, by providing a different penalty for incorrect choices in separate blocks. The use of a low penalty encouraged the subjects to make hasty choices, thus ensuring a high urgency ($Urgency_{High}$ context), while a high penalty promoted accurate choices and ensured a low urgency ($Urgency_{Low}$). We exploited TMS to elicit motor evoked potentials (MEPs) at different times during the token jumps in each context, in muscles that were either involved in the task (i.e., index finger "task-related" muscles) or not (i.e., thumb, pinky and leg "task-unrelated" muscles). MEP amplitudes obtained from these muscles provided us with a muscle-specific assay of corticospinal excitability at the time of stimulation. MEP amplitudes increased over time in all the investigated muscles (including in the leg) independently of the context, putatively reflecting a global time-dependent gain effect of urgency on corticospinal excitability. Further, amplitudes were higher in the $Urgency_{High}$ than in the $Urgency_{Low}$ context for task-related muscles, specifically when the MEPs were measured in the hand that was selected for the forthcoming action. The latter finding suggests the presence of a more specific context-dependent effect of urgency on corticospinal excitability.

Title: Between hand coupling during response inhibition

Authors: C. G. WADLSEY, J. CIRILLO, ***W. D. BYBLOW**;
Dept. of Exercise Sci., Univ. of Auckland, Auckland, New Zealand

Abstract: Response inhibition reflects the process of terminating inappropriate pre-planned or ongoing movements. When one hand is cued to stop after preparing a bimanual response (Partial trial) there is a substantial delay on the responding side. This delay is termed the interference effect and identifies a constraint that limits selective response inhibition. Gamma-aminobutyric acid (GABA)-mediated networks within primary motor cortex (M1) may have distinct roles during response inhibition. In this study we examined whether the interference effect is the consequence of between-hand "coupling" into a unitary response, and whether this is reflected in GABAergic intracortical inhibition within M1. Eighteen healthy right-handed participants performed a bimanual synchronous (easy) and asynchronous (hard) anticipatory response inhibition task. Electromyographic recordings were obtained from the first dorsal interosseous muscle bilaterally. Motor evoked potentials were elicited by single- and paired-pulse transcranial magnetic stimulation over right M1. As expected, performance was better and paradoxically response delays were worse, with the easier versus the harder version of the task. Although task difficulty did not modulate GABAergic intracortical inhibition, there was a trend for between-hand coupling to be associated with greater inhibitory tone and lower synaptic inhibition. The novel findings indicate that the interference effect is in part a consequence of between-hand coupling into a unitary response. The ability to respond independently with the two hands may rely on modulation of distinct inhibitory processes.

Abstract: Modulation of GABA-mediated inhibition in primary motor cortex is important for the induction of training-induced plasticity. The downregulation of inhibition during acquisition may promote cortical reorganisation, whereas an upregulation once performance has plateaued may promote consolidation of the newly acquired skill. GABA related inhibition in human primary motor cortex is routinely assessed using the paired-pulse transcranial magnetic stimulation paradigm of short-interval intracortical inhibition (SICI). However, modulation of SICI with motor skill learning is not a consistent finding and may be influenced by transcranial magnetic stimulation parameters. The aim of this study was to compare the modulation of SICI by motor skill learning between conventional and adaptive threshold-hunting techniques with an anterior-posterior (AP) and posterior-anterior (PA) induced current. Sixteen participants (21 - 33 years) trained with their dominant (right) hand on a sequential visual isometric pinch task. Electromyographic recordings were obtained from the right first dorsal interosseous muscle. Corticomotor excitability and SICI were examined before and immediately after 12 blocks of training. Skill increased throughout the training, with performance plateauing before the completion. Corticomotor excitability increased after motor training for both AP and PA induced current. The amount of SICI was greater with AP stimulation than PA for both conventional and adaptive threshold-hunting techniques. SICI increased after motor training, but this was only evident for adaptive threshold-hunting with AP induced current. These findings indicate that increased GABA-mediated inhibition after motor skill learning may promote consolidation of the newly acquired skill. Our findings also highlight the importance of selecting appropriate transcranial magnetic stimulation parameters, supporting the notion that adaptive threshold-hunting SICI using an anterior-posterior current provides a robust and sensitive assessment in interventional studies.

Title: Directed connectivity markers for transcallosal interactions: A finger movement study

Authors: *H. WEI[1,2], A. FRANCOIS-NIENABER[2], J. MELTZER[2,1];
[1]Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Baycrest Hosp., Rotman Res. Inst., Toronto, ON, Canada

Abstract: Stroke patients frequently exhibit increased task-induced activation of the contralesional hemisphere (cH). This may be either beneficial or detrimental to functional recovery, an ongoing debate with important implications for treatment, especially using transcranial magnetic stimulation (TMS). It is theorized that the cH exerts an inhibitory influence on the lesioned hemisphere, impairing recovery. Transcallosal inhibition (TCI) between motor cortices may be directly measured using TMS to elicit motor-evoked potentials (MEPs), which may be reduced in the presence of TCI. However, this measure does not generalize easily to other cognitive domains and regions beyond the motor cortex. Thus, we aimed to quantify TCI directly from magnetoencephalography (MEG) data, using finger movement as a starting point. 29 right-handed young healthy performed a finger movement task during MEG, executing visually cued left or right index finger movements in different blocks. We implemented frequency-domain Granger Causality analysis to measure directed connectivity between virtual channels localized to motor cortices (M1s) and visual cortices (V1s). A high-frequency (10-100 Hz) connectivity signal appears 500 ms after movement onset from moving to non-moving M1, whereas a similar signal from non-moving to moving M1 is elevated at baseline but drops off upon movement onset. The signal is overall stronger inter-hemispherically between M1s than intra-hemispherically from M1 to V1 (Figure 1). Moreover, post-movement connectivity exhibits a strong asymmetry with greater left-to-right influence, presumably related to right-handedness. These findings suggest that high-frequency directed connectivity may index TCI. Ultimately, the establishment of electrophysiological markers of TCI can guide post-stroke intervention in the optimal direction.

Title: Layer specific contributions to imagined and executed hand movements in primary motor cortex

Authors: ***A. S. PERSICHETTI**, J. A. AVERY, L. HUBER, A. LIU, E. P. MERRIAM, P. BANDETTINI, A. MARTIN;
Lab. of Brain and Cognition, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: The extent to which representations of imagined and executed movements overlap in primary motor cortex (M1) is an old and important question in cognitive science. Until now, it has been difficult to answer this question due, in part, to the poor spatial specificity of neuroimaging techniques. We used a 7-Tesla MRI scanner to measure the cerebral blood volume (CBV) in M1 using a cutting-edge method called vascular space occupancy (VASO). Using VASO to measure changes in CBV, instead of using traditional functional MRI methods that

measure changes in blood oxygenation levels (i.e., BOLD signal), we achieved sub-millimeter spatial specificity that allowed us to measure changes across cortical layers of the hand-selective region of M1. Since previous studies have shown that cortico-cortical connections with M1 terminate predominately in superficial layers (II/III), while cortico-spinal output from M1 originates predominantly in the deep layers of cortex (Vb/VI), we hypothesized that imagined hand movements would activate neurons in the superficial layers of M1 only, while executed hand movements would activate both superficial and deep layers. As predicted, our data show an increase in CBV when participants imagined tapping their thumb and index fingers together in the superficial layer only, but we see increased CBV when participants were actually tapping their fingers together in both superficial and deep layers of M1. Finally, a motion detecting glove was used to confirm that any neural activation found while participants imagined tapping their fingers together was not due to actual motion. These data suggest that imagined and executed movements are differentially represented across layers in M1. Furthermore, these data are evidence of a mechanism responsible for simulating motor performance without actually executing the movements.

Title: Dissociating the causal role of the dorsolateral prefrontal cortex and the dorsal premotor cortex in preparing and executing a bimanual coordination task - A neuro-navigated rTMS study

Authors: *R. L. J. MEESEN[1], S. VERSTRAELEN*[1], S. DEPESTELE[1], K. VAN DUN[1], J. DUQUE[2], H. FUJIYAMA[3], S. P. SWINNEN[4], O. LEVIN[4], M. A. NITSCHE[5], E. GHASEMIAN[5], K. CUYPERS[4];
[1]Univ. Hasselt, Hasselt, Belgium; [2]Univ. Catholique Louv, Brussels, Belgium; [3]Murdoch, Murdoch, Australia; [4]K.U.Leuven, Leuven, Belgium; [5]Leibniz Res. Ctr. for Working Envrn., Dortmund, Germany

Abstract: Background: Previous neural imaging studies have shown that the dorsolateral prefrontal cortex (DLPFC) and dorsal premotor cortex (PMd) are active during complex bimanual tasks.
Objective: This study used disruptive repetitive transcranial magnetic stimulation (rTMS) to

further explore (1) if respective correlational evidence is a representation of a causal relationship and (2) if DLPFC and PMd show a differential causal contribution to specific task outcome measures.
Methodology: A total of 41 young healthy adults (mean age: 22.20 years ± 2.95 SD) were enrolled in this study. We applied disruptive short-train rTMS (5 pulses, 10 Hz) on either DLPFC or PMd during either the preparation or execution of a complex bimanual tracking task (BTT). Specifically, we examined the effect of disruption on two BTT performance measures: task accuracy (TA), and movement stability (MS). While TA is assumed to measure the conscious monitoring of the task, MS measures only the stability (smoothness) of the bimanual movement.
Results: DLPFC disruption during motor preparation had a short detrimental effect on TA, while MS was unaffected. There was no effect of DLPFC disruption during motor execution on either TA or MS. In contrast, PMd disruption during motor preparation and execution had a short detrimental effect on MS, while TA was unaffected.
Conclusion: The current findings revealed a differential causal involvement of DLPFC and PMd in preparing and executing a complex bimanual coordination task. More specifically, DLPFC is suggested to be more involved in the conscious monitoring of the task and these cognitive operations of movement control were most crucial during motor preparation. In contrast, the role of PMd is restricted to the integration of two unimanual movements into a single control structure for both hands during both motor preparation and execution.

Title: Cerebellar transcranial direct current stimulation (ctDCS) to modulate cerebello-cerebral networks in bimanual coordination in young and older adults

Authors: *K. VAN DUN[1], S. VERSTRAELEN[2], S. DEPESTELE[3], F. MICHIELS[3], R. MEESEN[4];
[1]Uhasselt, Hasselt, Belgium; [2]REVAL Rehabil. Res. Centre, Biomed. Res. Institute, Fac. of, Univ. of Hasselt, Diepenbeek, Belgium; [3]UHasselt, Hasselt, Belgium; [4]Univ. Hasselt REVAL, Diepenbeek, Belgium

Abstract: Background: Complex bimanual coordination requires a good coordination between different neurological networks. Despite a crucial role of the cerebellum in motor coordination and motor learning, little is known about the cerebellar role in bimanual coordination, especially in aging. In young people the cerebellum is consistently activated during finger and hand movements, but it appears to be a truly crucial structure during development and in older adults, in whom it is the strongest predictor of bimanual coordination performance. By measuring the neurophysiological changes after cerebellar transcranial direct current stimulation (ctDCS), we have investigated the crucially implicated cerebello-cerebral networks in bimanual coordination. **Study design:** An ALE meta-analysis of functional MRI studies was performed to identify the cerebellar areas that are involved in bimanual coordination. 14 young (18-30 years old) and 14 older adults (65-77 years old) performed a bimanual tracking task (BTT) while being stimulated with ctDCS (real or sham). EEG was recorded before and after to measure neurophysiological changes. **Results:** Seven clusters were identified in total with a large cluster in the right anterior cerebellum (antCB). Contrasted with unimanual coordination, the right globus pallidus externus (GPex) was the most significant one. Behavioral and EEG data will be analysed to identify behavioural and neurophysiological changes during bimanual coordination after ctDCS in young and older adults. **Discussion:** Bimanual coordination is mainly controlled by the dominant hemisphere explaining the involvement of the left precentral gyrus and right antCB. In addition, the GPex plays a crucial role in the control of voluntary movement by suppressing unwanted movements. By stimulating the cerebellum, we expect to modulate cerebello-cerebral networks involved in bimanual coordination. By linking behavioural performance to neurophysiological changes, we will be able to identify the networks that are crucially involved and controlled by the cerebellum.

Title: The impact of cognitive functioning on driving performance of older persons: A systematic review

Authors: *S. DEPESTELE, T. BRIJS, V. ROSS, K. VAN DUN, S. VERSTRAELEN, R. MEESEN;
Hasselt Univ., Hasselt, Belgium

Abstract: BACKGROUND: The proportion of persons aged 65 and over is steadily increasing worldwide. Thus, the number of older adults in the possession of a valid driver's license has been growing. As mobility is considered a fundamental need, driving cessation at a higher age could negatively impact quality of life. However, the driving performance of healthy older persons can decrease due to normal aging processes. For instance, cognitive capabilities can deteriorate, possibly leading to higher risk of crash involvement in healthy older persons. OBJECTIVE/HYPOTHESIS: To investigate the association between cognitive functioning and driving performance in a simulator in an older population. We hypothesize that driving ability of older persons is negatively influenced by a deterioration of cognitive function (such as dual-tasking, reaction time, attention strategies, executive function). METHODS: A systematic literature search was conducted on the PubMed, Web of Science, Scopus and Cochrane electronic databases. Articles of the last ten years that examined the differences in cognitive functioning between older and younger persons, using either behavioral assessment or neuroimaging techniques, and its association to driving ability in a driving simulator were identified. Methodological quality was assessed using an adapted checklist based on the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines for observational studies. The findings are reported according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. RESULTS AND CONCLUSIONS: A total of 1933 articles were identified. Twenty-nine articles met the inclusion criteria. Cognitive functioning was assessed using neuroimaging techniques (EEG, fMRI) in 4 studies. Other studies employed a variety of neuropsychological tests or behavioral tests to assess different aspects of cognitive functioning (attention, reaction time, mental workload, dual-tasking, executive function, intelligence). In general, cognitive functioning was found to be worse in older persons and this was associated to a decrease in driving ability. A more in-depth analysis is still in progress. As cognitive functioning in relation to driving is rarely studied using neuroimaging techniques, future studies should employ this more fundamental approach to identify the underlying neurological mechanisms that impact driving performance of older persons.

Abstract: During the control of reaching, motor commands are integrated with sensory feedback to enable robust movements. Yet, it remains unclear how sensorimotor cortical areas achieve this integration. Isolating cortical activity related to ongoing motor commands from the sensory-related signals will help us to understand the neural control of movement. Recent advances have shown how “subspaces” that capture population-wide patterns of neural covariation can mediate specific functions, such as motor planning or adaptation. We hypothesized that interactions between primary motor (M1) and somatosensory (S1) cortex - such as efference copy to S1 or reafference to M1 - are captured at a population level within a “communication subspace” that is isolated from the other inputs to and outputs from these regions.
We trained two monkeys to reach for, grasp and pull an object while we recorded limb kinematics, pulling force, and the activity of neural populations in M1 and area 2 of S1. Using Principal Components Analysis, we identified a low-dimensional manifold within each region capturing the majority of neural variance. Since the interactions between these regions is only a subset of the functions performed by each, we expected the communication between them to be lower-dimensional than the full population activity. We also expected that such communication should be separable from activity directly related to the inputs and outputs of each cortical area. We developed an optimization framework that identified two orthogonal subspaces within these M1 and S1 manifolds. The communication subspace robustly linked M1 and S1, while the “behavior subspace” was strongly correlated with limb movement.
We then explored the roles of these subspaces during movement and the separability of the information and cortical dynamics within each. We first used linear regression to decode limb kinematics from the activity of the communication or behavior subspaces. We found that the behavior subspaces were the superior predictor. We then trained Generalized Linear Models that used the communication or behavior subspaces within one area to predict single neuron spiking in the other area. As predicted, the communication subspaces contained the most information about cortical spiking. These results indicate that population level interactions between M1 and S1 can be isolated from other features of the population, which may include inputs from, or

outputs to, spinal circuits. This method could help us to understand rapid sensorimotor integration for feedback control, and enable robust decoding for brain computer interfaces.

Abstract: Current theories suggest that an error-driven learning process updates trial-by-trial to facilitate motor adaptation. The mechanism by which motor cortical preparatory activity interacts with this process or drives learning remains unknown. We previously found that visuomotor learning is correlated with systematic changes in preparatory activity on single trials (Vyas et al., Neuron 2018). The goal of this study was to investigate if there exists a causal relationship between motor preparation and learning. We began by correlating preparation time and learning as a Rhesus macaque adapted to a visuomotor rotation. We found preparation time was inversely correlated to both variance of errors on current trials ($p < 0.01$), and mean error on subsequent trials ($p < 0.01$). Next, we performed intracortical microstimulation (ICMS) in premotor (PMd) and primary motor (M1) cortex. We found no statistically significant difference, including between the error distributions of ICMS and non-ICMS trials, except for the previously reported reaction time penalty (Churchland et al., JNP 2006). Surprisingly, we found a disruption to the "expression of learning," i.e., trials following ICMS showed a significant disruption compared to trials following no-ICMS ($p < 1e-3$). This suggests that ICMS of preparatory activity engages an error-driven learning process, and in particular disrupts its update computation, thus manifesting as a disruption on subsequent trials instead of current trials. In separate experiments we varied the time of ICMS during preparation and found that disruption to expression of learning was

only present when ICMS was performed near the go-cue. We also observed a “dose-dependent” effect to the disruption by manipulating brain region (PMd vs. M1; where M1 has less preparatory activity), and amount of preparation time prior to ICMS ($p < 0.05$). State-space models revealed that disruption to expression of learning was consistent with a gain-control mechanism whereby the error-driven learning process reduces the gain associated with its update when faced with unexpected perturbation. Consistent with the data, the model predicted that gain returns to baseline with a slow time constant, compared to the original decrease, but only when stimulation ceases. With additional stimulation, gain no longer changes, but stays at a decreased, albeit saturated level ($p < 1e-3$). To our knowledge, this constitutes the first causal evidence for the role of preparatory activity during learning. This study also establishes a link between motor preparation and the error-driven learning system, which may provide a new lens into investigating trial-by-trial adaptation.

Title: Time-dependent modulation of spinal excitability during action observation in the macaque monkey

Authors: *S. J. JERJIAN[1], R. N. LEMON[2], A. KRASKOV[1];
[1]Dept. of Clin. and Movement Neurosciences, [2]UCL Queen Square Inst. of Neurol., London, United Kingdom

Abstract: Neurons in the primate motor cortices, including identified pyramidal tract neurons (PTNs) which project directly to the spinal cord, respond to the observation of others’ actions, yet these responses do not give rise to any movement in the observer. Human studies, using transcranial magnetic stimulation (TMS) or H-reflex responses, have reported motor ‘resonance’ between observed and executed actions in the corticospinal system.
Here, we investigated time-dependent modulation in the level of spinal excitability by monitoring electromyographic (EMG) responses produced by single shocks delivered directly to

the pyramidal tract (PT) of two adult rhesus macaque monkeys. It is well known that H-reflex is very difficult, if impossible, to record in intrinsic hand muscles. TMS evoked response represents a sum of multiple indirect volleys (I-waves) whereas direct PT stimulation evokes a clear short-latency descending volley in corticospinal axons and therefore allows to investigate spinal excitability without influence of cortico-cortical interactions We recorded and analysed short-latency PT evoked responses in hand and digit muscles while monkeys performed, observed or withheld reach-to-grasp and hold actions. On some observation trials, we also altered the visibility of the observed action and the information available regarding the upcoming grasp, in order to test the dependence of any spinal modulation on the visual information available to the monkey.
We found modest grasp-specific facilitation of hand muscle responses around the time of grasp observation, which persisted when the grasp was predictable but obscured from the monkey's vision. We also found evidence of a more general inhibition of movement before the grasp. Interestingly, MEPs during initial part of the observation trial were comparable in amplitude to MEPs after cued with a NoGo signal when monkeys explicitly suppressed their movement.
In summary, we confirm that the spinal circuitry controlling hand muscles is modulated during action observation, and this may be driven by internal representations of actions. The relatively modest changes in spinal excitability during observation suggest that the corticospinal activity present exerts only minor, sub-threshold changes on hand motoneuron pools, thereby preventing any overflow of mirror activity into overt movement.

Title: Toward electrophysiological and behavioral effects of causal perturbations in the hand grasping network of rhesus monkeys

Authors: *A.-D. GINDRAT[1], H. SCHERBERGER[1,2];
[1]Deutsches Primatenzentrum GmbH, Goettingen, Germany; [2]Fac. of Biol. and Psychology, Univ. of Goettingen, Goettingen, Germany

Abstract: Voluntarily grasping objects with the hand is crucial for primates and constitutes a highly complex sensorimotor process. In macaque monkeys, the fronto-parietal hand grasping

network includes the anterior intraparietal area (AIP), the hand area of the ventral premotor area (F5 or PMvr) and the hand area of primary motor cortex (M1). Important insights into the functioning of this network were obtained using techniques that perturb brain activity in monkeys. For example, while electrical intracortical microstimulation (ICMS) in F5 could not elicit any hand movements, it was shown to exert a facilitatory effect on M1 outputs to upper limb motoneurons. Nevertheless, the specific functional contributions of each area of this network to hand grasping remain elusive.
This study is part of a larger project aiming at causally investigating the primate hand grasping network using the newly established and highly innovative technique of neuro-optogenetics. We aim to compare the effects of optogenetic stimulation in F5 on the electrophysiological activity in the grasping network and on hand grasping behavior, with those induced by well-established interference methods, here ICMS.
We trained two adult female rhesus monkeys (*Macaca mulatta*, age: 15 years) to perform a visually-instructed delayed grasping task, in which they had to lift different objects presented on a turntable in random order. During this task, we recorded spiking activity in areas F5, M1 and AIP with single movable microelectrodes, and we simultaneously measured hand kinematics using a custom-made instrumented glove able to record 32 degrees of freedom of the fingers, hand and arm. Recordings confirmed previous findings of the grasp-related activity of these areas and their associated hand kinematics.
Using this setup and paradigm, we will deliver ICMS in F5 in 50% of all trials, randomly interleaved with no-stimulation trials. We expect that ICMS in F5 *per se* will not elicit overt hand movements (Umilta et al., 2007), but induce a reduction in movement time, indicating a facilitatory effect of F5 on M1 (Prabhu et al., 2009). Furthermore, the instrumented glove will allow us to track detailed alterations of hand kinematics.

Title: The causal role of three frontal areas in object grasping

Authors: *I. CAPRARA[1], P. JANSSEN[1,2];
[1]Dept. of Neurosciences, KU Leuven, Leuven, Belgium; [2]Leuven Brain Inst., Leuven, Belgium

Abstract: In order to perform real-world tasks like grasping efficiently, the primate brain has to process visual object information so that the grip aperture can be adjusted before contact with the object is made. Electrical microstimulation of 3D shape-selective clusters in AIP during fMRI activates areas F5a and 45B (Premereur E et al., 2015, PLoS Biology *13: e1002072*), indicating that these frontal areas represent important downstream areas for object processing during grasping, but the role of area 45B in grasping is unknown. To assess the causal role in the grasping network of these frontal areas located in the arcuate sulcus, we reversibly inactivated 45B, F5a and F5p during a visually guided grasping task in macaque monkeys. Using a robot, we presented two different spheres (large and small – 3 and 1.5 cm diameter), within reaching distance (36 cm) at chest level. First, we recorded single neuron activity in 45B, F5a and F5p to functionally identify the center of object selectivity during grasping. Then, we injected muscimol (three sessions per area) or saline (one session per area) to measure the grasping deficit induced by the temporary disruption of these three nodes in the grasping network. Behavioral data were collected before and after muscimol injection and were compared to saline sessions. The inactivation of all three areas resulted in a significant increase in the total grasping time (i.e. the time between the go-signal and the pull of the object, t-test $p<0.01$). However, we observed a different pattern of deficits across sessions: while inactivation of area F5p resulted in a very strong deficit only during the first session, inactivation of area 45B produced more stable deficits in grasping across sessions. Finally, the pattern of deficits after inactivation of area F5a was intermediate between the two previous neighboring areas. Overall, these results not only confirm a clear involvement of F5p, in line with previous studies, but also suggest a causal contribution of area F5a to grasping, and an unexpected role for area 45B in object grasping, even though previous studies suggested an involvement in oculomotor control.

Title: The neuroethoroom: A new tool for neurobehavioral studies in freely behaving monkeys

Authors: *F. LANZARINI, M. LANZILOTTO, L. BONINI;
Dept. of Med. and Surgery, Univ. of Parma, Parma, Italy

Abstract: Neurophysiological studies in non-human primates (NHP) typically require the use of primate chairs and constrained laboratory settings. This is necessary to make the recording of

neuronal activity technically possible and to achieve a sufficient behavioral control, but at the same time strongly limits the possibility to understand brain functioning underlying unconstrained, natural behavior. In recent years, thanks to newly developed technologies, untethered neural recording from unrestrained animals is becoming more and more feasible (Mimica et al., 2018; Omer et al., 2018), and video behavioral tracking is improving dramatically, making possible to apply these technologies to large animals, such as NHP. Here, we present a new setup and methodology to simultaneously study NHP behavior and brain activity during unconstrained situations. To this purpose, we designed and built a transparent plexiglass enclosure (WxHxD, 208x205x181 cm) in which the space can be easily manipulated and/or flexibly filled with different devices, such as food and non-food items, ropes and wooden structures, in order to elicit a wide variety of NHP ethologically relevant behaviors (NeuroEthoRoom, NER). A system of 8 IR-sensitive cameras was set around the NER, to record NHP behavior at a frequency up to 100 Hz from multiple viewpoints. Two macaque monkeys, housed in pair (one dominant and one subordinate), were individually trained to enter in the NER. We could automatically track the monkey's position during natural behaviors through a customized head-post cover equipped with one or up to 4 retroreflective markers (RMs). Each monkey performed multiple sessions in the NER, where it was free to climb and walk over a wooden structure to reach food rewards and to manipulate a dangling plastic ball filled with fruit pieces. We automatically tracked the RM position by means of SIMI technologies software (SIMI Motion). We could then calculate, off-line (MATLAB), the exact position of the monkey's head relative to the enclosure bounding walls, the wooden structure and the plastic ball, as well as kinematics parameters regarding monkey's head motion, such as speed and acceleration. By using 4 RMs we could also extract information about head orientation, roll and pitch. This new setup makes it possible to study a large variety of ethologically relevant behaviors in the NHP repertoire, which were impossible to investigate with conventional methods. By integrating this technology with wireless neural recordings synchronized with the multicamera system, the NER will allow to correlate neural activity with NHP natural behavior.

Title: Calibrating temporal expectations through flexible tuning of neural dynamics

Authors: *N. MEIRHAEGHE[1], H. SOHN[2], M. JAZAYERI[3];
[1]Harvard-MIT Div. of Hlth. Sci. & Technol., [2]McGovern Inst. for Brain Research,Center for Sensorimotor Neural Engin., MIT, Cambridge, MA; [3]Brain and Cognitive Sci., Massachusetts Inst. of Technol. Dept. of Brain and Cognitive Sci., Cambridge, MA

Abstract: Humans continuously form expectations about the world based on prior experience, and combine this information with incoming sensory inputs to refine their behavior. This process critically relies on the ability of the nervous system to predict and simulate events based on environmental cues and statistical regularities. Moreover, in a dynamic environment, predictions must be continuously adjusted to match the ever-changing behavioral demands. How regularities in the environment constrain neural activity to afford predictive capacities, and how neurons change their patterns of activity to update predictions is not known.
To tackle these questions, we trained monkeys on a time reproduction task in which we could readily manipulate statistical regularities. Animals had to measure a sample interval between the first two beats of a rhythm, and initiate a saccade on the third omitted beat. When exposed to various distributions, animals' responses were biased toward the mean of the learned distributions. These biases were accompanied by an adjustment of the speed of neural activity during the measurement epoch within dorsomedial frontal cortex. Specifically, the speed of population dynamics was adjusted according to the mean of the distribution. We hypothesize that this population tuning reflects the ongoing temporal expectations of animals throughout learning. We tested this hypothesis using a two-stage computational model. The model consists of two serially coupled drift-diffusion processes (DDP)—an unbounded DDP for the measurement epoch (DDP_m), followed by a bounded DDP for production (DDP_p). DDP_m uses a fixed drift rate to track elapsed time between the first two beats. When the second beat comes, the deviation of DDP_m from a fixed threshold serves as sensory prediction error, and is used to adjust the drift of DDP_p controlling movement initiation. Critically, the drift of DDP_m is adjusted to reduce prediction error in subsequent trials, allowing the model to tune to the interval distribution. The model captured the history dependence of behavioral biases and provided a readout of animals' ever-changing estimate of the distribution mean. Ongoing work seeks to validate our model by exposing animals to new distributions while tracking changes in cortical activity.

Title: Rapid feedback responses in primary motor cortex are sensitive to goal redundancy

Authors: *K. P. CROSS[1], D. J. COOK[2], S. H. SCOTT[3];
[2]Neurosurg., [3]Dept Biomed. and Mol. Sci., [1]Queen's Univ., Kingston, ON, Canada

Abstract: A hallmark of our motor system is the ability to flexibly alter motor actions to attain a behavioural goal. Recently, we had human participants reach for either a narrow or wide target while we unexpectedly applied a mechanical load that displaced the hand along the redundant spatial dimension of the wide target. We found subjects corrected less when reaching for the wide target and found muscle responses reflecting target shape started in <100ms after the mechanical disturbance. We hypothesized that this rapid muscle response was generated by transcortical feedback involving primary motor cortex (M1). We tested this hypothesis by training a monkey (macaque mulatta) to make goal-directed reaches to targets that primarily required elbow extension. The goal target could either be a narrow (width=3cm) or a wide goal resembling a chevron (width=28cm), and target shape was changed randomly on a trial-by-trial basis. On random trials a mechanical load was applied that deviated the animal's hand lateral to the target. When no loads were applied, monkeys tended to reach towards the center of both targets. However, reach endpoints were far more variable for the wider target as the endpoint ellipses were ~4x larger than the ellipses for the narrow target (paired t-test $t(7)=7.3$, $p<0.001$). When loads were applied, monkeys made large corrections for the narrow target. In contrast, monkeys corrected less for the wide target exploiting that a small correction could still attain the goal. Kinematic changes due to target shape could be detected in the lateral velocity starting at ~210ms. We recorded from M1 using a 96-channel floating micro-electrode array. We examined the population response following mechanical disturbances across all 96 channels and across multiple days. We found changes in the population firing rate started ~50ms after the applied load. The initial response (50-75ms) was similar regardless of target shape (paired t-test $p>0.1$). Critically, in the 75-100ms epoch we observed a significant increase in firing rate for the narrow as compared to the wide target (t-test $p<0.01$). Our data suggests that a transcortical feedback pathway through M1 is involved in generating flexible, target-dependent feedback responses during reaching.

Title: Encoding spaces for multiplexing movement representations across timescales in motor cortex

Authors: ***P. MALONIS**[1], N. G. HATSOPOULOS[2], J. N. MACLEAN[3];
[1]Committee on Computat. Neurosci. Grad. Program, [2]Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL; [3]Neurobio., The Univ. of Chicago, Chicago, IL

Abstract: Primary motor cortex (M1) has been reported to exhibit activity that encodes current movement as well as planning for future movements. These distinct signals have, for the most part, been studied using behavioral tasks in which motor planning and execution occur during distinct epochs of the task. However, in the case of natural behavior, it is often necessary to plan future movements while simultaneously executing ongoing movement. Here, we record from ensembles of neurons in motor cortex during continuous movement, which allows us to determine the extent to which ensembles exhibit planning signals for future movements simultaneously with representations of ongoing movements in motor cortex. By training decoders that use neural activity to predict movement at different points of time relative to the activity and comparing the decoders' parameters, we can compare the subspace of ensemble activity that encodes movement at each time point. Comparison of these "encoding spaces," provides insight into the degree to which representations of movement at different timescales are multiplexed in the same cortical area. In M1 of macaque monkeys, we find a component of the encoding space for arm movements at specific time points in the near-term (~150ms) that is orthogonal to the encoding space for arm movements further into the future (~600ms), but not to encoding spaces for movements at other time points. This result suggests that movement representations for these two timescales could to some extent be linearly distinguished in a multiplexed code.

Title: Neural activity of units not controlling BCI directly during a BCI task

Authors: *Z. LIU[1], M. H. SCHIEBER[2];
[1]Biomed. Engin., Univ. of Rochester, Rochester, NY, NY; [2]Neurol. and Neurosci., Univ. of Rochester, Rochester, NY

Abstract: The development of brain-computer interfaces (BCI) that use spike recordings for input has primarily used neural recordings from the primary motor cortex (M1). Nevertheless, the firing rates of many M1 units not directly involved in controlling the BCI (non-BCI units) has shown varied in relation to the BCI task. We investigated non-BCI units among multiple cortical areas while a BCI is controlled with a small number of M1 units.
We trained two monkeys (*Macaca mulatta*) to perform an 8-target center-out task using a BCI with four M1 units. We recorded the spike activity of non-BCI units simultaneously in 6 cortical areas—M1, dorsal premotor cortex (PMd), ventral premotor cortex (PMv), the primary somatosensory cortex (S1), the anterior intraparietal area (AIP), and dorsal posterior parietal cortex (dPPC).
For units that are not controlling the BCI directly (non-BCI units) in Monkey P, over 60% of the units in each of the six cortical areas are modulated with the BCI task ($p < 0.05$). For Monkey Q, more than 75% of the units in each of the six cortical areas are modulated with the BCI task ($p < 0.05$). For the population neural activity in each cortical area, we partitioned the variance of firing rates that were related to 1) the execution of a movement in general (condition-independent or general task), 2) the dependent variables of the behavioral task -- eight target locations (condition-dependent), and 3) the remaining noise. Condition-dependent variance only starts after Go Cue, and peaks at around 500ms after Go Cue, with BCI M1 units having significantly greater variance than any other areas. The condition-independent variance peaks at about 200ms earlier than the condition-dependent variance. BCI units, Non-BCI M1 units and PMd units have larger condition-dependent variance than the condition-independent variance, while AIP units have larger condition-independent variance than the condition-dependent variance. We further decode the task variable (instructed targets) with the firing rates of neurons. We started with using all available units in each cortical area, and the decoding accuracy with non-BCI M1, PMd, and PMv units is higher than that with BCI units. However, if we perform the decoding using four-unit combinations, the average decoding accuracy with BCI units is

higher than that with units in any other cortical area.
Our findings demonstrate that non-BCI units in many cortical areas are modulated significantly while M1 units control a BCI, with the condition-dependent and condition-independent variance varying among areas. We suggest that control of a BCI using M1 neurons may require a network extending well beyond M1.

Title: Primary motor cortex employs similar yet distinct population dynamics during locomotion and obstacle avoidance

Authors: *D. Y. XING[1], W. TRUCCOLO[2], D. A. BORTON[1];
[1]Sch. of Engin., [2]Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: Primary motor cortex (M1) is necessary in primates for generating precise, voluntary actions. However, the involvement of M1 during locomotion, which may not require attention or even online control, as well as how M1 integrates voluntary actions onto ongoing locomotor rhythms, such as obstacle avoidance, is not well understood. It has been postulated that voluntary limb movements like reaching and grasping may have evolved out of precise gait modifications during locomotion, in which case, we would expect to see similar neural activity patterns during these motor behaviors. To investigate the relationship between M1 activity during locomotion and the activity during directed, volitional actions, we employed an obstacle avoidance paradigm which requires the generation of directed limb movements both from rest as well as during locomotion. We recorded leg-M1 and arm-M1 activity with implanted microelectrode arrays from nonhuman primates (Rhesus Macaque) while the animals performed basic walking on a treadmill at 2.2 km/h (“autonomous” locomotion), stepping over an obstacle moving towards them at 2.2 km/h while stationary (volitional movements), and stepping over the obstacle while walking on the treadmill (integrated movement and transition of states). In arm area, we found that 42/53 neurons changed their depth of modulation and 26/53 neurons changed their gait cycle phase tuning between stationary obstacle avoidance steps and locomotion steps (unpaired t-test,

n=39 obstacle trials, n=73 walking trials, Benjamini-Hochberg correction with FDR=10%), suggesting that voluntary movements and basic locomotion are encoded differently in M1. To compare the cortical activity on a population level, we utilized a Poisson linear dynamical system (PLDS) model to explicitly extract the neural dynamics from recorded neurons. Low-dimensional trajectories in the latent state-space revealed similar rotational structure for both basic locomotion and stationary obstacle avoidance. However, we also found a single dimension, using linear discriminant analysis (LDA), that separated the neural trajectories during the diverse movements. During integrated movements, e.g. obstacle avoidance while walking, the neural latent state smoothly transitioned from the putative locomotion region to the putative volitional movement region in the LDA dimension while maintaining its rotational structure. These findings suggest that for voluntary movements and autonomous locomotion, rotational dynamics are conserved in motor cortex, but additional dimensions distinguishes the population activity between the two movement modalities.

Title: Activity in macaque primary motor cortex during a motor inhibition task

Authors: *T. TOHYAMA, S. N. BAKER;
Inst. of Neuroscience, Newcastle Univ., Newcastle upon Tyne, United Kingdom

Abstract: Voluntary motor control requires not only execution of desired movements, but also inhibition of inappropriate responses. Such motor inhibition has received less attention, especially in experiments performing direct neural recordings in non-human primates. Studies with the stop-signal paradigm have shown that suppressing a prepared response depends primarily on the prefrontal cortex, however it is unclear what downstream structures enact the stop command. The primary motor cortex (M1) is a key center for motor execution. It is unclear whether M1 activity changes to stop the movement, or whether downstream inhibition prevents the execution of the unaltered go command from M1. We therefore investigated how M1 activity modulates during motor inhibition. A macaque monkey was trained to perform a stop-signal task. Trials were initiated by grasping a handle. On 75% of trials, a green LED illuminated and the handle had to be released to earn a reward (a go trial). On 25% of trials, the green LED was followed by illumination of a red LED after a delay (a stop trial); a reward was then only earnt if

the monkey did not release the handle. Using a race model[1], the stop-signal reaction time (SSRT, an estimate of the latency of the stop process), could be calculated. Single cell recordings from the contralateral hand area of M1 were made during task performance; pyramidal tract neurons (PTNs) were identified by antidromic activation from a chronically implanted PT stimulating electrode and collision test. The estimated SSRT was 221 ms (the 95% confidence interval: 218-223 ms; n=97 sessions). PTNs were classified according to whether they fired significantly more in the period 0.3-1 s after the go cue during go (81/139 cells) or stop trials (37/139 cells). Average firing rates compiled selectively over these two PTN populations revealed a change in rate between stop and go trials prior to the end of the SSRT. The response of corticospinal cells to the stop-signal occurs prior to completion of the stop process, suggesting that the descending command from M1 is modified as part of the response to prevent movement.

Title: Simultaneous multichannel recordings in dorsal and ventral premotor cortex during a reach-to-grasp task

Authors: *S. DE SCHRIJVER, E. PREMEREUR, T. DECRAMER, P. JANSSEN;
Kuleuven, Leuven, Belgium

Abstract: The premotor cortex is involved in visually guided motor behavior with the dorsal premotor cortex (PMd) more implicated in reaching and the ventral premotor cortex (PMv) more involved in grasping. To investigate the potential of both areas for novel brain-machine interfaces (BMIs) based on visuomotor activity, we implanted 96-channel Utah arrays in dorsal premotor area F2 and in ventral premotor area F5c. Single unit (SUA) and multiunit activity (MUA) were recorded while the monkey performed a reach-to-grasp task towards 3 identical objects at different locations in space, hence requiring different reach directions. In 19 sessions, we recorded the activity of 2097 MUA sites (PMd: 1054; PMv: 1043) and 1005 single neurons (PMd: 571; PMv: 434) with significant task-related activity. On average, neuronal activity in PMd showed a strong increase in spike rate at object onset and remained elevated throughout the trial until the grasp movement. In contrast, the average activity of PMv neurons decreased below

baseline level after object onset and only sharply increased after the onset of the hand movement. A visuograsp index (comparing the activity after object onset with the activity around pull of the object) differed significantly between dorsal (MUA: -0.0202, SUA: 0.0256) and ventral premotor cortex (MUA: -0.0300, SUA: -0.3112; t-test MUA: $p<0.01$, SUA: $p<0.001$). Furthermore, the activity during the reaching phase was higher in PMd than in PMv, whereas the opposite was true during the grasping phase (reach-grasp index comparing the activity after the lift of the hand with the activity around the pull of the object, PMd MUA: 0.0183, SUA: 0.0137; PMv MUA: -0.0209, SUA: -0.1992; t-test MUA: $p< 0.001$, SUA: $p<0.001$). Finally, both areas showed significant direction selectivity (selectivity indices comparing the activity for the best direction versus the worst direction, PMd: >0.0364, t-test: $p<0.001$; PMv: >0.0299, t-test: $p<0.001$), which was significantly higher for SUA than for MUA (anova, $p<0.001$). Taken together, we can conclude that the premotor cortex is functionally heterogeneous, with high visual responses in PMd and more movement-related responses in F5c. Furthermore, PMd neurons show higher activity for reaching, whereas PMv neurons show higher activity during grasping, although both areas encode reaching and grasping. Finally, our data indicate that SUA differentiates more between reach directions than MUA, which has strong implications for the development of novel BMIs based on visuomotor activity.

Title: Optogenetic inhibition of premotor-to-parietal projections reveals a top-down modulation in rule-based sensorimotor transformations in rhesus monkeys

Authors: *H. GUO[1,2], M. FORTUNA[1], J. HUEER[1], J. GRUBER[1], S. TREUE[1,2,3], H. SCHERBERGER[1,2,3], A. GAIL[1,2,3];

Abstract: Context-dependent sensorimotor transformations have been associated with the frontoparietal network in the cerebral cortex of primates. It has been hypothesized that the mutually connected parietal reach region (PRR) and the dorsal premotor cortex (PMd) coordinate their activity for context-dependent motor goal selection, particularly, that parietal motor goal encoding might be contingent upon PMd input in non-standard visuomotor mappings. Yet, such causal functional link has not been shown so far.

We used pathway-selective optogenetic reversible inhibition (AAV2/5-CaMKIIα-eArchT3.0-eYFP) of the neural projections from PMd to PRR while the monkey performed a memory-guided center-out anti-reach task with ocular fixation. Continuous laser stimulation (532 nm, 330 ms) of the neuropil was applied simultaneously with the visual cues which were presented to the animal prior to an instructed delay period and which instructed the reach goal. Stimulation trials were randomly interleaved with no-stimulation trials. Stimulation was applied either in the transfected PMd or in PRR. Single-unit microelectrode recordings were performed simultaneously in the light-stimulated neuropil, with an inter-tip linear distance between electrode and optical fiber of 500-950 μm.
Laser stimulation in PMd resulted in reliable silencing of nearby PMd neurons. Light-induced inhibition of projections from PMd within PRR resulted in neural response modulations in nearby neurons during the movement planning following light stimulation. In both pro- and anti-reach trials, directional selectivity of individual neurons could be preserved, erased or evoked. At the population level, motor goal encoding in PRR was delayed after laser-stimulation exclusively in anti-reach trials. These results support the hypothesis that dynamic reorganization in PRR, as it is selectively needed for spatial remapping in anti- but not pro-reach trials, is contingent on functional input from PMd. Our findings provide causal evidence that encoding of rule-based reach goals in parietal cortex partly builds on frontal-to-parietal functional interactions.

Title: Constraints on the time course of neural population activity

Authors: *A. D. DEGENHART[1,3], E. M. GRIGSBY[1,3], N. T. MCCLAIN[1,3], E. R. OBY[1,3], A. P. BATISTA[2,3], B. M. YU[4,3];

Abstract: Across different tasks and brain areas, the time course of neural population activity has been suggestive of network-level mechanisms, such as point attractors and line attractors, underlying sensorimotor behavior. These mechanisms, if present, specify particular sequences of population activity patterns that are naturally produced, given the underlying network constraints. A key prediction suggested by these constraints is that it is difficult for the brain to produce time-reversed sequences of the naturally-produced activity. To test this prediction, we leveraged a brain-computer interface (BCI) to probe the ability of Rhesus monkeys to volitionally produce time-reversed sequences of population activity. The key advantage of using a BCI in this context is that it allows us to place task requirements on the generation of specific sequences of neural activity. Animals performed a BCI task where they moved a cursor between two targets in a virtual environment. This task design required animals to move between the same two targets (A and B), but in time-reversed sequences (A->B and B->A). Neural activity, recorded using a 96-electrode "Utah" array, was mapped onto the 2D position of the BCI cursor. Animals first performed the two-target task using an "intuitive" BCI mapping calibrated to yield proficient control. We observed that even though the paths traversed by the cursor were highly overlapping in the animal's workspace, high-dimensional neural population trajectories exhibited distinct paths for each target. We then sought to determine the extent to which animals could violate these observed sequences of neural activity. We used neural activity observed during intuitive BCI control to define a "rotated" mapping from the high-dimensional neural activity space to the 2D cursor workspace where the A->B and B->A neural trajectories were most different. Using this rotated mapping, animals were then required to generate cursor trajectories which were inconsistent with those predicted from intuitive BCI control. We found that it was difficult for animals to modify their cursor trajectories in the rotated projection when task success was contingent upon doing so, indicating that they were incapable of producing time-reversed sequences of neural activity. These results provide evidence that it is difficult to violate the naturally-occurring sequences of neural population activity. This implies that the underlying network imposes strong constraints on the time course of population activity and, therefore, appears capable of implementing widely-hypothesized network-level mechanisms that specify particular sequences of population activity patterns.

Title: Chronic wireless neural population recordings in freely behaving marmosets

Authors: *J. D. WALKER[1], D. MOORE[2], M. SUNDIANG[4], J. N. MACLEAN[3], N. G. HATSOPOULOS[1];
[1]Univ. of Chicago, Chicago, IL; [3]Neurobio., [2]The Univ. of Chicago, Chicago, IL; [4]Organismal Biol. and Anat., Univ. Of Chicago, Chicago, IL

Abstract: Studying the brain during natural ethologically relevant behavior will yield important insights into cortical function. This goal presents substantial technical challenges for the acquisition of neurophysiological data particularly in non-human primates. The common marmoset presents a number of advantages for the neurophysiological study of natural behavior [1]. Here we report the design and implementation of an acrylic free surgical preparation for implanting multielectrode arrays to chronically record sensorimotor cortical population activity from common marmosets across a range of behaviors and brain states. Moreover, our approach is both flexible and robust, and has allowed us to record sensory motor cortical responses for multiple years. Additionally, we present a wireless headstage configuration that minimizes the need for excessive handling of the marmosets while maximizing the ease of replacing batteries to facilitate long recordings. We show that we are able to use these surgical techniques and headstage configuration to record across the marmoset's behavioral repertoire, such as during locomotion, foraging, grooming and during sleep. Coupled with the in home-cage approach to behavioral training we have developed, this wireless recording preparation provides a viable alternative to neurophysiology with chair restraint for recording neural activity from marmosets during behavioral training paradigms.

Title: Examination of shared and non-shared neural subspaces in the primary motor cortex between active movement and brain machine interface control

Authors: S. GUPTA[1], S. SHEEN[1], V. PAPADOURAKIS[3], K. TAKAHASHI[3], N. G. HATSOPOULOS[3], ***A. J. SUMINSKI**[2];

Abstract: The notion that the primary motor cortex (M1) is simply a driver of voluntary movements has long masked its true identity as the major hub of sensorimotor processing in the cerebral cortex. Indeed, the activity of single neurons in M1 is highly heterogeneous often varying greatly based on the state of the limb, the presence and fidelity of sensory feedback, and the type of end effector being controlled. However, it remains unclear how variations in motor task and sensory context are represented by neural ensembles in the high dimensional space that describes M1 activity. Here we take advantage of dimensionality reduction methods to characterize shared and non-shared neural subspaces between these conditions.
Two monkeys (Macaca mulatta) were trained to move a visual cursor to hit a sequence of randomly placed targets while resting their arm in a two-link robotic exoskeleton. They performed the task under four different conditions. During active movement (AM), they used their arm to move the exoskeleton. In the visual observation (OBS) condition, the monkeys observed replay of AM task performance while holding their arm still. In the BMI conditions, the monkeys used a neural decoder to hit targets while holding their arm still (V BMI) and while the exoskeleton moved their arm along with the BMI controlled visual cursor (V+P BMI). Single unit activity was recorded using a 10x10 micro-electrode array chronically implanted in M1. We identify a set of latent variables that define the neural activity in M1 using dimensionality reduction. A novel unsupervised machine learning technique then structures combinations of latent variables as feature vectors and separates the conditions using a similarity metric. It finally quantifies and ranks the separability of the subspaces for all conditions.
While much of the variance in population activity is shared across the conditions, we find significant non-shared subspaces between the four conditions. In particular, AM condition often occupies an entirely different subspace than the OBS and BMI conditions possibly due to the activation of muscles to move the arm. In addition, the two BMI conditions also seem to have separable subspaces as we find significant non-shared variance between the V BMI and V+P BMI conditions, suggesting that differences in the availability of sensory feedback modulates the encoding properties of neural ensembles in M1.

Title: Temporal basis functions reveal systematic variation in rotational dynamics in monkey M1

Authors: *D. A. SABATINI[1], M. T. KAUFMAN[2];
[1]Organismal Biol. and Anat., The Univ. of Chicago, Chicago, IL; [2]Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: Neurons in monkey motor cortex (M1) exhibit complex, multiphasic patterns of activity over time during reaching. These patterns are not fully explained by correlations with kinematic variables or muscle activity, and are incompletely fit by dynamical models of pattern generation. Here, we present a simple application of Principal Component Analysis (PCA), which we name Temporal Component Decomposition (TCD). TCD provides a new view of motor cortex activity. Typically, in the motor literature, PCA is performed on a neural data matrix organized as neurons by time and condition (N x TC), focusing on patterns of activity across neurons. TCD instead applies PCA to a matrix that is T x NC. TCD decomposes the data into a small number of temporal basis functions that are combined in a potentially unique way for each neuron in each condition (reach shape). Applying TCD to previously analyzed Utah array recordings from monkeys making curved reaches, we find several novel results. First, nine Temporal Components (TCs) account for ~90% of the variance in firing rates, compared to ~60% with nine components when using PCA over neurons. Six of these TCs comprise three rotational planes. This low-dimensional response cannot be accounted for by smoothing of a Poisson processes, 1/f spectral properties, or as a consequence of instantaneous encoding for muscle activity or kinematic variables. Second, the orientation of the TCs in neural state space (embeddings) varies substantially across reach conditions. The structure of these embeddings is systematic, with similar embeddings for similar reach conditions and low overlap in embedding between dissimilar conditions. This confirms previous findings that M1 has several rotational planes with preserved temporal structure, but shows that these planes are oriented differently for distant conditions. Finally, TC embeddings in state space have a simple, linear relationship with coarse-level parameterizations of the executed reach, revealing a relationship between motor cortex activity and kinematics not observable at the level of individual neurons. These results demonstrate that temporal decomposition can reveal variations in the neural dynamics across conditions that have confounded previous analyses.

Title: The spatio-temporal organization of M1 activity during reaching and grasping in monkeys

Authors: *N. CHEHADE, O. A. GHARBAWIE;
Dept. of Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Primary motor cortex (M1) is crucial for controlling arm and hand movements in primates. The spatial organization of M1 outputs is reflected in the somatotopic organization of the forelimb representation. Even through the arm and hand representations can be readily defined with intracortical microstimulation, the spatio-temporal organization of M1 activity that supports coordinated arm-hand actions is less clear. The present study is part of an effort to understand how the neural activity that supports reaching and grasping is encoded in the M1 forelimb representation. To achieve this objective, we trained a macaque monkey to perform a reach-to-grasp task while head-fixed. Target objects were presented in near (200 mm) and far locations (250 mm). Power grip and precision grip were elicited by large (32 mm diameter) and small (13 mm diameter) target objects. A chronic optical window provided access to M1, which we investigated with intrinsic signal optical imaging (ISOI, 630 nm illumination) and linear electrode arrays. ISOI (10 frames/s, 8 s/trials) revealed at least 3 domains (~1 mm^2/domain) that were activated in M1 in response to reaching and grasping. M1 domains expanded spatially (up to 8 mm^2/domain) even after the end of movement. Systematic shifts in the 'go' cue showed that peak reflectance change was temporally-locked to reach onset (~5.5 seconds) thus confirming that ISOI modulation was driven by task-related movements. Intracortical microstimulation in the same optical window showed that the activation domains spatially coincided with parts of the arm and hand representations. Unit activity recorded from linear electrode arrays in dozens of penetrations showed that ISOI domains contained units that were reach-modulated (18% of recorded units), grasp-modulated (38% of recorded units) and task-modulated (32% of recorded units). A preliminary map of the spatial locations of the recorded single units showed that reaching and grasping are encoded throughout the forelimb representation. Our findings thus far show that combining ISOI with neurophysiology has the potential to reveal the spatial-temporal organization of movement encoding in cortex.

Title: Emergence of lateralized population activity in motor cortex across instructed-delay and execution phases of reaching

Authors: *T. C. DIXON[1], C. M. MERRICK[2], R. T. KNIGHT[2], R. B. IVRY[2], J. M. CARMENA[3];
[1]Bioengineering, [2]Psychology, [3]Electrical Engin. and Computer Sci., Univ. of California, Berkeley, CA

Abstract: While motor cortex predominantly drives movements of the contralateral arm, there is growing appreciation for the bilateral representation of arm movements within a single hemisphere. This apparent conflict between shared and independent representation of movements for either side of the body may be partially resolved by considering the phase of processing and level of information coding. Indeed, previous and ongoing studies have begun to reveal the contribution of each of these factors. Yet, it remains unclear how the lateralized structure of population activity in motor cortex evolves during the course of reach preparation and execution. In this study, we record ensemble spiking activity in bilateral primary motor (M1) and dorsal premotor (PMd) cortices in one macaque monkey performing an instructed-delay reaching task with one arm at a time. During the instructed-delay, both the reaching target and arm are cued. We analyze the time course of this population activity as it transitions from early integration of reach-related stimulus parameters to execution of the actual action. In particular, we ask how these signals are unique (or not) to each arm, and how that changes across phases of processing. Additionally, we characterize the structure of lateralization whenever present, aimed at describing the degree to which hemispheric divisions (ipsi vs contra) and sparsity of the network representation contribute to the segregation of arm signals. We find that, while information about both arm and target are represented during the full time course of the task, the organization of population activity underlying these lateralized representations is quite different before and after movement onset.

Title: Towards a neural population-level understanding of the effects of methylphenidate (Ritalin) in motor cortex of reaching monkeys

Authors: *J. R. VERHEIN[1], S. VYAS[2], K. V. SHENOY[3];
[1]Stanford Univ. Sch. of Med., Stanford, CA; [2]Bioengineering, Stanford Univ., Mountain View, CA; [3]EE, BioE & Neurobio., Howard Hughes Med. Inst. - Stanford Univers, Stanford, CA

Abstract: A fundamental goal of motor neuroscience has been to understand how patterns of motor cortical activity drive behavior. One successful strategy has been to "perturb" neural activity and/or behavior using, e.g., electrical or optogenetic stimulation, task-related (e.g., mechanical or stimulus) perturbations, or pharmacological agents. Many of these studies to date have focused on the effects of local pharmacological manipulation (e.g. with muscimol) of particular cortical regions. However, research regarding the relationship between population-level cortical activity and behavior has not rigorously addressed the effects of common cognition-altering drugs. Here we take a first step towards this goal by studying the effects of methylphenidate (MPH), a common stimulant which inhibits catecholamine reuptake, on motor control in rhesus macaques. This approach provides both a precise behavioral assay and the opportunity to study the correlates of the behavior in populations of single neurons.
We administered either oral MPH or vehicle alone (cookie filling) as a control to two adult male macaques (U and P) 15 min prior to the start of a center-out delayed reaching task, and measured two classic motor variables: peak reach speed and reaction time (RT), as well as a measure of early reach variability (the distribution of hand position at peak speed on each trial). We tested the effects of two doses in each animal. Preliminary results show significantly faster speeds during MPH treatment at individually optimized doses (U: 6 mg/kg, P: 1.3 mg/kg) compared to control sessions in both animals (U: $p < 0.001$, P: $p < 0.02$). RTs and reach variability were significantly reduced in U only (RT: $p < 0.01$, variability: $p < 0.03$). Our results show some dose

dependence, with increased reach variability ($p < 0.001$) and a trend toward decreased speed in P at a higher MPH dose (3 mg/kg); as well as attenuated effects on RT, speed, and reach variability in U at a lower dose (4.5 mg/kg).
Concomitant to the behavioral measurements, we recorded motor cortical neural activity (in U through 3 96-channel Utah arrays in premotor and primary motor cortex, and in P through V-probes in premotor cortex). Given our observed significant behavioral effects of MPH, this presents an opportunity to study population-level effects of the drug in motor cortex, including its effects on previously described neural population correlates of RT and speed. Preliminary results in U suggest that MPH reduces motor cortical variability during reach preparation and execution. To our knowledge, this study constitutes one of the first investigations of the effects of MPH on reaching behavior and neural population activity.

Title: Spatially heterogenous tuning in rhesus motor cortex revealed using neuropixels probes

Authors: *E. TRAUTMANN[1], D. J. O'SHEA[2], X. SUN[2], S. VYAS[3], S. RYU[4], K. V. SHENOY[5];
[1]Stanford Neurosciences, Stanford, CA; [2]Stanford Univ., Stanford, CA; [3]Bioengineering, Stanford Univ., Mountain View, CA; [4]Dept Neurosurg, Palo Alto Med. Fndn., Palo Alto, CA; [5]EE, BioE & Neurobio., Howard Hughes Med. Inst. - Stanford Univers, Stanford, CA

Abstract: Recent advances in multichannel extracellular recording technologies have enabled dense sampling from large populations of neurons in-vivo. Here, we used high-density silicon Neuropixels probes to record in premotor and primary motor cortices (PMd/M1) of awake rhesus macaque monkeys performing delayed reaches to radially spaced targets. Clustering of neural tuning properties has been commonly observed in visual areas of higher-order mammals such as

cats and rhesus macaque monkeys [1,2]. The motor cortex displays large-scale somatotopic organization (e.g.: [3,4]), though it is not well understood how macroscopic functional organization relates to fine-scale organization of neuronal tuning properties.
Results: Using high-density silicon Neuropixels probes, we quantified the pairwise correlation between tuning curves and PSTHs for reaches to radially-spaced targets. We found no relationship in the pairwise correlation between PSTHs or tuning for reach targets and the distance between neurons. This suggests that A) functional properties of neurons are not spatially clustered at the level of individual cortical columns in PMd and M1, and B) random sampling (i.e.: non-spatially targeted sampling) of neurons in PMd/M1 may be sufficient to fully capture relevant dynamic patterns in motor cortex [5].
Methods:A Neuropixels probe was inserted normal to the brain surface to sample neurons across cortical lamina. Neuropixels probes feature a thin, silicon shank specifically designed for used with mice and rats, creating several challenges for use with larger animals. In particular, the shank is not sufficiently stiff to penetrate the dura, and too short for insertion through a guide tube. We addressed this challenge by sharpening the tip of the Neuropixels probe as well as by creating a small perforation in the dura. In addition, we introduced gentle mechanical stabilization to the surface of the dura, 2-3mm from the recording site in order to reduce tissue motion due to pulse, respiration, and unconstrained motion. Together, these techniques enable acute recording of 200-400 neurons per probe from 384 recording channels, distributed 3.84mm along the length of the probe shank. Using this approach, repeated insertions in one recording site for up to two weeks were possible.

Title: Inter-areal functional neuronal network dynamics in primate primary and premotor cortex during reaching and grasping movements

Authors: *J. B. HYNES[1], C. E. VARGAS-IRWIN[2], J. P. DONOGHUE[2];
[1]Neurosci., Brown, Providence, RI; [2]Neurosci., Brown Univ., Providence, RI

Abstract: Classical models of movement processing propose that the reaching and grasping components of object-driven movements are independently processed along distinct dorsal-reach and ventral-grasp circuits before converging in the primary motor cortex (M1). More recent studies have provided evidence to suggest that dorsal and ventral premotor (PM) neurons directly influence one another during object-driven movement generation; however, little is known about the organizing principles and computational properties of these inter-areal functional networks. Mapping the functional structure of dorso-ventral networks is important for understanding how the cortex implements the complex computations underlying the object-driven movements. Previous work has shown that M1 and PM neurons exhibit moment-to-moment fluctuations in their functional properties across different computational stages of movement processing. Our goal with the current work was to determine if M1, PMd, and PMv neurons also exhibit moment-to-moment fluctuations in their functional relationships in a computation-dependent manner or exhibit fixed relationships. We simultaneously recorded primate M1, PMd, and PMv single unit activity during skilled reach and grasp behaviors using multi-electrode arrays. We then used a novel unsupervised mathematical approach to generate low-dimensional neuron functional similarity maps across different phases of the movement planning and reach-to-grasp actions. Our approach allowed us to visualize the functional relationships of the recorded neurons across different stages of movement processing without having to impose tuning functions *a priori*. Our analyses revealed that groups of neurons with common computational motifs (i.e. functional sub-networks) were not confined to single anatomical areas; instead, the detected functional sub-networks were typically comprised of neurons from all three areas. We also observed that the relationships between neurons changed dynamically across different stages of movement generation. Collectively, our results suggest that reach-and-grasp movements engage a distributed network of neurons that can dynamically alter their associations to meet the computational demands of the movement context. These findings support the emerging view that object-driven movements engage a densely interconnected network of neurons that span both dorsal and ventral motor cortical areas. Our results suggest that characterizing functional sub-networks spanning multiple areas may be a more accurate way to describe computation in cortical networks than comparisons performed based on gross anatomical location.

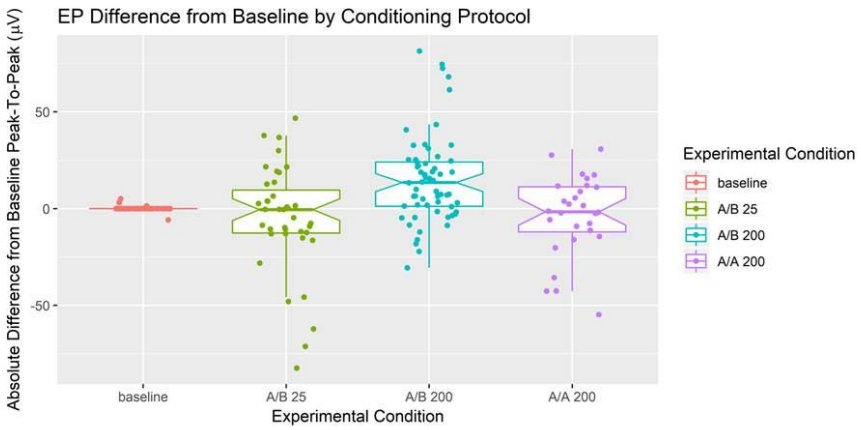
Abstract: Timed cortical stimulation protocols can induce changes in cortex. Non-human primate studies have shown cortical evoked potentials (CEPs) can be enhanced with short-delay paired pulse stimulation of two cortical regions. We implemented a paired pulse conditioning paradigm intraoperatively in patients receiving DBS implants through acutely implanted macroscale intracranial EEG electrodes to induce changes in cortical plasticity. Electrodes with identifiable CEPs were used, with a primary stimulated electrode (A) and the site of strongest CEP (electrode B) utilized. We compared paired site cortical stimulation (AB) relative to single site stimulation (AA), and time lags including 25 ms and 200 ms between conditioning trains. In fourteen (14) subjects, conditioning paradigms with 200 ms delays resulting in greater degrees of change than 25 ms conditions, and with paired stimulation between sites being more effective than single site stimulation ($p<.001$). Additionally, longer conditioning sessions result in greater potentiation of CEP magnitude relative to shorter sessions. We found no significant differences between disease conditions, supporting the generalizability of these results beyond a particular disease process. Our findings of enhanced CEPs using existing medical devices may offer a path for enhanced use of cortical stimulation for recovery, as from stroke. The timing of optimal paired stimulation (200msec) was a longer delay than found in non-human primates. This may reflect the larger scale of stimulation with clinical macroscale electrodes (2.4mm diameter) with a larger extent of depolarized cortex, yielding compound and multiplexed effects.



Evoked potential amplitude was enhanced with a paired pulse stimulation conditioning paradigm using a 200msec delay between regions. A shorter delay and same-electrode stimulation had weaker effects.

Title: Auditory spelling by an ALS patient with a fully implanted brain-computer interface

Authors: *E. J. AARNOUTSE, S. LEINDERS, Z. V. FREUDENBURG, B. VAN DER VIJGH, E. G. M. PELS, M. P. BRANCO, M. J. VANSTEENSEL, N. F. RAMSEY;
UMC Brain Center,University Med. Ctr. Utrecht, Utrecht, Netherlands

Abstract: Late stage ALS patients have, with progression of the disease, increasing difficulty to communicate. Assistive and augmentative communication methods help them to keep autonomy and independence. One method is a Brain-Computer Interface, which translates brain signals to a means to spell words. However, most BCI methods rely on eye sight, something many ALS patients develop problems with. Here we report on an ALS patient with an implanted BCI (Utrecht Neuroprosthesis; UNP) who has been using the system at home for almost 3 years. The UNP is fully implantable and wirelessly interfaces with a tablet with speech synthesis for communication (Vansteensel, Pels, Aarnoutse et al. 2016). The patient has until now used the UNP with visual feedback, but given that her eye and eye lid movement control deteriorates we investigated feasibility of auditory system interaction. The patient is a woman with late stage ALS, who was diagnosed with the disease in 2008. In October 2015 the participant (then 58 y) was implanted with the UNP. The UNP records ECoG signal from 2 subdural electrodes strips (Resume II®, Medtronic, 4 electrodes each, 4 mm diameter, 1 cm distance, off label use) which were implanted, after fMRI prelocalization, over the hand area of the left motor cortex and the left dorsolateral prefrontal cortex. The strips were connected subcutaneously to an amplifier (Activa® PC+S, Medtronic, off label use), implanted under the clavicle. ECoG data is streamed to a tablet computer running BCI software. The participant generates a distinguishable signal by attempting to move her hand. Bandpass filtered data with center frequencies of 20 Hz and 80 Hz are streamed 5 times per second to the tablet where the BCI software filters the data and translates the data into a click and subsequently to a keypress signal in Communicator-5 AAC software (Tobii Dynavox). The AAC software uses a visual or auditory scanning paradigm to select letters. Auditory feedback required a slower scan rate to allow for pronouncing the selected rows and letters. 12 runs of purely auditory spelling was performed. In 9 runs the word was spelled correctly, 2 runs were aborted to decrease the scan rate, 1 run was aborted for technical reasons. In all runs, corrections (erasing the last spelled letter) were allowed. The total accuracy was 90.2%. On average 1.3 correct characters were spelled per minute. This study shows that auditory BCI with an implant is feasible. Although the speed was reduced in comparison with visual feedback, the speed is encouraging and higher than other auditory BCIs. For patients who are at risk of losing eye sight an (implanted) auditory BCI based on scanning might be a solution for sustaining communication.

Title: Oligodendrocyte and myelin loss impairs recording performance of neural interfaces in cuprizone-induced model of demyelination

Authors: *S. M. WELLMAN[1,5], K. GUZMAN[6], L. E. BRINK[6], S. SRIDHAR[6,2], J. CHARLES[6], L. LI[1], F. CAMBI[6,2,7], T. D. Y. KOZAI[1,3,4,8,5];

Pittsburgh, Pittsburgh, PA; [7]Dept. of Neurol., Univ. of Kentucky, Lexington, KY; [8]NeuroTech Ctr., Univ. of Pittsburgh Brain Inst., Pittsburgh, PA

Abstract: Neural electrode technology used to interface with the central nervous system (CNS) holds the potential to answer basic, fundamental neuroscience questions and offer critical therapeutic rehabilitation for patients afflicted with neurological disorders. However, intracortical electrode implantation induces overwhelming biological inflammation which can reduce the quality of recordable neural signals over time. Oligodendrocytes, the myelin producing cells of the CNS, regulate neuronal health and signaling by providing neurotrophic and metabolic support as well as axonal myelination. Due to their high energy demands, oligodendrocytes can be susceptible to the oxidative and metabolic stresses that occur during electrode implantation, which brings into question their contribution to the biological failure modes of neural interfaces. Cuprizone-induced demyelination was used to probe the effects of oligodendrocyte and myelin loss on the recording performance of intracortical microelectrode devices. A Michigan-style electrode array was implanted into the visual cortex of C57BL/6J wild-type mice 5 weeks after cuprizone administration in order to completely demyelinate the cortex prior to insertion. Cuprizone diet was continued alongside electrophysiological recording for 7 weeks post-insertion. Control mice were implanted similarly while being maintained on normal rodent diets. Prior to electrode insertion, immunohistochemistry was used to confirm reduced oligodendrocyte densities and myelin loss in the cortex of cuprizone-treated animals compared to control mice. At the onset of implantation, cuprizone-treated mice exhibited significantly reduced recording performance yields, amplitudes, and signal-to-noise ratios compared to control mice, remaining relatively low but stable over time. Interestingly, control

mice demonstrated elevated recording metrics within the acute period during implantation before declining to the chronic performance levels of cuprizone-treated mice. This suggests that oligodendrocytes residing within the recording radius of the electrode microenvironment in control mice undergo a functional and/or anatomical decline similar to that of the cuprizone-treated mice, implicating the preservation of oligodendrocytes and myelin as necessary tissue components for neural recording quality. These results reveal an oligodendrocyte-dependent regulation of neuronal electrophysiological properties, contribution to the quality of intracortical recording devices, and sensitivity to biological inflammation that can impact wound healing and repair following neurodegenerative injury.

Title: Transcranial wireless power and MIMO backscatter communication with multiple neural dust recording sites

Authors: *D. K. PIECH[1], J. M. CARMENA[2], M. M. MAHARBIZ[3];
[1]UC Berkeley - UC San Francisco Grad. Program in Bioengineering, Univ. of California Berkeley, Berkeley, CA; [3]EECS, [2]UC Berkeley, Berkeley, CA

Abstract: Freely-floating wireless implantable neural recording and stimulation devices are an emerging type of neural interface with promise for scalable distributed recording, reduced micromotion-induced gliosis, and very low risk implantation modalities. The *neural dust* recording interface is an ultrasonically-powered untethered recording system consisting of sub-mm sensors implanted in the brain which wirelessly relay extracellular voltage signals to an external transceiver through ultrasonic backscatter communication. In order to scalably record from these sensors (‘motes’), methods for achieving a high SNR wireless link, many-device simultaneous communication, and low-volume implant size must be realized. Furthermore, the

skull provides a formidable challenge for ultrasonic communication, as it is attenuating and scattering.
Here we show that by utilizing extremely short pulses of ultrasound to interrogate the dust motes, the reflection from a mote can be resolved by time-of-flight from other motes and from the skull. Separation of the skull reflection and mote reflection in the time domain enable high gain digitization of the mote reflection without saturating the transceiver front-end with the very high skull reflection amplitude, enabling high SNR recovery of neural dust signals through the skull. We develop a backscatter communication algorithm which isolates backscatter signals independently on many external transceiver elements to achieve multiple-input multiple-output communication, improve SNR, and help to overcome scattering through the skull. We demonstrate ultrasonic wireless communication through an ex-vivo primate skull, and communication simultaneously between multiple sensor sites and many external transceivers. This technique is applicable to neural sensor motes with either sophisticated modulators and encoding schemes, or simple modulators consisting of only an impedance change. These results demonstrate that improved signal processing on the external side of the wireless link can enable extremely small and simple wireless neural sensor motes.

Abstract: Functional interactions between neurons in different brain regions has been studies using a variety of technologies. For example, metal-based microwires, silicon-based multichannel arrays and electrode arrays with flexible substrates have been shown to provide high-resolution electrophysiological recording with high signal-to-noise ratio. However, with single implantation, the physical properties of these devices limit their access to a single, small brain region. To overcome this limitation, we developed a platform that provides three dimensional coverage of brain tissue through multifunctional polymer fiber-based neural probes that can interface simultaneously with neurons in multiple sites. To achieve electrode expansion after implantation, a scaffold with spiral hollow channels is utilized here to direct multifunctional fiber probes into brain tissue at specified angles. For multisite interfacing within a single branch, we can expose electrode recording sites, microfluidic channel opening, and waveguide windows along the fiber length. Our femto-second laser micromachining technique allows us to fabricate these spatial interfacing sites based on the specific biological application. We obtained recordings from transgenic mice to show application of optical stimulation causing distinctly different brain activities from spaced electrodes. Similarly, we were able to detect varying electrophaphic activities from different brain regions during ictal and interictal periods in a mouse model of chronic epilepsy. Finally, chronic recordings validate the ability of these fibers to provide long term neuronal readout with little or no rejection. Our data suggest that this three dimensional multiplexing brain interface has the potential to allow for multimodal analysis of brain circuitry activity between brain regions under physiological and pathological state.

Title: Different coating approaches to address the inflammation around the implanted neural electrode

Authors: *A. GOLABCHI, Z. J. DU, T. CUI;
Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Foreign body response (FBR) around the neural implant is a key factor that affects the long term performance of these devices. These limitations can be addressed through an advanced surface coating which provides a combination of recording and stimulation advantages, including lowered impedance and increased charge transfer as well as the ability to modulate the inflammatory tissue response. Here we present two coating approaches targeted to the conducting and insulation regions of the electrode, respectively, and explore the impact of these coating technologies on chronic recording performance of neural implants. Firstly, we used multi-walled carbon nanotubes (CNTs) and anti-inflammatory dexamethasone doped poly(3,4-ethylenedioxythiophene) (PEDOT) as electrode coatings to improve the chronic neural interface. Previously, we have reported PEDOT/CNT/Dex coated electrodes lowered impedance and reduced inflammation after 14 days of implantation in rat dorsal root ganglion compared to uncoated electrodes. Here, we report the electrochemical behavior of the coated electrode/tissue interface during the prolonged implantation period of 12 months. Secondly, the insulation of the neural probes was coated with neuronal adhesion molecule L1 using silane chemistry. We have previously shown L1 when covalently bound to the surface of the electrode, reduces the initial microglial attachment, gliosis, and promote electrode-neuron integration at 1, 4 and 8 weeks. The chronic recording performance of L1 coated arrays was compared to uncoated arrays over 16 weeks. The PEDOT/CNT/DEX coated electrodes demonstrated stable impedances and recorded high quality visually evoked a neural response with minimum degradation even at time points past 1 year. Meanwhile, L1-coated probes showed significantly higher SU yield compared to the control group over 16 weeks of the implantation. Additionally, by aligning the implant depth across animals between 2-16 weeks to layer IV depth and identifying signals from two depths (cortex and hippocampus), we observed significantly higher SU yield in L1-coated compared to the control in both depths, with the more dramatic difference found in the hippocampus. Finally, quantitative image analysis demonstrated significantly reduced expression of microglia, astrocytes and BBB leakage within 40 μm zone around the L1 probes compared to the control at 16 weeks. Taken together, these results demonstrated the feasibility of reducing inflammatory tissue response and improving chronic neural recording via surface coatings. The combination of the coating approaches should further improve the quality and longevity of neural implants.

Title: Examining deep neural network decoders for BCI motor control in tetraplegia

Authors: *N. F. HARDY[1], D. B. SILVERSMITH[3], S. REDDY[4], R. ABIRI[5], E. F. CHANG[2], S. LEVINE[4], A. DRAGAN[4], K. GANGULY[1];
[2]Neurosurg., [1]UCSF, San Francisco, CA; [3]Bioengineering, Univ. of California San Francisco, San Francisco, CA; [4]UC Berkeley, Berkeley, CA; [5]Dept. of Neurol., Univ. of California, San Francisco, San Francisco, CA

Abstract: Recent advances in Brain Computer Interface (BCI) research have enabled severely impaired patients to perform complex tasks, including composing emails, navigating the internet, and controlling robotic limbs. While significant progress has been made, developing BCI algorithms that are robust and feel intuitive to patients remains challenging.
Current state of the art BCI decoding algorithms rely on linear decoders, e.g. Kalman Filters, to map spiking activity to output commands. Linear decoders are well suited to tasks with relatively small datasets and simple outputs, but can struggle when applied to complex tasks. On the other hand, nonlinear decoding algorithms such as deep neural networks can find complex relationships between input features and outputs, but require very large datasets to train.
In this work, we tested the performance of deep neural networks (DNN) as decoders in electrocorticography (ECoG) based BCI. ECoG has several advantages over spikes-based BCI: ECoG does not penetrate cortical tissue, can sample from many brain regions at once, and can potentially maintain stable recordings over a long period of time. Recent work has shown that ECoG BCI with linear decoders allows partially paralyzed patients to perform a 3D cursor control task (Degenhart et al., 2018). In addition, Anumanchipalli and colleagues (2019) demonstrated that DNNs can decode speech from ECoG signals recorded from epileptic patients. Here, we examined DNNs as BCI decoders of ECoG data recorded chronically from a human subject with tetraplegia caused by a bilateral pontine stroke. The subject was chronically implanted with a 128-channel ECoG grid over the left motor and somatosensory cortices. We then trained multiple DNN architectures on data recorded over multiple months during real time 2D cursor control with a velocity Kalman Filter. Results indicated that DNN decoders might outperformed Kalman Filters in the 2D cursor control task. Further, we applied our DNN decoding framework to a typing task with an assistive agent. These findings provide support for

the use of chronic ECoG recordings for neuroprosthetic control, and for using DNN decoders to improve BCI control in complex environments.

Title: Neural signal quality and decoding performance following intracortical brain-computer interface hardware failure

Authors: C. F. DUNLAP[1], S. C. COLACHIS, IV[3], N. V. ANNETTA[3], D. A. FRIEDENBERG[4], P. D. GANZER[3], G. SHARMA[3], *M. A. BOCKBRADER[2];
[1]Biomed. Engin., [2]PM&R/Biomedical Engin., The Ohio State Univ., Columbus, OH; [3]Med. Devices & Neuromodulation, [4]Advanced Analytics, Battelle Mem. Inst., Columbus, OH

Abstract: Introduction: Signal quality of chronic recordings from intracortical microelectrode arrays (MEA) may progressively degrade due to tissue-implant interactions, including glial scarring and neuronal death at the neural interface. MEAs are also susceptible to hardware failures such as electrode corrosion and wire bundle or connector damage. Each of these bioelectronic failure modes may decrease neural decoding performance, but once identified, may also be amenable to different strategies for compensation. Our goals were to identify signal metrics characteristic of failure modes in an aging array and also evaluate solutions to maintain decoding performance. **Methods:** Five years of neural recordings were evaluated from a participant in the Reanimation in Tetraplegia clinical trial (NCT01997125). The participant is a 28-year-old man with C5 ASIA A spinal cord injury who used an investigational, intracortical BCI with a left motor cortex Utah MEA (Blackrock Microsystems, Utah). Neural activity (mean wavelet power across 234-3750Hz) was decoded with machine-learning algorithms. Decoding accuracy and signal metrics were characterized for a 4-movement motor imagery task that the participant regularly performed. **Results:** Overall, neural decoding performance remained high across 5 years, with decoder accuracy exceeding 85%, even though impedance and signal-to-noise declined over time. Four potential failing channels were identified in the 96-channel array. They had weak signal correlations (<0.5) with other channels, variances greater than 2 standard deviations from the array-wide mean, and highly variable session-to-session impedances.

Malfunctioning recording channels were associated with a damaged amplifier connector and a pedestal connector failure. Excluding the flagged channels improved offline decoding accuracy by up to 9%. **Conclusion:** Chronic impedance and signal-to-noise decline in an aging array impacted decoder performance less than isolated malfunctioning channels. When problem channels with high signal variance, low signal correlation, and high session-to-session impedance were identified and excluded during decoding, BCI performance recovered. Automating detection of and compensation for these types of bioelectronic failures is important for translating BCIs out of the laboratory where a technician may not be available to check signal quality.

Abstract: Brain-machine interfaces (BMI) allow users to interact with their external environments by decoding neural signals to control external effectors ranging from computer cursors to robotic arms. In situations where decoders are held constant, it has been shown that neural population activity consolidates and generates more coordinated patterns over learning. Furthermore, previous work has shown that BMIs can be "two-learner" systems, in which both neurons and decoders co-adapt over the course of learning. This is particularly useful in situations where decoders need to be refit over the course of training due to neural drift or changes in neural ensembles available for decoding. However, it is unclear how population firing patterns may change as a result of these perturbations. In this study, we analyzed previous BMI experiments with nonhuman primates and found neural activity to continuously consolidate and generate more coordinated patterns over learning. Changes in decoder weights or neurons did not hinder the formation of these patterns. Instead, neurons exhibited exploratory behaviors that were separate from previously consolidated strategies. Our results indicate that neurons may be simultaneously exploring and exploiting neural strategies by modifying learned patterns rather than generating completely new ones even from the onset of learning a new task.

Title: Implementing an integrate-and-fire neural network on a closed-loop brain-computer interface

Authors: *J. MISHLER[1], R. YUN[1], S. I. PERLMUTTER[2], R. P. RAO[3], E. E. FETZ[4]; [1]Bioengineering, [2]Dept Physiol. & Biophysics, Washington Natl. Primate Res. Ctr., [3]Paul G. Allen Sch. for Computer Sci. and Engin., [4]Physiol. and Biophysics, Univ. of Washington, Seattle, WA

Abstract: Stroke disrupts neural communication and impedes sensorimotor function. One potential strategy to restore the lost function is to use closed-loop electrical stimulation to restore

communication between cortical neurons disconnected by the lesion. We hypothesized that an integrate-and-fire (IAF) neural network could be used to artificially communicate information from one population of cortical neurons to another. To investigate the effects of such a closed-loop brain-computer interface on neural dynamics, we recorded the spontaneous activity of multiple single neurons with a Utah array implanted in primary motor cortex of a pigtail macaque. Each experimental session was divided into 'pre stimulation' and 'closed-loop stimulation' epochs. Several recorded neurons served as inputs to a simple two-layer IAF network. When these "input" neurons spiked, a virtual "post-synaptic potential" was generated in each of its connected IAF units in the neural network. An IAF unit spiked whenever its "membrane potential" reached a predefined threshold, which subsequently generated a trigger to deliver an electrical stimulus (cathodal, biphasic stimulation; 15 µA amplitude; 200 µs pulse width) at a cortical site adjacent to a subset of the input neurons. The stimulation evoked distinctive excitatory and/or inhibitory responses at each of the nearby input neurons. We compared the spike dynamics of the input neurons between the pre and closed-loop stimulation epochs using auto- and cross-correlograms. This allowed us to measure the effects of each of the artificial connections on the spike dynamics of each of the input neurons. During the closed-loop stimulation epoch, we found that if an input neuron excited/depressed another input neuron through an artificial connection, there were corresponding peaks/troughs in their cross-correlograms following the stimulation trigger. If an input neuron artificially activated itself, the resultant positive feedback loop sustained activity. Over sessions lasting a few hours there was no evidence that the monkey altered the firing properties of the input neurons. Our results show that an IAF neural network can be used in a closed-loop brain-computer interface to artificially connect a set of cortical neurons. The changes in spike dynamics resulting from the artificial connections were dependent on the connectivity of the neural network and effects of outputs on the input neurons. Taken together, this suggests that IAF neural networks provide a flexible means of connecting neural populations to modulate their neural activity.

Title: Chronic large-area neural recording using microwire arrays

Authors: *A. M. O. OBAID[1], Y.-W. WU[2], M.-E. HANNA[1], J. B. DING[4], N. MELOSH[3]; [1]Stanford Univ., Stanford, CA; [2]Dept. of Neurosurg., Stanford Univ., Palo Alto, CA; [3]Materials

Sci., Stanford Univ., Stanford, CA; [4]Neurosurg., Stanford Univ. Dept. of Neurosurg., Palo Alto, CA

Abstract: Mammalian brains typically consist of billions of neurons operating at millisecond time scales, of which current recording techniques only capture a tiny fraction. Electrical recording techniques capable of sampling neural activity at such timescales have been difficult to scale due to the need for application specific designs as well as the mismatch between the three-dimensional architecture of the brain and largely two-dimensional microfabrication techniques, limiting both neurophysiological research and neural prosthetics. Recent advances in CMOS device design have led to high-recording quality planar probes, with diminishing sizes to ameliorate the extent of tissue damage. Matching these powerful silicon electronics to the inherently three dimensional architecture of the brain has remained challenging however, as devices are constrained to the planar two dimensional surfaces required for silicon processing. Here we describe a new methodology whereby we perform a heterogeneous integration of a bundle of microwires to CMOS chips, such as pixel arrays found in modern camera chips or displays, and precise microwire spacing, critical for mitigating tissue damage. Microwires have long been known to have low insertion damage and good electrical recording performance yet required individual mounting and connectorization. Arranging them into bundles controls of the spatial arrangement and three-dimensional structure of the distal (neuronal) end, while providing a robust parallel contact plane on the proximal side which is interfaced to a planar pixel array. The modular nature of the design enables a variety of microwire types and sizes to be integrated with different types of silicon-based arrays, allowing channel counts to be scaled from a few dozen to thousands of electrodes using the same fundamental platform. This system has excellent recording performance, demonstrated via single unit and local-field potential recordings in isolated retina, and in the motor cortex and striatum of awake moving mice. This concept links the rapid progress and power of commercial multiplexing, digitisation and data acquisition hardware together with a chronic three-dimensional neural interface.

Title: A novel bi-directional implantable brain machine interface with versatile stimulation capabilities

Authors: *J. RICKERT, **S. MARTIN**, C. STOLLE, F. WENZEL, O. BRUNNER, J. HOLUB, N. GRIGAT, M. OBERT, M. LEISTNER, D. GRIESHABER, J. HUMMEL, S. RIEGER; CorTec GmbH, Freiburg, Germany

Abstract: Bi-Directional implantable brain machine interfaces not only read from the brain but also provide options to write to the brain. Electrical stimulation is a well-established method of interacting with the nervous system, applied to the brain, it leads to modulation of neural network function (as it is done e.g. in deep brain stimulation for treatment of M. Parkinson). This effect is strongly dependent on the stimulation intensity as well as stimulation frequency. It also depends on the location at which the stimulus is delivered, and the electrical field spatial distribution associated with stimulus current.
The Brain Interchange system developed by the authors generates current-controlled, charge balanced pulses with amplitude of up to 6 mA and pulse widths of up to 2.5 ms. The compliance voltages available for driving the current are asymmetric -12 V as negative and +6 V as positive rail. The current can be directed to any of its 32 electrode contacts the system also uses for brain recording. The current return electrode can be selected to also be any of the 32 electrode contacts or subsets of them, or an additional counter electrode. These options make the system very versatile to use. Electrical patient safety is warranted by the use of blocking capacitors switched in between electronics and electrodes.

Title: Clinical use of laser-micromachined cortical grid electrodes

Authors: *M. SCHUETTLER[1], S. BENSCH[1], N. F. INCE[2], S. PRABHU[4], J. RICKERT[1], C. HANSER[1], C. HENLE[1], A. MARX[1], P. ASMAN[3];
[1]Cortec GmbH, Freiburg, Germany; [3]Dept. of Biomed. Engin., [2]Univ. of Houston, Houston, TX; [4]Dept. of Neurosurg., MD Anderson Cancer Ctr., Houston, TX

Abstract: Cortical grid electrodes are widely used for mapping of the human brain, especially as a diagnostic tool to permit geometrically exact resection of brain tissue in case of surgical therapy of brain tumors and epilepsy.
Although cortical grids are commercially available and established since many years, the market provides devices that are hand-made and rather stiff, compared to the brain tissue, leading to difficulties when larger areas of the brain need to be covered by a planar grid that the surgeon tries to put on the natural curvature of the brain.
To overcome problems with current electrodes, we fabricated cortical electrodes using laser-based micromachining of traditional implant materials (silicone rubber and platinum-iridium alloy) that are highly reproducible and precise in dimensions but also are very soft. In spring 2019, a set of cortical electrodes produced with our novel methods received pre-market notification 510(k) by the FDA. The following briefly describes some initial clinical findings.
To map the sensory-motor cortex, the electro-corticogram (ECoG) was recorded intraoperatively during awake brain surgery from a patient (Male, 45 years old) with high grade glioma. The tumor was located anterior to the motor cortex. Vibrotactile simulation was delivered using coin vibration motors, individually placed on the fingertips and palm. The stimulation was delivered for 1s at 250Hz with an inter trial interval from 2 to 4s between consecutive stimulations.
ECoG was recorded from 53 channels using a cortical grid with 4 x 8 contacts of 2.7 mm diam. spaced in check-board pattern with 1 cm, 3 x 7 contacts of 1 mm diam. spaced in between. The grid was placed adjacent to the tumor and extended posteriorly towards the hand knob overlapping with anatomically (or imaging) defined motor and sensory regions. Recordings were obtained intraoperatively in awake state at 2.4kHz sampling frequency with gHIAmp (gTec, Austria) bioamplifier. In total 118 trials were recorded.
The vibrotactile stimulation was well identified in the ECoG and its strongest representation was localized. The majority of the neural responses were located posterior to the central sulcus. A broadband energy increase reaching up to 800Hz was observed immediately after the stim onset. 200 ms later this energy increase was limited to a frequency range between 60-200 Hz overlapping with traditional gamma band and lasted for the duration of the vibrotactile stimulation.

Title: Low frequency spectral responses in dlPFC measured with fully implanted BCI during working memory task differ between two LIS users with different etiologies

Authors: S. LEINDERS[1], K. VAN DEN BERG[2], E. J. AARNOUTSE[1], M. P. BRANCO[1], E. G. PELS[1], B. VAN DER VIJGH[1], M. J. VANSTEENSEL[1], *N. F. RAMSEY[1], Z. V. FREUDENBURG[1];
[1]UMC Utrecht-Rudolf Magnus Inst., Utrecht, Netherlands; [2]Univ. Utrecht, Utrecht, Netherlands

Abstract: People with severe paralysis may be fully conscious but unable to communicate without some communication aid, a condition commonly referred to as locked-in syndrome (LIS). Whereas traditional communication aids require some minimal motor control, brain computer interface (*BCI*) technology uses brain activity for computer control, and is therefore a promising communication method for some people with LIS. As part of the Utrecht NeuroProsthesis project (Vansteensel et al., NEJM, 2016), two people with LIS caused by late-stage ALS or pontine stroke were implanted with a BCI, to test the feasibility of independent home use for communication. For BCI control, our users use activity measured from sensorimotor hand cortex by subdural electrocorticography (*ECoG*) electrodes. Correctly timed attempted hand movement allows them to produce clicks in scanning-based software to select on-screen options in games or spelling applications. Using sensorimotor activity for control is the current paradigm for self-paced BCI systems. However, sensorimotor-based BCIs may not work well for all end-users. Partly as a backup in case sensorimotor signals would deteriorate due to disease progression, but also to investigate its potential as a BCI control signal by LIS users, our participants also received ECoG electrodes over their left-dorsolateral prefrontal cortex (*dlPFC*). We have shown previously that mental arithmetic consistently increased high frequency band (65-95Hz) power in the dlPFC which can be used for 1-d cursor control (Vansteensel et al., Ann Neurol 2010). Here, we focus on low frequency band power during mental arithmetic in two LIS users. In summary, taken across all runs, the pontine stroke user showed a decrease in low frequency band power (alpha: 8-12Hz) during mental arithmetic ($p = 0.0004$), whereas the ALS user showed a clear increase ($p < 0.0001$). The fact that different LIS etiologies affect brain signals differently and in unexpected ways is not surprising, as research has shown low

frequencies are affected in ALS patients (Shantosh et al., Neurol. India, 2005). Also, electrophysiology work with brainstem stroke patients has established clear but heterogeneous brain signal changes in the majority of cases (Patterson & Grabois, Stroke, 1986). Changes in these basic brain signal characteristics can affect BCI performance. Ideally, signal characteristics relevant for BCI control are quantified before implantation of future systems and should inform BCI system details (e.g. sensor location), leading to BCI systems personalized for optimal performance.

Title: Networking in primary motor cortex predicts arm-reaching speed variation

Authors: *M.-K. KIM, S. CHAE, T. KIM, S.-P. KIM;
UNIST, Ulsan, Korea, Republic of

Abstract: Neuronal ensemble activity of the primary motor cortex (M1) produces intricate patterns associated with the speed of arm movements. Unlike directional tuning properties of single neurons, collective changes of the population of neurons are known to characterize speed. However, such a collective activity may or may not contain neurons directly coding speed information. For example, trial-by-trial variability of the speed profile of arm movements is predominantly predicted by preparatory activity, but without detailed aspects of the maximum speed and its latency. To address these issues, we investigated kinematics-related latent components of neuronal populations and their interactive patterns. Kinematics-related latent components were estimated by canonical correlation analysis (CCA). Then, we analyzed connectivity between latent variables using Pearson correlation coefficients, from which we formed a network of latent components. We further quantified the characteristics of the network by a clustering coefficient based on the graph theory, which reflects the degree of clustered networks and node density. Dataset for this study was acquired from M1 of a rhesus macaque that performed a two-dimensional center-out reaching task, which is available at a public database on the collaborative research in computational neuroscience (CRCNS). To analyze the variability of the speed profile, we separated individual profiles into three disjoint groups having

early- (≤ 25 %), mid- (> 25 % or < 75 %) and late- (≥ 75 %) latency of the maximum speed regardless movement direction. Plus, the trials of the speed magnitude were also separated in the same manner into three groups. We found that the clustering coefficient increased as it took longer to reach the maximum speed in arm movements. We also found that the clustering coefficient increased as the maximum speed increased. Our results suggest that the property of networking among latent components of peri-movement M1 population activities may elucidate the variability of the speed profile of point-to-point arm movements with an identical distance.

Title: *In vivo* characterization of the stability of cortical response to electrical microstimulation

Authors: *X. S. ZHENG[1], Q. YANG[1], A. VAZQUEZ[1], T. CUI[2];
[2]Dept. of Bioengineering, [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Intracortical microstimulation is not only a useful tool in neuroscience research for dissecting circuitry and modulating behaviors, it has also shown promise in restoring sensory functions in humans with neural deficits. While efficacious, it is unclear how the cortex dynamically responds to electrical stimulation over time, and how different electrode materials differ in effectiveness and safety. Traditionally, *In vivo* characterizations of stimulation performance have been largely based on electrophysiological, behavioral, or end point histological outputs. Using meso-scale fluorescent microscopy and two photon microscopy (TPM), we can observe and quantify the result of microstimulation in transgenic animals in real time, chronically.
NeuroNexus electrodes with iridium sites (703 μm^2) were dual-modified with iridium oxide (n = 8) and PEDOT/fCNT (n = 8), and were implanted in Thy1-GCaMP6s mice. Electrical stimulations (biphasic charge balanced waveforms with 100 µS cathodic pulse, 100 µS interphase delay and 200 µS anodic pulse half the cathodic amplitude) between 0.5nC/phase to 6nC/phase at 50Hz were applied sequentially to each electrode site at 1s on 3s off (25% duty cycle), repeated 6 times. This stimulation was applied on day 1 and weekly thereafter. The GCaMP responses were imaged.
Preliminary results showed a dynamic change in cortical response to stimulations over time. Specifically, on day 1, higher GCaMP response was evoked at a lower stimulating current

amplitude. This suggests that the acute damage by the implant severed axonal (likely inhibitory) connections, resulting in elevated cortical response at lower stimulation intensities. Additionally, on day 1, we observed a drop off in GCaMP response in 62% channels at stimulating amplitudes higher than 4nC/phase , indicating that the acute neuronal damage hindered the brains' ability to endure metabolic demand at higher stimulation amplitudes. Current intensity to evoke a maximum cortical response significantly increased from day 1 to 5.5nC/phase on day 21 ($p = 0.0043$, $n = 16$), suggestive of reconstitution of local neuronal network. Furthermore, we observed qualitative chronic inconsistencies in cortical response recruitments in 37.5% channels. This is likely due to the micromotion between the electrode and the neural tissue which lead to changes in the immediate tissues activated. Notably, we observed no neuronal recruitment differences in the meso-scale between material types despite PC being significantly lower in impedances and higher in charge injection limits. Results on changes to neuronal soma distributions nearby stimulating sites will be reported from TPM studies.

Title: Glial cell mediated neurodegeneration surrounding the Utah electrode-tissue interface

Authors: *C. BENNETT, A. ALVAREZ-CIARA, A. PRASAD;
Univ. of Miami, Miami, FL

Abstract: Relaying valuable neural signals from the central nervous system is made possible with the use of intracortical microelectrode arrays. However, the presence of an intracortical electrode within the tissue creates a reactive local microenvironment, which leads to a cascade of proinflammatory and prooxidant factors, affecting the transcriptional rates of glial cells. Quantitative real time polymerase chain reaction (qRT-PCR) and immunohistochemistry (IHC) was used to quantify gene and protein expression, respectively, at acute to chronic time-points of 48-hr, 1-wk, 2-wk, and 4-wk. Genes that mitigate the reactivity of glial cells (astrocytes and microglia), which act as the main supporting cells of neurons, were monitored in rats implanted with a non-functional 4x4 Utah microelectrode array in the somatosensory cortex. Electrode implantation alters transcriptional rates of astrocytes and microglia as compared to unoperated controls, leading to the activation and prolongation of the complement cascade, which

chronically tags and phagocytoses cellular debris and neuronal axons surrounding the electrode-tissue interface. Moreover, chronically stimulated pathways such as the complement pathway could prolong the initial implant-induced trauma and become deteriorative to the brain parenchyma, potentially affecting chronic neuronal recordings.

Title: Decoding reach speed using a hybrid artificial neural network decoder for brain-computer interfaces

Authors: *H. MAO[1], Y. INOUE[4], S. B. SUWAY[2], J. ORELLANA[5], A. B. SCHWARTZ[3]; [1]Systems Neurosci. Inst., [3]Dept. of Neurobio., [2]Univ. of Pittsburgh, Pittsburgh, PA; [4]Dept. of Neurosurg., Osaka Univ. Grad. Sch. of Med., Osaka, Japan; [5]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Neuronal firing rates in the primary motor cortex encode the direction and speed of arm reaching movement. Neural prostheses that extract this encoded information are used by paralyzed subjects to regain lost arm movement. Although the performance of moving the prosthetic arm approximates that of normal subjects moving their native arms, stopping at the end of a reach as a target is acquired is still challenging. This difficulty is due to the way speed modulates firing rate of individual neurons: Speed affects the amplitude and offset of the tuning function. The speed-dependent offset acts in a nonlinear manner on linear decoders. Therefore, typical decoders, for example the Population Vector Algorithm (PVA) and some variations of the Optimal Linear Estimator (OLE), could be suboptimal as they work by inverting linear tuning functions without taking the speed-offset effect into account. We demonstrate the influence of the speed-offset effect on decoding with both simulated activity and empirically recorded activity as monkeys performed center-out arm reaching movement. One solution to this nonlinear tuning function problem is an artificial neural network (ANN) decoder that finds a direct nonlinear mapping from neuronal firing rates to velocity. On both the simulation and monkey arm reaching data, the ANN decoder improved decoding accuracy compared with the PVA and OLE decoder. For brain-computer interface (BCI) applications, we propose a hybrid artificial neural network (hANN) algorithm that combines neuronal tuning function modelling and the decoding power of the ANN. First, recorded data are used to fit empirical tuning functions for individual neurons that account for both the gain and the offset effect of speed. Then, an ANN decoder is trained with velocity and simulated neural data according to these empirical tuning functions. When a

monkey performed a center-out cursor movement task via a BCI, the hANN decoder led to skillful control of both direction and speed as demonstrated by stereotypic bell-shaped speed profiles, straight trajectories, and steady cursor positions before and after the movement. This work suggests that hybrid decoders that combine detailed encoding models with nonlinear computational approaches are likely to provide substantial gains in BCI performance.

Title: Neural dynamics in primary motor cortex during BCI calibration in a person with tetraplegia

Authors: *J. E. DOWNEY[1], J. M. GOODMAN, JR[1], A. K. SURESH[1], J. L. COLLINGER[3], S. J. BENSMAIA[2];
[2]Dept. of Organismal Biol. and Anat., [1]Univ. of Chicago, Chicago, IL; [3]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Rotational dynamics have been observed in primary motor cortex (M1) during reaching in mice, monkeys, and humans. In the present study, we investigated whether such dynamics were also observed during calibration of a Brain-Computer Interface (BCI) a subject used to move a cursor based on intracortical recordings in M1. Indeed, one might hope to exploit orderly neural dynamics when decoding intended movements from M1 signals. Before we can exploit them, however, we must verify that they are present when the subject cannot make overt movements.
The subject in this study has a C5/C6 spinal cord injury resulting in the paralysis of his hands. For the clinical BCI study, we placed 2 Utah arrays with 88 recording channels each in the hand and arm area of M1. Unsorted threshold crossings on each channel were counted in 20 ms bins and smoothed with a 25-ms Gaussian kernel. Data were collected during the first phase of a two-phase decoder training process. During this first phase, the subject attempts to move the cursor to one of 8 targets in a standard center-out task while the computer actually moves the cursor to the targets. The resulting neural data and observed cursor velocities are used to develop the decoder. We assess whether M1 exhibits orderly dynamics during this phase, and compare these to the dynamics observed in the presence of overt movements in able bodied organisms.

Title: Electrophysiological and histological characterization of the foreign body response to implantable neural interfaces in the African spiny mouse brain

Authors: *A. M. BRAKE[1], E. ATKINSON[2], C. SIMMONS[3], M. MADEN[4], K. J. OTTO[1,2,5,6,7]; [1]J. Crayton Pruitt Family Dept. of Biomed. Engin., [2]Dept. of Neurosci., [3]Dept. of Mechanical and Aerospace Engin., [4]Dept. of Biol. & UF Genet. Inst., [5]Nanoscience Inst. for Med. and Engin. Technol., [6]Dept. of Neurol., [7]Dept. of Materials Sci. and Engin., Univ. of Florida, Gainesville, FL

Abstract: Mammalian tissue injury typically results in the formation of a collagenous scar at the site of injury. In the field of neural interfaces, chronically implanted neural interfaces in the central nervous system (CNS) lead to an encapsulating glial scar. Glial encapsulation serves as an ionic barrier, thus reducing the signal-to-noise ratio of electrophysiology and overall functionality of the device. While other non-mammalian species have shown remarkable ability to fully regenerate tissue, such as the axolotl, the African Spiny Mouse (ASM) is the only known mammal able to fully regenerate injured tissues with minimal scarring. The unique regenerative abilities of this species make it a prime candidate for investigating the foreign body response (FBR) to implanted devices, which has traditionally been a highly variable and complex system to understand.

Without a clear understanding of the FBR's biological mechanism, research focused on FBR minimization has typically focused on altering the properties of the device. While this can be effective in FBR mitigation, it can negatively impact the functionality of the device. If the biological mechanism of the FBR could be identified and targeted, the FBR could be reduced or eliminated completely, allowing next generation device design to be optimized while achieving a favorable tissue response. Here we take a novel approach to CNS FBR mitigation by comparing the FBR of the ASM to that of the C57BL/6 mouse.

Marked discrepancies in cytokine expression and macrophage activation have been observed between the ASM and C57BL/6 mouse in endothelial tissue, indicating that there may be a

similar difference in the FBR of the brain. This study aims to draw a similar comparison in the brain within the context of implantable electrodes. Our preliminary data indicates reduced astrocytic response to neural implants in the ASM, motivating further investigation. Here, we present a histological and electrophysiological examination of the FBR in the ASM brain. Electrophysiology was recorded from functional, single-shank electrodes at longitudinal time points and immunohistochemistry was performed on cryosectioned tissue from tissues harvested at several relevant FBR endpoints.

Title: High-bandwidth wireless implantable multichannel neural recording system

Authors: *B. CROFTS, A. WILDER, D. MCDONNALL, **S. HIATT**;
Ripple Neuro, Salt Lake City, UT

Abstract: High channel count microelectrode arrays provide access to spatially and temporally selective neural data, given a method for multichannel data recording and high bandwidth transmission. Percutaneous implementations are limited by large connectors that commonly fail, require heavy pedestals, and are prone to infection. An implantable neural recording system is proposed as a chronically viable system for digitizing and wirelessly transmitting electrode array data at sample rates appropriate for cortical neuron extracellular spike events. This work extends a developed and extensively tested implantable system for recording electromyographic data. A proof-of-concept study illustrates successful data transmission at high sample rates. The implant is constructed with an electronic circuit board with multichannel biopotential amplifier, hermetically sealed ceramic enclosure, brazed titanium ground band, electrode connection feedthrough structure, lead attachments, and silicone-filled epoxy header. Implant electronics are wirelessly powered via a pair of loosely coupled printed circuit board-based coils in highly resonant mutually inductive circuits. Digitized data are transmitted over a high-speed infrared (IR) link that exploits a near IR epidermal/adipal transparency window. An external transceiver device drives the implant power coil and receives and decodes IR data. The implantable system was configured for thirty-two electrode channels digitized at 30,000 samples per second. These specifications represent an order of magnitude rate increase from an existing implantable electromyographic recording system. The implant's power consumption and IR transmission configuration, external transceiver's data reception circuitry, and IR decoding algorithm are key

aspects to this design. Benchtop data transmission performance was verified over a volume defined by a viable range of implant to external transceiver displacements and depth using a robot positioner and tissue representative light obstruction and in-air media. Biopotential amplifier and digitization performance have been previously verified in other studies. A chronically implantable system for wireless transmission of multichannel neural data extends the possibilities for a wide range of research including brain-machine interfaces, cortical mapping, and electrode efficacy.

Title: *In-vitro* mechanical and electrical validation of a flexible microelectrode

Authors: ***R. MODI**[1], U. AHMED[2], J. FALCONE[3], R. SHARMA[5], S. ZANOS[4], L. RIETH[3]; [2]Inst. for Bioelectronic medicine, [3]Ctr. for Bioelectronic Med., [1]Feinstein Inst. for Med. Res., Manhasset, NY; [4]Bioelectronic Med., Feinstein Inst. for Med. Res., Roslyn Heights, NY; [5]Electrical and Computer Engin. Dept., Univ. of Utah, Salt Lake City, UT

Abstract: Neuromodulation aims to treat various disorders and diseases related to autonomic function by stimulating, blocking, and recording activity from peripheral nerves. The efficacy and success of neuromodulation depend heavily on the quality of the interface (electrode) used. Unfortunately, commonly used interfaces are either stiff or rigid, which leads to both biotic and abiotic breakdown of the bioelectronics. To address this point, we are working on refining bench test procedure with a goal of clinical translation.
Currently, no effective interface exists to monitor and/or stimulate autonomic nerves chronically in the mouse model. The implicit design challenges for chronically interfacing with the mouse cervical vagus nerve include developing electrodes that can conform to tight curvature and still maintain mechanical and electrical integrity. To validate the in-vivo longevity of the polyimide-based microfabricated flexible electrodes we have carried out in-vitro studies.

Multiple layouts of flexible electrodes were fabricated using polyimide (PI-2611) as substrate and insulator, and state-of-the-art iridium oxide (SIROF) for the electrode interface. To evaluate the electrical integrity of the polyimide, an accelerated soak test was carried out by soaking the insulted test structure in 67°C Phosphate-buffered solution (PBS) for 30 days. Over the course of (specific time frame), we will periodically carry out electrical impedance spectroscopy (EIS) over the course of time to measure the longevity of the devices.
Sputtered Iridium oxide (SIROF) stability testing was also carried out on multiple layouts with the help of stimulation stability tests. This was done by placing SIROF electrodes in PBS. The electrodes were tested for up to 100 million biphasic pulses (166µs phase with 66µs interphase delay) with current amplitudes ranging from 100 µA t0 1000 µA. EIS and cyclic voltammetry (CV) was measured before and after the pulse trains were applied. Initial results suggest that iridium oxide is a stable metal for long-term stimulation applications.
To increase the longevity of the fully assembled device, we have developed stretchable helical coiled interconnects; these interconnects will help absorb micro motion, and eventually increase the longevity of the devices. To date, formal tests have not yet been carried out to provide structural support for our hypothesis.
These bench testing strategies will help us to achieve successful in-vivo chronic interface with the mouse cervical vagus nerve. The data we are going to present here are from rats chronic in-vivo impedance spectroscopy and SNR.

Title: Temporally-precise vagus nerve stimulation increases motor learning of a dexterous reach task through cholinergic neuromodulation

Authors: *S. G. BOWLES, J. L. HICKMAN, X. PENG, W. R. WILLIAMSON, C. G. WELLE; Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Vagus nerve stimulation (VNS) has been shown to increase the effectiveness of motor rehabilitation after a stroke in animal models. Additionally, lesions of cholinergic basal forebrain (BF) neurons prevented VNS driven cortical plasticity. However, it remains unknown if VNS can improve motor performance in healthy animals, and by what mechanisms VNS acts to improve motor outcomes. To address these questions, we implanted chronic stimulating electrodes on the left cervical vagus nerve of the mouse (Cortec; Microleads). Animals were trained to perform a dexterous forelimb reach for a food pellet using an automated behavioral system, CLARA. Reach kinematics were tracked using a deep learning network (DeeplabCut) to allow for 3D markerless tracking of multiple digits. Through a combination of the CLARA and DeepLabCut systems, we performed closed-loop stimulation based on reach outcome. VNS paired with successful completion of a dexterous reach task in healthy animals enhances acquisition of the task (30hz, 100us pulse width, 0.6mA, 0.5s train). To explore the role of cholinergic modulation in mediating the VNS behavioral effect, cholinergic cells in the basal forebrain were either excited through activation of virally-mediated channelrhodopsin (20hz, 10ms pulse width, 0.5mW, 0.5s duration) or inhibited by activation of virally-mediated archaerhodopsin (continuous, 0.5mW, 0.5s duration). We found that excitation of cholinergic projection neurons improved motor learning in a manner similar to VNS models. Moreover, cholinergic inhibition was sufficient to prevent VNS enhancement of motor learning. Together these results show that VNS, when paired with the successful outcome of a dexterous reach, can increase motor learning in healthy animals. These data implicate activation of the BF cholinergic system as one mechanism by which VNS enhances motor learning.

Title: Neural dynamics underlying generalization in motor cortex

Authors: *V. R. ATHALYE[1], P. KHANNA[2], S. GOWDA[3], A. L. ORSBORN[5], R. M. COSTA[1], J. M. CARMENA[4];
[1]Neurosci., Columbia Univ., New York, NY; [2]UCSF, San Francisco, CA; [3]Electrical Engin., [4]UC Berkeley, Berkeley, CA; [5]Electrical & Computer Engin., Univ. of Washington, Seattle, WA

Abstract: The repertoire of motor commands that are sent to arm muscles to generate one set of behaviors, such as straight trajectories, may also be used in different temporal sequences to drive the arm in new trajectories. The motor commands sent to the muscles are generated by neural activity patterns. Are the neural activity patterns used to generate a specific motor command re-used when the command appears in a new behavioral sequence? To address this question, rhesus macaques are trained to operate a brain-machine interface (BMI) that causally maps high dimensional neural activity patterns to two-dimensional motor commands that control the x and y velocity of the BMI cursor. Monkeys proficiently perform two different tasks with the BMI; a center-out task composed of straight movements and an obstacle avoidance task composed of curved movements. We find that the neural activity patterns used to generate motor commands in the obstacle task deviate from the activity patterns used in the center-out task. Online results show that calibrating decoders with task-specific neural activity patterns improves the animals' ability to perform that task. What then, is the neural policy used to select a neural activity pattern for a given motor command? By using statistical modeling, we find that differences in neural activity patterns are not accounted for by modeling the kinematic state of the cursor, but rather can be explained by linear neural dynamics that are general to both classes of behavioral trajectories. Across different movement trajectories, a given motor command is followed by different future motor commands. Being in different neural states to generate the same motor command may be advantageous by allowing the neural dynamics to assist in reaching an appropriate neural activity pattern for the generation of the next motor command. We demonstrate that the neural activity patterns used for a motor command leverage the neural dynamics for generation of the next motor command. Thus we find that in motor cortex, a neural activity pattern generating a motor command is not a static map that is re-used in the middle of diverse neural and behavioral trajectories, but rather that motor cortex flexibly generates neural activity patterns for the same motor commands in a way that leverages its high dimensional dynamics. These results suggest the practical application of using the neural dynamical state as a BMI control signal to enable better generalization to complex movements.

Title: Home-cage based behavioral and wireless neural recording setup for unrestrained rhesus macaques

Authors: *N. S. AGHA[1], A. TRUNK[2], M. BERGER[3], A. M. GAIL[4];
[2]Vat: 15329080-2-41, [3]Cognitive Neurosci. Laboratory, Sensorimotor Group, [1]German Primate Ctr., Göttingen, Germany; [4]German Primate Ctr., Goettingen, Germany

Abstract: System-level neurophysiology studies in awake behaving monkeys usually require partial movement restraint and separation from social groups during experiments. This allows detailed control over or surveillance of as many behavioral parameters as possible, together with tethered neural data acquisition at high bandwidth. Recent developments, like our Reach Cage (Berger et al. 2018, bioRxiv), use wireless neural recordings and allow studying neural correlates of motor behavior in less restricted experimental settings, thereby alleviating the movement restraint requirement. However, animal transport and social separation is still required during the experiment. Other recent developments allow animals to perform increasingly advanced cognitive tasks in a self-paced manner, while remaining within their home environment. Multiple monkeys in our facility have previously used our XBI (eXperimental Behavioral Instrument) as an interactive home-cage based device for automated behavioral training and testing (Calapai et al., 2017; Berger et al. 2018). Here, we combine both our previous experimental approaches towards system-level neurophysiological recordings within the housing environment. For this, we incorporated a wireless neural recording system into our XBI for synchronized behavioral and neural recordings. We recorded up to 192 broad-band neural signals (upgradeable to 256) at single unit resolution from three cortical sensorimotor areas from two animals while they conducted a visually instructed, goal-directed, memory-guided reach task. We were able to use our portable wireless system to extract reach-goal selective movement planning activity from simultaneously recorded neural and behavioral activity. In conclusion, our new system allows for wireless recording of neural data correlated with spatially and temporally precise instructed behavior in rhesus monkeys without physical restraint of the animal, but otherwise highly similar to conventional chair-seated touch screen experiments. With this, we achieved system-level neurophysiological recordings during trained cognitive task performance in the animals housing environment.

Title: Next-generation high-channel count neural implant arrays and modular head-mounted package for chronic human-use neuromodulation applications

Authors: *R. HAQUE, S. PATRA, J. ZHOU, M. TRIPLETT, J. PEBBLES;
Lawrence Livermore Natl. Lab., Livermore, CA

Abstract: The development of human-grade implants for treating a variety of neural disorders has garnered much interest recently. These chronic solutions provide recording and stimulation capability while also providing a higher channel count than currently commercially available. Here we present two types of microfabricated flexible polymer arrays and head-mounted titanium packages for electronics encapsulation as a modular platform for human neuromodulation applications. Each of the polymer arrays are attached to a small, pill-size titanium can (29mm x 6.3mm x 6mm) with a ceramic base providing 64 high-density platinum feedthroughs in a hermetically-sealed package. A 6-pin platinum-iridium cable attached to the pill-size can terminates in a 0.9mm BalSeal SYGNUS connector. This module (array, pill-sized can, and cable) is called a SmartLead. The 64 channel cortical and subcortical arrays are permanently-attached to the SmartLead and are constructed of thin-film metals encapsulated in polyimide, coiled, and molded in silicone. The electrode contacts are 800µm in diameter and made of platinum-iridium and are capable of both recording and stimulation. Measured impedances are typically less than 500Ω. An embedded inner-tube for a removable stylet aids implantation of the arrays through a burr hole. The cortical array is sized 32mm x 14mm and the subcortical array is 1.27mm diameter to match commercial deep brain stimulator probes. The SmartLead can be connected to a head-mounted titanium package, also designed for chronic, long-term use. This module, sized 31.5mm x 40mm x 7mm is designed to be embedded in the skull and provides 5 BalSeal SYGNUS ports and accepts up to 4 SmartLeads of either cortical or subcortical variety simultaneously, providing access to 256 channels for both recording and stimulation enabling the prospect of closed-loop neuromodulation capabilities with the proper electronics. The 5thport can be used for an additional SmartLead, an antenna to provide external communications, or a cable to another implanted module in the chest depending on what the embedded electronics are designed to do. An earlier version of the arrays have separately been tested in an intraoperative setting by collaborators at UCSF under an FDA Non-Significant Risk Designation and with IRB approvals and have demonstrated good functionality matching or exceeding commercial arrays. Combined, we present a modular, head-mounted solution aimed at chronic human use for neuromodulation, enabling new techniques such as distributed closed-loop neuromodulation.

Abstract: Communication between living brain tissue and engineered devices is the key link to understand the brain fundamental function and to clinically restore neurological deficits.
The tools that are currently broadly available for this interface exhibit some limitations such as invasiveness, low channel count, complicated implantation strategies and bulky connectorization, which hinder these devices from optimal performance and widely accepted clinical solutions. Enabled by new materials and device designs, a new generation of brain interface technologies is replacing bulkier, non-compliant systems with the aim of seamless electronic-biological interfaces with lower tissue damage, reduced immunogenicity, high-density, tunable spatial distribution, and long-term stability. Recent successful examples leveraging mechanically compliant materials have demonstrated major breakthrough in brain research using ultra-flexible systems for ECoGs recordings, and for depth electrodes. Yet, surgical implantation damage, scalable channel count and the number of devices implanted simultaneously are still significant challenges.
Neuroroots is a new platform enabling facile implantation of ultra-low damage and scalable channel-count penetrating electrodes for chronical brain recording and stimulation. The platform consists of dangling 'root' electrodes only 5 μm wide by 1μm thick, matching both cell-size dimensions and tissue mechanical properties, yet without interconnectivity between electrodes. For insertion, we developed a strategy based on an ultra slim, 35μm diameter microwire as a temporarily shuttle onto which numerous individual electrodes self-align. Once inserted, these wires delaminate, and the shuttle is removed, leaving only the electrodes into the neural tissue. First, we demonstrated chronic implantation of an array of 32 electrodes into the hippocampus of freely behaving rats. Recordings exhibit single-unit with a remarkable stability over a period of 7 weeks. The open structure of the mesh is believed to minimally perturb the ecosystem and nutriment diffusion, thus minimally impacting the sampled neural region. Furthermore, we

implanted NeuroRoots into the cerebellum both in-vitro and in-vivo and recorded clear single-units in both, which demonstrate the unique ability of this platform to be implanted into region which are difficult to access for traditional probes.

Title: Long-term stability of recordings and microstimulation of intracortical microelectrodes is depth-dependent

Authors: ***M. E. URDANETA**[1], N. G. KUNIGK[2], S. W. CURRLIN[1], J. D. PEÑALOZA-APONTE[2], F. DELGADO[2], K. J. OTTO[3];

Abstract: Advances in brain-machine-interfaces (BMI) and implantable technologies have opened the door for bidirectional neuroprostheses capable of restoring function in patients with neurological deficits. Intracortical recordings in motor cortex have allowed tetraplegic patients to control robotic arms with several degrees of freedom. Analogously, touch feedback from these prosthetic limbs has been established via intracortical microstimulation (ICMS) of the somatosensory cortex (S1). However, these implanted devices consist of multi-electrode arrays with a single electrode-site at the tip of each shank, confining the recording and/or stimulating interface to a single layer of the cortex. Moreover, intracortical microelectrodes are prone to biotic factors such as the foreign body response (FBR) that severely reduce the functional life of these devices. In order to assess the optimal cortical depth for longitudinal recordings and microstimulation, a silicon microelectrode with 16 equally spaced electrode-sites spanning all the layers of the cortex was chronically implanted the S1 of rats. Longitudinal neural recordings and microstimulation detection thresholds were obtained for more than 25 weeks. Our results showed that compared to superficial channels, more sites located in layers IV and V remained functional over the course of the experiment. These sites also exhibited higher signal-to-noise ratio (SNR) in electrophysiological recordings. Similarly, microstimulation thresholds obtained via a conditioned avoidance behavioral paradigm showed that ICMS sensitivity was also depth-dependent. In particular, electrode-sites in layers IV and V required significantly less charge to evoke behavioral percepts. Furthermore, these cortical layers displayed the highest stability for

long-term microstimulation. Collectively, our results suggest that cortical depth plays an important role in the functionality and long-term performance of implantable neuroprostheses and bidirectional BMIs.

Hosp., Boston, MA; [12]Neurol., Harvard Med. Sch., Boston, MA

Abstract: Brain-computer interfaces (BCIs) aim to restore a means of interacting with their environment to those who have lost motor function due to spinal cord injury or disease. They do so by transforming neural signals into movement of external end effectors, such as a cursor used to control a computer or tablet-computer interface by decoding a 2D continuous space and a discrete “click” signal. The utility of such an interface can be estimated with selection rate (bits/s). To date, efforts to increase information throughput have involved adding more targets to the interface or decreasing time required per selection. But adding too many targets can decrease accuracy and thus a maximum information throughput exists. Here we investigate another means

of increasing information throughput: varying the number of click options available to the user. For example, using a mouse with two click options instead of one to act on one of eight targets doubles the number of potential targets, resulting in a maximum 1 bit increase, compared to a maximum improvement of 0.2 bits that would be achieved by adding a ninth target with only one click option. We tested the potential for decoding four click signals in addition to 2D continuous cursor velocity, which has the potential to nearly double the bit rate (relative to a single click).
A participant with tetraplegia enrolled in the BrainGate2 clinical trial had two electrode arrays implanted in hand-knob area of motor cortex. He moved a cursor to one of eight peripheral targets in a center-out task using a ReFit Kalman decoder. Once over the target, he was instructed to perform one of four movements to generate one of the 4 clicks. Three different sets of four instructed body movements were tested: (1) hip abduction, adduction, and flexion and ipsilateral elbow flexion, (2) flexion the individual fingers on the contralateral hand and (3) flexion of the thumb, index, middle or little fingers. Offline analysis of the click signals was performed using a naive Bayes classifier.
Offline classification of the intended click, using 20 ms bins of thresholded neural spiking activity, predicted the intended click target on held-out data with maximum accuracy of 98.6% for movement set 1, 87.5% for movement set 2 and 90% for movement set 3. Importantly, when the participant was controlling the translation of the cursor, his ability to hold the cursor over the targets was unimpeded by his attempts to generate the click signals.
Future work is needed to test this online to identify click state in real time. If successful, this could improve BCI information throughput and meaningfully improve the user's ability to navigate real-world computer interfaces.

Hosp., Boston, MA; [14]Dept. of Neurol., Harvard Med. Sch., Boston, MA

Abstract: Intracortical brain-computer interfaces (iBCIs) for people with paralysis have largely built upon work investigating the neural representation of overt reaching movements in monkeys. However, in people with paralysis, iBCIs leverage neural features related to attempted movement of paralyzed limbs. These attempted movements' neural representation may differ substantially from overt movement. Although prior work in humans has shown proficient iBCI-enabled control of cursors and robotic arms, relatively little is known about how paralysis affects movement representation at a single unit level. Furthermore, it is not known whether neural activity during attempted movement of paralyzed limbs is similar to closed-loop iBCI control in which the neural activity is guiding the cursor. We addressed these questions with neural recordings from two 96-channel microelectrode arrays implanted in "hand knob" area of motor cortex in a participant with a C4 spinal cord injury enrolled in the BrainGate2 clinical trial. We first compared our participant's neural activity during attempted movement of the paralyzed arm and overt movement of the head to neural activity during monkey arm movement. We found that neural activity during overt head movement had strong modulation to distance and force magnitude, similar to monkey arm movement. In contrast, attempted movement of the paralyzed arm had weak modulation to distance and force. Interestingly, we found that neural activity during closed-loop iBCI control was more similar to overt movement than to attempted movement of the paralyzed limb (i.e. it also had a strong representation of distance). To further clarify the relationship between attempted movement of a paralyzed limb and closed-loop iBCI control, the participant controlled the cursor using a series of different joint movement strategies. We found that neural activity changed during closed-loop iBCI control, becoming more similar across different movement strategies. Surprisingly, we also found that the cursor could be controlled equally well when instructed to control it without attempting (or imagining) any particular movement at all. These results suggest that neural activity may change during iBCI control to reflect a generic "cursor control" signal that somewhat dissociates it from any particular attempted movement representation. Future work will be needed to clarify how and why these neural changes occur, and to elucidate the mechanism behind body-dissociated iBCI control.

Abstract: Intracortical brain-computer interfaces (iBCIs) record signals directly from the brain and harness those signals to control external devices, such as computer cursors. Typically, iBCIs rely on activity associated with intended movements recorded from the precentral gyrus (PCG). Another promising source of iBCI control signals is the middle frontal gyrus (MFG). However, other signals, such as activity associated with eye movements, may be present along with information about intended hand movements. Here, we compared single unit activity in PCG and MFG in response to eye movements and intended hand movements in a person with tetraplegia. We collected data from participant T10, a 35-year-old, right-handed man with a spinal cord injury (C4 AIS-A), in the BrainGate2 pilot clinical trial. T10 had two 96-channel microelectrode arrays (Blackrock Microsystem, Inc) implanted—one in the left MFG and one in the left PCG. T10 performed an instructed-delay, center-out task with 4 radially-distributed targets. T10 acquired targets using two different control modes in alternating blocks. In eye control blocks, he

acquired targets using eye-gaze (Tobii eye-tracker), while holding a neurally-controlled cursor stationary within a centrally-located target. In hand control blocks, he acquired targets by moving the neurally-controlled cursor and fixating on the central target. Single units with significantly different firing rates for movements to different targets were deemed directionally-tuned (Kruskal-Wallis, $p<0.01$).
As expected, more units in PCG were directionally-tuned during hand control blocks than eye control blocks. Notably, approximately equal numbers of MFG units were directionally-tuned during hand control and eye control blocks. However, MFG ensemble activity patterns could distinguish between the two control modes. This suggests that MFG, to a greater degree than PCG, represents both eye and hand movements, but may still provide information about intended hand movements for iBCI control.

Abstract: Handwriting is a fine motor skill in which straight and curved pen strokes are strung together in rapid succession. Because handwriting demands fast, richly varying trajectories, it could be a useful tool for studying how the motor cortex generates complex movement patterns. Additionally, attempted handwriting movements could be decoded by a brain-computer interface (BCI) and then translated to text in real time, restoring the ability to communicate to people with severe paralysis. In healthy adults, the average handwriting speed is 120 characters per minute (Jebsen 1969), which is three times the record rate for point-and-click intracortical BCI typing (Pandarinath 2017).

Here, we investigated the representation and decodability of attempted handwriting movements in a person with C4, ASIA-A spinal cord injury who was paralyzed from the neck down. We recorded from two microelectrode arrays in hand knob of precentral gyrus while the participant attempted to write letters using an imaginary pencil. The participant wrote letters one at a time in an instructed delay task with a 2-3 second delay period followed by a 1 second movement period. Encouragingly, a cross-validated naïve Bayes classifier achieved 87% accuracy across all 26 letters (and 2 punctuation symbols) using only three, 300 ms time bins of neural activity after the go cue. However, this simple classifier doesn't account for temporal variability across trials. We designed a recurrent neural network classifier to account for how letters can be written at slightly different speeds each time. It achieved 92% accuracy, with the majority of misclassifications confined to a small set of similarly-written letters (e.g. q and g). These preliminary results suggest that a handwriting BCI could be accurate enough to achieve high communication rates.

Finally, to gain insight into how motor cortex contributes to handwriting, we examined the neural activity during the instructed delay period. Recent theories of neural population dynamics during arm reaching suggest that neural dynamics in motor cortex might "unroll" the preparatory state into patterns of activity that generate the movement. Interestingly, we found that preparatory activity represented upcoming letter features only within a short time-horizon. That is, letters that differed only near the end (e.g. m and n) had seemingly identical preparatory representations, suggesting that motor cortex requires additional inputs during the movement to complete the letter. However, letters that begin identically but quickly diverge (e.g. l, t, and k, which all begin with a downstroke but then diverge) had separable (but similar) preparatory representations.

Title: Comparing human primary motor cortex (M1) and posterior parietal cortex (PPC) neuron population activity using a brain-machine interface

Authors: *S. SAKELLARIDI[1], T. AFLALO[1], V. N. CHRISTOPOULOS[1], K. W. PEJSA[1], E. ROSARIO[2], D. S. OUELLETTE[2], N. POURATIAN[3], R. A. ANDERSEN[1];

Abstract: A brain-machine interface (BMI) enables people with severe paralysis to communicate with the external world by creating a direct communication pathway between the brain and external prosthetic devices. One of the central questions in the field of intracortical BMI is which are the most suitable areas to record neural activity to drive prosthetic devices. Although the primary motor cortex (M1) and the posterior parietal cortex (PPC) are two of the most popular implanted areas in previous studies, there is no a systematic, direct comparison between them. In the current study, a patient with tetraplegia (C5-C6 lesion, 2 years post injury) was implanted with two 96 channel microelectrode arrays in M1 and PPC. The participant learned to modulate the activity of the recorded neurons in M1 and/or PPC to control a 2-dimensional computer cursor in a center-out-center task to eight radially arranged stimuli. The only instruction given was to attempt intended movements using only the right thumb and to not switch effectors during the task. Each session started with an initial observation-training phase (O), in which the participant observed the cursor moving from the center to the cued target and back to the center, and was instructed to follow the cursor with his right thumb. Neural activity was recorded from both M1 and PPC. Then, two separate linear decoders were trained; one trained on the units recorded from M1 (D_{M1}), and the other trained on units recorded from PPC (D_{PPC}). Finally, in the BMI control phase, the subject controlled the cursor using only one area (M1 or PPC) at a time as determined by the corresponding decoder (D_{M1} or D_{PPC}). Our goal was to understand how each brain area behaved during brain control depending on which area was causally involved in producing movement of the cursor. To do that, we compared offline the neural behavior of each brain area when it causally controlled cursor motion versus when activity

was recorded but had no causal influence on cursor motion. In our decoding approach, units highly predictive of the subject's intent are assigned weights of larger magnitude than neurons with lower predictability and consequently have a larger impact on decoder output. For each unit we calculated the magnitude of the decoder weight assigned to it after normalizing for firing rate differences. Preliminary results suggest that the behavior of the individual units as measured by the decoder weights did not significantly vary depending on which brain area played a direct causal role in controlling the cursor. This result suggests that M1 and PPC are part of an interconnected network that translates plans into actions with limited short-term plasticity.

Title: Identifying changes in volitional state and BCI task engagement based on the intrinsic structure of neural ensemble activity patterns in motor cortex of people with tetraplegia

Authors: *T. K. PUN[1,2], A. J. CATOYA[3], C. E. VARGAS-IRWIN[4,2,5], S. S. CASH[6,8], J. D. SIMERAL[5,1,7,2], L. R. HOCHBERG[5,1,7,8,2];

Ctr., Providence, RI; [6]Dept. of Neurol., [7]Ctr. for Neurotechnology and Neurorecovery, Dept. of Neurol., Massachusetts Gen. Hosp., Boston, MA; [8]Dept. of Neurol., Harvard Med. Sch., Boston, MA

Abstract: Neuromotor deficits resulting from conditions such as amyotrophic lateral sclerosis (ALS), brainstem stroke, and spinal cord injury (SCI) result in loss of volitional movement

reducing independence. Brain-computer interfaces (BCI) bypass damaged motor pathways and provide new links to assistive technologies. Voluntary action engages vast networks of neurons performing complex calculations which are still not fully understood. It is widely accepted that motor cortex incorporates a mix of incoming sensory, cognitive, and motor planning information, reflecting latent variables that are not directly related to kinematic motor output. Reliably identifying neural activity patterns indicative of a set of latent factors impacted by task and cognitive context is a challenge for developing BCI systems that support continuous, multi-effector use.

Here we present a new approach to generate state spaces based solely on the intrinsic properties of single unit ensemble recordings. We used Spike train SIMilarity Space (SSIMS) analysis to map neural activity patterns into low dimensional state spaces (based on spike train metrics combined with dimensionality reduction). These state space projections can be used to identify clusters of similar, recurring activity patterns, without the need to define task-related tuning models for individual neurons. We applied this method to data collected from two participants enrolled in the BrainGate2 clinical trial - T10, an adult male with tetraplegia due to SCI (C4 AIS-A), and T9, an adult male with tetraplegia due to ALS (ALSFRS-R of 8). T10 had two 96 microeletrode arrays (Blackrock Microsystem, Inc) implanted on the left middle frontal gyrus (MFG) and precentral gyrus (PCG), and T9 on the left PCG. We collected data during sessions where T10 & T9 controlled either a computer cursor or a JACO robotic arm to perform a 2D target acquisition task via intracortical BCI. We demonstrate that our approach can be used to generate state spaces that differentiate between effectors (cursor vs. robotic arm) in both T10 & T9 (81.4±8.0%, 99.5±0.58% accuracy). Additionally, we recorded data from T10 over a 24 hour period; we can identify 5 partially overlapping states related to session tasks, interaction with caretakers and others, engagement with a sip-and-puff computer system, eating, and sleeping (Nearest Neighbor Classifier: 46.5±0.6%, $p<.01$; against chance classification: 23.5±0.8%). Our findings suggest that state space models based on intrinsic similarity can be used to detect context-dependent changes in volitional state, providing a useful indicator of when BCI control modes should be adjusted.

Title: Coding of intent in M1 and PPC: Simultaneous array recordings in a human tetraplegic subject for neural prosthetic applications

Authors: *T. AFLALO[1], S. SAKELLARIDI[1], K. KADLEC[1], E. ROSARIO[2], N. POURATIAN[3], R. A. ANDERSEN[4];

Abstract: Individuals with spinal cord injuries resulting in paralysis are still able plan and imagine or attempt movements. The major cortical sensorimotor circuit responsible for planning and producing movement involves the posterior parietal cortex (PPC) and motor areas of the frontal lobe. Cortical implants in both primary motor cortex (M1) and PPC have been used to record movement intention signals in tetraplegic humans in order to control external devices such as robotic limbs and computers. One outstanding question is how the functional properties of these areas differ when used for direct brain control. We have recently initiated a clinical trial in which neural activity is recorded from the hand-knob region of M1 and the superior parietal lobule of PPC in the same patient in order to make direct comparisons. The neural populations from both arrays were used together or individually to perform a variety of tasks in which the participant guided a cursor under brain control. These tasks included reaction time and delayed memory tasks with different sensory motor contexts (Pro-, Anti-, Symbolic, and NoGo trials) to better understand the underlying factors driving neural responses in the two areas. We used off-line analysis at both the single-unit and population levels to understand the functional properties of the >200 units simultaneously recorded from M1 and PPC during each brain-control session. M1 neurons were found to code the desired movement almost exclusively during the execution of cursor movements whereas PPC neurons were active during both the planning and execution epochs. Direction selective signals in M1 and PPC were largely invariant to sensory-motor context, reflecting the intention of the subject invariant to the visuomotor context used to instruct movement. Intriguingly, the relative timing of intention related signals was context dependent: intention signals were coded about 100ms earlier in PPC than M1 when instructed with simple intuitive visual stimuli, but the pattern reversed, with M1 leading PPC (~20ms), when an abstract rule was needed to remap a spatial cue to inform movement. These results show that the network architecture for sensory-motor planning and execution are largely preserved post-injury, even under novel functional demands (closed-loop cortical control). Further, our results suggest a more complicated network architecture for how movement emerges from combining information from our external world with internally stored contextual information.

Title: The influence of object presence on M1 activity during movement planning and execution

Authors: *A. J. HERRERA[1,4], R. A. GAUNT[2,4,1], M. L. BONINGER[2,1,5], A. P. BATISTA[1,3,4], B. M. YU[6,7,4], S. M. CHASE[7,4], J. L. COLLINGER[2,1,4,5];

Abstract: Brain-computer interfaces (BCIs) can restore upper limb function by providing control of various end effectors using neural signals recorded from motor cortex (M1). Previous studies in our lab have found that during BCI control, a majority of recorded neurons show an increase in firing rate as an object is approached relative to when the same movement is performed in the absence of an object. Here we quantify how population-level neural dynamics during planning and movement are impacted by object presence.
A 32-year old man with tetraplegia who had intracortical microelectrode arrays implanted in M1 participated in this study. Neural data were collected while the participant used a BCI to move a robotic arm and hand to a specified location. He then either grasped an object or closed the fingers at that location. Data were recorded over 5 sessions.
To uncover the latent dynamics underlying the population neural activity during the task, we used factor analysis to identify a low-dimensional subspace summarizing neural co-activation patterns. In this subspace, we observed clear separation in the time course of population activity between the conditions across all sessions. Even prior to movement onset, the neural activity occupied a different area of the neural subspace for trials with and without an object. Since the object-present and object-absent trials were collected in blocks rather than randomized from trial to trial, this may suggest a change in strategy or preparation state. The separation between the neural trajectories tended to increase as the hand approached the target. To understand the dynamics of the trajectories, we defined an object context axis (OCA) as the line connecting the average object-present and object-absent neural trajectories at each time point. The angle of the OCA remained stable during the reach phase and then rotated (by ~60 degrees in 8D space) when the subject was instructed to grasp. The angle remained constant during the grasp phase. These findings demonstrate the existence of a clear separation of motor cortical activity patterns

when reaching to an object rather than an empty location in space. The difference in neural activity during preparation may be driven by visual feedback or a change in motor control strategy that occurs before movement onset. The substantial rotation of the OCA between the reach and grasp phases may reflect a dynamic change in neural states used to control these different movement types. However, the parallel nature of the neural trajectories within each movement phase may allow the movements to be driven through a constant downstream linear readout without being impacted by the presence or absence of an object.

Abstract: In people affected by high spinal cord injury (tetraplegia), movement can be restored through brain-machine interfaces (BMIs), capable of controlling prosthetic arms with upwards of 10 degrees of freedom using intracortical activity from the sensorimotor cortex [Wodlinger et al. 2015]. Critical to successful BMI-based motor control is the ability to design decoders that translate neural activity to purposeful actions with high fidelity. Decoders are conventionally built by instructing BMI users to watch motor activities while imagining that they are performing them, and mapping these movements to simultaneously recorded neural signals [Collinger et al. 2013]. Such approaches are founded on the concept of neural simulation [Jeannerod 2001], which may be supported in part by mirror neurons [Rizzolatti and Sinigaglia, 2016]. While

mirror neurons have been established in premotor and parietal areas [e.g. Mukamel et al. 2010], their existence in primary motor cortex (M1) is a matter of debate: evidence has been shown directly in monkeys using intracortical electrodes [Tkach et al. 2007, Dushanova and Donoghue 2010], but only indirectly in humans using noninvasive methods such as electroencephalography [Eaves et al, 2016].
For the purpose of a study to achieve BMI-based simultaneous control of two robotic arms, we implanted 6 microelectrode arrays (Blackrock Microsystems, Salt Lake City, UT; 2 arrays in M1 and 2 in S1 in left/dominant hemisphere; 1 in M1 and 1 in S1 of right/non-dominant), comprising 384 neural recording channels in a human participant affected by a high spinal cord injury. As an assessment of microarray placement and recordings, we showed videos of a person performing shoulder abductions and wrist extensions on both sides of the body, and the participant was prompted to either passively observe, attempt (imagine) without initiating, or execute the movement along with the video. During each experimental block, one type of movement (randomized) on a side of the body (also randomized) was repeated at a base period of 2 s (plus jittered delay).
Peristimulus activity across electrodes revealed a subset of neurons that modulated across observation, imagery, and execution trials, providing direct evidence of a mirror-like activity in human primary motor and sensory cortices. Increases in activity relative to baseline were detected bilaterally, suggesting these networks may exist in parallel in both ipsi- and contralateral brain hemispheres to the controlled arm. These results provide novel biological support for the use of motor imagery and passive observation to construct and train decoders for BMI prostheses.

Title: Intracortical microstimulation feedback improves grasp force accuracy for high forces when using a brain-computer interface

Authors: *K. M. QUICK[1,3], J. M. WEISS[1], R. A. GAUNT[1,3,2], J. L. COLLINGER[1,3,2,4];
[1]Physical Med. and Rehabil., [2]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [3]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA; [4]DVA, Pittsburgh, PA

Abstract: After a spinal cord injury, a person may grasp objects using a brain-computer interface (BCI) to control a robot arm. With this approach however, people lack somatosensory feedback on their grasp force. Intracortical microstimulation (ICMS) of sensory cortex can evoke tactile sensations and may therefore offer a viable solution for grasp force feedback. We investigated whether a bidirectional BCI could improve grasp force control over a motor-only BCI. When evaluating the BCI force error during a force matching task, we found that ICMS feedback improved BCI grasp force accuracy when the participant attempted to grasp at a high force, but not for low or medium forces.

We recorded neural activity from motor cortex (M1) using intracortical arrays in a 31-year-old man with tetraplegia. While collecting BCI training data, the participant attempted to mimic a virtual reality hand ("VRH") as it closed around an object, applied a cued force level, and released the object. From this data, we trained a BCI to decode intended grasp force and grasp velocity. During BCI control of the VRH, we provided feedback on the VRH's applied force via single-channel amplitude-modulated ICMS. We then evaluated the accuracy of the BCI's applied force under various ICMS feedback conditions (sham stimulation or actual stimulation) and visual feedback conditions (no visual "NoVis" feedback, VRH feedback, or VRH + applied force trace "VRH + F" feedback).

In addition to success rate on the force matching task, we quantified performance two seconds after grasp onset by evaluating the error between the cued force and the BCI's applied force. This time period was chosen in order to capture the participant's first attempt to match the force target. For high-force targets, ICMS feedback improved the BCI's applied force accuracy during the NoVis and VRH feedback conditions. For medium and low-force targets, ICMS feedback did not affect BCI grasp force accuracy during any visual feedback condition. For medium-force targets, the participant already had an accurate implicit representation of the cued force such that ICMS did not provide added benefit. For low-force targets, the subject had difficulty concurrently closing the gripper and applying a small force; the BCI frequently overshot the low-force target regardless of the provided feedback. Some of the performance hurdles encountered resulted from the dual velocity-force decoding scheme which made it difficult for the participant to keep the VRH closed for low-grasp forces or for long duration grasps. To better realize the potential for increased grasp force accuracy with ICMS feedback, new decoders for maintaining grasp force will need to be developed.

Abstract: The sense of touch is a key component of motor function. Several efforts have successfully used a brain-computer interface (BCI) to restore motor function alone. Importantly, sensory information relevant for BCI control is potentially represented in the brain, even following severe spinal cord injury (SCI). Unfortunately, severe SCI should essentially eliminate sensory information transmission to the brain, that originates from skin innervated from below the lesion. We assessed the hypothesis that, following SCI, residual touch-related hand sensory information is transmitted to the brain, can be decoded amongst competing sensorimotor signals, and used to enhance the sense of touch via an intracortically controlled closed-loop BCI. Experiments were performed with a participant who has an AIS-A C5 SCI and an intracortical recording array implanted in left primary motor cortex (M1). Recordings of evoked M1 activity from hand tactile stimulation, neural decoding, and standard clinical assessments of sensorimotor functions were used throughout a series of experiments. Our results demonstrate that residual afferent hand sensory signals surprisingly reach M1 following SCI, and can be simultaneously demultiplexed from ongoing efferent motor intention (~85% accuracy, using non-linear support vector machines), enabling intracortically controlled closed-loop sensory feedback during BCI operation. The closed-loop sensory feedback system was able to detect residual sensory signals from up to the C8 spinal level. Using the closed-loop sensory feedback system enabled significantly enhanced object touch detection, sense of agency, movement speed, and other sensorimotor functions. To our knowledge, this is the first demonstration of simultaneously decoding multiplexed afferent and efferent activity from human cortex to control multiple assistive devices, constituting a ‘sensorimotor demultiplexing’ BCI. Overall, our results support the hypothesis that sub-perceptual neural signals can be decoded reliably and transformed to conscious perception, significantly augmenting function. Additional experiments using deep learning architectures also demonstrate the ability to demultiplex touch, movement intention, and

proprioception simultaneously as well as decode discrete pressure levels during object grip. We hope this new set of findings will enable patients with an implanted BCI to maximize the information encoded in the recorded neural activity for new functional gains.

Title: Habituation of perceived intensity with intracortical microstimulation

Authors: *C. L. HUGHES[1], S. N. FLESHER[3], M. BONINGER[2], R. A. GAUNT[2]; [1]Bioengineering, [2]Physical Med. and Rehabil., Univ. of Pittsburgh, Pittsburgh, PA; [3]Dept. of Neurosurg., Stanford Univ., Stanford, CA

Abstract: Somatosensation is crucial for motor control and is an important part of the human experience. In an ongoing experiment, we are studying the use of intracortical microstimulation (ICMS), delivered through Utah arrays implanted in somatosensory cortex, to restore tactile percepts in a human participant with a C5/C6 spinal cord injury. For ICMS to be practically useful, the percepts should be consistent and reliable. However, we have observed that continuous stimulation can alter perceived intensity, as has been observed with peripheral stimulation. We aimed to systematically document habituation to ICMS and understand how this might affect clinical BCI applications. To quantify how continuous stimulation alters perceived intensity, we delivered stimulation on single electrodes at 80 uA for 60 seconds at 100 Hz. The participant used an analog slider to indicate how the intensity changed throughout the stimulation interval. We found that on 25 out of 27 trials tested across 9 electrodes, the perceived intensity decreased to be imperceptible within the 60 second stimulation period. Interestingly, the change in intensity was not gradual but rather happened in steps, often shifting quickly from baseline intensity to imperceptible. To quantify how intermittent stimulation alters perceived intensity, we delivered a 1-second pulse train at 60 uA and 100 Hz on single electrodes every four seconds for 50 pulse trains and asked the participant to report the perceived intensity on a self-selected scale following each pulse train. To measure recovery, we then presented a 1-second pulse train every 60 seconds for 5 pulse trains. We found that the perceived intensity decreased with each additional stimulus on all but one electrode, with the most significant changes occurring within

the first 10 pulses, although the degree and time course of habituation varied by electrode. During the recovery period, the perceived intensity partially recovered in the first minute following stimulation with no significant changes after this recovery. Furthermore, intensity would rarely recover to the original reported intensity within test days on any tested electrode. We found that continuous stimulation could result in complete loss of perception, typically within 15 seconds. Intermittent stimulation also decreased intensity, but over three minutes, the sensations never became imperceptible. In clinical application of BCIs, intermittent stimulation should be used to drive consistent percepts. This supports a stimulation approach in which ICMS is delivered transiently based on changes in force rather than tonically, as is the case when ICMS is mapped to the absolute value of force.

Engin., [4]Neurosurg., [5]Neurol., Johns Hopkins Univ., Baltimore, MD; [6]NIH, Bethesda, MD

Abstract: Intracortical brain-machine interfaces (BMIs) have been used to effectively control multidimensional manipulators such as cursors and robotic arms. Prior intracortical BMIs in humans have relied on neural inputs from sensorimotor regions in a single hemisphere. Recording neural activity simultaneously from both hemispheres may improve on these prior demonstrations by: (1) enabling additional dimensions of control via unique information in each hemisphere and (2) improving on the reliability of existing dimensions of control via information that is related or shared between hemispheres. This work represents the first demonstration of an intracortical BMI leveraging input signals from bilateral sensorimotor implants in a human participant.
A volunteer with incomplete quadriplegia was implanted with the Bidirectional Cortical Neuroprosthetic System (BiCNS) [1] consisting of 3 pairs of NeuroPort arrays (Blackrock

Microsystems). Each array pair included one 96-channel array implanted in primary motor cortex (M1) and one 32-channel array implanted in primary sensory cortex (S1). Two array pairs were implanted in the dominant hemisphere and one array pair was implanted in the non-dominant hemisphere.
Beginning 4 weeks after implantation, the participant practiced controlling a multidimensional manipulator in up to 3 sessions per week. At the start of each session, spike sorting to isolate multi- and single-unit neural inputs from one or more arrays was performed. Calibration was then performed with an imagery task in which the participant observed a series of automated center-out movements by the virtual Modular Prosthetic Limb (vMPL) and imagined that he was performing the movements. Given the participants's novel combination of bilateral arrays, separate decoders for velocity outputs were trained for two vMPLs: the right vMPL used inputs from dominant (left) M1 and the left vMPL used inputs from non-dominant (right) M1. Decoders were trained using indirect optimal linear estimation and then used for online control of the vMPLs. Initially an assistive training scheme was used in which control inputs for an ideal trajectory were added to the participant's own inputs. The assistive input was progressively reduced as the participant learned to generate his own control.
Performance for different decoder configurations is assessed using a combination of online and offline metrics including overall accuracy during real-time control tasks and R^2 values on data withheld from decoder training. Additionally, stability of neural recordings and decoder performance are discussed.

Abstract: A growing body of research suggests that cortical neural ensemble activity during motor behaviors is well-described by orderly dynamics in a low-dimensional underlying neural state space. Most of this prior work has examined neural activity during limb movements, in animals. Is there similar neural population structure during different types of movements, such as the uniquely human behavior of speaking?
We recorded neuronal spiking activity from two 96-electrode arrays implanted in the 'hand knob' area of dorsal motor cortex of a participant in the BrainGate2 brain-computer interface clinical trial. This individual has tetraplegia, but can still speak, allowing us to record neural activity leading up to and during speech production.
Individual neurons in this area modulated strongly and distinctly while speaking different words. This allowed us to examine neural population dynamics at the resolution of action potentials, complementing previous speech neurophysiology studies which have been primarily conducted at the coarser resolution of electrocorticography (e.g., Anumanchipalli et al. 2019).
We found that two motor cortex dynamics motifs previously reported during arm/hand movements were also strongly present when speaking. When the person was beginning to produce speech, the largest component of the population activity (found via dPCA) was largely invariant across speaking different words. This population-level structure is similar to Kaufman et al. 2016's finding of a condition-invariant motor cortical signal when monkeys initiated a variety of reaching movements.
During the subsequent speech production (i.e., a time epoch centered on acoustic onset), neural population firing rates largely followed rotatory dynamics (found via jPCA) as previously described for monkey reaches (Churchland et al. 2012) and human hand movements (Pandarinath et al. 2015).
These conserved motor cortical dynamics patterns across reaching and speaking could indicate that this is a widely-deployed computational strategy for producing different kinds of movements. In particular, such neural trajectories may be an effective way to transition the neural state from a preparatory regime to a different regime in which time-varying motor outputs are assembled from an oscillatory basis set (Sussillo et al. 2015).

Title: Classification and fitting of phonemes and words are the underlying basis of an invasive speech prosthetic that uses chronically recorded single units

Authors: P. R. KENNEDY[1], *M. GEARING[2];
[1]Neural Prosthetics, Neural Signals Inc, Duluth, GA; [2]Emory Univ., Atlanta, GA

Abstract: Data will be presented on the classification and fitting of phonemes and words using single units recorded from a person speaking audibly and silently. Phonemes showed no difference in correlations between audible and silent speech, but both modalities demonstrated a significant difference to control periods ($P < 0.05$, 2 tailed 't' test) using the Fitting app from Matlab. These results indicate that silent speech can be detected with a correlation coefficient (R) that is not significantly different from the R for audible speech, and both can be distinguished from control periods of rest. Twenty words were classified using a support vector machine paradigm with accuracy of 85.3% using 3 words, falling to 59.7% with 20 words.
These results provide confidence that classification and fitting paradigms can detect silent speech.

Title: Changes in target-dependent neuromodulation during BCI learning

Authors: F. B. MCAFEE[1], *A. G. ROUSE[2];
[1]Biomed. Engin., [2]Neurosci., Univ. of Rochester, Rochester, NY

Abstract: Brain-computer interface (BCI) research provides a unique opportunity to study neural adaptation and learning. In this analysis, we investigate the degree to which the subjects identified and selectively modulated the four neural dimensions used for control of a BCI. We analyze whether the dimensions used for BCI control have (i) larger magnitude and/or (ii) more consistent modulation than non-BCI dimensions. In the BCI experiment, a hybrid controller that included both active dimension selection and velocity control along the selected dimension was used. The BCI task involved the direct control of a virtual hand by 16 neurons to attain a target hand position. The 90 session experiment started with only two control dimensions with a set of four targets, then adding a new dimension each time the monkey was competent in the previous set until four control dimensions with eight targets were included.
For each BCI session, the target independent, target dependent, and noise portions of the recorded firing rates were analyzed. The neural dimensions were analyzed separately to compare the four orthogonal BCI dimensions used for control with the 12 non-BCI dimensions. We analyzed both the magnitude and consistency of the neural firing rates. We defined magnitude as the sum of the target dependent variance across the target hand postures. We defined consistency as the sum of the target independent and dependent variance divided by the total variance.
With the addition of each new BCI dimension the magnitude increased rapidly during the first couple sessions and then later decreased as the subject became more practiced with the new task. There was a steady increase in consistency throughout the experiment, which tracked the constantly improving performance of the subject. The neural activity in the BCI control dimensions increased slowly in both consistency and magnitude over the entire experiment relative to the non-BCI dimensions. Indicating that with practice, the subject learned to selectively modulate neural activity more in the BCI-specific dimensions than in the null dimensions.

Our analysis of the magnitude and consistency of neural modulation suggested three distinct processes with different time courses (i) initial large changes in magnitude, (ii) increases in consistency that lead to increased performance, and (iii) finally selective modulation in only BCI-specific dimensions for increased efficiency. These techniques identifying the magnitude and consistency of neural signals could be translated to future studies of learning to better characterize the time courses of such neuromodulation under different conditions.

Title: Robot arm and hand control by neural activities from primary motor cortex in rhesus monkey

Authors: *S.-M. KIM[1,2], H. PARK[1,2], J.-W. SOHN[1,2];
[1]Dept. of Med. Sci., Catholic Kwandong Univ., Incheon, Korea, Republic of; [2]Biomed. Res. Inst., Catholic Kwandong Univ. Intl. St. Mary's Hosp., Incheon, Korea, Republic of

Abstract: Brain-machine interface (BMI) is a direct communication channels between the brain and external devices. It enables to control external device using neural activities. BMI is often used to restore function for patients with paralysis. It is important that external device in BMI provide high-precision movement like actual arm. To develop high-precision BMI technique, we designed a platform that external device (in this research, robot arm and hand) is controlled by neural activities from M1 area in rhesus monkey, at the same time, kinematic information of robot is encoded to the brain directly using intracortical microstimulation (ICMS).Reaching to grasp is natural movement and it happens frequently for serving daily functions in human life. For this reason, we designed reaching to grasp task and trained rhesus monkey so that he could perform task using his own arm and hand. For 11 days, the monkey achieved 86% of success rate (3845/4450 trials). After training, we implanted two 96-channel intracortical microelectrodes in the primary motor cortex (M1) and posterior parietal cortex, respectively. After two weeks of the surgery, we confirmed neural activities and started recording. We set up the task in which a monkey only observed reaching to grasp motion of robot arm and hand. We recorded neural activities from M1 and determined that neural activities respond to movement by observations. We developed decoder based on this result for real-time BMI platform. Using developed

decoder, the monkey was trained to control robot arm and hand using real-time population vector of neural activities. As a result of the monkey training, the success rate was gradually improved during 10 days from 50.0% of success rate on first day (9/15 trials) to 84.8% of success rate on 10th day (28/35 trials). The success rate is 83.8% (62/74 trials) on average for 10 days. This result enables us to study the effect of bi-directional BMI combining with ICMS method to encode kinematic information of robot arm directly to the brain in the future.

Title: Improving decoding from high-density ECoG recordings by optimizing single-trial latent factor dynamics

Authors: *R. ABIRI[1], D. B. SILVERSMITH[2], N. NATRAJ[1], E. F. CHANG[3], K. GANGULY[4]; [1]Univ. of California, San Francisco, San Francisco, CA; [2]Bioengineering, Univ. of California San Francisco, San Francisco, CA; [3]Neurosurg., [4]UCSF, San Francisco, CA

Abstract: Electrocorticography (ECoG) is a promising method to allow direct neural control over Brain-Machine Interfaces; it is less invasive and may allow for the recording of stable signals over long periods of time. However, it remains unclear how best to optimally capture single trial dynamics using mesoscale ECoG measurements. In contrast, there is a rapidly growing body of work showing that latent factor estimation can allow more robust single-trial decoding and control using spike-based recordings.
Here, we hypothesized that the activities of motor skill can be represented using a low dimensional manifold of single-trial ECoG signals recorded from high-density grids. ECoG signals were collected from 4 subjects with implanted ECoG grids (with 256 channels) while they were instructed to perform individual finger movement. The subjects performed around 20 trials of individual finger movement (flexion & extension) while the kinematics of fingers was captured by a Leap Motion device. ECoG signals and kinematics of fingers were synced and recorded for further analysis.
Among various dimensionality reduction methods, Principal Component Analysis (PCA) was applied to generate latent factors of cortical dynamics from high-density ECoG grids. For each individual finger movement, PCA was applied to concatenated trials or averaged trials of ECoG data for raw data as well as different bands including delta, theta, alpha, beta, low gamma and

high gamma band. The first 10 extracted principal components were used to project single-trial ECoG data and decode the corresponding kinematics of fine movements using multiple linear regression.
The results showed that PCA of averaged trials of ECoG demonstrated better performance than using PCA of concatenated trials. Furthermore, the accuracy of kinematic decoding was higher when using the delta band. Our results suggest that ECoG processing using latent factor dynamics can improve decoding. We anticipate that the generated low dimensional manifold can facilitate the development of a robust and real-time controller for a ECoG-based control of neurprosthetic devices.

Title: Deep learning-based classification for rat visual cortical electrocorticogram

Authors: *D. KONNO[1], N. MATSUMOTO[1], T. SUZUKI[2], Y. IKEGAYA[1];
[1]Grad Sch. Pharma Sci, Univ. Tokyo, Tokyo, Japan; [2]Natl. Inst. of Information and Communications Technol., Osaka, Japan

Abstract: Machine-learning techniques have been used to extract information from electrophysiological signals of neural activity. Recently, deep learning techniques have been used to classify neural signals. Specifically, convolutional neural networks (CNNs), one type of deep learning techniques, have shown good performance in classification of electroencephalogram (EEG) signals. However, it is well known that EEG has a low signal-to-noise ratio. To achieve better classification accuracy, we introduced electrocorticogram (ECoG) rather than EEG because in general, ECoG has a better signal-to-noise ratio than EEG. In this study, we first designed a novel ECoG probe which has 32 electrodes and mesh structure for stable electrode contact to the curved brain surface. Next, we recorded ECoG signals from the visual cortex of rats while presenting either of two distinct visual stimuli, vertical or horizontal grating. Rats were head-fixed, and a virtual cylinder comprising a vertical or horizontal sinusoidal grating was displayed in the three-dimensional coordinate space on four 24-inch

monitors that were arranged in a quadrangular arena. The images on the monitors were extended using two mirrors on the top and bottom of the arena. Then we tried to construct a CNN model that can classify which visual stimuli rats watch using raw ECoG signals as inputs. We collected 2,400 training data and 600 test data, reaching an accuracy of 58% in the test data. Although this accuracy is not so high, it seems that this CNN model learned some features of ECoG signals between vertical and horizontal stimuli. In the future, we aim to improve the accuracy by increasing the number of data.

Title: Improved classification of individual finger movements using temporal dynamics of ECoG

Authors: L. YAO, ***M. SHOARAN**;
ECE, Cornell Univ., Ithaca, NY

Abstract: Decoding of individual finger movements is a fundamental step for advanced prosthetic control. In this work, we exploit the temporal dynamics of the multi-channel electrocorticography (ECoG) signal in the feature space to improve the movement decoding accuracy compared to prior work, through classification of five finger movements and a resting state.
The ECoG recordings were segmented into 200ms epochs with 40ms step size. Nine features were subsequently extracted from each epoch to quantify the movement state, including alpha (8-13Hz), beta (13-30Hz), low-gamma (30-60Hz), gamma (60-100Hz) and high-gamma (100-200Hz) power, local motor potential (LMP) calculated as running average of the raw time-domain signal, the Hjorth activity, mobility, and complexity (Hjorth 1970). In order to precisely infer the current movement state, we concatenated the ECoG features extracted from the previous 15 epochs to form an expanded feature vector.
We evaluated the performance of our supervised machine learning model using a five-fold chronological cross-validation on the BCI competition IV dataset (3 subjects) and a similar paradigm ECoG dataset (9 subjects). By using the extreme gradient-boosted decision trees (XGB) as the classifier and the concatenated features of ECoG as input, we achieved an average accuracy of 72.3%±6.5%, about 8% higher than conventional XGB without sequential features ($P<0.0001$), as shown in Fig. 1. Moreover, the XGB classifier with concatenated features obtained a mean accuracy of 73.5% on the BCI competition IV testing set, outperforming the

state-of-the-art by 7.3% on the same dataset (Saa et al., 2016). Our approach offers the potential for high-performance and minimally invasive ECoG-based BMI control.

Title: A fully implantable brain machine interface for restoration of functional hand grasp in cervical SCI

Authors: ***N. W. PRINS**[1], *. I. CAJIGAS[2], S. GALLO[1], J. A. NAEEM[1], A. E. PALERMO[3], A. WILSON[4], L. FISHER[4], S. VANNI[2], M. E. IVAN[2], J. R. JAGID[2], A. PRASAD[1];
[1]Biomed. Engin., [2]Dept. of Neurolog. Surgery, [3]Physical Therapy, [4]Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL

Abstract: Spinal cord injury (SCI) is a devastating disease, which exerts a disproportionate medical, social, and economic toll on both the affected individuals and society at large. However, to date, no therapeutic intervention has been demonstrated to definitively improve neurological

outcomes or mitigate the effects of secondary neural injury. The objective of our study was to assess the feasibility of using the Medtronic Activa PC+S as a therapeutic system to restore movement to paralyzed muscles by: (1) evaluating the ability of the system to sense electrocorticographic (ECoG) signals in subjects living with quadriplegia (C5 or C6 level), and (2) assessing the feasibility of activating upper extremity muscles via functional electrical stimulation to reproduce hand grasp. We recruited a research participant (ClinicalTrials.gov NCT02564419) with a cervical SCI (C5 ASIA A) as a result of a motor vehicle accident to undergo implantation of the PC+S device with cortical electrodes placed stereotactically in hand motor region of the dominant hemisphere which was identified using pre-operative diffusion tensor imaging and fMRI while the subject performed motor imagery of his dominant hand. Intraoperative electrical stimulation and electromyograms (EMG) were used to further isolate the implant location. Currently, the subject is able to modulate his ECoG signals by following cues on a screen to trigger an external orthosis (Bioness H200) to cause opening and closing of his hand, with an online decoding accuracy of 88.2%. The subject is also able to grasp, transfer, and release objects of varying sizes by using brain signals to trigger the orthosis and write simple words. Our results demonstrate that a fully implantable brain machine interface can be safely implanted and used to reliably decode movement intent allowing for volitional control of hand grasp in a laboratory setting.

Title: Laminar origin of distinct high-frequency components of cortical surface electrical potentials revealed with biophysically detailed simulations

Authors: *V. L. BARATHAM[1,2], K. E. BOUCHARD[1,2];
[1]UC Berkeley, Berkeley, CA; [2]Lawrence Berkeley Natl. Lab., Berkeley, CA

Abstract: Electrocorticography (ECoG) is a powerful neural recording technique which allows for high temporal resolution monitoring of distributed brain circuits at mesoscale spatial resolution in both humans and model organisms. However, its use as a basic research tool is hindered by an incomplete understanding of the biophysical mechanism generating the signals.

The primary goal of this research is to determine where, within the laminar structure of cortex, different frequency components of surface potentials (e.g., ECoG) are generated. Here, we use a large scale, anatomically detailed simulation of a cortical column, where our ability to precisely control the biophysics allows us to refine our understanding of ECoG signals. We first employ the Line Source Approximation (LSA) to compute cortical surface electrical potentials (CSEPs) from simulations. Simulated CSEPs show qualitative agreement of the frequency content with experimental CSEPs obtained from rat auditory cortex. Under the LSA, we can compute exact contributions to CSEPs from subsets of neurons, such as those located in specific layers: initial results suggest layer dependent contributions to different CSEP frequencies.
The LSA models extracellular space as homogenous and purely ohmic, thus electrical signals propagate with no frequency dependence. However, our previous simulation efforts to understand ECoG found that a spatially varying low-pass filter was needed to reproduce the experimentally observed surface frequency spectrum. We are particularly interested in frequency filtering properties of brain tissue, as neuroscientists often extract information from frequency-resolved analyses of neural data. Extending recent theoretical work showing that non-neuronal cells in the brain can become polarized and thus imbue the extracellular medium with nonzero capacitance, we are implementing such filters in the simulation via biophysically realistic mechanisms.
A parallel experimental effort to determine the laminar origins of ECoG using simultaneously recorded surface and depth data is currently ongoing. Future work will directly integrate experimental data with simulations: using a large volume of simulated data with different input magnitudes, spatial distributions, etc., it may be possible to use the surface signal to predict current sources through the cortical depth (or from specific neuron types). With an accurate forward model of CSEP generation, we hope to enable inference of laminar specific processing from experimental cortical surface recordings.

Title: Brain-computer interface for finger movement decoding

Authors: J. GRÜNWALD[1], A. ZNOBISHCHEV[2], C. KAPELLER[3], K. KAMADA[4], J. SCHARINGER[5], A. CICHOCKI[2], ***C. GUGER**[1];

Abstract: Linear discriminant analysis (LDA) is the de-facto standard for classification in non-invasive and invasive brain-computer interfaces. It is however static in nature and not suited to exploit transient information in features. We therefore developed a time-variant extension of linear discriminant analysis, termed TVLDA. Besides its time-variance, TVLDA also features an internal feature reduction stage. This makes manual channel selection or spatial projection approaches (such as common spatial patterns) obsolete in the given context. TVLDA is easy to implement, fully automatic and deterministic. It is suitable for real-time applications. We assessed the performance of TVLDA on experiments involving motor tasks for invasive brain-computer interfaces. Our study comprises six epilepsy patients with temporarily implanted subdural grids, who volunteered to participate in additional research experiments besides clinical treatment. We conducted two types of experiments involving three high-level gestures (rock, paper, scissors) and individual finger movement. We used log-transformed band-power features from the high-gamma band (50 Hz - 300 Hz). We evaluated our processing pipeline by 20 repetitions of a full 10-by-10 cross-validation. TVLDA outperformed LDA by 11.3% on average and yielded more stable results, even if only few trials were available. For the experiment involving three high-level gestures, TVLDA achieved 88% accuracy on average for standard-sized grids, and 99% on average for high-density grids. In the finger-movement experiment, the average accuracy over all subjects was 97% (chance level 20%). To our knowledge, this is the highest ever reported brain-computer interface performance for three-class gesture control and five-class finger control. The convincing offline classification performance of TVLDA opens the door to high-performance online applications. For example, a real-time and asynchronous TVLDA classification framework will enable online prosthetics control at very high accuracies. As well, TVLDA produces a reliable output metric for trial-based high-gamma mapping. And lastly, first evaluations have shown that the results from invasive data extend to the non-invasive domain, where TVLDA reliably outperforms CSP and LDA in motor-imagery experiments. This may have a considerable impact for motor-imagery based rehabilitation systems, such as for stroke recovery.

Title: Online DNN-based synthesis and recognition of isolated syllables in electrocorticography

Authors: *Q. RABBANI[1], S. LUO[1], H. HERMANSKY[1], N. E. CRONE[2];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Neurol., Johns Hopkins Hosp., Baltimore, MD

Abstract: Deep neural networks (DNNs) have recently been used to synthesize speech directly from electrocorticographic (ECoG) signals during speech production and speech perception. Recently, we developed an online keyword spotting system for spoken syllable stimuli with near-perfect speech detection and a level of accuracy determined by the quality of electrode coverage. Here, we extend these results to demonstrate, using pseudo-online streaming data, a system that synthesizes and recognizes speech with high quality and accuracy, and with latency under 1 s. Our system is composed of a modified DenseNet architecture that regresses from the raw ECoG spectrum to 18 Bark cepstral coefficients and 2 pitch parameters that may then be used for synthesis with a pre-trained LPCNet vocoder or for recognition triggered by neural voice activity detection (VAD). We show that the duration of the utterance can be precisely estimated and that our network is highly sensitive to speech-vs-non-speech discrimination and to self-generated speech vs perceived speech. Additionally, we demonstrate that these results extend to silently spoken speech in the absence of any auditory feedback, a necessary step for proving the feasibility of such a system for locked-in patients, who are otherwise unable to speak.

Abstract: Recent brain decoding studies have utilized semantic space as a medium for modeling and decoding brain activity. A prior study has shown that a semantic space, derived from a natural language processing model word2vec, could be used to build a brain decoder that could infer perceptual contents in words (Nishida and Nishimoto, 2018). This study explores the potential use of the semantic modeling approach to realize practical brain-machine interface (BMI) by applying it with electrocorticography (ECoG), which has a higher temporal sampling rate than the functional magnetic resonance imaging used in the prior study. Seven patients under clinical monitoring for epileptic seizures participated in this study. During ECoG recording, the patients were shown a 60-min training video and a 10-min evaluation video (four times repetitions of 2.5-min video), both composed of short films or animation clips, with no overlapping scenes between the two videos. Movie scenes were extracted as still images once per second from the videos, and annotated manually using a natural language. Based on vector representations learned by word2vec using a Wikipedia dump, *scene vectors* were constructed by averaging 1,000-dimensional vector representations of the words in the annotation to each scene. The scene vectors were then decoded using ridge regression, and powers of the ECoG signals in four frequency bands (α, β, low-γ, high-γ). Nested cross-validation was applied to optimize the penalty term in order to decode the training scene vectors; on the other hand, evaluation scene vectors were decoded using a decoder trained with the training scenes vectors. Decoding performance was measured by two-alternative forced choice. For each scene in a test dataset, predicted vector of the tested scene was paired with another predicted vector randomly selected within the test dataset; for all possible pairs, binary test to distinguish predicted vector of the tested scene from that of the randomly selected one, solely based on the correlation coefficient with true scene vector of the tested scene. The averaged classification accuracy of the two-alternative forced choice was 61.6% (range: 58.2 - 65.3%) for the training video, and 58.9% (56.7 - 61.7%) for the evaluation video. This study demonstrated that the vector representation of movie scenes could be decoded from the ECoG signals in the semantic space of the word2vec model. The decoder could also infer scenes that were new to both the patients and the decoder. The combination of the semantic space and ECoG could be a promising approach to realizing practical BMI.

Title: Small amounts of involuntary muscle activity reduce passive joint range of motion

Authors: ***J. DIONG**[1], S. C. GANDEVIA[2], D. NGUYEN[2], Y. FOO[1], C. KASTRE[3], K. ANDERSSON[3], J. E. BUTLER[2], M. E. HÉROUX[2];

Abstract: Contracture is the loss of passive joint range of motion common in people with neurological conditions. When passive joint range of motion is assessed, any concomitant involuntary muscle activity is generally regarded small enough to ignore. This assumption is untested. If false, many clinical and laboratory studies that rely on these assessments may be in error. We determined to what extent small amounts of involuntary muscle activity limit passive range of motion in thirty able-bodied adults. Subjects were seated with the knee flexed 90° and the ankle in neutral, and predicted maximal plantarflexion torque was determined using twitch interpolation. Next, with the knee flexed 90° or fully extended, the soleus muscle was continuously electrically stimulated to generate 1, 2.5, 5, 7.5 and 10% of predicted maximal torque, in random order, while the ankle was passively dorsiflexed to a torque of 9 Nm by an investigator blinded to stimulation intensity. A trial without stimulation was also performed. Ankle dorsiflexion torque-angle curves were obtained at each percent of predicted maximal torque. On average (mean, 95% CI), each 1% increase in plantarflexion torque decreases ankle range of motion by 2.4° (2.0 to 2.7°; knee flexed 90°) and 2.3° (2.0 to 2.5°; knee fully extended). Thus, 5% of involuntary plantarflexion torque, the amount usually considered small enough to ignore, decreases dorsiflexion range of motion by ~12°. Our results indicate that even small amounts of involuntary muscle activity will bias measures of passive range, and hinder the differential diagnosis and treatment of neural and non-neural mechanisms of contracture.

Title: A novel robot for separete body weight supported treadmill training to modulate gait patterns in patients with hemiparetic stroke

Authors: *H. FUJIMOTO[1], T. TERAMAE[3], T. NODA[3], A. TAKAI[3], N. FUJITA[2], M. HATAKENAKA[1], Y. HIRAMATSU[1], A. JINO[2], J.-I. FURUKAWA[3], H. YAGURA[1], T. KAWANO[1,4], H. OTOMUNE[1], J. MORIMOTO[3], I. MIYAI[1];
[1]Neurorehabilitation Res. Inst., [2]Dept. of Rehabil., Morinomiya Hosp., Osaka, Japan; [3]Dept. of Brain Robot Interface, ATR Computat. Neurosci. Labs, Soraku-gun, Kyoto, Japan; [4]Dept. of Neurology, Graduate. School. of Med., Osaka Univ., Suita, Japan

Abstract: Background:
Body weight-supported treadmill training (BWSTT) is used as an effective therapy to improve post-stroke gait disorder. However, because conventional body weight supported (BWS) training continuously supports the body with identical forces to both paretic and non-paretic sides, the temporal feature of each leg support force coordinated with the gait cycle cannot be optimized. To challenge this problem, we started clinical trials of a novel split-force BWS robot that two Pneumatic Artificial Muscles (PAMs) provide the vertical support forces to the right and left sides of the body separately to induce natural gait patterns.
Objective:
The aim of this study is to assess whether the split-force BWS can modulate gait patterns of patients with hemiparetic stroke.
Methods:
Five patients with stroke (M:F = 4:1, 39.0 ± 23.3 years-of-age, 90.6 ± 60.8 days after onset) with mild to moderate hemiplegia (Lower-extremity Fugl-Meyer assessment score: 28.4± 3.3) admitted for inpatient intensive rehabilitation participated in this study. Participants wore custom-made shoes with load cells and a harness. The magnitude of split-force BWS support forces changes according to the walking movement, while the total BWS was kept at constant.

The lateral distribution of support forces was set to proportional to the ratio of ground reaction forces. Before experimental measurement, comfortable walking speed (1.3 to 2 km/hour) and degree of total BWS (10% to 33%) were set for each patient. In the experimental sessions, patients walked on the treadmill without holding handrails according to the following control mode: 1) split-force BWS mode; 2) total BWS mode; and 3) no BWS mode. We measured swing and stance time for each leg. The study protocol was approved by the local ethical committee.

Results:

There was no adverse event. The single stance time (SST) of the paretic leg increased under split-force BWS compared to no BWS and total BWS. The SST of the non-paretic leg increased under total BWS compared to no BWS, while the time varied under split-force BWS. The symmetry of the SST as assessed by the mean SST ratio (SST paretic/SST non-paretic) tended to be improved under split-force BWS than the other protocols.

Conclusion:

Our preliminary results suggest that split-force BWS treadmill training will be a potential tool to modulate gait patterns of stroke patients with mild to moderate hemiplegia. Further studies are needed to optimize its parameters to increase efficacy for gait training of stroke patients with various severity.

Title: Effects of aging on muscle activation patterns and postural control during a sit-to-stand with different initial foot positions

Authors: *W. JEON[1], H.-Y. HSIAO[2], B. WREFORD[2], C. CORONADO[2], L. GRIFFIN[2]; [1]The Univ. of Texas At Austin, Austin, TX; [2]Kinesiology and Hlth. Educ., The Univ. of Texas at Austin, Austin, TX

Abstract: ***Introduction:*** The ability to perform a sit-to-stand (STS) is particularly challenging for elderly individuals because of age-related declines in muscle strength and neuromuscular coordination. The initial foot position (IFP) is an important strategy determinant of successful STS performance. The purpose of this study is (1) to investigate the effect of IFP on kinematics and muscles activation patterns during a STS and (2) to identify differences between healthy

younger (18-45 years) and older (>65 years) individuals during a STS. ***Methods:*** Two initial foot positions (IFPs) were tested: 1) reference; the feet were placed shoulder-width apart with the knee angle at 100 degrees of flexion, and the feet placed in parallel on separate force plates. 2) Toe-Out; toes turned out symmetrically with a toe-out angle of 20° from the reference IFP. EMG activity of the rectus femoris (RF), adductors (Add), tibialis anterior (TA), and soleus (Sol) were recorded along with trunk flexion angle during the STS and center of pressure (CoP) sway area during the stabilization phase (time interval between completion of uprising and the start of quiet standing). ***Results:*** Compared to the reference IFP, EMG activity of Add was greater for the Toe-Out IFP (reference: 25.76 ± 5.96%, Toe-Out: 32.57 ± 6.83% EMGmax, $p < 0.01$, respectively), whereas the TA EMG was smaller for the Toe-Out IFP (reference: 39.81 ± 10.23%, Toe-Out: 31.89 ± 8.86% EMGmax, $p = 0.03$). There was no difference in RF EMG amplitude between the two IFPs. The normalized CoP sway area (mm^2/s) during the stabilization phase was smaller for Toe-Out IFP than for the reference IFP (Toe-Out: 16.01 ± 4.26 mm^2/s, reference: 22.39 ± 5.20 mm^2/s, $p < 0.01$). The EMG activity of the RF and Add was greater for older adults (RF: reference IFP; 45.51 ± 3.91%, 31.87 ± 3.33%, Toe-Out IFP; 39.43 ± 4.33%, 31.50 ± 4.45% EMGmax, for older and young adults respectively, $p < 0.01$). The trunk forward tilt-angle was also greater for older adults (reference: 31.54 ± 12.25° and 18.44° ± 3.45°, Toe-Out: reference: 35.24 ± 4.32° and 17.60° ± 6.61, for older and younger adults respectively, $p < 0.01$). ***Conclusion:*** The RF and Add participate more in generating vertical force in older adults during rising from a seated position. Older adults initiate a STS by flexing their trunk further forward to prevent possible backward displacement of the body's center of mass. A Toe-Out IFP is an efficient foot position to engage the adductor muscles to assist the knee extensors during uprising while it decreases TA activation. The Toe-Out IFP also improves balance during the stabilization phase possibly by increasing the medio-lateral margin of stability for both younger and older adults.

Title: Prolonged exposure to split-belt walking promotes energetic optimization during locomotor adaptation

Authors: *N. SANCHEZ[1], S. N. SIMHA[2], J. M. DONELAN[2], J. M. FINLEY[1];
[1]Div. of Biokinesiology and Physical Therapy, USC, Los Angeles, CA; [2]Dept of Biomed. Physiol. & Kinesiology, Simon Fraser Univ., Burnaby, BC, Canada

Abstract: Introduction: The dominant paradigm for studying locomotor adaptation involves having people walk on a dual belt treadmill with one belt moving faster than the other. During the first 15 minutes of adaptation, people transition from taking longer steps with the leg on the slow belt to taking steps of equal lengths. Researchers hypothesize that adaptation toward symmetric step lengths occurs because this pattern minimizes the energetic cost of walking. However, we demonstrated that when participants use visual feedback of their steps to take longer steps with the leg on the fast belt, which is not typically seen during adaptation, they reduce energetic cost below the cost of symmetric step lengths. What remains to be seen is whether adoption of this more economical pattern requires explicit instruction, or if participants converge to this asymmetric behaviour when given sufficient exposure to walking on the split belt treadmill. We hypothesized that after prolonged exposure to split-belt walking in the absence of instruction, participants will take longer steps on the fast belt, supporting the theory that locomotor adaptation is driven by energetic optimization. **Methods**: 15 participants walked on a split-belt treadmill for 45 minutes at a 3:1 ratio and belt speeds of 1.5 and 0.5 m/s. We measured step lengths as the distance between the feet at foot strike and we measured metabolic cost using expired gas analysis. We defined step length asymmetry as the difference between the fast and slow step lengths, normalized by their sum, such that negative asymmetries refer to longer steps on the slow belt and positive asymmetries refer to longer steps of the fast belt. We calculated metabolic cost and step length asymmetry at the 15^{th} and 45^{th} minute, to determine if people continue to modulate step length asymmetry in a manner that reduces energetic cost. **Results and Discussion:** Although participants took steps of approximately equal length after 15 minutes (not Normal, median ± IQR, -0.013 ± 0.050), they adopted positive step length asymmetries after 45 minutes (mean ± standard deviation, 0.030 ± 0.037, paired Wilcoxon p=0.083), in the same range as those we identified previously to minimize energetic cost. There was also a reduction in metabolic cost of 0.14 ± 0.21 W/kg from minute 15 to minute 45 (median 4.46, IQR 8.6%, sign rank p=0.021). These results suggest that adaptation involves a process that continuously adjusts step length asymmetry to minimize energetic cost and that taking steps of equal length is not the goal of adaptation but a point along the path toward energetic optimization.

Title: Changes in the common synaptic drive to the ankle dorsiflexor muscle by adaptation during split-belt walking in humans

Authors: *A. OSHIMA, H. MURAI, N. TSUJIUCHI, K. KAMIBAYASHI;
Doshisha Univ., Kyoto, Japan

Abstract: Humans can maintain physical activity by adapting their motor program flexibly to varied environmental conditions. These adaptations in physical activity have been studied using a split-belt treadmill, on the basis of changes in electromyography (EMG) activities and ground reaction force (GRF). To clarify the neural adaptation to environmental changes, few studies have focused on changes in the common synaptic drive to a muscle. The purpose of the present study was to investigate changes of the common synaptic drive to adaptation during a novel physical activity using a split-belt treadmill by an EMG-EMG coherence analysis. Twelve adult subjects walked on a split-belt treadmill with two belts controlled separately. The treadmill was operated moving together "tied" or at difference speeds "split." The walking speeds were 0.5 and 1.25 m/s for the slow and fast conditions, respectively. The experimental paradigm consisted of three baseline phases ("tied" slow, "tied" fast, and then "tied" slow speeds for 2 min each) for 6 min, an adaptation phase ("split" condition of slow and fast speed) for 10 min, and a washout phase ("tied" slow speed) for 6 min. Each leg on the slow or fast belt speed during the adaptation phase was defined as the "slow leg" or "fast leg" respectively. A wireless surface EMG measurement system was used to investigate the EMG-EMG coherence. EMG electrodes were placed on the proximal and distal ends of the tibialis anterior (TA-p and TA-d), soleus, medial gastrocnemius, rectus femoris, and biceps femoris muscles. The intramuscular coherence in the 300 ms before heel strike was evaluated at the TA-p and TA-d pair. For the index of coherence strength, values by frequency domain analyses were calculated in 1 min (0.5-1.5 min) of each baseline phase; in the first and last minutes of the adaptation phase as early and late adaptations, respectively; and in the first and last minutes of the washout phase as early and late washouts, respectively. During the adaptation phase, the anterior component of the GRF during the stance phase and the amount of TA-TA coherence at the gamma band (35-60 Hz) in the slow leg decreased at late adaptation as compared with early adaptation. By contrast, the amount of TA-TA coherence at that band in the fast leg was not changed between the early and late adaptation phases. During the washout phase, the amount of TA-TA coherence at that band in the slow leg

significantly deceased at late washout as compared with early washout. These results suggest that the common synaptic drive to the ankle dorsiflexor muscle might be changed during the adaptation and washout phases.

Title: Effect of cognitive fatigue on static and dynamic postural control in healthy older adults and stroke

Authors: *G. VARAS-DIAZ, S. WANG, T. BHATT;
Univ. of Illinois, Chicago, IL

Abstract: ***Background:*** Mental fatigue is a psychobiological state induced by sustained periods of demanding cognitive activity and characterized by feelings of tiredness. It has been well described that cognition plays an important role in movement and balance control, however the effect of cognitive fatigue on balance changes with aging and with a neurological insult remain unclear. The aim of this study was to examine the effect of cognitive fatigue on balance under different sensory conditions in healthy older adults and stroke population.
Methods: 10 healthy older adults (>65yrs) and 10 older adults with chronic stroke were asked to stand on a force platform while performing 2 cognitive condition (no cognitive task and serial subtractions (SS) task) across the 6 sensory conditions of the sensory organization test of the Balance Master before and after a cognitive fatigue task (stop-signal task for 60 min). The conditions were: eyes open, fixed surface (EO/FS); eyes closed, fixed surface (EC/FS), eyes open, sway referenced vision (EO/SRV); eyes open, sway referenced surface (EO/SRS); eyes close, sway referenced surface (EC/SRS); eyes open, sway referenced surface and vision (EO/SRSV)). Center of mass (COM) acceleration changes were recorded using an inertial sensor (Xsens Inc.). Jerk, as an indicator of the smoothness of postural sway and the root mean square (RMS) of the COM acceleration signal were analyzed for all the experimental conditions.
Results: Jerk and RMS were higher in the stroke group compared to the older adults group for all the 6 sensory conditions (p&lt0.05). Both groups showed a significant increase of Jerk and RMS after the cognitive fatigue task for all the sensory conditions (p&lt0.05). Differences in balance, assessed by jerk, between single and dual-task condition were observed only during EO/SRSV after the cognitive fatigue task for older adults group, and during EO/SRS, EC/SRS, and EO/SRSV after the cognitive fatigue task for stroke group. In addition, a loss of balance

incidence of 10% in EC/SRS and 35% in EO/SRSV, and 30% in EC/SRS and 10% in EO/SRSV was observed in older adults and stroke respectively, which increased post cognitive task to 45% in EC/SRS and 55% in EO/SRSV for older adults, and to 55% in EC/SRS and to 65% in EO/SRSV in stroke.
Conclusion: Our results indicate that mental fatigue, induced by sustained cognitive activity, can impair balance during single and dual-task in older adults and stroke population. Cognitive fatigue could be considered as an intrinsic risk factor for falls in older people and stroke population, and should be taken into account for preventive and therapeutic strategies.

Title: Fall risk predictors in community dwelling ambulatory stroke survivors

Authors: *R. GANGWANI[1], S. DUSANE[2], T. S. BHATT[3];
[1]Dept. of Physical Therapy, Univ. of Illinois At Chicago, Chicago, IL; [2]Dept. of Physical Therapy, [3]Physical Therapy, Movt Sci., Univ. of Illinois at Chicago, Chicago, IL

Abstract: Background: Given the diversity of stroke specific impairments and the multifactorial nature of falls in stroke, identification of measurements that best predicts fall risk is important. Thus, the purpose of this study was to determine clinical and laboratory measures that best predict fall risk among community dwelling ambulatory chronic stroke survivors.
Methods: 36 chronic stroke survivors were subjected to a battery of tests to assess balance and other potential risk factors. Balance was assessed using clinical performance-based tests (Berg Balance Scale (BBS), Timed Up and Go (TUG)) and instrumented measures (Sensory Organization Test (SOT) and dynamic gait stability) as well as balance confidence (Activities specific Balance Confidence (ABC)). Other risk factors assessed were gait speed (10-meter walk time (10MWT)), severity of impairment (Fugl-Meyer Assessment (FMA)), Chedoke McMaster Scale (CMSA)), disability status (Modified Rankin Scale (MRS)), muscle strength, physical activity level (Physical Activity Scale for Elderly (PASE)) and social integration (Community Integration Questionnaire (CIQ)). Participants were subjected to an unannounced slip perturbation on the paretic side while walking on an over ground instrumented walkway during which perturbation outcome (fall or recovery) was identified. Accuracy of each measure was examined for prediction of perturbation outcome based on its sensitivity (accurate identification

of fallers) and specificity (accurate identification of non-fallers). Univariate logistic regression was performed for all the variables. Variables with a significance of $p<0.3$ were selected for further analysis with multivariate modeling. **Results:** On the slip perturbation, 17 participants fell while 19 recovered their balance. Univariate logistic regression analysis identified dynamic stability as the only variable to predict fall perturbation outcome with a sensitivity of 64.7% and specificity of 73.7%. The multivariate regression analysis model identified a combination of dynamic stability and SOT score successfully predicted falls with a sensitivity of 75% and specificity of 85.7%. **Conclusion:** Assessment of dynamic stability and posture control during fall risk assessment might help in distinguishing fallers from non-fallers. Moreover, fall prevention interventions specifically designed to improve dynamic stability and SOT score might help in reducing fall risk in chronic stroke survivors.

Title: Motor adaptation and transfer of fall resisting skills to overground slips in chronic stroke survivors- A randomized control trial

Authors: *S. DUSANE[1], T. S. BHATT[2];
[1]Physical Therapy, Univ. of Illinois At Chicago, Chicago, IL; [2]Physical Therapy, Movt Sci., Univ. of Illinois at Chicago, Chicago, IL

Abstract: Background: Chronic stroke survivors have demonstrated motor adaptation and transfer of the acquired fall resisting skills with repeated treadmill-based, stance slip perturbations. Evidence indicates an increased preference for compensatory stepping with the non-paretic limb signifying failed recovery with paretic stepping. Given the evidence of inter-limb transfer in healthy adults, if non-paretic overground gait slips could prime and improve paretic stepping it might ensure better patient safety and training tolerability than directly initiating paretic slip training. Considering the unexpected demands placed on either of the limbs during real life gait slips, reducing slip-induced fall-risk on both paretic and non-paretic limbs is equally important. Thus, this study aimed to determine whether chronic stroke survivors can acquire motor adaptation to repeated overground gait slips under the non-paretic limb and further demonstrate immediate inter-limb transfer of the acquired fall resisting skills to the untrained paretic limb. **Methods:** 45 community-dwelling chronic stroke survivors were randomly

assigned to either the training group (n=24), which received 8 unannounced, non-paretic slips prior to the novel paretic slip or the control group (n=21), which received a single novel paretic slip only. Participants were asked to walk on an 8-meter instrumented overground walkway while the computer controlled moveable platforms were used to induce slips with a maximum slip distance of 45cms. Slip outcome (falls and backward loss of balance (BLOB)), recovery strategies, pre-slip and post-slip COM state stability and step length were analyzed. **Results:** With repeated non-paretic slips, the training group demonstrated significant falls reduction, from 33% to no falls and reduced BLOB from 67% to 0% ($p<0.05$); along with decrease in aborted stepping strategy from 42% to 0% and increase in recovery stepping strategy from 58% to 100%. There was also significant improvement in pre and post-slip COM stability at TD and step length ($p<0.05$). Although the training group demonstrated better control of COM state stability at TD on the novel paretic slip and reduced falls (63%) than the control (76%), the differences were not significant ($p>0.05$). **Conclusion:** The results indicate that the chronic stroke survivors can acquire immediate proactive (pre-slip) and reactive (post-slip) adaptation following repeated slip training under non-paretic limb leading to reduced falls and improved recovery strategies. However, there was no significant inter-limb transfer of acquired fall resisting skills from trained non-paretic limb to untrained paretic limb.

Title: Interactive perceptual support can improve postural balance

Authors: *M. RUSSO[1], A. KROTOV[2], D. STERNAD[3];
[1]Biol., [2]Bioengineering, [3]Departments of Biology, Electrical & Computer Engineering, and Physics, Northeastern Univ., Boston, MA

Abstract: Frail individuals often use a walker or a cane to reduce the risk of falling. In contrast, trained humans, like ballet dancers or gymnasts, can achieve astonishing balance abilities. For example, during a *pas de deux* a ballerina can hold very unstable position, like a pose on the tip of one foot, by only lightly touching the hand of her partner. What is the role of the hand in this challenging balancing task? While numerous studies already showed that not only mechanical but also perceptual support can reduce sway, we hypothesize that active support from another human provides further compensation or guidance for stabilization of posture. However, is the

support provided by a human supportive enough? How stable does support have to be to increase postural stability? This study examined the effect of mechanical and human support on postural sway with different levels of stability. Participants were asked to balance in a tandem stance on a narrow beam to create postural instability. While maintaining balance, participants used their dominant hand to hold the end effector of a robotic arm, measuring the force applied at the interaction. The nature of the support could be of two types: mechanical and human. For each of these two categories the participant experienced 4 increasing levels of stability. The handle of the robotic arm could be either fixed (stable) or simulating a cane of different lengths (2 unstable conditions). For control a set of trials was included in which the robotic arm was fully compliant. For the human support, a second participant held the handle of the robotic arm together with the target participant. The two performed the same 4 conditions presented before. Interaction force was measured together with EMG activity of 13 muscles from the active arm, torso and both legs. Postural sway was quantified by the center of pressure on a force platform below the beam. In addition, whole-body kinematics of both subjects was recorded via motion capture system. Participants included 16 healthy students and 16 professional ballet dancers. Preliminary results showed that mechanical support decreased the sway more than active human support. In contrast, ballet dancers significantly improved their balance when supported by another dancer over and above mechanical support. Ongoing analyses examine the nature of this active information transmission in its relation to postural sway. Further insights into active perception and control will inform the design of a robot controller that assists humans with impaired postural control.

Title: Muscle synergies for murine and human locomotion

Authors: *A. SANTUZ[1,2], O. D. LAFLAMME[1], T. L. WELLS[1], A. EKIZOS[2], L. BRÜLL[3,2], M. SCHWENK[4], A. ARAMPATZIS[2], T. AKAY[1];

Abstract: The coordination of vertebrate locomotion results from the intercorrelation of an enormous number of variables and is computationally challenging. It has been suggested that the central nervous system might overcome the overabundance of degrees of freedom by synchronously activating different muscle groups in patterns called muscle synergies. From human experiments, we found that four synergies are enough to describe locomotion when considering 13 muscle activities (Santuz et al. 2018, Sci. Rep. 8, 2740). Our more recent study showed that three synergies can sufficiently account for the patterns observed in walking mice (Santuz et al. 2019, J. Physiol. JP277515). However, the results from mouse experiments were obtained by pooling the data recorded in animals implanted with a variable amount of electromyogram (EMG) recording electrodes. In this study, we aimed to compare human and murine synergies for walking when a) the number of recorded muscles is reduced from 13 to eight in humans and b) recording from eight functionally-matched muscles simultaneously in mice.We extracted synergies using non-negative matrix factorization from eight ipsilateral muscle activities of the right lower limb recorded during treadmill walking (1.3 ± 0.1 m/s) in 94 young and healthy humans (53 males, 41 females, age 28 ± 5 years). In addition, we extracted synergies from eight functionally-matched ipsilateral muscle activities of the right hindlimb in one wild-type adult mouse (male, age 67 days) walking on a treadmill at 0.2 m/s.Despite lowering the number of considered muscles from 13 to eight, humans still showed four synergies (3.7 ± 0.5) related to as many phases of the walking gait cycle (i.e. weight acceptance, propulsion, early swing, and late swing). Four synergies with similar function were enough to describe the walking patterns of a mouse implanted with eight EMG electrodes, in contrast with what we recently found pooling data from different animals. The number and function of these synergies were similar to those found in humans. We do not exclude the possibility that our current efforts to increase the sample size could lead to different conclusions. Yet, we show for the first time that human and mice share the same number of synergies extracted from eight functionally-matched muscles of the lower/hindlimb.

Title: Coordination between quadriceps muscles activity in rats suggests neural regulation of joint stresses and strains

Authors: *C. ALESSANDRO[1], D. SONG[2], D. TENTLER[2], A. PRASHARA[2], H.-Y. YEH[2], F. BARROSO[4], M. C. TRESCH[3];
[1]Physiol., [3]Biomed. Eng, Physical Med. and Rehab, Physiol., [2]Northwestern Univ., Chicago, IL; [4]Neural Rehabil. Group - Cajal Inst., Spanish Natl. Res. Council (CSIC), Madrid, Spain

Abstract: How does the central nervous system (CNS) determine motor commands? One obviously important criterion is to generate motor commands that result in the desired movements. However, muscle activity also produces mechanical stresses to structures such as bones, ligaments, and articular cartilage. Poor regulation of such internal joint stresses could lead to pain and degeneration. We therefore hypothesize that the CNS generates motor commands that, while producing the desired movements, minimize stresses and strains within the joints.
To evaluate this hypothesis, we exploited the biomechanical properties of the rat knee joint. As we previously showed, in the rats the quadriceps muscles vastus medialis (VM) and vastus lateralis (VL) produce very similar knee extension torque, but opposite mediolateral forces on the patella. To avoid excessive mechanical loading between the patella and femur, the activity of VL and VM should therefore be closely coordinated in order to reduce the net mediolateral force on the patella.
We recorded quadriceps muscles activity in rats (n=10) during treadmill locomotion at different speeds and inclines, and evaluated their coordination patterns. The activation profiles (i.e. time course of electromyographic signals) of VL and VM during each locomotor cycle were strikingly similar, and were clearly different from those of the other quadriceps muscles vastus intermedius and rectus femoris. Similarly, the activation intensities (i.e. integral of activation profiles across each locomotor cycle) of VL and VM covaried consistently across locomotor cycles, while those of the other muscles varied more independently to one another. Accordingly, both the activation profiles and the step-to-step activation intensities of VL and VM were highly correlated ($r>0.8$), and significantly more correlated than those of the other muscle pairs.
These results suggest that the CNS tightly coordinates the activity of VL and VM both within and across gait cycles, hence minimizing the net mediolateral force on the patella, consistent with the regulation of internal joint stresses and strains. We are currently investigating the neural underpinnings of these phenomena, evaluating in particular the role of joint afferent activity.

Title: Recognition of leg muscle motion in children with cerebral palsy using off-line EMG signals

Authors: *R. TANG, C. LI, X. XIE, Z. LI;
Hainan Univ., Haikou, China

Abstract: Cerebral palsy(CP)is a very common physical defect, which is caused by brain injury, and 90% of children with cerebral palsy have difficult in walking. Therefore ,the method of improving the walking ability of children with CP has been widely concerned. Gait training for children with CP is a common method to improve their walking ability in clinic. But previous studies on gait training based on angle and pressure sensors, which cannot follow the user's intention because it use constant gait speed and motion. In recent years, Surface electromyography(sEMG) signals plays an important role in the control of modern electric prosthesis and rehabilitation robotics. Due to the difference SEMG signal between subjects with CP and normal people, it is difficult to apply the results of EMG signals of normal people directly to patients with CP. Therefore, in this study we propose a method to recognize the muscle movement of CP children based on off-line SEMG signal. In this experiment, five girls and six boys with spastic cerebral palsy participated, and their age span was 7-16. Each participant walked for one minute at the speed chosen by the participants. The experiment was repeated in three groups, with a five-minute break between groups. At the same time, Data acquisition mainly divided into two categories, one is EMG signal, the other is angle information. The function of angle signal is to divide EMG signal into five stages. But one patient's data , so we totally got ten patients ’data. All obtained SEMG signals are processed using our proposed method. Wavelet processing is used to denoise , elliptic filters are used for filtering and Derivative processing is used to change the expression of data. Feature extraction using SPA combine RMS. Finally, five classifications are established by SVM, and in order to evaluate the performance of the proposed method, two traditional feature extraction methods which are MVA and ZC are used for comparison.From the above, the results of the model we learned are shown in the table below. The average accuracy of the proposed model is 92.8%(±4.3%),and we also find that the modeling effect of two commonly used feature extraction methods are 71.7%(±13.3%) of MVA and 77.1%(±9.0%) of ZC respectively . We find traditional methods have limited performance in extracting the characteristics of SEMG signals of CP children. And the proposed method can extract the information of SEMG signals of CP children effectively. which means we find an effective way to use off-line SEMG signal to recognize leg muscle movements in CP children, i.e. We can use EMG signals to identify the CP children’s motional intentions, which can be used in future rehabilitation control strategies.

Title: Detecting task-dependent modulation of spatiotemporal module via tensor decomposition: Application to kinematics and EMG data in locomotion and running at various speed

Authors: *K. TAKIYAMA[1], H. YOKOYAMA[1], N. KANEKO[2], K. NAKAZAWA[2];
[1]Tokyo Univ. of Agr. and Technol., Tokyo, Japan; [2]The Univ. of Tokyo, Tokyo, Japan

Abstract: How the CNS controls our body is a fundamental question. The spatiotemporal module is an influential hypothesis for how the CNS manages a tremendous amount of degree of freedom (DoF) inherent in our body (Bizzi+, 1991). In the theory, the CNS controls a group of joints or muscles, referred to as spatial module, rather than a single joint or a single muscle separately to reduce the DoF. The time-varying recruitment pattern of each spatial module is referred to as a temporal module.
How the brain attains various repertoire of motions is another fundamental question. A possible solution is to modulate the spatiotemporal modules depending on the task. The temporal module rather than the spatial module can be modulated (Ivanenko+, 2005; Chvatal+, 2012). On the other hand, the spatial module rather than the temporal module can be modulated (Torres-Oviedo+, 2010). In our findings, the number of modules can change (Yokoyama+, 2016). In sum, there are seemingly different perspectives on the task-dependent modulation of the spatiotemporal modules.
Here, we propose a novel method to discuss the task-dependent modulation of the spatiotemporal modules flexibly. We apply tensor decomposition (Kolda+, 2009) to joint angle and EMG data. Although conventional methods or matrix decompositions (i.e., PCA and NNMF) are suitable for discussing two factors (i.e., spatial and temporal modules), there are limitations to consider more than three factors. For example, with the matrix decomposition, the task-dependent modulation of the temporal module between two tasks was discussed under the constraint of the same spatial module, or the modulation of the spatial module was discussed without considering temporal module. Without those constraints, the tensor decomposition enables to examine the task-dependent modulation of the spatiotemporal modules.
The tensor decomposition extracted the three types of spatiotemporal modules inherent in joint angle and EMG data in walking and running at various speed: 1) the modules recruited more significantly in a higher speed, 2) those mainly recruited in walking, and 3) those recruited primarily on the running. Further, the tensor decomposition extended a previous perspective on

switching walking and running: the CNS switches the two types of motions by modulating not only the temporal but also spatial modules via recruiting proximal muscles larger in the running than in walking.

Title: Relationship between multi-joint dynamics and rambling/trembling movements of center of foot pressure during quiet standing

Authors: *S. SASAGAWA[1], A. IMURA[2];
[1]Dept. of Human Sciences, Kanagawa Univ., Yokohama, Japan; [2]Tokyo Metropolitan Univ., Tokyo, Japan

Abstract: The trajectory of center of foot pressure (CoP) during quiet standing can be decomposed into rambling and trembling components (Zatsiorsky and Duarte, 2000). The former corresponds to slower migration of reference point with respect to which balance is controlled and the latter to faster deviation of the CoP from the reference equilibrium point. The purpose of this study was to investigate the relationship between multi-joint dynamics of the body and the rambling/trembling movements of the CoP during quiet standing. Healthy young participants (n=11) were required to stand quietly for 60 s on a force platform. At the same time, angular motions of the ankle and hip joints were measured by an optical motion capture system. We obtained the rambling component by low-pass filtering the CoP time-series with a cut-off frequency of 0.5 Hz. We then obtained the trembling component by subtracting the rambling component from the original CoP time-series. By using time-locked averaging technique with respect to unidirectional rambling or trembling movements, we investigated spatio-temporal relationship between the multi-joint dynamics of the body (i.e., joint kinetics and kinematics) and the rambling/trembling movements of the CoP. We first found that a forward shift of the CoP in the rambling trajectory was associated with increases in both the ankle plantarflexion and hip extension torques and was paralleled with increases in inclination angles of the leg and trunk segments. These slow increases in the joint torques along with the rambling trajectory tonically counteracted the effects of gravity. We next found that a forward shift of the CoP in the trembling trajectory was associated with rapid increases in both the ankle and hip joint torques.

These rapid increases in joint torques along with the trembling trajectory induced mutually opposite kinematic patterns in the ankle and hip joints (i.e., ankle plantarflexion and hip flexion) due to the inter-joint dynamic interaction and accelerated the body back to the reference equilibrium point. Our findings indicate that changes in joint torques in different time scales along with the rambling and trembling trajectories induce different kinematic patterns at the ankle and hip joints and play different roles in postural control.

Title: Human body sway echoes induced by visual optic flow in VR

Authors: *D. ENGEL[1,2], A. SCHUETZ[1,2], J. SCHWENK[1,2], A. MORRIS[3], F. BREMMER[1,2]; [1]Dept. of Neurophysics, Philipps-Universität Marburg, Marburg, Germany; [2]Ctr. for Mind, Brain and Behavior, Universities of Marburg and Gießen, Marburg, Germany; [3]Dept. of Physiology, Biomedicine Discovery Inst., Monash Univ., Melbourne, Australia

Abstract: To uphold our bipedal stance, amongst other senses, we rely on vision. When humans perceive their body as moving relative to the environment, they trigger compensatory movements, resulting in their center of mass swaying around its point of stability. This sway can be found in unperturbed standing as well as elicited by external perturbations. Body sway is traditionally investigated in a real, moving-room by monitoring the body's center of pressure (COP). Typically utilized patterns of room-movements describe linear displacements or (pseudo-)periodical oscillations. In our explorative study, we were interested in the body-sway response to a visual scene showing a random and thereby unpredictable succession of movements. For this purpose, we induced body sway by visually simulated self-motion in virtual reality, using 3-D random optic flow patterns. Subjects wore a head-mounted display while standing on a force plate to record the displacement of their COP. VR simulated subjects standing inside a 3-D tunnel, its walls comprised of random dots. During trials, the tunnel shifted its position along a world-fixed anterior-posterior axis according to a sequence of random displacements. The sequence contained frequencies at identical amplitudes (flattened white noise) ranging from 0 to 2 Hz. For each trial, COP trajectory in the anterior-posterior direction was cross-correlated with

the respecting presented sequence and its derivative, to obtain impulse responses to spatial displacement and velocity of self-motion, respectively. The cross-correlations revealed subjects to systematically adjust their sway to the stimulus. In all subjects, the impulse response was dominated by a transient oscillatory component at a specific frequency (echo). The oscillation exhibited a consistent phase-lag relative to the stimulus sequence. This component remained stable, even across different days of measurement, albeit the system, i.e. stable stance, being disturbed in an incoherent, unpredictable way. Considering all frequencies to be equally present in the stimulus, this oscillatory component could be interpreted as the outcome of an internal frequency filter, idiosyncratic to the subject. Our results demonstrate that human body sway responses can be characterized by the use of a random stimulus input along with reverse correlation techniques. These findings could be used to estimate an "eigenfrequency" of subjects, conceivably even allowing for future clinical applications.

Title: Analysis of hindlimbs locomotion kinematics in a mouse model of penetrating brain injury

Authors: *L. C. LEON-MORENO[1], R. CASTAÑEDA-ARELLANO[1], J. RIVAS-CARRILLO[2], G. MENDIZABAL-RUIZ[3], S. DUEÑAS-JIMÉNEZ[1];
[1]Lab. of Neurophysiol., Univ. De Guadalajara, Guadalajara, Mexico; [2]. Dept. of Physiology, Lab. of Tissue Engin. and Transplant, [3]Dept. of Computer Sci., Univ. de Guadalajara, Guadalajara, Mexico

Abstract: There is evidence suggesting that hippocampus plays an important role in locomotion control because of its connections with locomotor areas such as motor cortex, cerebellum, thalamus and diencephalon. An injury in the hippocampus produce theta wave alterations that result in kinematic dysfunction. Previously, our workgroup described that a penetrating injury in the rat hippocampus generates neuron loss, the interruption of the sensory-motor circuitry that resulted in kinematic speed changes. Regard the continuous development of genetic modified mice to study the effects of neurological diseases and treatments, it is important to know that these connection between hippocampus and locomotion system is conserved among different species and further analyze this mechanism. To confirm the connection previously mentioned, we positioned a 0.5 mm in diameter stainless steel cannula 1 mm to the left, 2 mm behind bregma and lowered to a 2-mm depth to injure the hippocampus of five mice. Kinematic patterns

were obtained before the PI and 7 days after de injury (DAI). Five joints of hindlimbs were studied (iliac crest, hip, knee, ankle and fifth metatarsal) plus the displacement movement. A control pattern was calculated by averaging three steps from each subject. Statistical analysis was carried out in the SPSS software using a Kruskal–Wallis test with a Dunn's test for multiple comparisons. A statistically significant value was taken when $p<0.05$. We found a shortening in the stride duration in the lesion group and a decrease of the distance traveled by those animals in comparison to the control pattern. Stride quality in both ipsilateral and contralateral hindlimbs remains uniform in the two groups, but locomotion speed was increased in injury animals. These results are comparable with the ones obtained in rat. Therefore, we can assume that locomotion kinematics can be used as a parameter to evaluate new treatments for neurodegenerative diseases or to further investigate the mechanisms of the connection between hippocampus and movement.

Title: Sample entropy analysis of postural sway in early Parkinson's disease patients

Authors: *G. JURAS[1], A. KAMIENIARZ[1], J. MICHALSKA[1], W. MARSZAŁEK[1], K. SŁOMKA[1], M. RUDZIŃSKA-BAR[2];
[1]The Jerzy Kukuczka Acad. of Physical Educ., Katowice, Poland; [2]Dept. of Neurol., Andrzej Frycz Modrzewski Krakow Univ., Kraków, Poland

Abstract: Introduction: Parkinson's disease (PD) is a neurodegenerative disease, which may affect the body balance. According to standard clinical tests the balance disorders may occur only in advanced PD, however it is crucial to detect such disorders in the earlier stages of disease. For this purpose computerized posturography is successfully used (Nardone et al. 2006). It was found that the amount of attention invested in postural control is related to the dynamic structure of postural sway, specifically to COP regularity (Stins et al., 2009). It was quantified with the use of sample entropy method (Richman et al., 2000) based on which it was proved that the automatic postural control processes increase the sample entropy, while volitional control decreases it (Roerdink et al., 2011). Therefore, the aim of this study was to assess the COP signal regularity using sample entropy in patients with early Parkinson's disease. **Methods:** The research was conducted on 15 PD patients at stage II H&Y (PD-II) (age: 61,9±8,6 years; body

mass: 75,7±9,0 kg; height: 170,4±6,7 cm) and 15 healthy elderly (age: 63,5±4,3 years; body mass: 70,2±7,9 kg; height: 167,3±4,3 cm). The procedure consisted of three quiet standing trials with eyes open (EO) and eyes closed (EC). Each trial lasted 30s. Further analysis was conducted for COP velocity [cm/s], COP range [cm], COP root mean square [cm] and sample entropy. **Results:** The values of sample entropy both in EO and EC was significantly lower in sagittal (EO: $p < 0.001$, EC: $p = 0.001$) and frontal planes (EO: $p < 0.001$, EC: $p = 0.005$) in the PD-II group compared to the elderly. In both, eyes open and eyes closed trials, the data showed no significant differences between PD-II and control group in all of standard measures of postural sway in sagittal plane ($p > 0.05$). The only significantly higher values were registered for frontal plane in the EO trials for COP range ($p = 0.009$) and COP root mean square ($p = 0.003$) in the PD-II compared to the elderly. **Conclusion:** The registered lower values of sample entropy in the PD suggest a more regular COP signal, which indicates the less automatic postural control. The PD patients need to invest more attention in postural control than healthy subjects. Sample entropy is a better measure compared to standard posturographic measures to detect early signs of postural control deficiencies.

Title: Anticipatory postural adjustment (APA) in different targeted weight shifting tasks

Authors: *G.-S. LI[1], Y.-J. CHANG[1], J.-W. LIAW[1], J.-K. YU[1], M.-J. HSU[2];
[1]Chang Gung Univ., Taoyuan, Taiwan; [2]Kaohsiung Med. Univ., Kaohsiung, Taiwan

Abstract: Anticipatory postural adjustment (APA) is important to maintain postural stability during a self-induced perturbation. For example, during a self initiated arm forward reaching task, the COP would move backward before the actual perturbation of COP by the arm movement occurs. APA is not easily to be standardized due to the perturbation is varied according to individual's movement speed and/or amplitude. It is not clear if APA is existed in self-initiated targeted weight shifting tasks in which the amplitude of weight shifting can be quantified. The purpose of this study was to investigate whether the APA component could be identified in targeted weight shifting tasks and to evaluate if the APA is influenced by the target

distance and direction. Seven healthy subjects performed two target distances (60% and 80% maximal) and five directions (0, 45, 90, 135, and 180 degrees) weight shifting tasks guided by a custom designed software. An APA component is defined if the COP moves to the opposite direction to the target. The results showed that the APA was detected in every trail. The duration and amplitude of APA was invaried to the target distance in all weight-shifting directions except the forward (90 degree) direction. This study supports the feasibility of evaluating APA during targeted weight shifting tasks. The underlying mechanism of APA control for forward weight shifting might be different from other directions. Future studies with patient groups are suggested.

Title: Characterisation and circuit analysis of anticipatory postural adjustments in mice

Authors: *E. X. MORINA, A. J. MURRAY;
Sainsbury Wellcome Ctr., Univ. Col. London, London, United Kingdom

Abstract: Whether it be lifting your leg to take a step or reaching to pick up an object, voluntary motor actions have the potential to disrupt postural equilibrium, destabilise the body and result in a fall. To prevent this destabilisation, purposeful movements are preceded by anticipatory postural adjustments (APAs), a subtle shift in the centre of mass (CoM) which prepares the body for the upcoming disturbance. A simple example of an APA is the movement of the CoM away from the initial swing leg during the initiation of locomotion. However, despite their key role in the initiation of movement, little is known about the neural circuits that generate and control APAs.
To allow us to probe the neural circuits involved in the generation of APAs we have developed a mouse behavioural assay to assess the APA associated with the locomotor initiation. The apparatus consists of linear track with four force sensors, used to measure the ground-reactive forces on each limb, embedded in the floor of a start chamber. Mice are trained to stand on the force sensors and perform a nose poke in order to open a door to receive a reward at the end of a linear corridor. This behavioural apparatus combined with high speed video allowed us to characterise in detail the APA associated with mouse gait initiation.

Previous studies have indicated that reticulospinal neurons in the pontine reticular nucleus are active during the generation of APAs. To probe whether pontine reticulospinal neurons are required for APA generation we have used archaerhodopsin to inhibit their firing at different phases of APA generation. Furthermore, we have carried out monosynaptic rabies tracing selectively from reticulospinal neurons and identified over 70 areas that provide input to these neurons. Overall these studies will give us a clearer understanding of the neural circuits that generate APAs.

Title: Effects of anodal transcranial spinal cord direct current stimulation on locomotor adaptation to lateral pelvis perturbation in people with spinal cord injury

Authors: *J.-T. LIN[1], C.-J. HSU[2], W. DEE[2], M. WU[3];
[1]Shirley Ryan Abilitylab, Chicago, IL; [2]Shirley Ryan AbilityLab, Chicago, IL; [3]Dept Physical Med. & Rehabil, Northwestern Univ. - Chicago, Chicago, IL

Abstract: Dynamic balance during walking is usually impaired in people with spinal cord injury (SCI). However, effective training in improving dynamic balance is still lacking. The less efficacy of neuroplastic changes following training may be due to the reduced excitability of spinal circuitries, where most people with SCI were affected because of the reduced descending motor signals. Anodal transcranial spinal cord direct current stimulation (tsDCS) has been used to modulate the excitability of motoneurone synapse, which is beneficial to forming a motor memory. The purpose of this study is to evaluate the effects of anodal tsDCS on the motor learning of dynamic balance during walking in people with SCI. We hypothesized that anodal tsDCS could increase the motor learning of dynamic balance because improved excitability of spinal circuities. Five subjects with SCI participated in this 2-day study. Each day of testing consisted 1-minute baseline, 10-minutes with either sham or anodal tsDCS paired with pelvis perturbation, and 1-minute with no perturbation. The anodal electrode was placed over the 7th thoracic vertebra, and the reference was placed over the shoulder blade. The intensity of current stimulation was set at 2mA. For sham tsDCS, the stimulation was turned off after 10s. A controlled pelvis perturbation was provided from heel strike to mid-stance phase of gait in the medial-lateral direction. The magnitude of force was randomly altered between 30% and 100%

of the determined force, which was set at 8-12% of body weight depending on subjects' tolerance. The outcome measure for dynamic balance was the minimal margin of stability (MoS). The learning outcome was assessed using the rate of adaptation within adaptation and the amount of improvement after adaptation. Cohen's d (d) was used to indicate the standardized difference between conditions. Subjects tended to adapt faster to the pelvis perturbation with tsDCS than without tsDCS (d= .506). Subjects reached stable MoS after 17±7 steps with tsDCS vs. 35±17 steps without tsDCS. Compared to baseline, subjects improved their dynamic balance, which is shown on the reduced MoS after locomotor adaptation to the pelvis perturbation either with or without tsDCS (d= 1.039 and 0.788, respectively). However, the amount of improvement was not different between conditions (d=.144). Our results suggested that tsDCS may improve the rate of motor learning in controlling dynamic balance in people with SCI, although the amount of improvement was determined by pelvis perturbation. Results from this study may be used to develop a balance training paradigm paired with tsDCS to accelerate the learning of dynamic balance in people with SCI.

Title: Segmental coordination changes during walking with and without haptic forces

Authors: *G. U. SORRENTO, P. S. ARCHAMBAULT, J. FUNG;
Sch. of Phys & Occ Therapy, McGill Univ., Montreal, QC, Canada

Abstract: Background: We have simulated walking with a dog leash by combining robot-controlled haptic tensile forces with a self-paced treadmill synchronized to a virtual environment. We have reported gait adaptation and post-adaptation effects, respectively during and after haptic force exposures, in healthy young, older, and chronic stroke individuals. The adaptations were, however, mainly in postural and gait spatiotemporal outcomes, most notably gait speed. This study focuses on the intersegmental coordination of the thigh, leg and foot segments during and after the tensile force exposure. Both planar and phase diagram methods are proposed for a 3D comparison of coordination. Methods: One chronic stroke participant (73 y.o., 8 months post-stroke) and one age-matched control participant (71 y.o.) walked on a self-paced treadmill in a virtual environment holding a robot-controlled haptic leash. Both participants walked an initial 30s baseline pre-force epoch with a slack leash. This was instantly followed by a 60s force epoch where the robotic arm applied and maintained a 15N tensile force to the hand via a leash handle. The force was then released, and the participants continued to walk an additional 60s in the post-

force epoch. Results: Both the post-stroke and control participant displayed changes in bilateral lower limb intersegmental coordination as gait speed increased during force and post-force epochs. For example, both subjects increased dorsiflexion in the non-dominant leg during and after the 15N force exposure. Specifically, the post-stroke individual increased dorsiflexion in the paretic leg by ~7 degrees in both epochs. Changes in limb segment coordination also corresponded to bilateral increases in 3D intersegmental trajectory areas and slight increases in angular velocity, just prior to, and during the swing phase of the paretic leg during force and post-force epochs. Conclusion: The use of haptic tensile forces elicited proportional increases in both the kinematic and dynamic profiles when haptic forces were induced and released. Further investigation on a wider range of chronic stroke functional levels will ascertain if tensile forces improve both segmental coordination and gait symmetry.

Title: Knee extensor fatigability during high- and low-load resistance exercise protocols in young and old adults

Authors: *J. D. DELGADILLO, C. W. SUNDBERG, M. KWON, S. K. HUNTER; Physical Therapy, Marquette Univ., Milwaukee, WI

Abstract: Resistance exercise training is a cornerstone in the prevention of the age-related decline in muscle mass and strength, and fatigability of limb muscle may be an important parameter for this adaptive response. It is unknown, however, whether fatigability and the underlying mechanisms differ between different types of resistance exercise protocols in young and old men and women. The purpose was to determine the fatigability of the knee extensors and identify the involved mechanisms in 20 young (19-24, 22.2 ± 1.3 yr, 10 men) and 20 old adults (64-85, 73.8 ± 5.4 yr, 10 men) elicited by a high- and low-load resistance exercise. Participants performed 4 sets of 8 repetitions with 3 min rest between sets for each exercise protocol. One leg performed a high-load protocol (HLP, 80% 1 Repetition Max, 1RM) and the contralateral leg a low-load protocol (LLP, 30% 1RM). Participants were instructed to kick as fast as possible for the HLP and perform a slow 12 s contraction (6-s shortening, 6-s lengthening) for the LLP. Voluntary activation and contractile properties were quantified with electrical stimulation before

and immediately following each set of exercise. The LLP induced greater reductions in the maximal voluntary isometric force (MVC) after the fourth set compared with the HLP (21% vs. 12%, P=0.003) with no age or sex differences in either protocol. There was a trend towards a greater reduction in the involuntary twitch amplitude in the LLP than the HLP (13% vs. 8% reduction, P=0.057), which was correlated with the reduction in MVC (r=0.500, P < 0.001). In contrast, the change in voluntary activation did not differ between protocols (5% vs. 2% reduction, P=0.329). The low-load with slow contractions induced greater knee extensor fatigability than a high-load with fast contractions due to greater disruptions in contractile function occurring within the muscle**.**

Title: Employing impedance to simplify the neural control of movement

Authors: *D. LUDVIG[1,2], M. W. WHITMORE[1], E. J. PERREAULT[1,2];
[1]Northwestern Univ., Evanston, IL; [2]Shirley Ryan AbilityLab, Chicago, IL

Abstract: Completing motor tasks that require contact is dependent on an ability to regulate the relationship between limb motions and interaction forces with the environment. This can be achieved by exploiting the mechanical properties of a limb or through active regulation of joint torques through changes in muscle activation Since the mechanical properties of a joint are not infinitely malleable, reliance on joint mechanics is only feasible for certain tasks. For example, healthy joints are stable, implying a positive joint stiffness that generates torques opposing externally imposed displacements. Hence, relying on joint stiffness would not be a feasible strategy for tasks that require torque to decrease with increasing angular excursions. In contrast, leveraging the mechanical properties of a joint might simplify neural control when they are matched to the functional requirements of a task. The purpose of this study was to determine if humans change their control strategy, relying on limb mechanics rather than regulated muscle

activation, when feasible. This was accomplished by measuring ankle impedance and muscle activation strategies in three tasks requiring joint torques to: oppose movements, assist movement, or remain constant during movement.Experiments were conducted on 10 subjects. The right foot of each was attached to a rotary motor that controlled motion and measured torques in the sagittal plane. Subjects were instructed to match a target torque aided by visual feedback, while an imposed sinusoidal movement (0.5 Hz) was applied. Three torque targets were used: torque opposing motion (TO; mechanically feasible), constant torque (TC), and torque assisting motion (TA; mechanically infeasible). The motor applied small, pseudo-random angular perturbations to estimate impedance during the tracking tasks. EMGs were measured from the tibialis anterior and triceps surae to assess neural control strategies across the tasks.We found that subjects leveraged ankle impedance to control torque during the TO task. The measured impedance accounted for 88 ± 5% of the measured torque variance during the TO task, but ~ 0% of the torque variance for the TC and TA tasks even though the accuracy with which the torque was tracked was similar across conditions. The reliance on ankle impedance simplified the neural control. There was significantly less muscle activation modulation in the TO task than in the TC ($p = 0.006$) or the TA ($p < 0.001$) tasks. These results demonstrate how leveraging the mechanical properties of a joint can greatly simplify the neural control needed to complete a task. The extent to which natural behaviors exploit mechanics remains to be determined.

Title: Inverted pendulum-like stance behavior during lateral walking maneuvers in persons with and without incomplete spinal cord injury

Authors: *W. L. OCHS[1], J. L. WOODWARD[2], K. E. GORDON[3];
[1]Northwestern Univ., Chicago, IL; [2]Shirley Ryan Ability Lab., Chicago, IL; [3]Northwestern Univ. - Chicago, Chicago, IL

Abstract: Inverted pendulum models have been widely applied to describe the stance phase of human walking. This simple model captures a substantial portion of the body’s center of mass (CM) dynamics and has provided insight on how the nervous system controls straight-ahead

walking. It is unknown how well an inverted pendulum model captures the challenging task of laterally maneuvering, where physical task requirements change from step-to-step. Pendulum model parameters, such as step width and time, can be manipulated to produce near pendulum-like behavior sufficient for maneuvering and favorable for control simplicity, but humans have the capacity to use alternative joint torque coordination patterns in ways that may yield maneuverability, stability, or energetic advantages. We hypothesized that during lateral maneuvers, non-impaired individuals would use more distinct frontal-plane behaviors step-to-step during maneuvers that deviate from pendulum-like behavior compared to ambulatory individuals with an incomplete spinal cord injury (iSCI). We assessed frontal plane stepping behavior during lateral walking maneuvers performed at preferred speed on an extra-wide treadmill and during overground walking across force plates. Degree of pendulum-like behavior was determined by comparison of CM acceleration predicted from a pendulum model to the measured CM acceleration during single-limb stance. Motion capture markers on the feet and pelvis were used to characterize stepping, estimate CM location, and in the case of treadmill walking, estimate center of pressure (CP) location. Treadmill results showed individuals with iSCI tended to use less step-to-step variation in foot placement within a maneuver compared to non-impaired participants. This trend had a positive correlation with decreased performance in clinical metrics of impairment. This behavior supports our hypothesis of using more consistent, simplified control strategy with impairment. A subgroup of individuals with iSCI showed larger lateral CM accelerations on all steps compared to non-impaired individual, which may reflect a deficit in control. The pendulum-like nature of this behavior will be reported once the treadmill model using a fixed CP is validated using overground data. The degree to which humans behave like an inverted-pendulum and modify parameters within that model during maneuvers will provide insight on control priorities and how they may change with impairment. This information aids in our understanding of how iSCI impacts neuromechanical control of an important walking task.

Title: Effects of pramipexole on the organization of gait in the myelin mutant: The taiep rat

Authors: *J. C. AHUMADA-JUÁREZ[1], J. EGUIBAR[2], C. CORTES[3];
[1]Inst. de Fisiología, Benemérita Univ. Autónoma de Puebla, Puebla, Mexico; [2]Benemerita Univ. Autonoma De Puebla, Puebla, Pue., Mexico; [3]B. Univ. Autonoma de Puebla, Puebla, Mexico

Abstract: The demyelinating diseases of the central nervous system (CNS) has a high prevalence worldwide, and one of the most important signs of disability caused by these diseases is walking disability which affects the coordination and the stepping sequence between anterior and posterior extremities. The *taiep* rat is a myelin mutant whose name is the acronym of the motor signs that characterizes it: tremor, ataxia, immobility, epilepsy, and paralysis. Pathologically is an homologue model for demyelinating diseases. Importantly, CNS *taiep* increase proinflamatory mechanisms with age. The objective of this study was to evaluate the effects of systemic administration of a D2-like dopaminergic pramipexole on walking pattern. We used six three month old male *taiep* rats. All subject were recorded under control (NaCl 0.9%) and after intraperitoneal injection of 0.5 and 1 mg/Kg of pramipexole. Walking was analyzed using CatWalk ™ system (Noldus, The Netherlands), measuring support base, speed, stride length, duration of support, swing phase duration, footprint width and step sequences. Pramipexole 0.5 mg/Kg administration decreased the duration of the swing phase ($P<0.05$), increased the cadence ($P<0.05$), and the footprint width ($P <0.01$). With pramipexole 1 mg/Kg increase only the step sequence ($P <0.05$) with respect to the control group. In conclusion, pramipexole improved the walking coordination and gait cycle. There results showed that D2-like receptors are capable to modulate the walking and ataxia in this myelin mutant of TUBB4 mutations in humans.

Title: Effects of Achilles tendon vibration and foot noise on postural control

Authors: *C. S. LAYNE[1], B. C. LEE[1], P. LEUNG[2], D. R. TEMPLE[1];
[1]Ctr. for Neuromotor and Biomechanics Res., [2]Grad. Col. of Social Work, Univ. of Houston, Houston, TX

Abstract: Stochastic resonance (SR) is a phenomenon where response of nonlinear systems to weak input signals, such as in sensory neurons, may be enhanced with noise added to the system. Small levels of noise can increase signal detection; however, too much noise degrades weak signals. Studies note improved balance when adding slight mechanical foot noise (FN) to the

plantar surface, presumably by increased sensory feedback through SR. The SR induced improvements in sensory feedback may lead to up-weighting of plantar mechanoreceptor afferents, resulting in improved balance. We aimed to determine if FN could modulate the postural effects of Achilles vibration (AV). Twenty-four young healthy adults stood with their eyes closed, under 30 second conditions of AV (on or off) and FN (on or off). Anterior-posterior (AP) center of pressure (CoP) was used to compute mean position, speed, and approximate entropy (ApEn). To assess body segment coordination, Anchoring Index (AI) was computed of three AP body segment angles (head, torso, and thigh) in relation to their inferior segment angles. Repeated-measures ANOVAs were used to analyze effects of AV, FN, and their interactions. An alpha level of 0.05 was adopted, and Bonferroni adjustments were made to correct for multiple comparisons. A significant interaction effect of FN and AV for CoP speed indicated FN modulated AV by producing significantly faster CoP speeds. CoP ApEn was significantly reduced by AV, regardless of FN condition, suggesting AV produces a more regular CoP motion. ApEn was also significantly increased by FN when no AV was present, suggesting it can produce more regular CoP motion in the absence of AV. The thigh AI was significantly increased by AV, regardless of FN condition, indicating AV modifies the coordination between the thigh and shank. Overall the findings signify that FN is capable of modulating the typical postural response produced by AV by increasing CoP speed, while AV reduces thigh stabilization on the shank. It is unclear if these findings are the result of SR leading to increased upweighting of foot plantar mechanoreceptors, as FN would have then likely led to decreased CoP speed. The study does however reveal novel findings of how AV and FN stimuli can interact to influence postural control.

Title: Effects of Achilles tendon vibration, fingertip light touch, and fingertip noise on postural control

Authors: *D. R. TEMPLE[1], B.-C. LEE[1], P. LEUNG[2], C. S. LAYNE[1];
[1]Hlth. and Human Performance, [2]Grad. Col. of Social Work, Univ. of Houston, Houston, TX

Abstract: Several studies note improved balance when sensory feedback is increased by fingertip light touch (FLT), despite not providing mechanical support. During FLT with slight mechanical noise added to the touch surface (FLT+N), postural stability is increased beyond effects of FLT alone. This presumably occurs if the noise elicits stochastic resonance (SR), a

phenomenon where response of nonlinear systems to weak input signals may be enhanced by adding noise. FLT also mitigates the destabilizing effect of Achilles vibration (AV) on postural control, but this effect has not been tested under FLT+N conditions. We explored whether FLT+N modulates the postural effects of AV, beyond that of FLT alone. Young healthy adults (n = 22) stood with their eyes closed, under 30 second conditions of AV (on or off) and touch (no FLT, FLT, or FLT+N). Anterior-posterior (AP) center of pressure (CoP) was used to compute mean position, speed, and approximate entropy (ApEn). To assess body segment coordination, Anchoring Index (AI) was computed of three AP body segment angles (head, torso, and thigh) in relation to their inferior segment angles. Repeated-measures ANOVAs were used to analyze effects of AV, touch, and their interactions. An alpha level of 0.05 was adopted, and Bonferroni adjustments were made to correct for multiple comparisons. FLT and FLT+N mitigated typical postural responses of AV with CoP mean position significantly less posterior and reduced CoP speed. FLT and FLT+N significantly increased CoP ApEn, regardless of AV condition (on or off), indicating FLT reduces the regularity of CoP motion. AV itself significantly reduced CoP ApEn under all touch conditions, indicating it increases CoP motion regularity. Torso AI was significantly increased by FLT+N under both AV conditions (on and off). FLT significantly increased torso AI when AV was off, but it did not when AV was on. This suggests FLT+N further modifies coordination between the torso and thigh beyond FLT alone, when AV is present. AV also significantly increased Torso AI during the no FLT and FLT+N conditions. The findings suggest that the stabilizing effect of FLT during AV is generally enhanced by FLT+N, which may occur as a result of SR further increasing sensory feedback beyond FLT alone.

Title: Effects of ankle tendon vibration on lean after-effect

Authors: *D. R. YOUNG, C. S. LAYNE;
Hlth. and Human Performance, Univ. of Houston, Houston, TX

Abstract: Previous research has identified deficits in postural adaptation due to inadequate sensory integration to be among the chief reasons for falls. Postural adaptation studies typically involve a change in environmental context to bias or decrease the reliability of the vestibular, visual, and/or proprioceptive systems. Lean after-effect (LAE) studies utilize an incline-intervention (Inc_I), a bout of quiet stance on an inclined surface for several minutes before returning to a flat surface post-test. Most subjects display a forward lean during the post-test

which may persist up to several minutes, known as LAE. LAE studies have been used as an effective proprioception-based illusion which leads to global alterations of the body schema and postural adaptation without a coinciding decrease in proprioceptive reliability. Previous LAE experiments have shown that stable, trait weighting of the vestibular and proprioceptive system effects the magnitude and duration of forward lean. This investigation sought to identify the effects of a concurrent proprioceptive illusion, tendon vibration of the Achilles (AT) or tibialis anterior (TA) tendon, on LAE. By adding tendon vibration to an Inc_I or post-test, we were able to identify if changes in state/dynamic sensory weighting affected LAE, and if those changes were directionally specific. Subjects were tasked with performing five bouts of an Inc_I, one baseline condition with no vibration, and bouts with tendon vibration of the AT or TA during the Inc_I or post-test. We compared LAE outcomes between these conditions using integrated area under the curve during the 5-minute post-test. AT vibration during the post-test led to a decrease in LAE. However, this posterior shift was not as great as when subjects were exposed to AT vibration alone, suggesting the Inc_I mediated the effect of tendon vibration. Conversely, TA vibration during the post-test led to an increased LAE compared to the baseline and compared to TA vibration alone, again suggesting the Inc_I served to mediate the effects of tendon vibration. While vibration during the post-test had direction specific effects, when presented with either TA or AT vibration during an Inc_I, subjects had an increase in LAE compared to the baseline. These results show that shank tendon vibration influences the development of LAE if presented concurrently with an Inc_I and moderates the expression of LAE if presented afterwards. This suggests a role of dynamic sensory reweighting as well as an effect of local proprioceptive inputs on the development and expression of LAE.

Title: Effects of levels of illumination and visual tasks on postural stability in older adults

Authors: *A. CHEONG[1], H.-Y. LAM[1], V. SUEN[1], C. TSANG[1], G. WOO[1], J. CHO[4], J. KWAN[5], L. A. ABEL[6], P. LEE[2], W. TSANG[3];
[1]Sch. of Optometry, [2]Sch. of Nursing, [3]Dept. of Rehabil. Sci., The Hong Kong Polytechnic Univ., Hong Kong, China; [4]Hong Kong Society for the Blind, Hong Kong, China; [5]UDA Consultants Ltd., Hong Kong, China; [6]Dept. of Optometry & Vision Sci., Univ. of Melbourne, Melbourne, Australia

Abstract: Background: Glare induced by excessive illumination affects our visual integration. Such interrupted visual input may affect balance control, especially in people with compromised balance function. Our study was aimed to investigate the impact of illumination and visual search on postural stability in community-dwelling older adults.
Method: 13 older adults (mean age: 61.8±1.4) without known pathology and normal vision were recruited. Static balance on a stationary surface was measured by a computerized dynamic posturograpy (SMART EquiTest). Subjects were asked to undergo either 1) a pure fixation task for 18 seconds, or 2) a combined task with visual search in the first 6 seconds followed by fixation for 12 seconds. To simulate visual search in daily life, subjects had to identify the target presenting on one of the 6 monitors which were located at 3 metres away in an arc shape, covering a visual field of 120 degree. Balance measures were conducted under 3 different illumination levels (100, 520 and 2100 lux). Postural sway in terms of sway area (mm2), maximum sway (mm) in anterior-posterior (A-P) and medio-lateral (M-L) directions were analyzed across 3 time-points (6 seconds each) to study the effect of illumination and visual tasks.
Results: Results from three-way repeated measures ANOVA showed that postural sway significantly reduced across time ($p<0.001$), with significantly larger sway area and displacement in the first time-point compared with others. Postural sway in combined task was significantly greater than pure fixation task ($p<0.001$). Significant interaction effect was found between time and task ($p<0.001$). In the combined task, visual search in the first 6 seconds impacted the postural sway, where subjects presented larger sway area, maximum A-P and M-L sway ($p<0.001$). However, when the task changed from searching to fixation, the postural sway substantially but gradually reduced ($p<0.01$), compared with pure-fixation task. Postural sway was similar among the 3 different levels of illumination ($p>0.10$), with no interaction effect of illumination and time or illumination and task ($p>0.05$).
Conclusion: Opposing to our hypothesis, our study did not find illumination imposing significant impact on postural stability among healthy older adults. Instead, visual search significantly altered their postural stability, which might be explained by the shift of attention contributing to postural stability to search task. Once the postural stability was interrupted, time was required to reacquire postural stability. Further study on older adults with comprised balance control will be conducted.

Title: Electrocortical activation in patients with an acute lateral ankle sprain during balance task

Authors: *J. KIM[1], Y. AN[3], B. ARWARI[1], N. PATEL[2], K.-M. KIM[1];
[1]Kinesiology and Sport Sci., [2]Psychology, Univ. of Miami, Coral Gables, FL; [3]Kinesiology and Dance, New Mexico State Univ., Las Cruces, NM

Abstract: Lateral ankle sprains have been reported as the most common injury in physically active populations. Poor postural control following the lateral ankle sprain is a key factor for chronic ankle instability, which is characterized by the feeling of the ankle giving way along with residual signs and symptoms for months to years. Up to 74% of acute lateral ankle sprain (ALAS) patients suffer chronic ankle instability with persistent postural control deficits. Recently, neuroimaging studies have shown that ligamentous injuries cause neural adaptation in the central nervous system (CNS), and such altered cortical activation may be underlying mechanisms for chronic ankle instability. However, to date, there is a limited study that identifies the centrally mediated neural adaptation in ALAS patients during a postural control task. Thus, the purpose of this case-control study was to identify the cortical activation pattern in ALAS patients compared with healthy controls during the bipedal balance task. A total of 10 subjects participated (5 ALAS patients, 5 healthy controls). Electrocortical activations over the frontal (Fz), parietal (Pz) and occipital (Oz) cortices were recorded using a 64-channel of Electroencephalograph (EEG) during a total of 12 trials of 10 second-bipedal balance task with eyes open. Theta (4-8 Hz) and alpha-2 (10-12 Hz) frequency bands power and total center of pressure path length ($tCOP_{length}$) were calculated for electrocortical activation and balance, respectively. We found that there was no significant difference in $tCOP_{length}$ between groups during the bipedal-balance (p=.099, ALAS: 13.73 ± 3.66, control: 10.23 ± .58cm). However, the ALAS group showed greater parietal theta (Pz, (p=0.003, ALAS: 0.28±0.03, control: 0.20±0.03) and less frontal alpha-2 (Fz, p=0.038, ALAS: 0.15±0.06, control: 0.24±0.05) compared to the control group. Theta frequency in the parietal cortex plays a key role in situational awareness to external stimuli, while less frontal alpha-2 power indicates more excitatory responses in the frontal cortex, which is the area for the cognitive decision-making process for motor tasks. These preliminary results suggest that ALAS patients were able to maintain postural stability similar to the healthy individual but different electrocortical activation patterns, indicating that ALAS patients demand more neural recruitments than the healthy individuals to process and integrate internalized attention and proprioceptive deafferented input.

Title: Development of an optogenetic method to stimulate gamma motor neurons *in vitro*

Authors: A. KAREKAL[1], S. K. BYRI[1], S. MASRI[1], N. VILLEGAS[1], S. HOCHMAN[2], *K. A. WILKINSON[1];

Abstract: The muscle spindle is a sensory organ located in skeletal muscle that is critical for motor control and proprioception, or the sense of body position in space. It is innervated by the Group Ia and II muscle spindle afferents, which respond to changes in the length of the muscle. The gamma motor neurons control the length of the intrafusal fibres, and therefore the sensitivity of the muscle spindle afferents. However, it has been challenging to study the gamma motor neurons since it is hard to specifically stimulate the gamma but not the alpha motor neurons that control the force generating extrafusal fibers. A previous study showed that alpha motor neurons were recruited from small diameter to large diameter with increasing optical intensities in mice expressing the blue light gated Channel rhodopsin 2 (ChR2) in motor neurons (Llewellyn, et al., 2010). This is the reverse recruitment pattern of electrical stimulation. We hypothesized that gamma motor neurons, which are smaller than even the smallest alpha motor neurons, will be recruited first using low optical stimuli and that this will allow us to characterize their effects on muscle spindle afferent sensitivity. The extensor digitorum longus muscle and peroneal branch of the sciatic nerve from adult mice expressing ChR2 in choline acetyltransferase (ChAT) positive motor neurons were dissected and placed in an in vitro tissue bath with oxygenated synthetic interstitial fluid. The sciatic nerve was attached to an extracellular suction electrode that recorded muscle spindle afferent activity. We used a light guide to deliver blue LED light (470nm; 0.5mW-5 mW) to the end of the nerve. We found that, as expected, the lowest optical intensities recruited the more slowly conducting gamma motor neurons. Higher optical intensities recruited the shorter latency alpha motor neurons, as evidenced by the presence of twitch contraction. At the lowest optical intensities we observed an increase in muscle spindle afferent firing rate in the absence of twitch contraction, confirming that gamma motor neurons alone had been recruited. Further, increasing the gamma motor neuron firing frequency led to a greater increase in muscle spindle afferent firing rate. We are currently using this technique to characterize gamma motor neuron control of muscle spindle afferent tone. In summary, we have

developed an optogenetic technique to recruit gamma motor neurons in vitro that can be used to study fusimotor control of the muscle spindle. Future studies will develop this approach for use in vivo to better study gamma motor neurons and their contribution to motor control under normal and disease conditions.

Title: Frequency analysis of the static postural stability after a self-mobilization exercise program

Authors: *D. SHIBATA;
Dept. of Health, Exercise and Sports Scienes, Univ. of New Mexico, Albuquerque, NM

Abstract: Central processing of multi-sensory feedback and motor commands responsible for force production is critical for postural control. A self-mobilization exercise program was developed to realign spinal curvature, and immediate and sustained effects on balance control were documented. However, it is unknown to what extent the exercise program influences central processing for postural control. This study addressed this question through the use of spectral analysis of center of pressure (CoP) displacements in standing before and after the intervention of exercise program. Sixteen subjects were randomly assigned into Exercise (n = 8) and Control group (n = 8). The Exercise group performed the exercise program while lying supine on a cylinder-shaped tube (98-cm length, 15-cm diameter), consisting of three preparatory positions and seven small motions. The duration was approximately 15 min. The Control group rested on a flat surface for 15 min. Center of pressure (CoP) was measured while subjects were asked to stand quietly on a pressure mat (Tekscan, Inc. USA) for 3 trials of 10 sec each with eyes open and closed (EO and EC, respectively). CoP displacements in anteroposterior (AP) and mediolateral (ML) directions were used to calculate power spectrum by fast Fourier transformation. The power spectrum was analyzed in three frequency bands: low (LF: 0-0.3 Hz), medium (MF: 0.3-1 Hz), and high (HF: 1-3 Hz) reflecting contributions from the visual, vestibular, and proprioceptive systems, respectively. The total power spectrum of each band was normalized by the sum of the three bands and is expressed as percentage in this study. Repeated measures ANOVAs were used to examine changes in percent power spectrum for each of three

frequency bands in the AP and ML directions for the EO and EC conditions (Pre vs. Post) and group differences (Exercise vs. Control). There was no significant change in percent power spectrum of the three frequency bands in the ML direction for the EO and EC conditions. In the AP direction, percent power spectrum of LF band significantly increased while that of MF band decreased for the EO and EC conditions in the Exercise group ($p < 0.05$), but not in the Control group. There was no change in percent power spectrum of HF band in the AP direction for the both groups. These findings may indicate that the contributions of visual and vestibular systems for postural control became greater and lesser, respectively, while a proprioceptive contribution remained the same after performing the exercise program. In sum, the exercise program altered central processing of sensory inputs for postural control in the AP direction regardless of visual feedback.

Title: A new system to objectively measure ankle proprioception

Authors: *J. HOLST-WOLF, J. PIEKARSKI, J. KONCZAK;
Human Sensorimotor Control Lab., Univ. of Minnesota, Minneapolis, MN

Abstract: Proprioceptive afferents of the ankle are essential feedback signals for the maintenance of balance and posture. While the importance of ankle proprioception for balance control has been recognized, there is no widely accepted test or measurement system available. We here present newly developed hardware and a psychometric testing protocol suitable to measure ankle proprioceptive acuity. The aims of this study were: 1) to establish system reliability and validity, 2) to obtain normative values of ankle proprioceptive acuity in healthy adults, and 3) to determine, if ankle proprioceptive acuity correlates with kinetic measures of balance. METHODS: While sitting, participants placed their foot on a footrest of the device, which could tilt in the sagittal plane allowing for foot dorsiflexion/plantarflexion. An examiner rotated the footrest to two different ankle positons (standard and comparison). Then participants judged which positon was furthest from the neutral starting position. Using a Bayesian inference based adaptive algorithm, 30 pairs of ankle positions were presented and the just-noticeable-difference (JND) threshold was determined as a measure of ankle proprioceptive acuity. A subset of healthy adult participants completed the assessment three times on different days to establish the system reliability. Using a force platform, participants underwent a balance assessment, which consisted of a series of 30-second double- and single-leg stance in an eyes open and eyes

closed sensory condition. The center-of-pressure sway path length and sway area were obtained as balance measures. RESULTS: We show exemplar and group data of ankle JND thresholds for both the dominant and non-dominant leg and present the relationship between ankle JND threshold and the balance measures. DISCUSSION: Here we introduce a novel, objective measure of proprioceptive acuity for the ankle and document the instrument reliability. This assessment has potential to become a simple tool for clinicians to identify proprioceptive impairment at the ankle and measure the efficacy of sensorimotor interventions for balance.

Title: What triggers modulation of proprioceptive reflexes: Environment dynamics or perturbation properties?

Authors: *W. MUGGE[1], A. DEL VALLE HIDALGO[1], P. A. FORBES[2];
[1]Delft Univ. of Technol., Delft, Netherlands; [2]Dept. of Neurosci., Erasmus Med. Ctr., Rotterdam, Netherlands

Abstract: Effective upper limb control in the face of unpredictable disturbances relies on our ability to vary limb resistance, which can be achieved by regulating both intrinsic muscle visco-elasticity (i.e. cocontraction) and reflexive feedback from sensory organs (i.e. proprioceptors). There is considerable controversy surrounding the adaptability of reflexive feedback mechanisms in upper limb motor control. Notably, one view is that reflex modulation is governed by stability constraints such that reflexive feedback is tempered to prevent oscillations under conditions with reduced stability margins (De Vlugt et al. 2002). This view requires that humans assess the stability margins when interacting with environments and any accompanying perturbations. On the other hand, since the influence of the perturbations themselves depend on the properties of the environment, it may be possible that we sense changes in the characteristics of the perturbation and modulate reflexive feedback accordingly.
This study aims to identify whether the trigger for reflex modulation is driven to a greater extent by environmental dynamics (i.e. damping and stability margin) or the resultant perturbation properties. Subjects were instructed to minimize arm displacements caused by continuous force perturbations applied to the hand. Joint admittance (i.e. arm displacement due to the imposed

force) and combined admittance (i.e., human and environment) were estimated as a function of frequency to quantify dynamics of the resultant motor control behaviour. Admittance is known to modulate with environmental damping, but in conventional damping conditions both the stability margin of the combined system and the perturbation properties change. Therefore, we applied sham conditions where the perturbations were prefiltered to mimic or compensate for the filtering effect of the added environmental damping. As a result, the velocity profiles that the subjects experienced were held constant despite the underlying changes in the stability margin across different damping conditions.
The results validated that the force and displacement properties of the perturbations in the sham conditions were indeed similar to the conventional damping conditions they mimicked. The change in admittance in the sham conditions was less than what was observed in the conventional damping conditions, suggesting that stability constraints are not solely responsible for the admittance modulations.

Title: Evaluating the role of electrically-evoked plantar sensation in an ambulatory searching task

Authors: *B. P. CHRISTIE[1,2], H. CHARKHKAR[2], C. E. SHELL[3,2], D. J. TYLER[1,2], R. J. TRIOLO[2,1];
[1]Biomed. Engin., Case Western Reserve Univ., Cleveland, OH; [2]Louis Stokes Cleveland Dept. of Veterans Affairs Med. Ctr., Cleveland, OH; [3]Biomed. Engin., Cleveland Clinic, Lerner Res. Inst., Cleveland, OH

Abstract: Plantar cutaneous inputs and vision contribute to correct foot positioning in response to obstacles and while walking over uneven terrain [Rossignol 2006]. When visual resources are not available, such as while walking in the dark, somatosensory cortex activation increases [Oliveira 2017]. Yet, it is still unclear how plantar cutaneous sensation aids in searching tasks when vision is obstructed. We hypothesized that plantar sensation is used to acquire action-

relevant information during locomotion, and that this information improves task performance and modulates foot placement strategy.
The horizontal ladder walking test has been used to evaluate cutaneous sensation in animal models [Bouyer & Rossignol 2003]. In the present study, two trans-tibial amputees (LL01 and LL02) performed a version of this test adapted for clinical trials and while blindfolded. Both participants had nerve cuff electrodes installed around their residual sciatic and tibial nerves. In half of the trials, electrical stimulation was delivered directly to the nerves to evoke somatosensory percepts referred to the missing feet. Closed-loop stimulation was triggered and modulated by readings from pressure insoles placed underneath the prostheses. Stimulation parameters were selected to elicit sensations referred to a region of the missing foot that matched the activated insole region: forefoot, midfoot, and/or rearfoot. We measured completion time, number of foot placement errors, and ground reaction forces. Errors included missing a rung, slipping off a rung, and placing the foot on two rungs at once.
Preliminary results indicate that task performance improves when sensation is restored, but foot placement strategy is not affected. During trials with sensation, task performance improved in different ways for the two participants: for LL01, completion time decreased (t-test, $p=0.01$). For LL02, the number of errors decreased ($p<0.001$). LL02 performed the task faster than LL01 but had a higher error rate ($p<0.001$), which could explain why restoring somatosensation affected each participant differently. Foot placement strategy, i.e. the region of the foot that stepped onto a ladder rung, did not change during trials with feedback.
In summary, our results suggest that restoring plantar cutaneous sensation in lower-limb amputees could improve their performance in searching tasks, but its mechanism may be subject-dependent. Overall, findings from this study demonstrate how sensory-enabled prostheses could aid lower-limb amputees in searching tasks when vision is compromised.

Title: Response patterns of mouse spinal central pattern generator neurons to stimulation of low-threshold hindlimb afferents

Authors: *E. Z. LI, D. L. GARCIA-RAMIREZ, L. YAO, K. J. DOUGHERTY;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The basic hindlimb locomotor pattern is generated in the thoracolumbar spinal cord by neural circuits known as central pattern generators (CPGs). The locomotor CPG integrates descending commands and ascending sensory information to activate, modulate and halt the rhythmic program. In spinal cord injury and stroke, descending control is impaired but afferent pathways to the CPG remain comparatively intact. Thus, understanding the specific structure of CPG afferent processing circuits may have therapeutic relevance for gait recovery in these disease states. Modeling experiments suggest a two-layer architecture in which rhythm-generating (RG) neurons produce the basic motor program and indirectly recruit motoneurons through pattern-forming (PF) neuron populations. Activation of ankle afferents has been shown to strongly modulate locomotor phase transitions, which is predicted to be mediated by synapses at the RG level with possible involvement of the PF layer. Several genetically-labeled neuronal populations have been shown to participate in CPG circuits based on locomotor alterations following ablation or inhibition and have hypothesized connectivity in this two-layer structure. The transcription factor Shox2 marks a heterogeneous population of CPG neurons that can be subdivided into neurons contributing to rhythm generation ($Shox2^{RG}$) and neurons thought to be pre-motor PF neurons ($Shox2^{PF}$) by presence/absence of the transcription factor Chx10. To directly test integration of afferent signaling by CPG neurons, we developed a lumbar-hemisected isolated spinal cord preparation with preserved peripheral nerves in neonatal Shox2::cre;Rosa26-lsl-tdTomato;Chx10GFP mice. $Shox2^{RG}$ and $Shox2^{PF}$ neuron responses to activation of functionally-specific hindlimb afferent pathways were measured using whole-cell patch clamp. Both $Shox2^{RG}$ and $Shox2^{PF}$ neurons displayed postsynaptic currents following afferent activation. Surprisingly, many Shox2 neurons displayed long-lasting inhibitory responses following stimulation of both flexor- and extensor-related ankle afferents. These results are consistent with data from neonatal mouse preparations showing that stimulation of either flexor- and extensor-related afferents during fictive locomotion resets the phase to flexion. Developmental changes in afferent effects on ongoing locomotion have been shown in the rat and investigation of Shox2 response patterns in older animals may reveal functional maturation of these pathways.

Title: Plantar tactile augmentation improves lateral balance with and without cognitive load, but palmar tactile augmentation improves lateral balance only without cognitive load

Authors: *J. S. AZBELL[1], J. K. PARK[2], S.-H. CHANG[3], M. ENGELEN[2], H. PARK[1]; [1]Electrical and Computer Engin., [2]Hlth. and Kinesiology, Texas A&M Univ., College Station, TX; [3]Dept. of Physical Med. and Rehabilitation, UTHealth, Neurorecovery Res. Ctr. At TIRR Mem. Her, Houston, TX

Abstract: Peripheral neuropathy (PN) is common among individuals with diabetes; about 50% of them develop the condition within 10-15 years. PN with reduced plantar cutaneous feedback increases the risk of slips, trips, and falls. To mitigate these risks, several sensory augmentation approaches have been proposed. However, the majority of these methods provide sensory cues via visual, audio, or vibrotactile feedback rather than addressing the original plantar sensory deficiency. The efficacy of such methods can be limited by the cognitive load involved in processing these sensory cues, because cognitive capability varies upon the situation and cognitive load increases response time and fatigue. The objective of this study is to test our hypothesis that tactile augmentation, by stimulating the sensory nerves on the foot sole, is more effective than indirect sensory cues in improving lateral balance for individuals with reduced plantar cutaneous feedback. In our study, four healthy human subjects repetitively stood on a lateral balance board and maintained balance for as long as possible. Balance time was defined as the total time the subject remained on the board without touching the ground on either side. Subjects were instructed to close their eyes during the experiments to increase dependency on plantar cutaneous feedback for balancing. A layer of foam was placed on top of the board to replicate the reduced plantar cutaneous feedback of PN. For tactile augmentation on the foot sole or palm, low-intensity electrical stimulation was transcutaneously applied on either the calcaneal or ulnar nerve, respectively. To test the effect of cognitive load (CL), subjects were asked to count backward from a given random number. Experiments were performed with five conditions: control with no augmentation, plantar augmentation with and without CL, and palmar augmentation with and without CL, in a random order to remove the motor learning effect. Experimental data shows that both plantar and palmar augmentation increase average balance time. However, with a CL, palmar augmentation has no effect on average balance time, while the increase in average balance time remains with plantar augmentation. This result suggests that plantar augmentation may be more effective than providing indirect sensory cues (i.e., palmar) to treat balance deficit associated with reduced plantar cutaneous feedback in persons with PN.

Title: Molecular and circuit analysis of functions of a neuropeptide family, *Aplysia* CCK

Authors: ***G. ZHANG**[1], J. W. CHECCO[2], S.-Q. GUO[1], Y.-Y. XUE[1], E. V. ROMANOVA[2], D. H. MAST[2], S.-C. QIAN[1], W.-D. YUAN[1], K. YU[1], Z. YANG[1], F. S. VILIM[3], E. C. CROPPER[3], K. R. WEISS[3], J. V. SWEEDLER[2], J. JING[1];
[1]Nanjing Univ., Nanjing, China; [2]Dept. of Chem., Univ. of Illinois at Chicago, Urbana, IL; [3]Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: All behaviors are implemented by specific neural circuits, but the initiation and termination of a behavior, and the frequency and form of a behavior are often mediated by actions of neuromodulators. Neuropeptides represent one of most diverse class of neuromodulators, and many of them have been shown previously to have a profound impact on behaviors and the underlying neural circuits. Despite this progress, the functions of some peptide families remain to be elucidated. We sought to use an experimentally advantageous model system, the marine mollusc *Aplysia* to study a neuropeptide family, cholecystokinin (CCK), that appears to be present in both invertebrates and vertebrates. CCKs are well studied in mammals, and undergo a rare form of posttranslational modification, i.e., sulfation of the tyrosine residue. Sulfated and nonsulfated forms of CCKs make CCKs diverse, and they may act on at least two types of G protein-coupled receptors. Interestingly, there is evidence suggesting that CCKs may act in both feeding and locomotor networks in *Drosophila*, but the neural mechanisms are poorly understood. Here, we cloned the *Aplysia* CCK precursor, which generates two forms of CCK, i.e., CCK1 and CCK2. Both CCK1 and CCK2 have two tyrosine residues that may be sulfated. We obtained mass spectrometry evidence of unmodified and mono-sulfated CCKs in the *Aplysia* central nervous system (CNS) via liquid chromatography-tandem mass spectrometry (LC-MS/MS) and trapped ion mobility spectrometry (IMS). Specific locations of the sulfated tyrosine and the presence of di-sulfated CCKs remain to be determined. Importantly, we also cloned two putative CCK receptors from the *Aplysia* CNS by RT-PCR. We determined the tissue distribution of both the CCK precursor and receptors using whole mount in situ hybridization. We then found that different forms of CCK peptides have different activity at the two CCK

receptors when recombinantly expressed in CHO-K1 cells. Furthermore, in *Aplysia* intact ganglia, some of these peptides appeared to be active in the feeding and locomotor networks. Overall, the di-sulfated CCK appears to be the most potent in receptor assay and intact ganglia experiments. Notably, in the feeding network, active CCKs shortened the protraction duration of *Aplysia* feeding motor programs and made ingestive programs egestive, consistent with a role of the CCKs in satiation. Because of diverse presence of CCKs across phyla, our findings may have broad implications regarding peptide functions in general, and CCK actions in particular.

Title: Glutamatergic and serotonergic higher order neurons drives exploratory like and avoidance locomotion in *aplysia*

Authors: K. YU[1], Z. YANG[1], S.-Y. YIN[1], D.-D. LIU[1], G. ZHANG[1], R.-N. JIA[1], S.-Q. GUO[1], W.-D. YUAN[1], Y.-Y. XUE[1], E. C. CROPPER[2], K. R. WEISS[2], ***J. JING**[1];

Abstract: To deal with different situations, animals generate two forms of locomotion, i.e., exploratory and avoidance. Neural, mechanisms that distinguish between these behaviors are poorly understood. Here, we address this issue in *Aplysia*. In *Aplysia* both forms of locomotion are mediated by rhythmic pedal rolling waves propagating from front to back. Previous studies often monitored locomotion using the parapedal commissural nerve (PPCN). We verified the efficacy of this method with implanted electrodes in PPCN and recorded PPCN bursts corresponding to tail contraction in intact animals, establishing PPCN as a monitor of locomotion. Moreover, PPCN during escape locomotion showed higher cycle frequency than

during spontaneous locomotion. Previous work showed that a high-order neuron, cerebral CC9/10 evokes locomotion (Jing et al 2008). We show that another high-order neuron, cerebral-pedal regulator (CPR), also drives locomotor programs. CPR mediates food-induced arousal (Teyke et al 1991). We found that locomotor programs elicited by CC9/10 and CPR are different. With the same stimulation parameters (10 Hz, 2 min), CC9/10-elicited programs had a higher cycle frequency (CC9/10: 4.0/min; CPR: 2.3/min) and higher frequency activity in PPCN (CC9/10: 7.6 Hz; CPR: 4.5 Hz), and also lasted longer (duration post stimulation of CC9/10: 2.8 min; CPR: 0.5 min). We also observed a difference in sensory activation. CC9/10 responded to tail nerve shock, whereas CPR responses were quite weak. In semi-intact preparations, CPR was strongly activated by food prior to consummatory feeding, and by mechanical stimulation of the tentacles. CC9/10 responses to these stimuli were weak. CC9/10 is immunoreactive to serotonin. We found that CPR is immunoreactive to *Aplysia* vesicular glutamate transporter. At 10 μM, glutamate receptor agonist, AMPA activated a relatively slow locomotor program (peak cycle frequency: 4.2/min) that decayed fast (6 min) in the maintained presence of AMPA. AMPA receptor antagonist, CNQX, blocked CPR-elicited programs (cycle frequency from 2.5/min to 0.7/min) but had little effect on CC9/10-elicited programs. Conversely, serotonin at 10 μM activated relatively fast locomotor programs (peak cycle frequency: 5.72/min) that remained active for more than 20 min in the presence of serotonin. The serotonin receptor antagonist, methysergide, slowed CC9/10-elicited programs (cycle frequency from 4.7/min to 2.6/min), but had only a slight effect on CPR-elicited programs. Overall, our data suggest that two higher-order neurons use different transmitters, glutamate and serotonin respectively, to mediate exploratory-like and avoidance locomotion.

Title: Turned on by blue: Activation of pyloric neurons by light

Authors: *S. KEDIA, E. MARDER;
Brandeis Univ., Waltham, MA

Abstract: The earliest reports of photoreceptive behavior independent of visual systems were made in invertebrate systems decades ago. The phenomenon has since been widely encountered in species from annelids to mammals. Many instances of direct photoactivation of neurons are known, and most of these are selective for blue wavelengths of light. Blue light causes depolarization and an increase in firing in neurons in the abdominal ganglion of crayfish, *Aplysia*, *Helix* and *Onchidium* but the function of this response and the underlying photoreceptive molecule remain unidentified. Entrainment of circadian rhythm is an established role of photosensitive neurons in brain structures other than the eye, as in the case of *Drosophila*, in which the light-responsive molecule has been identified as a cryptochrome and the underling molecular pathways are well described. Melanopsin is a non-visual photopigment found in vertebrates that plays a similar role in circadian regulation. We describe a blue light (λ460-500nm) dependent activation of pyloric neurons in the *Cancer borealis* stomatogastric ganglion (STG); a circuit previously not known to exhibit light sensitivity. We find a light-induced increase in oscillatory frequency of the pyloric neurons in an *in vitro* preparation of the intact circuit; measured intracellularly through sharp electrode recordings. LEDs were used for illumination of the samples. The effect is more pronounced in the absence of the neuromodulatory inputs that are necessary for maintaining the pyloric rhythm, often restoring rhythmicity to a network rendered silent by removal of neuromodulators. The activation is cell intrinsic and independent of synaptic parameters and accompanied by a small depolarization of membrane potential. There is a correlation between intensity of illumination and increase in frequency, time to peak change, and decay period. There is also an interaction with duration of exposure and these factors. Longer wavelengths of light (540-580nm; 620-650nm) do not have the same impact on neuronal activity. We identified putative cryptochrome sequences within the *C.borealis* transcriptome and have checked the expression of these via PCRs from STG samples. We have further confirmation of the expression of these as opposed to opsin family genes in the STG, based on RNAseq data. We are examining the potential contribution of this protein to the light response in STG neurons.

Title: State-dependent modulation of rhythmic motor activity by a native peptide hormone

Authors: *M. P. NUSBAUM[1], D. J. POWELL[2], E. E. MARDER[3];
[1]Dept. of Neurosci., Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA; [2]Dept. of Neurosci., [3]Volen Ctr. and Biol. Dept., Brandeis Univ., Waltham, MA

Abstract: Different circuit states often generate divergent output patterns, but they can also generate convergent patterns. For example, stimulating the modulatory projection neuron MCN1 or bath applying CabPK peptide elicit similar gastric mill (chewing) rhythms (GMRs) in the crab *Cancer borealis* stomatogastric ganglion (Saideman et al, 2007 J Neurosci). CabPK does not activate MCN1 nor is it a MCN1 cotransmitter. We are using this system to test the hypothesis that the same input to different circuit states generating convergent patterns would cause those patterns to diverge. We showed previously, in separate experiments, that the peptide hormone CCAP (1 µm) slows the MCN1-GMR by prolonging the protraction phase, while it causes the CabPK-GMR to cycle faster by shortening the retraction phase (DeLong et al, 2009 J Neurosci; Powell et al, 2017 SfN Abstr). CCAP excites the reciprocally inhibitory rhythm generator neurons LG & Int1, but it modulates the MCN1-GMR by activating the voltage-sensitive current I_{MI} in LG (Delong et al, 2009). Here we test whether CCAP-activated I_{MI} in LG also mediates its distinct effect on the CabPK-GMR.
We first confirmed our previous results by applying CCAP to both GMRs in the same preparations. As before, CCAP prolonged MCN1-GMR protraction (Control- Pro: 4.6 ± 2.2 s; Ret: 11.4 ± 3.4 s; CCAP- Pro: 6.3 ± 1.8 s, p=0.001, n=6; Ret: 8.8 ± 2 s, p=0.03; Bonferroni correction $\alpha = 0.017$), while it shortened CabPK-GMR retraction (Control- Pro: 3.7 ± 1.8 s; Ret: 9.2 ± 1.5 s; CCAP- Pro: 4 ± 1.8 s, p=0.6, n=6; Ret: 7.2 ± 1.9 s, p=0.01). We next determined if the CCAP action on the CabPK-GMR was likely to also result from its activating I_{MI} in LG by using the dynamic clamp to inject an artificial I_{MI} conductance (g_{MI}) into LG during the CabPK-GMR. This approach did mimic the CCAP influence on the CabPK-GMR, using up to a ~6-fold range of g_{MI} values (n=7/8). For example, during applied CabPK, injecting g_{MI} into LG (15 - 100 nS) shortened the retraction phase (Control: Ret, 9.2 ± 1.9 s; $g_{MI\text{-}CCAP}$: Ret, 6.6 ± 1.9 s, p=0.009, n=8), thereby reducing cycle period (Control: 13.2 ± 2.6 s, $g_{MI\text{-}CCAP}$: 11.0 ± 2.5, p=0.02, n=8). Also, injecting negative g_{MI} into LG during a CabPK-GMR while bath applying CCAP nullified the CCAP effect (Control- Ret: 9.2 ± 1.9 s; CCAP- Ret: 6.6 ± 1.7 s; CCAP plus -$g_{MI\text{-}CCAP}$- Ret: 8.7 ± 2.3 s; p=0.003, n=8), thereby returning cycle period to the Control level (Control: 13.2 ± 2.6 s; CCAP: 10.9 ± 3.7 s; CCAP plus -$g_{MI\text{-}CCAP}$: 13.5 ± 4.0 s, p=0.001, n=8). These data suggest that the peptide hormone CCAP is using the same mechanism, selective modulation of one of its target neurons, to differently modify the output of the MCN1- and CabPK-GMR circuit states.

Title: Network neuron recruitment and coordination via distinct modulatory actions

Authors: *S.-R. H. FAHOUM, D. M. BLITZ;
Miami Univ., Oxford, OH

Abstract: Network reconfiguration can include neuronal switching (i.e. changes in neuron participation between networks), in which changes in synaptic strength can recruit a neuron into another network (Dickinson, 1995 Curr Opin Neurobiol). Here, we propose that modulation of intrinsic properties can also underlie neuronal switching, with changes in synaptic strength enabling coordination between the switching and network neurons. We are studying switching mechanisms in the crab *Cancer borealis* stomatogastric nervous system (STNS), which contains two small well-defined networks (gastric mill [chewing, 10 s cycle period]; pyloric [food filtering, 1 s cycle period]) and identified modulatory inputs. Modulatory projection neuron MCN5 activity decreases pyloric cycle period, inhibits pyloric neuron LP, activates the gastric mill network, and switches LPG neuron participation from pyloric-only to dual pyloric/gastric mill (Norris et al, 1996 J Neurophysiol; Blitz et al, 2019 J Neurophysiol). To study this LPG pattern switch, we model MCN5 activity by bath-applying its peptide co-transmitter Gly^1-SIFamide (SIF; $5x10^{-6}$ M) and photoinactivating the LP neuron (Fahoum & Blitz, 2018 SfN Abstr). Gastric mill neurons are not necessary for LPG to switch to pyloric/gastric mill bursting (Fahoum & Blitz, 2018), but strengthened synaptic input from gastric mill neurons to LPG may underlie its coordination with this network. We identified inhibitory synaptic actions from gastric mill neurons IC, DG, & LG onto LPG in SIF, not evident in control saline (IC:LPG, n=7/7; DG:LPG, n=5/7; LG:LPG, n=5/6), which may enable them to regulate LPG gastric mill activity. Indeed, LG and IC regulated LPG's gastric mill-timed burst period ($p<0.05$, n=7-8) and burst duration (LG: $p<0.05$, n=8). LPG maintains coordination with the pyloric pacemaker neurons likely due to maintained electrical coupling (Blitz et al, 2019). This coupling is not necessary for the LPG gastric mill-timed bursting, as it continued when the pyloric rhythm was eliminated (n=9), but it may underlie the fact that changing pyloric cycle period in SIF evoked a negative correlation between the pyloric and gastric mill cycle periods (r^2=-0.89, $p<0.05$, n=7). Thus, although the LPG neuron switch from single (pyloric) to dual (pyloric/gastric mill) bursting appears to occur via intrinsic mechanisms (Fahoum & Blitz, 2018), the LPG bursting pattern is regulated by synaptic inputs from gastric mill and pyloric network neurons. Thus, separate modulatory actions on intrinsic and synaptic properties can enable a neuron to exhibit a dual network bursting pattern and underlie its intra- and inter-network coordination.

Title: Frequency-dependent gating of neuromodulator-activated currents

Authors: *A. C. SCHNEIDER, J. GOLOWASCH, D. BUCHER, F. NADIM;
Federated Dept. of Biol. Sciences, Inst. for Brain and Neurosci. Res. (IBNR), NJIT & Rutgers U-Newark, Newark, NJ

Abstract: Neural circuits produce distinct activity patterns, depending on behavioral needs. This flexibility is provided by neuromodulators that reshape the output of neural circuits. The effect of neuromodulators is often state-dependent, so that it depends on the circuit activity pattern, but the mechanisms and function of such state-dependence are not well understood.
We explored the state-dependent actions of modulation of network oscillations using the pyloric circuit (*freq*.: 0.5 - 2 Hz) of the crab stomatogastric ganglion, which is influenced by multiple neuromodulators. Many peptide modulators enhance the circuit activity, but only when the network frequency is below some threshold value. These peptides activate a single ionic current (the modulator activated inward current, I_{MI}). Because I_{MI} is fast and non-inactivating, its levels do not depend on the membrane potential frequency, indicating other potential mechanisms for frequency dependence.
We used the identified lateral pyloric (LP) neuron to directly measure the frequency dependence of currents activated by proctolin. Because cycle frequency affects the depolarization and hyperpolarization rates during bursting activity, we examined the dependence of the proctolin-activated current on these rates. We voltage-clamped LP with symmetric triangular ramp or ramp-and-hold (ramp slope ±100 to 400 mV/s), and found that 1 µM bath-applied proctolin activated two kinetically-distinct ionic currents: the previously characterized I_{MI}, which was activated by both positive and negative ramps, and whose amplitude did not depend on ramp slope, as well as an inactivating current (here called I_{MI2}), which was only activated by positive ramps and whose amplitude increased with ramp slope. We also voltage clamped the same neuron with a pre-recorded (realistic) waveform of the LP bursting activity, applied periodically at different frequencies (0.5-2 Hz). On average, the total steady-state current activated by proctolin did not change with the realistic waveform frequency, although frequency-dependence was present in some individual experiments.
A model fit of the ramp currents showed that the frequency-independence of the proctolin-activated current by realistic waveforms is because they range only from ~-60 to -20 mV, well

below voltages where I_{MI2} is activated at any significant level. Increasing the amplitude of the realistic waveform or shifting the activation curve of I_{MI2} to the left exposed a frequency-dependent effect in the model. Together, these results demonstrate a potential mechanism for a frequency-dependent action of proctolin. Experiments are ongoing to test these model predictions.

Title: Does co-modulation produce consistent circuit activity?

Authors: *E. CRONIN, A. C. SCHNEIDER, F. NADIM, D. BUCHER;
Federated Dept. of Biol. Sci., New Jersey Inst. of Technol. & Rutgers University-Newark, Newark, NJ

Abstract: Neural circuits are modified by many neuromodulators. Neuromodulation is typically studied with the expectation that the modulator configures the circuit to produce a specific output. In most systems, however, many modulators have overlapping and often convergent effects. Additionally, neural circuits are always subject to actions of multiple modulators at any time. Yet, the behavioral needs of the animal require that circuits produce consistent outputs. If multiple neuromodulators have convergent effects with the same sign, but also diverge on their targets, it is reasonable to assume that co-modulation results in a similar circuit output, even if, in each case, the circuit is not exposed to the same combination of neuromodulators. We therefore propose that convergent co-modulation increases the inter-individual consistency of circuit output.
We examined this hypothesis in the triphasic oscillatory pyloric circuit of the crab stomatogastric ganglion (STG). The STG is modulated by an astounding number of neurotransmitters and hormones. In this system, multiple peptide and muscarinic modulators converge to activate a single ionic current and enhance synaptic interactions. Yet, these modulators target distinct subsets of neurons and have different dose-dependent effects. In our protocol, we used a total of five peptides and a muscarinic agonist. We bath applied the modulators in singlets, doublets or triplets (Cases 1 to 3). In each case, the modulator(s) was applied at three concentrations, low (1 nM), medium (30 nM) and high (1 uM).
We compared circuit activity by comparing these circuit attributes: cycle period, burst onset and

end latencies (and therefore phase=latency/period) for the three pyloric phases, and #spikes/burst (equiv., spike frequency). We made a quantitative assessment of these 8 circuit attributes within each Case. We also examined the (state-)dependence of inter-individual consistency on frequency of the unmodulated circuit. Our expectation is that, from Case 1 to 3, inter-individual consistency of most circuit attributes increases. In addition to addressing the main hypothesis, these data also allow a direct comparison of the effects of individual modulators on circuit output, which has not been previously published.

Title: Proprioceptive feedback and its modulation in a crustacean nervous system

Authors: D. GRININGER, ***J. T. BIRMINGHAM**;
Santa Clara Univ., Santa Clara, CA

Abstract: The gastropyloric receptor (GPR) neurons in the stomatogastric nervous system of the crab *Cancer borealis* respond to both muscle contraction and passive muscle stretch (Katz et al., 1989). In this exploratory investigation we have found that GPR1 and GPR2 spiking can be measured extracellularly on both the lateral ventricular nerve (*lvn*) and dorsal ventricular nerve (*dvn*). In particular, we have observed that GPR1 spikes are always larger than GPR2 spikes on the *dvn* (n=15), that both types of spikes can be observed on the *dvn* in the presence of a pyloric rhythm, that nerve-evoked contraction of the gastric mill 4 (gm4) muscle elicits many more GPR2 than GPR1 spikes (n=4), that GPR1 spiking can be modulated by some of the same substances (serotonin (n=5), GABA (n=5) and TNRNFLRFamide (n=5)) that modulate GPR2 spiking (Birmingham et al., 1999), and that simultaneous neuromodulation of gm4 muscle contraction and GPR2 response has implications for how muscle movements shape motor patterns in this system. The quality of the recordings and the possibility of improving them suggest that in vivo recordings of GPR spiking may be possible.

Title: Differential neuropeptide modulation of cell types in the lobster cardiac ganglion underlies alteration of different characteristics of patterned neuronal output

Authors: E. R. OLEISKY[1], J. J. HULL[2], A. E. CHRISTIE[3], *P. S. DICKINSON[1];
[1]Neurosci., Bowdoin Col., Brunswick, ME; [2]Arid Land Agr. Res. Ctr., USDA, Maricopa, AZ;
[3]Békésy Lab. of Neurobiology, PBRC, Univ. of Hawaii, Honolulu, HI

Abstract: Central pattern generators (CPGs) are simple neural networks that generate rhythmic motor patterns. Flexibility in CPG output can be achieved via the actions of neuromodulators. Peptides, the largest class of neuromodulators, are integral for communication within neuronal systems, as well as for altering outputs of individual neurons and neuronal networks. The cardiac neuromuscular system of the American lobster, *Homarus americanus*, is a model CPG system for understanding the modulatory control of rhythmic motor patterns. The CPG, the cardiac ganglion (CG), consists of nine neurons: five large motor neurons and four smaller pacemaker neurons. The electrical and chemical coupling of these neurons is complex. Here, we show that the pacemaker and motor neurons are capable of establishing independent bursting patterns when physically decoupled by a ligature. Myosuppressin (pQDLDHVFLRFamide), a well-characterized crustacean neuropeptide, has been shown to act both centrally on the CG and peripherally on the cardiac muscle. In this study, we asked if myosuppressin was capable of modulating the decoupled pacemaker and motor neurons of the CG, and how their differential modulation might underlie the role that these neurons play in the motor pattern generated by the CPG. In the intact CG, application of 10^{-6} M myosuppressin elicited a significant decrease in burst frequency and a significant increase in burst duration; however, at 10^{-7} M, only a significant decrease in burst frequency was observed. In the ligatured CG, myosuppressin elicited a significant decrease in burst frequency in the motor neurons at 10^{-6} and 10^{-7} M, but in the pacemaker neurons, frequency decreased only at 10^{-6} M. Moreover, myosuppressin elicited a significant increase in burst duration in the isolated pacemaker neurons only at 10^{-6} M; even at

this concentration, myosuppressin failed to change the duration of bursts in the motor neurons. These data suggest (1) that the threshold for effects of myosuppressin differs between the motor and pacemaker neurons, and (2) that motor neurons are more important in determining the burst frequency of the CG, whereas the pacemaker neurons have a greater impact on the burst duration of the ganglionic output. The distribution of five putative myosuppressin receptors within the CG was simultaneously investigated. Transcriptomic analyses previously predicted five myosuppressin receptors (MSR1-5); PCR profiling revealed expression of only three transcripts (MSR2, MSR3, and MSR4) in the two neuron sets. Differential distribution of these receptors may contribute to the distinct physiological responses of the pacemaker and motor neurons to myosuppressin.

Title: Lateral transverse muscles mf21-23 in *Drosophila* are targets of crustacean cardioactive peptide (CCAP)

Authors: *M. G. HOUPERT, A. J. BERNDT, A. ELLIOTT, B. WHITE;
NIMH Section On Neural Function, Bethesda, MD

Abstract: Neuromodulators are important determinants of behavior, but they are also often released into the blood as neurohormones to act on non-neural tissues. Many examples exist of neurohormones acting on skeletal muscles, but in most cases the role of this type of modulation on behavior is unknown. A behavior in which neuromodulators play a critical function is the pupal ecdysis sequence of *Drosophila melanogaster*. The pupal ecdysis sequence consists of three distinct phases, the second of which (Phase II) requires signaling by CCAP, which has previously been shown to act on a subset of motor neurons. Using a driver (CCAP-R-Gal4) that targets cells that express the CCAP receptor (CCAP-R), we find that in addition to a subset of motor neurons, three lateral transverse muscles, mf21-23, are also targets of CCAP. CCAP-containing type III terminals are found on the neighboring longitudinal muscle mf12, which traverses muscles mf21-23 and could be a source of CCAP acting on mf21-23 via the hemolymph. Bath administration of CCAP to pupal fillets shows that CCAP specifically activates mf21-23 as measured by Ca++ imaging using GcaMP6s. The larval musculature

similarly expresses CCAP-R in mf21-23 and responds to CCAP, however the pattern of activation differs from that seen in the pupa. The activation appears to depend on extracellular calcium, as bath administration of CCAP to pupal fillets in solution lacking Ca++ failed to activate mf21-23. Monitoring muscle contraction *in vivo* using a UAS-GcaMP6s reporter suggests that, at Phase II, the known time of CCAP release, mf21-23 contract for a longer duration than in other phases. Taken together, our data suggest a role for CCAP in modulating the ecdysis behavioral sequence at the level of muscle as well as motor neurons.

Title: Sites of CCAP neuromodulator activity in the pupal ecdysis behavioral sequence

Authors: *A. J. BERNDT, A. D. ELLIOTT, M. G. HOUPERT, B. H. WHITE;
NIH/NIMH, Bethesda, MD

Abstract: Neuromodulators play important roles in regulating the activity of brain circuits, often to promote changes in behavior. To better understand how they do so, we have focused on a neuromodulator-governed behavioral sequence performed by pupal fruit flies called the “pupal ecdysis sequence.” This sequence consists of three behavioral phases, the last two of which are prevented by silencing a subset of the neurons that express the neuromodulator Crustacean Cardioactive Peptide (CCAP). We have previously shown that the CCAP receptor (CCAP-R) is expressed in a large population of motor neurons, indicating a role for CCAP in neuromuscular control. However, the identities of the CCAP-R-expressing motor neurons and their muscle targets have remained unknown, in part due to the limited characterization of the pupal musculature, which is reduced relative to the well-characterized larval musculature and its stereotyped pattern of innervation across repeating hemisegments. During pupal development many larval muscles undergo histolysis, and we have now shown that at the time of pupal ecdysis, a maximum of 19 muscles remain per hemisegment. However, from anterior to posterior segments, individual muscles stop repeating (mfs 4, 5, 12, 30). Approximately half of all muscles (n=9) are consistently innervated by CCAP-R-expressing motor neurons, as determined by co-expression of CCAP-R and the motor neuron-specific gene VGlut. Muscles in this set were either dorsal (mfs 1-3, 9, 10), or ventral (mfs 15, 28, 13, 30), but not lateral. The remaining set of muscles (i.e. mfs 4, 5, 8, 12, 21-26), were innervated by motor neurons expressing VGlut only

and contained all lateral muscles. Interestingly, we find that although the principal lateral muscles of the pupal bodywall were not innervated by CCAP-R motor neurons, mf21-23 themselves do express CCAP-R, suggesting that CCAP modulates the pupal ecdysis sequence at both the level of identified motor neurons and muscles. To facilitate future analysis of neuromuscular innervation patterns, we are also implementing machine learning algorithms to automate identification of synapses based on their bouton characteristics, beginning with a K-Nearest Neighbors approach. Our results lay the groundwork for future studies to determine exactly how activity in the neuromuscular system is altered by manipulations of CCAP signaling during pupal ecdysis.

Title: Dynamics of the Na^+/K^+ pump and dopamine within a locomotor central pattern generator

Authors: ***A. VARGAS**[1], G. S. CYMBALYUK[2];
[1]Neurosci. Inst., [2]The Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: CPGs are oscillatory neuronal circuits controlling rhythmic movements across vertebrates and invertebrates(1). The Na/K pump contributes to the dynamics of bursting activity across several CPGs in various species such as leech, tadpole, and mouse (2,3,4,5,6). Some rhythms, like locomotion in vertebrates and heartbeat in leeches, must be continually regulated for an animal to meet environmental and behavioral demands(3). In vertebrate CPGs, dopamine has been shown to induce a range of subtle to pronounced effects on diverse motor rhythms. Dopamine neuromodulation affects Na+/K+ pump, GIRK2-, A-, and h-currents through D1 and D2 receptors (7,8); this contributes to stabilization of CPG rhythmic activity. We developed a half-center oscillator (HCO) model of a spinal locomotor CPG, which comprises of four populations, two inhibitory and two excitatory. The neuronal populations are intrinsically bursting supported by a persistent sodium current within a physiologically relevant parameter space. We investigated activity regimes of endogenously bursting neurons either in isolation or incorporated into a HCO. In a range of high modulation level we found stable periodic bursting, while within some range of low dopamine modulation levels, pronounced intermittent intrinsic patterns. We investigated a reduced model with the Na+/K+ pump, h-current, and persistent

sodium only. The dynamics within the reduced model qualitatively represented those of the full scale single cell and network. We also investigated the hypothesis that dopamine affects the network through activation of inward rectifying potassium currents, IGIRK and IA, and opposing changes of h-current all while interacting with pump current. The reduction in modulatory level of dopamine in the spinal locomotor CPG causes the model to transition from normal periodic bursting into intermittent bursting and then to silence. Robust rhythmic output within our locomotor CPG model is a consequence of the co-modulation of the Na/K pumpalong with GIRK2-, A-, and h-currents.

Title: Bursting mechanisms based on interplay of the Na/K pump and persistent sodium current

Authors: *G. S. CYMBALYUK[1], R. ERAZO[1], A. VARGAS[1], C. ERXLEBEN[2], A. WENNING[2], R. L. CALABRESE[2];

Abstract: To maintain vital rhythmic functions like breathing and leech heart beating, specialized oscillatory neural circuits, Central Pattern Generators (CPGs), produce functional bursting activity appropriate to variety of physiological conditions. To ensure such robustness of operation different subsets of inward and outward currents can come into action and dominate the dynamics under different parametric regimes. The Na/K pump partakes in rhythm generation and is targeted by neuromodulators in the leech heartbeat CPG [1, 2]. We have investigated the interplay of the Na/K pump current (I_{Pump}) and h-current in rhythm generation by this CPG [3]. In the dynamics of this CPG, persistent Na current (I_P), which does not inactivate, plays an influential role in supporting spiking phase of bursting activity. We suggest that interaction of I_P and I_{Pump} could produce a flexible mechanism supporting bursting. We apply modeling and experimental hybrid system approach to investigate dynamical properties of this mechanism. We developed a hybrid system using the biophysical model from Kueh et al. 2016 [3]. In hybrid-system experiments, we investigate effects of upregulation or downregulation of I_P and I_{Pump} on bursting activity in single leech heart interneurons neurons that pace the leech heartbeat CPG. We show that interaction of I_P and I_{pump} constitutes a mechanism, which is sufficient to support

endogenous bursting activity. Interestingly, this mechanism can reinstate robust bursting regime in heart interneurons, which when recorded intracellularly have increased leak and would otherwise fire tonically. In contrast to typical role of I_P in bursting, according to this mechanism the increase of the maximal conductance of I_P can lead to decrease of the burst duration and increase of the interburst interval. We also developed a simple 2D model describing dynamics of the membrane potential and intracellular Na^+ concentration through instantaneous I_P and I_{Pump} and investigated how basic kinematic parameters governing dynamics of I_P and I_{pump} affect responses of the system to up- and down regulation of these currents.

Title: Bimodal modulation of short-term motor memory via dynamic sodium pumps in a vertebrate spinal cord

Authors: L. HACHOUMI, R. RENSNER, C. RICHMOND, *K. T. SILLAR;
Univ. St Andrews, St Andrews, United Kingdom

Abstract: Activity-dependent Na^+/K^+-pumps play an evolutionarily conserved role in regulating locomotor network output (Picton *et al.* 2017). In the spinal cord of *Xenopus laevis* frog tadpoles, recruitment of these "dynamic" Na^+/K^+ pumps produces an ultra-slow afterhyperpolarisation (usAHP) following intense locomotor activity (Zhang and Sillar 2012). The usAHP lasts ~1 minute and facilitates a short-term motor memory (STMM) mechanism that attenuates the intensity and frequency of subsequent bouts of locomotor activity. In this study, whole cell current clamp recordings of spinal neurons and ventral root recordings were performed to investigate modulation of dynamic Na^+/K^+ pumps and its effects on fictive motor activity. Our recordings show that two established modulators of locomotor activity in *Xenopus* tadpoles, serotonin (5-HT) and nitric oxide (NO), differentially regulate the usAHP in spinal neurons.

Perfusion of 5-HT (1.5 µM) alone had no discernible effect on the amplitude or duration of the usAHP. However, selective activation of 5-HT7 receptors with 30 µM AS-19 significantly augmented the usAHP an effect that was reversed by the 5-HT7 receptor antagonist, 20 µM SB-269970. Conversely, 5-HT2A receptor activation with 30 µM 25CN-NBOH or inhibition with 50 µM MDL 11,939 significantly reduced and increased the usAHP, respectively. The NO donor, DEA-NO (100 - 200 µM), suppressed the usAHP, but this effect was negated following exposure to the NO scavenger, PTIO (100 µM). Exclusively inhibiting 5-HT7/2A receptors or scavenging NO significantly altered usAHP properties thus demonstrating endogenous roles for 5-HT and NO in regulating the usAHP. Next, the influence of these neuromodulators on STMM was assessed *via* ventral root recordings. 5-HT7 receptor activation following 5-HT2A receptor inhibition strengthened the relationship between swim episode duration and inter-swim interval, whilst NO consistently weakened this relationship. Furthermore, in preparations where STMM was weak in control conditions, removing the inhibitory effects of NO with the scavenger PTIO or 5-HT2A receptors with the antagonist MDL 11,939 reinforced STMM. This suggests that the STMM mechanism can be controlled by endogenous 5-HT and NO signalling within the spinal cord. In conclusion, this investigation demonstrates that usAHP dynamics can be differentially modulated by 5-HT receptors (by up to ± 15 mV) as well as by NO (down to 0 mV) and that this consequently alters the strength of the STMM mechanism in tadpoles. Title: The Kv7.2 (KCNQ2)-mediated M-current tunes the locomotor rhythm

Authors: *J. VERNEUIL[1], C. BROCARD[1], L. VILLARD[2], J. PEYRONNET-ROUX[1], F. BROCARD[1];
[1]Inst. de Neurosciences de la Timone, CNRS UMR 7289, Marseille, France; [2]Marseille Med. Genet. Center, INSERM U1251, Marseille, France

Abstract: The locomotion is a complex behavior consisting in a coordinated sequence of muscle activation promoted by a Central Pattern Generator (CPG). To gain insight into the function of the CPG, it is important to characterize individual ion channels in locomotor-related neurons and determine their roles in generating rhythmic and coordinated movements during locomotion. Our previous studies for the biophysical basis for rhythmogenesis has identified the persistent sodium current (I_{NaP}) as contributing to rhythmic bursting in locomotor-related interneurons. The

immediate conclusion was that the locomotor rhythm generation could emerge from excitatory circuits incorporating I_{NaP} as a "pacemaker" current. In a "push-pull" organization of the spinal locomotor network, the present study investigates the role of a persistent potassium current mediated by Kv7.2 (KCNQ2)-channels, also called M-current (I_M), into the operation of the locomotor CPG. As a first result, *in vivo* intraperitoneal injection of Kv7.2 channel blocker (XE991) lengthens the step duration of juvenile rats whereas the opener (Retigabine) shortens it. These data are consistent with the drugs effects on the NMA-induced fictive locomotor rhythm recorded from the *in vitro* isolated spinal cord preparations of neonatal rats. The early postnatal expression of Kv7.2 channels in the spinal locomotor network has been confirmed with confocal imaging and electrophysiological recordings. We demonstrated that Kv7.2 channels expressed in the axon initial segment contributes to oscillatory processing in the locomotor CPG. The Kv7.2 pharmacological blockade, as well as the $KCNQ2^{T274M/+}$ mutation, leads to an increase of the duration of (1) autorhythmic activities in interneurones and (2) NMA-induced voltage oscillations in motoneurones. Opposite effects were obtained with KCNQ enhancers. In conclusion, our study provides evidence that the locomotor rhythm may be modulated by balancing the relative contribution of I_M and I_{Nap}.

Title: Data driven modeling of the rhythmogenic potential of spinal Shox2 neurons

Authors: *N. HA, N. A. SHEVTSOVA, I. A. RYBAK, K. J. DOUGHERTY;
Dept. of Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The mammalian spinal cord contains neuronal circuits that can generate the basic locomotor rhythm in the absence of supraspinal and afferent inputs. These spinal circuits include the rhythm-generating kernel consisting of neurons capable of generating the populational rhythmic activity. The mechanisms underlying spinal rhythmogenesis are still unknown, but intrinsic properties and interconnectivity of excitatory interneurons are believed to play a significant role. Though no single genetically identified neuron type has been shown to be solely responsible for rhythm generation, a prominent candidate to participate in locomotor

rhythmogenesis is a subset of Shox2 neurons. Experimental studies of the cellular basis for rhythmic bursting in the Shox2 neurons in neonatal mice have shown evidence for expression of T-type Ca^{2+}, hyperpolarization-activated (I_h), A-type K^+, and persistent inward currents in subsets of these neurons. A small subset of these neurons continues to display rhythmic activity in the presence of NMDA and serotonin following blockade of AMPA receptors. Further, bidirectional gap junctional coupling was detected within a distinct subset of Shox2 neurons, providing a potential mechanism for synchronization of populational activity of Shox2 neurons which may be implicated in locomotor rhythmogenesis. To theoretically investigate a potential role of intrinsic properties and connectivity of Shox2 neurons in generation of rhythmic activity, we developed a series of models of single Shox2 cells incorporating intrinsic currents identified experimentally and a population model of these cells sparsely connected by electrical synapses. We have found that the rhythmic activity emerges in a coupled population of modelled cells, even if no single cell demonstrates the intrinsic bursting. We investigated potential roles of different ionic currents expressed in single cells in population bursting and the dependence of the shape and frequency of population bursts on the probability and weights of mutual connections in the network. The model proposes a mechanistic explanation for emergence of a synchronized rhythmic activity in a subset of Shox2 neurons and provides insights into the mechanisms of the locomotor rhythm generation.

Title: Spinal cord injury-induced plasticity of Shox2 interneurons following treadmill training and epidural stimulation in mouse

Authors: *D. GARCIA-RAMIREZ, N. T. HA, L. YAO, K. A. SCHMIDT, S. F. GISZTER, K. J. DOUGHERTY;

Abstract: The neuronal circuitry that generates locomotion is located in the thoracolumbar spinal cord. Although the locomotor circuitry is able to produce the rhythm and the patterning of locomotion without descending inputs, these are necessary to initiate and adapt the locomotion. Most spinal cord injuries (SCI) are above level of the spinal locomotor circuitry but a disruption

in the descending control results in cellular and network plasticity. Current clinical therapies to recover motor control after SCI include treadmill training and epidural stimulation (ES), which access the locomotor circuitry by targeting proprioceptive afferents. However, the state of the spinal circuits targeted after SCI and further plasticity following rehabilitation is poorly understood. Interneurons (INs) expressing the transcription factor Shox2 are part of the circuitry that generates the locomotor rhythm and patterning and should be a prime access point for these treatments. Previously, we performed whole cell patch clamp recordings targeting Shox2 INs in lumbar spinal slices from uninjured adult Shox2::Cre;Rosa26-lsl-tdTomato mice and found that Shox2 INs are modulated by serotonin (5-HT) producing inhibitory and excitatory actions depending the concentration. In slices from mice 6 weeks after complete thoracic spinal transection, 5-HT only increased the excitability of Shox2 INs. However, in mice in which ES wires were implanted at lumbar spinal level L2 and received treadmill training and ES after SCI for 5 weeks, 5-HT hyperpolarized Shox2 INs. The aim of this study is to identify the contributions of treadmill training and ES independently on the hyperpolarizing effects of 5-HT on Shox2 INs. We found similar inhibitory modulatory effects of 5-HT in the mice that received ES with no treadmill training, demonstrating that treadmill training is not necessary for the 5-HT receptor plasticity in Shox2 INs that is observed with treadmill training and ES. Our results suggest that ES alone can cause changes in the expression of 5-HT receptors on locomotor-related neurons after SCI, altering pharmacological targets for the improvement of ES efficacy.

Title: A spinal CPG controller that is compatible with neuromodulation and homeostasis

Authors: A. I. RAMÍREZ-HINCAPIÉ[1], T. O'LEARY[2], *A. FRANCI[3];
[1]Univ. Nacional Autónoma De México, Ciudad De Mexico, Mexico; [2]Univ. of Cambridge, Cambridge, United Kingdom; [3]Dep. Matematicas, Facultad De Ciencias, UNAM, Mexico City, Mexico

Abstract: Many periodic automatic movements such as breathing, chewing, swimming and walking are controlled outside the brain by autonomous neural circuits called Central Pattern

Generators (CPG). The study of crustacean CPGs for chewing and swallowing revealed that the activation of specific rhythmic patterns and the switch between different patterns is mediated by the modulation of intrinsic and synaptic neural properties [1]. This modulatory signal must cope with ongoing homeostatic control of cellular activity [2]. Spinal CPGs for quadruped locomotion exhibit a higher level of complexity, both in the circuit composition and in the number and types of possible rhythmic patterns, as compared to their invertebrate analogs. Genetic knockdown of specific neural types provided some insights on how quadruped CPGs can switch between different activity pattern [3] but how this control is physiologically achieved remains largely unknown.
We propose a general CPG control mechanism that uses neuromodulation of intrinsic properties as control input and that is compatible with homeostatic regulation. We suggest that inhibitory interneuron modulation can control the phase relation between pairs of excitatory neurons without perturbing the homeostatic set point. The proposed control mechanism is fast enough to be compatible with quadruped motor behavior control and does not require synaptic plasticity. Mathematical modeling provided deep insights into the structure of quadruped CPG circuits, in particular, in terms of their symmetries [4]. In this framework, quadruped gaits and the transitions between them arise as symmetry breaking of the underlying CPG circuit. However, the physiological mechanism underlying gait transition remains obscure. Interneuron neuromodulation provides such physiological and homeostasis-compatible control mechanism. Using a computational model, we show how the same connectome can produce all six primary gaits through Ca-mediated neuromodulation of the inhibitory interneurons in an eight coupled-cell system.

Abstract: Fictive scratching (FS) patterns were evaluated in brain-cortex-ablated cats (BCAC), in spinal cats (SC) and in midcolicular-decerebrated cats (MCC) to disect pathways comprising the scratching patterns. Aditionally, in MCC the effects of electrical stimulation of cutaneous and extensor nerves were also studied. In BCAC, the scratching aiming phase (AP) initiates with the activation of flexor or extensor motoneurons. The application of serotonin during the AP produced simultaneous extensor and flexor bursts. Furthermore, WAY 100635 (5HT1A receptors antagonist) produced a very brief burst in the flexor TA (tibialis anterior) nerve followed by a reduction in its electroneurogram (ENG), whilst the soleus (SOL) ENG remained silent. In SC, rhythmic phase (RF) activity in SOL motoneurons was recorded. Serotin or WAY produced FS bouts with variability in flexor-extensor activity during the AP. In MCC, FS began with flexor activity, electrical stimulation of either deep peroneous (DP) or superficial peroneous (SP) nerves increased the duration of the TA electroneurogram. DP electrical stimulation during a TA bursts produced a large-amplitude and prolonged TA burst. MG stretching or electrical stimulation produced a reduction in the TA electroneurogram and an initial MG extensor bursts. MG and TA monosynaptic reflexes wax and wane during the scratch cycle. Present experiments support an asymetrical model for the scratching AP of the BCAC and the symetrical model in MCC. Serotonin and WAY produce several effects on FS pattern, assembling CPG modules to use disponible segregated motoneurons.

Title: The effects of T-type antagonists on the genesis of motor activity in the neonatal mouse spinal cord

Authors: *A. P. LOGNON[1], S. A. SHARPLES[1], P. J. WHELAN[2];
[1]Neurosci., [2]Comparative Biol. and Exptl. Med., Univ. of Calgary, Calgary, AB, Canada

Abstract: The spinal cord is important for the generation of locomotion as it contains sufficient neuronal circuitry to drive various forms of rhythmic and non-rhythmic motoneuronal output. T-type calcium channels have been previously described as important electrophysiological modulators of central pattern generators used to produce rhythmic spinal motor output. Studies have described the role of T-type channels in the generation of locomotor-like activity from the neonatal spinal cord. Many studies that investigate the role of T-type channels in neuronal function make use of the antagonist nickel. Here we investigate the effects of nickel in comparison to other T-type channel antagonists on the extracellularly recorded motor root output from the neonatal isolated spinal cord. Similar to previous findings, we demonstrate that nickel reduces pharmacologically evoked locomotor-like rhythmic bursting frequency. Furthermore, the burst amplitude increases and the bursting pattern changes from alternating to synchronous. In contrast, more selective T-type antagonists did not replicate nickel's effects on locomotor-like bursting. To further probe the differences between T-type antagonists, the more selective antagonists along with nickel were applied to a spontaneously active isolated cord. The results show a difference between the effects of nickel versus other T-type antagonists. Nickel depolarizes and increases bursting amplitude at T-type selective concentrations, which is not seen with the application of selective T-type channel antagonists. The effects of nickel persist in the presence of fast synaptic blockers, suggesting effects on either motoneurons themselves or via slow-synaptic modes of transmission. Although the mechanism of action for nickel has not been elucidated, we demonstrate inconsistencies in the actions of T-type antagonists on the motor rhythm produced by the neonatal spinal cord.

Abstract: The prevalence and limited treatments for anxiety disorders demand understanding of innate neural mechanisms promoting resilience. Endogenous NPY is anxiolytic, buffering stress and promoting resilience by decreasing excitatory output of the basolateral amygdala (BLA) through modulating the H current, carried by the hyperpolarization-activated cyclic nucleotide-gated channel subunit 1 (HCN1). We have shown that repeated application of NPY into the BLA induces a lasting behavioral stress resilience associated with the down-regulation of HCN1 expression. While these studies were conducted in male rats, the question remains whether NPY exerts similar actions in females. To test this, female rats received indwelling bilateral cannula in the BLA. After recovery, the animals received injections of NPY (10 pmol/100 nl) daily for 5 consecutive days. Social interaction (SI) was assessed at 1, 7, 14 and 28d post-injection and compared with a pre-injection baseline control. Stress resilience was measured with SI in animals immediately following a single 30 min restraint stress exposure. Brains were collected for determination of HCN1 and cFos expression. Contrary to the robust effects of NPY in males, in female rats NPY did not increase SI at the timepoints measured, nor prevent the effect of restraint stress-induced decreases in SI; no changes in HCN1 protein expression were observed. Using a model of reproductive experience (RE), known to buffer stress responsiveness, we tested whether primiparous (Prim) females experiencing the rearing of one litter would have increased resilience that might engage similar mechanisms as defined in males with NPY treatment. Female rats were mated; after delivery pups were culled or cross-fostered to 10 pups/litter, then weaned on postpartum (PP) day 21. SI was determined in Prim and age-matched nulliparous (Nul) females on PP d14 and 28 along with a single bout of restraint stress to test resilience. SI was not increased in Prim females compared to Nul controls. Restraint stress significantly decreased SI in Nul females, but SI after restraint in Prim females did not differ from baseline control. Determination of brain HCN1 and cFos expression in these animals is ongoing. We have identified a major sex difference in responses to intra-BLA NPY injections, and a model of physiologically inducible stress resilience which can be useful in determining brain circuity important for preventing stress-related disorders.

Title: Sex differences in the contribution of projections from the basolateral amygdala to lateral bed nucleus of the stria terminalis in anxiety-like behaviors

Authors: *J. VANTREASE[1], B. AVONTS[1], J. URBAN[2], J. ROSENKRANZ[1];
[1]Cell. and Mol. Pharmacol., [2]Physiol. & Biophysics, Rosalind Franklin Univ., North Chicago, IL

Abstract: Men and women display different symptomology in anxiety disorders and respond differently to treatments, yet our understanding of the sex differences in the neurobiology related to these disorders is limited. The basolateral amygdala (BLA) is a critical component of anxiety neurocircuitry, is hyperactive in patients with anxiety disorders and exhibits sex differences in activation during specific affective tasks. Prior studies have demonstrated that sex differences in BLA neuronal activity exist; however it is not known whether specific subsets of BLA neurons exhibit this disparity. BLA outputs to the lateral bed nucleus stria terminalis (BSTL) play a critical role in the expression of sustained fear and general anxiety-like responses with female rats expressing less general anxiety-like behaviors compared to males. Therefore, the purpose of this study was to determine if BLA neurons projecting to BSTL (BLA-BSTL) in female rats are less active than in males. We utilized in vivo single-unit electrophysiological recordings to record antidromically identified BLA-BSTL neurons in anesthetized male and female Sprague Dawley rats. We observed that spontaneously firing BLA-BSTL neurons in females have lower firing frequencies compared to males, despite females having greater spontaneous BLA neuronal activity overall. To determine if this lower BLA-BSTL neuronal activity in females leads to decreased general anxiety-like behavior, we utilized a combinatorial chemogenic approach to selectively inhibit BLA-BSTL neurons during specific affective tasks using CAV2-Cre injections into the BSTL followed by bilateral Cre-dependent designer receptor exclusively activated by designer drug (DREADD) injections into the BLA; then assessed anxiety-like behavior and social interaction (SI) behavior in an open field 30 min after saline or CNO injections. Preliminary results suggest that inhibition of BLA-BSTL neurons during the open field task increased center exploration in males, but reduced time spent in center in females. Moreover, BLA-BSTL inhibition during SI resulted in a slight increase in SI time in females, but an even greater augmentation in SI was seen in males. Together these data suggest that the sex differences observed in BLA-BSTL neuronal activity may also mediate different anxiety-like behaviors in male and female rats. These results may help explain the apparent disconnect

between overall sex differences in BLA neuronal activity and its relation to particular anxiety-like behaviors.

Title: Oxytocin modulates the functional neuronal network in the oval nucleus of the bed nucleus of the stria terminalis (BNSTov) in male adult rats

Authors: *W. FRANCESCONI, F. BERTON, J. DABROWSKA;
Dept. of Cell. and Mol. Pharmacol., Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL

Abstract: Oxytocin (OT) plays a key role in the modulation of social and anxiety-like behaviors. Previous studies demonstrated that OT neurons from the hypothalamus project to the oval nucleus of the bed nucleus of the stria terminals ($BNST_{OV}$). $BNST_{OV}$ has one of the highest expression of oxytocin receptors (OTR) in a rodent brain. The $BNST_{OV}$ contains exclusively GABA-ergic neurons that were previously categorized based on their intrinsic membrane properties as type I, II and III neurons. The present study was aimed to understand the effects of OT on synaptic transmission as well as excitability of the $BNST_{OV}$ neurons. Therefore, we performed whole cell patch-clamp recordings from functionally identified $BNST_{OV}$ neurons in rat brain slice preparation in adult male Sprague-Dawley rats. We first recorded pharmacologically isolated spontaneous inhibitory postsynaptic currents (sIPSC). The $BNST_{OV}$ neurons were clamped at -70 mV, and the sIPSCs were collected before, during, and after bath application of OT (0.2 μM). Application of OT significantly increased the mean frequency (P = 0.0098, one-way ANOVA), but not amplitude of sIPSCs in type II $BNST_{OV}$ neurons. This effect was abolished in the presence of selective OTR antagonist (d$(CH_2)_5^1$,Tyr$(Me)^2$, Thr^4, Orn^8, des-Gly-NH_2^9)-vasotocin (OTA, 0.4 μM). The effect of OT was also abolished by application of tetrodotoxin (TTX, 1 μM), therefore the increase of sIPSCs frequency observed in type II $BNST_{OV}$ neurons could be mediated by OT-induced depolarization on other type of $BNST_{OV}$ interneurons. To identify the neuronal type involved in the control of inhibitory input on type II neurons, we investigated the effect of OT on the intrinsic excitability of type I, II and III neurons in a current clamp mode. We found that OT increased the intrinsic excitability on type I neurons as revealed by a left shift of the spike frequency-current relationship (P = 0.0328). The increase

in excitability was paired with an increase in the input resistance of the cells ($P = 0.0336$), suggesting that OT in type I neurons could block hyperpolarizing currents open at the resting membrane potential. Overall, these results present a model of fine-tuned modulation of the $BNST_{OV}$ neuronal network by OT, in which OT selectively increases the excitability of regular spiking type I $BNST_{OV}$ neurons, which are considered to be intrinsic interneurons. As a result, OT strengthens inhibitory input in type II low-threshold bursting $BNST_{OV}$ neurons, which belong to the $BNST_{OV}$ projection neurons. As a result, OT would inhibit $BNST_{OV}$ output, which might underlie some of the behavioral effects of OT in the $BNST_{OV}$.

Title: The expression and distribution of oxytocin receptors in the dorsolateral bed nucleus of the stria terminalis ($BNST_{DL}$) and their interaction with GABA-ergic system

Authors: *V. OLIVERA[1], S. H. OLSON[2], R. CHUDOBA[3], J. A. DABROWSKA[4];
[1]Dept. of Cell. and Mol. Pharmacol., [2]Dept. of Cell. and Mol. Pharmacolology, Rosalind Franklin Univ., North Chicago, IL; [3]Dept. of Cell. and Mol. Pharmacolology, Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL; [4]Chicago Med. Sch. RFUMS, North Chicago, IL

Abstract: The bed nucleus of the stria terminalis (BNST) is a heterogeneous brain structure that modulates fear and anxiety-like behaviors. Previously, we have shown that oxytocin receptors (OTRs) in dorsolateral BNST ($BNST_{DL}$) facilitate cued fear acquisition as measured in a fear-potentiated startle (FPS). Notably, inhibition of the BNST with $GABA_A$ receptor agonist also increased cued fear expression in FPS. First, we investigated the expression and distribution of OTRs in the $BNST_{DL}$ of male adult Sprague-Dawley rats. We performed double-immunofluorescence for OTR and marker of GABA-ergic neurons (67 kDa Glutamic Acid Decarboxylase, GAD67), marker of GABA-ergic terminals (vesicular GABA transporter, VGAT), as well as markers of specific populations of neurons of the $BNST_{DL}$, namely Enkephalin, Protein Kinase C delta (PKCδ) or Striatal-Enriched Protein Tyrosine Phosphatase (STEP). While OTRs show little co-localization with VGAT and GAD67-positive processes, OTRs co-localize with ENK-positive processes. As OT was shown to modulate GABA-ergic transmission, we next investigated if activating $GABA_A$ receptors in the $BNST_{DL}$ would affect cued fear in a manner similar to OTR. Here, $GABA_A$ receptor agonist Muscimol (1 ng, n = 9) or

vehicle (n = 10) were infused through bilateral cannulas into the $BNST_{DL}$ before fear conditioning, during which rats were presented with visual conditioned stimuli (CS) co-terminating with foot-shocks. 24 hours later rats were tested for fear recall, where acoustic startle responses (ASR) to white noise bursts were scored either during or between the CS presentations, which enabled measuring cued and non-cued fear, respectively. All rats showed a significant potentiation of ASR during (P = 0.0002) and between CS presentations (P = 0.0044), but there was no treatment effect, nor interaction between the trial type and treatment (two-way repeated measures ANOVA). In addition, there was no significant difference in the percentage change of cued fear (P = 0.3509), non-cued fear (P = 0.3310), or discrimination index (P = 0.9834, unpaired t-test) between groups. We also performed a trial-by-trial analysis to determine the effects of Muscimol on fear recall as a function of time. Two-way ANOVA showed a significant effect of treatment on ASR measured during fear memory recall (P = 0.0024) but there was no interaction between the treatment and trial type (P = 0.5443), indicating that Muscimol reduced ASR both during and between the CS presentations. We conclude that inhibition of the $BNST_{DL}$ reduces ASR during fear memory recall, independent of the trial type, in contrast to OTR, which affects ASR only during CS presentations.

Title: Physical activity as a moderator of the relationship between stress and limbic grey matter in older adults

Authors: *S. WEINER-LIGHT, S. M. WALTERS, N. DJUKIC, M. YOU, D. COTTER, M. ALTENDAHL, C. FONSECA, Y. COBIGO, F. ELAHI, A. M. STAFFARONI, C. A. LINDBERGH, J. KRAMER, K. CASALETTO;
Memory and Aging Center, Dept. of Neurol., Univ. of California, San Francisco, San Francisco, CA

Abstract: Background: Perceived stress is commonly associated with smaller amygdalar and hippocampal grey matter volumes. Atrophy in the hippocampus and amygdala are established indicators for conversion from “normal aging” to development of cognitive impairment. Thus, it is of great interest to identify strategies to support the function of these limbic structures. We

explored the potential role of physical activity as a moderator of the relationship between perceived stress and grey matter volume in older adults.
Method: 34 functionally normal older adults (ages 53-90; CDR =0) wore a FitBit Flex2 device for all waking hours for ≥14 days, blinded to activity levels. Fitbit-derived daily average steps and calories burned were calculated. Participants also completed the Perceived Stress Scale and a structural MRI via a 3-Tesla Siemens scanner. Regions of interest (ROI) included bilateral hippocampal and amygdalar volumes, as well as occipital volume as a control ROI; analyses adjusted for total intracranial volumes.
Results: Higher perceived stress was associated with smaller hippocampal and amygdalar volumes (ß range -0.28 to 0.36, *p*s<0.03). There was a significant interaction between perceived stress and average daily calories burned on grey matter volumes in the right hippocampus (stress*calories ß=0.29, p=0.04), and right (ß=0.33, *p*=0.03) and left (ß=0.27, *p*=0.04) amygdala, such that the relationship between perceived stress and grey matter volumes attenuated with increasing physical activity. In the left hippocampus, the interaction was not significant (ß=16, *p*=0.22). Parallel moderation models examining the control ROI were not significant (stress*calories ß=0.18, *p*=0.15). Models examining the moderating role of average daily steps did not reach significance for the hippocampi and amygdala (stress*average steps ß range 0.15 to 0.23, *p*s>0.26).
Conclusion: Our data provide early support for the protective role of physical activity on the relationship between perceived stress and limbic grey matter volumes in typically aging adults. Specifically, promoting higher intensity physical activity interventions aimed at burning more calories may support grey matter integrity among individuals reporting high stress. Given that limbic grey matter loss is the hallmark of Alzheimer's disease, these results suggest a possible avenue by which to combat this major public health issue in at-risk adults. Future research should consider a longitudinal study design in order to examine within person effects, which may further corroborate the utilization of high calorie burning routines as protective against the negative effect of stress on cognition.

Title: Inhibiting the central amygdala-bed nucleus pathway 'turns-off' stress-induced visceral pain

Authors: *A. C. JOHNSON[1,2], B. GREENWOOD-VAN MEERVELD[1,3];
[1]Res., VA Hlth. Care Syst., Oklahoma City, OK; [2]Neurol., [3]Oklahoma Ctr. for Neurosci., Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK

Abstract: Introduction: Psychological stress exacerbates abdominal pain experienced by patients with functional gastrointestinal disorders such as irritable bowel syndrome (IBS). Imaging studies of IBS patients have demonstrated abnormal corticolimbic circuitry in response to noxious visceral stimulation. In male rats, we have shown that optogenetic stimulation of central nucleus of the amygdala (CeA) terminals at the bed nucleus of the stria terminalis (BNST), a pathway that is abnormal in IBS patients, increases colonic sensitivity to distension. The hypothesis for this study was that inhibition of the CeA-BNST pathway would reverse stress-induced colonic hypersensitivity. **Methods:** We used stereotaxic procedures to infect neurons in the CeA with viral vectors to express channelrhodopsin (ChR2) or halorhodopsin (HR3.0) in male Fisher 344 rats. Bilateral cannulae were implanted at the BNST for fiber optic stimulation of CeA terminals. After 10 weeks, rats underwent 7 days of water avoidance stress (WAS) or SHAM-stress (1 hr/day). Twenty-four hours after the last WAS/SHAM-stress, laser stimulation at 473 nm for ChR2 (20 Hz, 5 ms) or 532 nm for HR3.0 (continuous) was used to modulate the response to graded, isobaric colorectal distension (20-60 mmHg, 10 min) quantified as the number of abdominal muscle contractions in freely moving rats. Results were analyzed with a repeated measure two-way ANOVA with Bonferroni's post-hoc analysis (mean ± standard deviation). **Results:** In rats with WAS-induced colonic hypersensitivity, HR3.0-mediated inhibition of CeA terminals at the BNST normalized colonic sensitivity to distension (60 mmHg: WAS+HR3.0: 20.7±6.4, P= 0.01 vs. WAS+ChR2: 39.0±10.0, P=0.99 vs. SHAM+HR3.0: 23.0±0.0). HR3.0 activation did not affect colonic sensitivity in SHAM exposed rats (60 mmHg: SHAM: 22.3 ± 3.1, P= 0.99 vs. SHAM+HR3.0). ChR2 stimulation of CeA terminals at the BNST in SHAM-stressed rats induced colonic hypersensitivity to distension (60 mmHg: SHAM+ChR2: 37.3 ± 8.7, P= 0.01 vs. SHAM). In rats exposed to WAS, ChR2 did not further increase the stress-induced colonic hypersensitivity (60 mmHg: WAS: 34.5 ± 12.5, P= 0.99 vs. WAS+ChR2). **Conclusions:** Neurotransmission from the CeA to the BNST is necessary for the expression of stress-exacerbated colonic sensitivity, without affecting normal responses to colonic stimulation in male rats. These results provide support for developing therapies targeting limbic circuits, which could decease chronic visceral pain in disorders such as IBS.

Title: The role of the amygdala in the autonomic regulation of stress and anxiety

Authors: *H. H. SUBRAMANIAN[1], G. HOLSTEGE[2];
[1]Boston Scientific, Valencia, CA; [2]Rijksuniversiteit Groningen, Groningen, Netherlands

Abstract: The amygdala is known to play an important role in the limbic system, which regulates fear and anxiety. Differences in fear and anxiety are associated with changes in breathing, cardiovascular and urinary function. Although the amygdala has been recognized as an important center within the limbic system, it is not known whether it has any direct causal influence on breathing, cardiovascular or urinary functions. In isoflurane anesthetized, vagi-intact, spontaneously breathing cats (*n*= 4, experiments undertaken at The University of Queensland, Australia) we stereotaxically stimulated the lateral and central areas of the amygdala with metabotropic glutamic acid (L-Glut, 500 mM, pH 7.4), and investigated the changes in diaphragm function, thoracic pressure, blood pressure, heart-rate and urodynamic control. Stimulation in the lateral amygdala generated tachypnea, inspiratory apneusis, hyperpnea, and double diaphragm breathing pattern, while stimulation of the central amygdala induced predominantly dyspnea and bradypnea. Apneas were never generated from either of the two regions of the amygdala. The cardiovascular effects generated from the amygdala were varied and did not show specific topography as respiration. Both the lateral and central amygdala induced hypertension as well as hypotension. Neither lateral amygdala nor central stimulation produced micturition. The results confirm the role of the amygdala in regulating the autonomic system during emotional processing including the levels of fear and anxiety. These effects also constitute a variety of autonomic indexes that can be used for clinical determination of stress and anxiety disorders including Post Traumatic Stress Disorder (PTSD) and panic disorders in humans.

Title: Voluntary exercise promotes sex-specific exploration and downregulation of neural oxytocin activity in socially isolated prairie voles

Authors: *W. WATANASRIYAKUL, M. C. NORMANN, M. COX, S. CIOSEK, S. SUJET, O. I. AKINBO, A. J. GRIPPO;
Psychology, Northern Illinois Univ., DeKalb, IL

Abstract: Loneliness is associated with anxiety, which may be mediated by neuropeptide function in the hypothalamus, including oxytocin (OT). Aerobic exercise improves anxiety symptoms, such as social avoidance and hypervigilance, in humans and animal models. However, the interactions of OT and exercise in the context of social stress and anxiety are unclear. The prairie vole is a valuable translational model to study social stress because this species lives in a similar social structure to humans, including exhibiting social monogamy, biparental care, and negative responses to social stressors. Additionally, exercise may serve a protective role against social stress in this species. Therefore, the current study examined the potential anxiety-reducing effects of voluntary exercise in socially isolated prairie voles. Ninety-one adult male and female prairie voles were randomly selected into 3 experimental groups: paired controls, isolation/sedentary, and isolation/exercise. Animals in the social isolation conditions were housed individually for 8 weeks, and animals in the exercise condition received a running wheel during the last 4 weeks of this isolation period. Control animals were pair-housed with a same-sex sibling for 8 weeks. Running behavior in physically active animals was categorized as low or high by a median split of the mean daily distance traveled. At the end of this 8-week period, all animals were exposed to a 20-min open field test (OFT) to examine anxiety-like behavior. Brains were collected from all animals 2 hours after the OFT was concluded. Overall, males were significantly more active in the OFT compared to females. Additionally, socially isolated males displayed significantly reduced total distance traveled in the OFT (v. paired control males), and low exercise prevented this reduction. No group differences were observed in exploratory behaviors of females. Interestingly, there was a significant positive correlation between running behavior and total distance traveled in the OFT, only in females. Immunohistochemical analyses revealed that socially isolated females had significantly higher activated OT cells (co-labeling of cFos and OT) in the hypothalamic paraventricular nucleus (v. paired females), and high exercise attenuated this elevation. No group differences were observed

in the OT activity of males. In summary, exercise protected against behavioral changes in males but neural changes in females. The current findings inform our understanding of the potential benefits of exercise for socially isolated or lonely individuals.

Title: How the hypothalamus regulate activity of solitary tract neurons and heart rate variability during psycho-emotional stress in rats?

Authors: *N. BEHNAM DEHKORDI[1], V. SARKISIAN[1], E. AVETISYAN[1], A. PETROSYAN1[1], N. SAHAKYAN[2], S. SHOGERYAN[2];
[1]Natl. Acad. of Sci. Republic of Armenia, Yerevan, Armenia; [2]Armenian State Pedagogical Univ., Yerevan, Armenia

Abstract: Objective: Central organization of emotional and visceral responses of hypothalamic structures and particularly, the paraventricular nucleus (PVN) determines the relationship of psycho-emotional stress with changes in the regulation of autonomic reactions.
However, to date there is no comprehensive studies of the mechanisms of central PVN regulation of impulse activity of solitary tract (ST) visceral sensory neurons, as well as their effects on the cardiovascular system in health and psycho-emotional stress
Methods: In rats under urethane anesthesia bipolar stimulating electrodes introduced in the anteromedial region of the hypothalamus. Extracellular recording of neuronal activity was carried out from the medial region of ST. Record of background impulses lasted for 10 seconds, tetanic stimulus duration was 1 s and post-stimulus changes the behavior of neurons in the PVN was recorded for 10 to 200 or 400 ms / bin. Analysis of cardiac activity was carried out by method of mathematical analysis of heart rate variability (MA HRV). We studied the most important indices: heart rate (HR), vegetative balance index (PSI) and the tension index of regulatory systems (TIRS). The data is processed using a Microsoft Excel spreadsheet, the level of statistical significance was determined by Student's t-test.
Results: Significant reactivity of solitary neurons (62%) to descending paraventricular inputs was revealed. The tetanic stimulation of PVN (100-Hz during 1-sec) resulted in pronounced tetanic depression with post-tetanic potentiation. In the mathematical analysis of some

functionally significant HRV parameters: the heart rate (HR), the vegetative equilibrium index (IWR), the intensity index of the regulatory systems before and immediately after immobilization a beneficial effect of the frequency stimulation of PVN was found.
Conclusion: Our results suggest that some decrease in the stress reaction is evidently due to the initiation of the neuro-regulative inhibitory control of PVN supporting the realization of vago-vagal reflexes via STN neurons.
KEYWORDS: Paraventricular nucleus of the hypothalamus, solitary tract nucleus, psycho-emotional stress, tetanic potentiation and depression, extracellular recording.

Title: Transcriptional responses to repeated restraint stress exposure in male and female rats

Authors: *T. J. PHILIPPE[1], M. DORDEVIC[1], P. PAVLIDIS[2], T. UNDERHILL[3], V. G. VIAU[1];
[1]Cell Physiological Sci., [2]Psychiatry, [3]Univ. British Columbia, Vancouver, BC, Canada

Abstract: Experience with a controllable challenge can protect an organism from the negative consequences of stress. Thus, determining the molecular mechanisms of adaptive responses has important implications for understanding stress resistance and vulnerability. Here we used a model of stress hypothalamic-pituitary-adrenal (HPA) axis habituation and compared transcriptional responses in male and female Sprague Dawley rats exposed to a single bout of 2h restraint or to multiple bouts repeated daily for 5 consecutive days. Serial blood sampling indicated comparable declines in corticosterone responsiveness to repeated restraint in males and females. However, this was met by very limited overlap, if not completely different transcriptional profiles between the sexes depending on the brain region surveyed. RNA sequencing revealed 3 types of responses in the raphe nucleus, reflected by 1) transient changes in differentially expressed genes (DEGs) that returned to baseline after repeated restraint; 2) sustained increments/decrements in DEGs unique to the repeat restraint condition; and 3) sustained changes in DEGs regardless of restraint experience. Distinct transcriptional patterns also occurred within forebrain regions known to be targeted by the raphe-serotonin system and/or mediating adaptive neuroendocrine and behavioral responses. DEGs uniquely associated

with the repeat restraint condition was the predominant response type in the septum and zona incerta. However, changes in gene expression in the septum occurred only in males, whereas changes in the zona incerta occurred only in females. In the paraventricular nucleus of the hypothalamus, the final common pathway regulating the HPA axis, only females responded to show DEGs induced by both single and repeated restraint. Many of these DEGs in the paraventricular nucleus, zona incerta and septum belong to key neurotransmitter (serotonergic, GABAergic) and neuroendocrine systems, in addition to those mediating synaptic remodeling and signaling pathways. The extent to which these transcriptional alterations contribute to the state of habituation, or otherwise respond to stress, remains to be seen. Nonetheless, the current findings provide several testable frameworks for determining factors controlling sex differences in adaptive responses.

Title: Predator odor evokes stress response and fos activation in sensorial and limbic regions: Role of PACAP-PAC1 signaling for circuit interactions

Authors: *L. ZHANG[1], V. S. HERNÁNDEZ[1], S. SWEAT[2], L. E. EIDEN[2];
[1]Av. Univ. 3000, Mexico City, Mexico; [2]Sec Molec Neurosci, NIH, NIMH-IRP, Bethesda, MD

Abstract: Pituitary adenylate cyclase-activating polypeptide (PACAP) signaling has been suggested as a pleiotropic transmitter for stress responding. We have recently observed, via RNAScope methodology, that PACAP and PAC1 expression is distributed with either excitatory or inhibitor co-transmitters in the mouse central nervous system in a pattern showing a marked dominance in sensorial pathways and limbic circuits. This pattern suggests that PACAP/PAC1 signaling may be importantly involved in emotion-based decision-making and motor coordination for stress coping. Here, we have assessed the effect of predator odor (cat urine) exposure on the behavior of wild-type compared to PACAP knock-out C57Bl6/N mice. Cat urine material was collected from domestic cat litter boxes and was inserted into a flask (A) (2cm of opening bore) within a custom-made wooden box (B) (28cm x 28cm x 28 cm, with a sliding

glass lid), located inside a hood. After introducing the subject, the lid of A was opened and the lid of B was closed. Video recording was made during 10 min period, after which animals were euthanized by cervical dislocation and brains rapidly removed and processed for double in situ hybridization histochemistry using the RNAscope 2.5 HD Duplex Assay. The neuronal activation in the olfactory bulb (OB), piriform cortex (Pir), medial and central amygdala (MeA and CeA), bed nucleus of *stria terminalis* (BNST), ventromedial hypothalamic nucleus (VMH), lateral septum (LS), parabrachial nucleus (PBN) and hippocampus were assessed for *fos* expression within PACAP, PAC1, VGluT2 and VGAT-positive cells. Cat urine exposure triggered purposeful movement such as object exploration/complete retreat and freezing behaviors in both wild-type and knock-out mice, with the PACAP-deficient (knock-out, ko) group showing significantly less of both behaviors than the wild-type group ($p < 0.001$ and $p < 0.05$ respectively). Spatial preference *heat map* showed that the wt mice had clear border preference in the 3 quadrants other than the quadrant where A was located, while the ko mice showed no difference in this parameter. Fos mRNA expression was significantly less in the PACAP-deficient compared to the wild-type group in OB (mitral and glomerular layers), MeA and CeA, BNSToval and BNSTam, VMH, PBN ($p < 0.001$ in all cases), with similar expression in both groups in the dorsal and ventral DG and in LS. These data provide some of the first evidence implicating the sensorial hypo-functioning and stress hypo-responding in PACAP-KO subjects and offer an initial step towards identifying the PACAP-PAC1 signaling in sensory-emotional circuits in stress susceptibility and responding.

Title: Sexually diergic effects of environmental enrichment and removal on baseline and restraint stress HPA axis responses in rats

Authors: *M. E. RHODES[1], G. C. NOEL[1], E. P. ROHM[1], B. R. SCHEIDER[1], R. T. RUBIN[2]; [1]Biol., St. Vincent Col., LATROBE, PA; [2]Psychiatry & Biobehavioral Sci., David Geffen Sch. of Medicine, UCLA, Los Angeles, CA

Abstract: Structural and social aspects of housing and husbandry conditions can influence the physiology and behavior of laboratory animals. Because many of our experiments incorporate

singly-housed, jugular vein-cannulated (JVC), male and female rats into pharmacological dosing studies, alleviating potential stress from single housing is imperative. Our laboratory has previously demonstrated that housing animals during the acclimation period with commonly used environmental enrichment (EE) toys resulted in lower hypothalamic-pituitary-adrenal (HPA) axis activity before and after mild stress. The specific EE toys, Nestlets® and Kong® Toys, were chosen because of their potential to accentuate nesting and gnawing/playing behaviors, respectively. The present study used these same toys to examine the effects of EE, and the removal of EE, on stress-responsive hormones of the HPA axis under basal conditions and after acute restraint stress in singly-housed, JVC, male and female rats. All animals were presented with EE upon arrival in our animal facility (Day 0). On Days 1-7, a daily blood sample was collected from each animal. After the blood sample collection on Day 4, EE was removed from randomly selected cages, such that two groups were formed: 1) male and female animals that remained housed with EE, and 2) male and female animals that had lost EE. On Day 8, blood samples were collected from each animal before and after 15 min restraint stress. Plasma adrenocorticotropic hormone (ACTH) and corticosterone (CORT) concentrations were determined by highly specific immunoassays. Consistent with our previous findings, baseline ACTH and CORT decreased over time in male and female groups housed with EE. Removal of EE resulted in sexually diergic baseline hormone effects: male ACTH and CORT increased, and female ACTH and CORT decreased, after EE removal. Moreover, removal of EE resulted in sexually diergic hormone responses to restraint stress: Overall, male ACTH and CORT responses were higher and returned to baseline more slowly, and female ACTH and CORT responses were lower and returned to baseline more rapidly, compared to males and females that retained EE. These data indicate that sudden changes to the housing environment of laboratory animals may have both immediate and lasting effects on their physiology and likely their behavior. EE provides a distraction from standard housing conditions and decreases the HPA stress response in laboratory animals. It also appears that the loss of EE influences baseline and stress-induced HPA axis activity in a sexually diergic manner, increasing hormone secretion in males and decreasing it in females.

Title: A cortico-hypothalamic pathway that mediates sympathetic and behavioral responses to psychosocial stress

Authors: *N. KATAOKA, Y. SHIMA, K. NAKAMURA;
Dept. of Integrative Physiol., Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan

Abstract: Psychological stress causes a variety of sympathetic and behavioral responses in mammals, which help animals cope with stressors. We have reported that psychological stress induces thermogenesis in brown adipose tissue (BAT), hyperthermia and tachycardia by activating a monosynaptic neural pathway from the dorsomedial hypothalamus (DMH) to the rostral medullary raphe. Here we found that the DMH receives glutamatergic sympathoexcitatory stress inputs from the dorsal peduncular cortex and dorsal tenia tecta (DP/DTT), located at the ventral limit of the medial prefrontal cortex. To determine how important the DP/DTT-DMH neural pathway is for the drive of sympathetic stress responses, we injected anterograde and retrograde adeno-associated viruses (AAVs) into the rat DP/DTT and DMH, respectively, to selectively ablate DP/DTT-DMH projection neurons with Cre-dependent expression of a genetically engineered caspase-3. Ablation of DP/DTT-DMH neurons did not affect the basal control of body temperature, but did eliminate BAT thermogenesis and hyperthermia induced by social defeat stress, a psychosocial stress model. We further tested the effect of optogenetic inhibition of the DP/DTT-DMH pathway on stress behavior. Social interaction tests were conducted by using rats given social defeat stress. The defeated rats exhibited reduced social interaction with the dominant rats by which they were defeated during the first confrontation. However, optogenetic inhibition of DP/DTT-DMH projection neurons, which expressed iChloC-mCherry, a chloride-conducting channelrhodopsin, restored social interaction, and also eliminated sympathetic stress responses including hyperthermia and tachycardia. These results indicate that the DP/DTT-DMH monosynaptic excitatory pathway transmits stress signals essential for the hypothalamus to drive sympathetic and behavioral responses for stress coping.

Title: Topographical and projection specific activation of basolateral amygdala neurons in response to stress

Authors: *R. J. AUKEMA[1], S. L. BAGLOT[1], B. K. LAU[2], G. N. PETRIE[1], A. S. NASTASE[1], M. MORENA[3], S. KADHIM[1], S. L. BORGLAND[4], M. N. HILL[2];

Abstract: The basolateral amygdala (BLA) is an important brain region activated by psychological stress, functioning to integrate sensory information with higher-order cognitive information such as learned behavior and motivational drive. In turn, it projects to several brain regions capable of modulating various behavioral and physiological processes. However, it is unclear which projection populations are recruited during stress exposure and how each population individually contributes to the overall stress response. Using adult male rats, we first mapped the topographical distribution of c-fos (a marker of neural activity) within the BLA in response to both appetitive (female odor, palatable food) and aversive (restraint, predator odor, foot shock, swim stress) stimuli. Noticeably, c-fos expression in response to these stimuli was not homogenously distributed, but rather expression was biased towards certain aspects of the BLA. We then investigated which BLA projection populations are recruited by exposure to acute restraint stress. We first mapped the topographical distribution of five projection populations within the BLA (targeting the ventral hippocampus, nucleus accumbens, prelimbic cortex, central amygdala, and lateral hypothalamus) using the retrograde tracer choleratoxin subunit B (CTb). Consistent with prior literature, each projection population exhibited a unique topographical distribution within the BLA. Next, we identified which of these populations were responsive to acute restraint stress. Discrete BLA projection populations were identified by choleratoxin subunit B (Ctb) and examined for colocalization with c-fos (indicating neural activation) following 30-minute restraint stress exposure. Populations targeting the nucleus accumbens, prelimbic cortex, and ventral hippocampus were robustly activated by stress. To a lesser extent, populations targeting the central amygdala and lateral hypothalamus were also activated. This suggests that these projections are important in the collective stress response and provides a framework to now begin investigating the individual role of each projection. Given that distinct amygdala projection neuron populations can influence discrete - and sometimes even opposite - behaviors, it is possible that each population uniquely contributes to discrete aspects of the collective stress response.

Title: Sexually dimorphic effects of stress and age on orexin receptor mRNA expression in the paraventricular thalamic nucleus

Authors: *A. VIGDERMAN[1], S. LUZ[1], A. SHINGALA[1], S. BHATNAGAR[2];
[1]Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Dept Anesthesiol., Univ. Pennsylvania, Children's Hosp Philadelphia, Philadelphia, PA

Abstract: Orexins are neuropeptides involved in states of motivational relevance such as addiction, reward, and anxiety, and are important for responses to both acute and repeated stress. Orexins have an anxiogenic effect when administered in the posterior paraventricular thalamic nucleus (pPVT), an area that coordinates input from stress-activated neurotransmitter systems to structures that regulate motivation and mood. Dysregulation of orexins is seen in stress-related psychiatric disorders, such as Major Depressive Disorder. Incidence of these disorders is twice as high in women compared to men, and sex differences in the prevalence and symptoms of these disorders emerge during adolescence. In previous work, we have shown that orexins are important in mediating sex-differences in the response to repeated stress and in cognitive function (Grafe et al., Biological Psychiatry 2017). Less is known about sex differences or the impact of stress on expression of orexin receptors 1 and 2 (HCRTR1/2) . This study examined the quantity and distribution of both orexin receptor mRNA in the pPVT across age, sex, and stress status. We ran cohorts of adult (PND 74) and early adolescent (PND 30) male and female rats through five days of social defeat, a repeated stress paradigm in which an experimental "intruder" rat is placed in the home cage of a dominant "resident" rat. This paradigm allows us to further separate the rats into vulnerable and resilient groups. Using an in-situ hybridization protocol from RNAScope, we co-stained HCRTR1 and 2 mRNA in the pPVT to quantify the overall number of transcripts as well as cell type (the number of cells containing both orexin transcripts versus a single orexin transcript type). In general, the results indicated similar findings with both HCRTR1 and HCRTR2. Male adolescent and adult defeated rats exhibit decreased orexin receptor mRNA expression compared to non-stressed controls, and in adults this effect of defeat is primarily seen in the vulnerable group. Female adults have decreased orexin receptor mRNA expression compared to adolescents regardless of defeat status, suggesting a stress-independent developmental shift in orexin receptor mRNA expression in the

pPVT of females. Thus, the expression of mRNA both orexin receptors was influenced primarily by stress in male rats but by age in female rats. These findings are a starting point to further investigate the neural differences that underlie sex-specific responses to repeated stress across age.

Title: Traumatic stress induces long lasting violent aggression through potentiation of a medial amygdala circuit

Authors: *J. NORDMAN[1], Z. LI[2];
[1]NIH, Bethesda, MD; [2]NIMH, Bethesda, MD

Abstract: Traumatic stress has long been shown in humans and rodents to promote excessive and recurring violent aggression, co-morbid with psychiatric diseases such as PTSD, intermittent explosive disorder, and schizophrenia. In individuals suffering from PTSD, hyperactivity of the amygdala is strongly correlated with stress responses that trigger anger and violence. The medial amygdala (MeA) is an evolutionarily conserved subnucleus of the amygdala that regulates attack behavior and has been implicated in stress induced aggression. The precise contribution of the MeA in traumatic stress induced aggression, however, requires further elucidation. In this study we used a modified foot shock protocol, a common method for inducing aggression in rodents, to evaluate the circuit level mechanisms of the MeA in driving long lasting attack behavior associated with traumatic stress. We observed that foot shock increased aggression for weeks after training. Previous studies have shown that the MeA regulates aggression through two canonical members of the aggression circuit, the ventromedial hypothalamus (VmH) and bed nucleus of the stria terminalis (BNST). Based on previous studies and our preliminary findings, we hypothesized that traumatic stress induces aggression through potentiation of these same pathways. In vivo electrophysiological recordings, a method for detecting neural activity in an awake and freely moving animal, revealed significant and sustained increases in optically evoked excitatory postsynaptic potentials, indicative of long-term potentiation. Intriguingly, low frequency photostimulation (LFPS), an optogenetic strategy for inducing synaptic depression in the brain, suppressed long-lasting aggression associated with our foot shock protocol when applied directly to the MeA, confirming that potentiation of these circuits is integral for the

observed attack behavior. Notably, these effects were irrespective of non-violent social behavior or fear memory. These results reveal an important function for the MeA in traumatic stress induced aggression and may be useful in developing therapeutic strategies to treat excessive aggression associated with traumatic stress and psychiatric disease.

Title: Stress responses are bidirectionally regulated through amygdalar orexin 1 and 2 receptors

Authors: *J. D. W. YAEGER[1], K. T. KRUPP[1], N. T. JONES[1], B. MEYERINK[3], T. R. SUMMERS[2], J. T. CAIN[3], C. H. SUMMERS[2];
[2]Dept. of Biol., [1]Univ. of South Dakota, Vermillion, SD; [3]Sanford Res., Sioux Falls, SD

Abstract: The orexin (Orx) system regulates adaptive stress reponses; therefore, maladaptive reactions to stress (susceptibility) may arise as a result of irregular orexin function. Orexin A (Orx_A) and B (Orx_B) are produced in the lateral/dorsomedial-perifornical (LH/DMH-PeF) regions of the hypothalamus. These neuropeptides activate neuronal targets through two receptors: orexin 1 (Orx_1) and 2 (Orx_2). Although Orx_A stimulates both receptors, Orx_B exhibits a binding preference for Orx_2. These receptors are dispersed broadly throughout the central nervous system, including the amygdala, a region associated with emotional interpretation/learning. Within the basolateral amygdala (BLA), susceptible mice express higher mRNA levels of Orx_1 and lower levels of Orx_2 compared to controls. Here, pharmacological manipulations of the Orx receptors in the BLA (intra-BLA) were performed after exposure to a social stress paradigm called the Stress Alternatives Model (SAM). The SAM is composed of an oval shaped, open field arena in which a small C57BL/6 mouse is paired, after a tone (conditioned stimulus), with a large CD-1 that aggressively pursues the smaller animal (unconditioned stimulus) over the course of four, 5-minute sessions. The SAM provides an opportunity for the smaller mouse to avoid defeat by escaping through tunnels too small for the aggressor. By the end of the second trial, mice select a stress-related phenotype from which they do not deviate in subsequent trials: Escape/Resilient or Stay/Susceptible. Therefore, treatments can be administered before the third session, after phenotype commitment, in an attempt to pharmacologically shift the stress state of the animal. In a series of experiments, the SAM was

paired with the open field (OF) and social interaction/preference (SIP) tests. With intra-BLA Orx_1 antagonism (SB-674042; 0.3 nmol), 63% of Stay mice are rescued to the Escape phenotype. Also, Orx_1 blockade reduced fear responses to both contextual and cued stimuli, decreased behavioral inhibition in the SAM and OF, and enhanced social learning in a non-social environment (OF). Intra-BLA infusion of Orx_A increased cued fear responses, enhanced freezing, and diminished social learning. Inhibition of BLA Orx_2 (MK-1064; 0.1 nmol) exaggerated freezing responses in the SAM and OF, and decreased social preference in the SIP test. Activating intra-BLA Orx_2 ([Ala^{11},D-Leu^{15}]-Orx_B; 0.1 nmol) produced the opposite effect in the SIP test. Together, the results illustrate a bidirectional role of Orx receptors in the BLA, with Orx_1 activity contributing to negative stress responses and Orx_2 stimulation promoting adaptive behaviors.

Title: Brainwide mapping of stress induced neuronal activation for large cohort

Authors: *H. WANG, C. YANG, Y. SHEN, S. HUANG, L. DING, Y. CHENG, Q. ZHU, P.-M. LAU, G.-Q. BI;
Univ. of Sci. and Technol. of China, Hefei, China

Abstract: Severe or chronic stress is thought to be related to mental disorders such as post-traumatic stress disorder and depression. In rodent models, multiple brain areas have been found to be activated by various stress stimuli. Meanwhile, it is also known that, similar to human beings, model animals also exhibit individual differences in their behavior coping with stress conditions. In an attempt to unbiasedly evaluate the activation of neural circuits in response to behavioral stress, we performed a “large” cohort brain-wide mapping of neuron activity trace at subcellular resolution, using our recently developed high-throughput volumetric imaging system (VISoR). Analysis of neuronal activation based on c-Fos expression in over 20 mice under resting or stressed conditions revealed marked variability in the activation of multiple subcortical

areas by stress across different individual animals. Intriguingly, stress-induced activation of several brain areas exhibited strong lateralization. These results corroborate the idea that stress response of an individual animal can be very sensitive to its genetic and environmental factors, and suggest the necessity of sufficient cohort size for studying the circuit basis of specific behaviors.

Title: Agrp and POMC neurons are involved in mediating chronic stress-induced depressive behaviors

Authors: *X. FANG, J. WANG, S. JIANG, Y. LEI, X.-Y. LU;
Augusta Univ., Augusta, GA

Abstract: The arcuate nucleus (ARC) of the hypothalamus contains two distinct subpopulations of neurons, expressing orexigenic agouti-related peptide (AgRP) and anorexigenic pro-opiomelanocortin (POMC). It is unknown that how AgRP and POMC neurons's response to chronic stress and the roles they play in the development of depressive-like behaviors. We demonstrated that chronic unpredictable stress (CUS) induces depressive-like behavioral phenotypes in mice, including anhedonia and behavioral despair. By using this model and electrophysiological recordings, we found that CUS decreased the firing rate of AgRP neurons but increased the firing rate of POMC neurons. Furthermore, synaptic input onto AgRP and POMC neurons were also differentially altered by CUS. Chemogenetic stimulation of these neurons cause opposite effects on CUS-induced behavioral changes. Our results suggest that AgRP and POMC neurons play an important role in chronic stress adaptation and associated behavioral deficits.

Title: Resilience gene expression profiles and metabolic pathways in the amygdala associated with corticorsterone induced posttraumatic growth

Authors: J. LI[1], J. CHEN[2], G. WOODWARD[3], C. LI[1], E. XING[3], L. ZHANG[3], ***H. LI**[3]; [1]2Department of Bioinformatics Biostatistics and Bioinformatics, Georgetown Univ., Washington DC 20057, WA; [2]Neurol., [3]Psychiatry, Uniformed Services Univ. of the Hlth. Sci., Bethesda, MD

Abstract: Resilience in the face of chronic stress or traumatic stress exposure is one of the critical neurobiological processes preventing the development of posttraumatic stress disorder (PTSD). Activating of glucocorticoid receptor signaling and subsequently mitigating the stress-induced symptoms after the traumatic events have been implicated in the posttraumatic growth (PTG). To discover molecule targets for pharmacological intervention in the PTG, current study examines the mitochondrial gene expression profile associated with glucocorticoid receptor signaling and the occurrence of stress-induced psychiatric symptoms utilizing mitochondria gene array and a rat model of PTSD. Our unsupervised clustering analysis revealed differential expression of 129 genes in the amygdala among 1500 mitochondria focused informative genes in the amygdala were dysregulated from three groups of experiments, including controls (n=10), stressed (n=10) and corticorsterone treated (n=10).These results suggested that stress dysregulated two main category genes including corticorsterone induced DRG and another is neuronal and/or other hormonal other than glucocorticoid involved DRG systems. These other than corticosterone activated systems appear to be involved in multiple neuronal and hormonal systems which contribute to the key symptom of PTSD, an exaggerated fear response. Thus, the corticosterone activated system appear to be involved in resilience to stress and attenuated the development of delayed and exaggerated fear response.

Title: Genetic and endocrinological analysis of stress response and anxiety-like behavior by cross-fostered hatano rats

Authors: *T. AKIMOTO;
Meiji Univ., Kawasaki-shi, Japan

Abstract: The fosterer is important factor in determining the traits of offspring because fostering behavior and the fosterer's hormones affect anxiety-like behavior and stress response of offspring. Cross-fostering is one method to determine whether a certain trait of a child is characterized by the fosterer. Hatano high- (HAA) and low- (LAA) active avoidance rats are inbred strains selected from SD rats. The strains have different breeding behavior and blood hormone concentrations. Previously, we did cross-fostering using Hatano rats and clarified that the anxiety-like behavior of their offspring differs depending on the strain of the fosterer. However, the mechanisms of this behavioral change, as well as stress response, are still unclear. Therefore, in this study, we measured the stress response reactivity and its related mRNA expression in the brains of cross-fostered Hatano rat offspring to clarify the genetic and endocrinological mechanisms of the fosterer effects on offspring traits. On postnatal day 1, HAA and LAA offspring were either fostered by dams of the opposite strainor an unrelated foster dam of the same strain. Then, at 9 weeks of age, restraint stress was applied to the offspring and we measured adrenocorticotropic hormone (ACTH) to observe stress responsiveness. HAA offspring had significantly higher concentrations of ACTH than LAA offspring. In addition, HAA offspring reared by HAA dam also had significantly higher ACTH concentrations than HAA offspring reared by LAA dam after restraint stress. These results indicate that the characteristics of the foster dam affected the stress responsiveness of the offspring.
Next, we assessed the anxiety-like behavior and stress reactivity of 5-week-old and 9-week-old cross-fostered Hatano rats by measuring the expression of related brain mRNA using RT-qPCR. Expression of Kcnj5 mRNA was significantly higher in the hippocampi of all 5-week old offspring reared by LAA dam than those of any offspring. In addition, expression of GR mRNA was initially higher in the hippocampus of 9-week-old HAA offspring reared by HAA dam than in HAA offspring reared by LAA dam, but after 60 minutes of restraint stress this significant difference disappeared. Furthermore, the expression of corticotropin releasing factor (Crf) hnRNA in 9-week old amygdala was significantly higher in the offspring reared by HAA dam than LAA dam before restraint stress, as was expression of CRH mRNA after restraint stress.

In summary, this study clarified that fosterer characteristics affect the genes involved in anxiety-like behavior and stress responsiveness in the brain of offspring.

Title: Identification of a tachykininergic projection onto melanin-concentrating hormone (MCH) neurons in the lateral hypothalamic area (LHA)

Authors: *A. FUJITA[1,2,3], L. ZHONG[1], A. C. JACKSON[1,2,3];
[1]Physiol. and Neurobio., [2]Connecticut Inst. for the Brain and Cognitive Sci., [3]Biomed. Engin., Univ. of Connecticut, Storrs Mansfield, CT

Abstract: The lateral hypothalamic area (LHA) is a highly conserved, though heterogeneous, brain region critical for maintaining physiological and behavioral homeostasis. A unique neuronal population within the LHA is defined by the expression of melanin-concentrating hormone (MCH), and regulates multiple homeostatic functions including sleep-wake states, energy balance and stress. However, cellular and functional diversity among MCH neurons is not well understood. Previous anatomical and molecular data suggests that MCH neurons may be parsed into at least two transcriptionally-distinct subpopulations, with one enriched in transcript for the neurokinin 3 receptor (NK3R), a G-protein coupled receptor for the tachykinin neuropeptide family member neurokinin B (NKB), encoded by *Tac2*. This tachykininergic ligand-receptor system has been implicated in reproduction, fear memory and anxiety in other brain regions, but the function of NKB interactions with a subpopulation of MCH neurons is unknown. To begin to understand possible functional connectivity between NKB-expressing neurons and LHA MCH neurons, we first asked which NKB+ neuronal populations in the brain may be innervating the LHA. To accomplish this, we used *Tac2*-Cre mutant mice crossed to an enhanced yellow fluorescent protein (EYFP) reporter line (*Tac2*-Cre;EYFP), bilaterally injected in the LHA with a cre-dependent retrograde virus (rAAV-Flex-tdT). In the course of mapping retrogradely-labeled *Tac2*/EYFP+ neurons in the brain, we identified the bed nucleus of the stria terminalis (BNST) as one of several candidate brain regions that may be innervating the LHA. We subsequently performed anterograde tracing through bilateral injections of a cre-dependent anterograde virus (AAV-DIO-ChR2-EYFP) in the BNST and mapped fibers in the LHA, apposed to MCH neurons. Finally, using optogenetics in slices, we interrogated fast

neurotransmitter release from BNST *Tac2*+ fibers onto identified MCH neurons using a dual-viral approach. These data provide a foundation for characterizing a novel NKB/MCH neural circuit, which will lead to further, circuit-level insight into the function of anatomically and molecularly distinct subpopulations of MCH neurons.

Title: Endocannabinoid regulation of basolateral amygdala input to posterior tail of dorsal striatum and effects of stress

Authors: *V. KONDEV, D. MARCUS, G. BEDSE, S. PATEL;
Vanderbilt Univ., Nashville, TN

Abstract: The role of the basolateral amygdala (BLA) is complex, positioned for emotional responding, valence processing, and the modulation of fear and stress-related behaviors. It has been suggested that the many roles of the BLA may be due to the anatomical projection targets; specifically, that the BLA may encode information about stimuli in a projection-specific manner. While significant research has been done on BLA projections to the ventral striatum, BLA input to the dorsal striatum has received relatively less attention. Recent evidence suggests that the posterior tail of the dorsal striatum (TS) may represent a functionally distinct striatal territory, related to external threat and avoidance reinforcement. However, the question remains what the significance of the BLA-TS projection is and how it is regulated. Here, we show that BLA-TS synapses are stronger than to anterior dorsal striatum, glutamatergic, and express functional endocannabinoid (eCB) CB1 receptors. Furthermore, using *in vivo* optogenetics, we assess the functional role of this circuit in the regulation of anxiety and fear-related behaviors. These data will begin to identify a novel functional role of BLA-TS glutamatergic projection and the capacity for experience-dependent synaptic plasticity in this circuit. Elucidating diverse BLA efferent projections could provide insight into the diverse functional properties of the BLA and elucidate fundamental mechanisms by which emotional information gains access to basal ganglia circuits.

Title: Pubertal- and sex-dependent changes in the activity of brain nuclei controlling hormonal stress reactivity

Authors: M. R. BAKER, ***R. D. ROMEO**;
Barnard Col. of Columbia Univ., New York, NY

Abstract: Adolescence is associated with the maturation of the hypothalamic-pituitary-adrenal (HPA) axis, the major neuroendocrine axis mediating the hormonal stress response. Specifically, prepubertal males and females show greater hormonal stress reactivity than adults. Adolescence is also a developmental stage marked by a variety of stress-related vulnerabilities, including mood disorders, such as depression and anxiety. Thus, it is possible that this heightened stress reactivity plays a role in these vulnerabilities. Along with increased hormonal responsiveness prior to puberty, stressors also induce greater activity, as measured by FOS immunohistochemistry, in the paraventricular nucleus of the hypothalamus (PVN). As the PVN initiates the hormonal stress response, the heightened reactivity observed in prepubertal animals may in part be mediated by greater central drive to the PVN at this development stage. The current study examined this possibility by measuring stress-induced FOS responses in forebrain nuclei known to contribute direct excitatory and inhibitory inputs to the PVN in prepubertal and adult male and female rats. Replicating previous work, we found that both prepubertal males and females showed a greater number of stress-induced Fos-positive cells in the PVN immediately and 40min after termination of a 30min session of restraint compared to adult males and females. We also found that the anterior bed nucleus of the stria terminalis (aBST), a nucleus with direct excitatory projections to the PVN, showed a significantly higher number of FOS-positive cells following restraint, with the increase greatest in adolescent males. Though additional nuclei projecting to the PVN, such as the medial preoptic nucleus, the dorsomedial hypothalamus, and posterior bed nucleus of the stria terminalis, are currently being analyzed, these data suggest that greater activation of the aBST contributes to these pubertal-related increases in stress-induced HPA reactivity, at least in males. As adolescence is a period often marked by the onset of stress-related mood disorders, some of which show sex differences in their prevalence, it will be crucial to continue research aimed at understanding the neural mechanisms that mediate changes in stress reactivity during adolescence in both males and females.

Title: Interneuron-specific expression of α1A adrenergic receptors drives patterned inhibitory synaptic transmission in the basolateral amygdala

Authors: X. FU, J. G. TASKER;
Cell and Mol. Biol., Tulane Univ., New Orleans, LA

Abstract: The central noradrenergic system plays a critical role in regulating the stress response, memory formation and anxiety behaviors. Recent clinical trials have shown the promise of the a1 adrenergic receptor blocker prazosin in treating posttraumatic stress disorder (PTSD). However, the distribution of the α1 adrenergic receptors in brain areas involved in emotional processing, like the amygdala, is controversial due to the poor specificity of adrenergic receptor antibodies. Here, we used mice with a genetic substitution of the α1A-subtype adrenergic receptor with β-galactosidase to investigate the location as well as the function of the a1A receptors in the basolateral amygdala (BLA). We found that the expression of a1A adrenergic receptors is restricted to GABAergic interneurons in the BLA, although not all the BLA GABA neurons show α1A receptor expression. Using whole-cell recordings of principal neurons in slices of BLA, we found that α1 adrenoreceptor activation induced specific patterns of synchronized inhibitory synaptic inputs from parvalbumin and CCK interneurons, both of which were eliminated in the α1A knockout animals. Our data suggest that α1A adrenergic receptors regulate local inhibitory neural circuits to drive patterned neural output from the BLA.

Title: Long lasting feedback inhibition of the HPA response to physical stress via glucocorticoid-induced changes in alpha-1 adrenergic receptor trafficking

Authors: *G. L. WEISS, A. NEILSON, S. NGUYEN, L. HARRISON, J. G. TASKER; Cell and Mol. Biol., Tulane Univ., New Orleans, LA

Abstract: Systemic release of glucocorticoids is regulated by negative feedback inhibition of corticotropin releasing hormone (CRH) neurons in the hypothalamus. Noradrenergic afferents provide a major excitatory input to the CRH neurons to drive sensory activation of the hypothalamic-pituitary-adrenal (HPA) axis by physiological stressors. Norepinephrine (NE) causes a robust increase in glutamatergic excitatory synaptic inputs to CRH neurons recorded by patch-clamp electrophysiology, which is completely abolished by prior restraint stress or glucocorticoid preincubation of brain slices. The NE desensitization lasts for at least 4 hours, extending beyond the expected two-hour time course of glucocorticoid release and recovery from a single stressor. Here, we found that mice subjected to prior restraint stress had a significantly attenuated glucocorticoid response to a physiological immune challenge (I.P. lipopolysaccharide, LPS) within a 4-hour window, but their response to a psychological stressor, predator odor exposure, was unaltered. The hypothalamic cell line N42 was used as an expression system to track intracellular alpha 1B receptor trafficking. Live-cell and FRET imaging revealed that dexamethasone suppresses alpha 1B receptor recycling to the membrane by increasing trafficking to late endosomes and decreasing trafficking to rapidly recycling endosomes. Analysis of post-translational modifications to b-arrestin showed that glucocorticoids alter b-arrestin ubiquitination and nitrosylation, which provides a mechanism for alpha 1 receptor desensitization. Modality-dependent HPA desensitization to stress may be adaptive by suppressing the neuroendocrine response to sensory stressors and allowing the animal to attend to life-threatening psychological stressors. However, this may be maladaptive to animals experiencing severe immune challenge, such as sepsis, as glucocorticoids are required to prevent an overactive immune response.

Title: Glucagon-like peptide 1 receptor signaling activates identified projection neurons within the central nucleus of the amygdala

Authors: *N. V. POVYSHEVA[1], H. ZHENG[2], L. M. RINAMAN[3];
[1]Univ. of Pittsburgh Dept. of Neurosci., Pittsburgh, PA; [2]Psychology, [3]Dept. of Psychology, Florida State Univ., Tallahassee, FL

Abstract: GLP1 receptor (GLP1R) signaling within the central nucleus of the amygdala (CEA) and the interconnected anterior lateral bed nucleus of stria terminalis (alBST) increases anxiety and other stress-related behaviors in rats. Here we examined whether GLP1 signaling activates CEA neurons that project to the alBST. Red fluorescent retrobeads were stereotaxically injected into the dorsal alBST in young adult male rats. One week later, whole-cell recordings were made in labeled neurons in brain slices containing the CEA. Ex-4 (400 nM), the synthetic GLP1 analogue, was bath applied to activate GLP1Rs. In current-clamp mode, Ex-4 produced an upward shift in the membrane potential of labeled neurons ($p<0.01$; n=11), which led to spontaneous firing in 4 out of 11 neurons. In other neurons (n=6), Ex-4 effects were blocked by prior application of the GLP1R antagonist Ex-9. Blockade of synaptic transmission eliminated the depolarizing effects of Ex-4 (n=6), suggesting an indirect effect of GLP1R signaling within the slice. In voltage-clamp mode, Ex-4 did not affect the amplitude or frequency of spontaneous IPSCs (n=7), but reduced the amplitude of miniature IPSCs ($p<0.05$, n=7). Ex-4 increased the amplitude of spontaneous EPSCs ($p<0.05$; n=5), but did not affect their frequency, and did not affect the amplitude or frequency of miniature EPSCs. Thus, GLP1R signaling promotes activation of dorsal alBST-projecting CEA neurons through membrane depolarization, enhanced excitatory drive, and reduced inhibitory drive, consistent with GLP1R-mediated recruitment of CEA-alBST circuits that contribute to anxiety and stress responsiveness.

Title: Identification of a central neural circuit that regulate bone mass

Authors: *F. YANG[1], Y. LIU[1,2], S. CHEN[1,2], D. GAO[1,2], J. SHAO[1,2], L. WANG[1];

Abstract: The central nervous system is crucial in controlling energy expenditure and metabolism homeostasis; the extreme and isolated microenvironment could not only induce the psychological changes through central neural networks but also send signals to regulate the peripheral metabolism in a top-down manner. The homeostasis of bone metabolism is finely regulated by the central nervous system and recent studies have suggested that mood disorders such as anxiety are closely related with bone metabolic abnormalities. However up to now the central neural circuits regulating bone metabolism is not clear. In this study we found that the confined isolation of crewmembers could result in both elevated anxiety and decreased bone density; then we established a mouse model of anxiety-induced bone loss to understand the neural circuitry underlying the anxiety-induced bone loss. We firstly demonstrated that the GABAergic neural circuitry in ventromedial hypothalamus (VMH) mediated the anxiety-induced bone loss; a specific group of GABAergic neurons in bed nucleus of the stria terminalis (BNST) sent neural projections to VMH, and this BNST-VMH neural circuitry was both sufficient and necessary to drive the anxiety-induced bone loss through nucleus of solitary tract (NTS). Our findings thus not only provide important clues to understand the neural mechanism of anxiety induced bone loss, but also help to further understand the mechanism of brain top-down control of bone metabolism.

Title: Early post hatch exposure to stressors altered growth and induced DNA hypomethylation of corticotropin releasing factor in the hypothalamic paraventricular nucleus of chicks predisposed to anorexia

Authors: *Y. XIAO, J. WANG, P. B. SIEGEL, M. A. CLINE, E. R. GILBERT;
Dept. of Animal and Poultry Sci., Virginia Polytechnic Inst. and State Univ., Blacksburg, VA

Abstract: When subjected to a combination of nutritional and thermal stressors at hatch, chicks from a line selected for low body weight (LWS), which are predisposed to anorexia, had increased expression of neuropeptide Y (*NPY*) in the arcuate nucleus (ARC) and corticotropin-releasing factor (*CRF*) in the paraventricular nucleus (PVN) of the hypothalamus at 5 days post-hatch. Also, they were refractory to the orexigenic effect of exogenous NPY on day 5 post-stress. We hypothesized that stressor-induced changes in gene expression involved epigenetic regulation, and determined global DNA methylation and DNA methyltransferase (DNMT) activity, as well as *NPY* and *CRF* gene-specific methylation. Stressor-exposure was associated with reduced yolk sac resorption, body weight, lean mass, and fat mass during the first 5 days post-hatch. Stressor-exposure induced global hypermethylation and increased DNMT activity in the ARC but not PVN. There was no effect on methylation status of CpG sites near the *NPY* gene in the ARC. In the PVN of stressor-exposed chicks, there was hypomethylation of a CpG site that is in the core binding domain of methyl cytosine binding domain protein 2 (MBD2) in the *CRF* gene promoter. These results demonstrate that early-life exposure to stressors intensifies the anorexic condition in LWS chicks. There was reduced utilization of yolk reserves, impaired growth, and hypomethylation of a CpG site on the *CRF* promoter that is a target for a transcriptional repressor, MBD2. These findings provide novel insights on molecular mechanisms through which stressful events induce or intensify anorexia in individuals predisposed to the condition and provide a novel molecular target for subsequent studies.

Title: Neuroactive steroid (3α,5α)3-hydroxypregnan-20-one alters the extrahypothalamic CRF signal and stress response with sex and regional specificity

Authors: *G. BOERO, I. BALAN, C. A. TODD, T. K. O'BUCKLEY, A. L. MORROW;
Dept. of Psychiatry and Pharmacology, Bowles Ctr. for Alcohol Studies, Univ. of North Carolina Sch. of Med., Chapel Hill, NC

Abstract: Alterations in steroidogenesis and dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis activity have been observed in several neuropsychiatric disorders, including drug addiction. Corticotropin-releasing factor (CRF) regulates the stress response in the hypothalamus, but also modulates neurotransmission across the brain through CRF receptors. Acute stress increases CRF in hypothalamus (HYP) as well as the endogenous neurosteroid (3α,5α)3-hydroxypregnan-20-one (3α,5α-THP, allopregnanolone) which subsequently attenuates this CRF response, and enhances GABAergic transmission throughout brain.To test the possibility that 3α,5α-THP inhibits CRF signaling in extrahypothalamic regions, we examined the effects of 3α,5α-THP on the CRF signal and stress response in the central nucleus of the amygdala (CeA), hippocampus (HP), nucleus accumbens (NAc) and ventral tegmental area (VTA), both in male and female rats. Sprague Dawley rats were injected with 3α,5α-THP (15mg/kg, ip) in hydroxypropyl-beta-cyclodextrin (45%) or an equivalent volume of vehicle and after 15 min subjected to 30 min of restraint stress, sacrificed instantly or after 3hrs, and brains were harvested for western blot measurements of CRF. We observed a sex difference in basal CRF expression in HYP (males +72% vs females, p&lt0.05; 2-way ANOVA, Tukey's post-hoc test), but not in CeA, HP, NAc or VTA. In males, 3α,5α-THP reduced basal levels of CRF in CeA (-64%, p&lt0.01), HP (-30%, p&lt0.05) and VTA (-54%, p&lt0.001), but not in the HYP or NAc. In contrast, 3α,5α-THP reduced basal levels of CRF only in the VTA (-38%, p&lt0.05) of female rats. Restraint stress for 30 minutes exhibited sex dependent effects in the HP and VTA. In male rats, stress reduced CRF (-72%, p&lt0.01) in the HP, but increased CRF (+36%, p&lt0.05) of female rats in the same area. In addition, stress increased CRF levels (109%, p&lt0.01) 3 hrs. after the start of restraint stress in VTA of male rats, but decreased CRF (-49%, p&lt0.05) in VTA of female animals. Furthermore, stress increased CRF in the HYP (178%, p&lt0.001) of female rats. 3α,5α-THP did not alter the stress-induced increase in CRF in VTA of male rats, but prevented the stress-induced change in CRF in female rat HP, HYP and VTA.The data indicate that 3α,5α-THP inhibits basal CRF protein expression in the VTA of both male and female rats but only inhibits stress-induced CRF in the VTA of female rats, suggesting that female rat VTA is particularly responsive to the effects of 3α,5α-THP. Further studies will focus on the mechanisms of 3α,5α-THP regulation of CRF across brain.

Abstract: Corticotropin-releasing factor (CRF) integrates endocrine, immune and behavioral stress responses in mammals. Clinical and preclinical evidence demonstrates that inappropriate CRFergic activity is a common factor shared by neuropsychiatric conditions associated with stress, for instance, anxiety-, depressive-, and substance abuse disorders. In this study, we submitted rodents to social defeat using an intermittent resident-intruder paradigm to mimic the human patterns of exposure to social stress. Our study aimed to provide insights for a better understanding of the role of the CRFergic system on anxiety and depressive-like symptoms induced by social stress. Social defeat was applied on three cohorts of male Wistar rats (n = 15-16 per cohort) by short confrontations with a reliably aggressive resident every three days for 10 days. Control animals (n = 14-17 per cohort) were left undisturbed in their home cages. Animals were evaluated for anhedonia before and after stereotaxic surgery for guide-cannula implantation in the bed nucleus of stria terminalis. Each cohort received different intra-BNST microinjections of selective CRFergic antagonists. Drugs used were the CRF binding protein antagonist CRF_{6-33}, the CRF receptor type 1 antagonist CP316311, and the CRF receptor type 2 antagonist Astressin 2B. The experience of intermittent episodes of social defeat stress disrupted social interaction behaviors in two out of the three cohorts. Microinjections of CRF_{6-33} and CP316311 in the bed nucleus of the stria terminalis, separately, restored social approach behavior in stressed animals. Effects of Astressin 2B could not be evaluated since animals did not present stress-induced symptoms during the social preference tests. These findings suggest a distinct interpretation for the CRF sequestrating role of the CRF binding protein, as proposed in the literature. It seems that the CRF binding protein enhances CRF receptor type 1 signaling, and that the antagonism of this protein also prevents the onset of anxiety responses.

Title: Role of CRF_1 receptors in the lateral hypothalamus in cardiovascular responses during acute and repeated restraint stress

Authors: *L. BARRETTO-DE-SOUZA, R. BENINI, C. C. CRESTANI;
Princípios Ativos Naturais e Toxicologia, Faculdade De Ciências Farmacêuticas De Araraquara, Araraquara, Brazil

Abstract: Introduction: The lateral hypothalamus (LH) is an important hypothalamic area that has been implicated in the integration of physiological and behavioral responses to stress. In this sense, studies have shown the involvement of this hypothalamic area in the cardiovascular responses to aversive stimulus. The CRFergic system has been shown to be an important mechanism in the central nervous system involved in the etiology of the physiological adjustments evoked by exposure to aversive situations. Data also showed that exposure to chronic stress affects the expression of CRF receptors and the levels of CRF and urocortins in brain regions involved in the control of stress responses. However, the role of CRFergic neutransmission within the HL in the cardiovascular responses during acute and repeated restraint stress has not been investigated. **Objectives:** Here, was investigated the effect of bilateral microinjection into the LH of the selective CRF_1 receptor antagonist CP376395 in the cardiovascular responses induced during the first and the 10^{th} session of restraint stress in rats. **Materials and Methods:** Male Wistar rats (250g) had cannula-guide bilaterally implanted within the LH. A catheter was implanted into the femoral artery for mean arterial pressure (MAP) and heart rate (HR) recording. The restraint stress was realized by placing the animals in a plastic cylindrical tube for 60 minutes. Independent sets of animals received CP376395 (5 mol/100nL) or vehicle into the LH 10 minutes before the onset of the first or 10^{th} session of restraint stress. **Results:** Bilateral microinjection of CP376395 into the LH did not alter the increase in MAP during either the first ($F(1, 16) = 3{,}043$ $P>0.05$) or the 10^{th} ($F(1, 12) = 0{,}1447$ $P>0.05$) session of restraint stress. However, the blockade of the CRF_1 receptor within the LH decreased the restraint-evoked tachycardiac response in both the first ($F(1, 16) = 4{,}659$ $P<0.05$) and 10th ($F(1, 12) = 5{,}903$ $P<0.05$) restraint session. The effects of the LH pharmacological treatment in tachycardic response to restraint was not statistically different between the restraint sessions ($F(1, 12) = 1{,}719$ $P>0.05$). **Conclusion:** The CRFergic neurotransmission in the LH,

acting through activation of the CRF_1 receptor, is involved in control of the tachycardiac response during aversive threats

Title: Inhibition of calcineurin attenuates stress-induced expression of CRF and IL-2 in the central nucleus of the amygdala

Authors: *P. J. RONAN[1], T. I. MEHTA[1], T. P. BERESFORD[2];
[1]Psychiatry and Basic Biomed. Sci., VA Research/USD Sanford Sch. of Med., Sioux Falls, SD;
[2]Psychiatry, Denver VA/UC Denver, Denver, CO

Abstract: We have shown that immunosuppressants acting through inhibition of calcineurin (CLN) in brain reduce alcohol intake in rodents. Calcineurin is an abundant phosphatase in brain and plays a key role in the transcription of both cytokines and signaling molecules related to addiction. Ethanol withdrawal is known to activate corticotropin releasing factor (CRF) signaling in the central nucleus of the amygdala (CeA). We sought to determine whether inhibition of calcineurin could prevent stress-induced transcription of CRF and cytokines in the CeA. Rats (n=8) were given either CsA (30 mg/kg, I.P.) or vehicle, exposed to 30 minutes of restraint stress and returned to their home cage for 90 minutes. Brains were rapidly dissected and frozen in isopentane on dry ice. The CeA was microdissected from 300 um frozen sections and qRT-PCR was performed. Stress-induced expression of both CRF and interleukin 2 (IL-2) mRNA was significantly attenuated in CsA treated animals relative to controls but c-fos mRNA, an immediate early gene product indicative of neuronal activation, was increased by CsA treatment. Conclusion: These data suggest a complex interaction resulting in decreased stress-induced expression of both CRF and IL-2 in the central nucleus of the amygdala while at the same time effecting an increase in CeA neuronal activation in response to stress. The significant anti-drinking effect of cyclosporine-A may be due to calcineurin's role in multiple pathways involved in brain stress, reward, and neuroimmune responses. Deciphering proximal mechanisms underlying the anti-drinking effects of calcineurin inhibition holds promise for the development of effective treatments where few exist.

Title: The role of central amygdala CRF+ neurons in conditioned place avoidance in adult Wistar rats

Authors: ***T. J. TEMPLETON**[1], M. M. WEERA[2], N. W. GILPIN[3];
[1]Physiol., LSU Hlth. Sci. Ctr., New Orleans, LA; [2]Physiol., LSUHSC New Orleans, New Orleans, LA; [3]Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA

Abstract: Post-traumatic stress disorder (PTSD) is a costly debilitating psychiatric condition that affects a subset of those exposed to a traumatic event. The neurocircuitry underlying this disorder is still unclear and treatments are often ineffective. Diagnostic criteria include symptoms from four clusters including avoidance of trauma-associated stimuli. Avoidance behavior is highly predictive of PTSD severity, duration, and treatment response. The central amygdala (CeA) contains a dense population of corticotropin-releasing factor (CRF) neurons that mediate behavioral responses to stressful stimuli. CRF in the CeA can be synthesized locally or imported via afferent projections from other brain regions. The purpose of this work is to understand the role of CeA CRF in the long-term effects of traumatic stress on brain and behavior. We hypothesized that selective activation of CRF+ cells in the CeA would produce avoidance of conditioned stimuli in otherwise experimentally naïve animals. In this study, male and female CRF:cre transgenic rats received intra-CeA infusions of the Cre-dependent adeno-associated viral vector (AAV5-hSyn-DIO-hM3Dq-mCherry) or control virus (AAV5-hSyn-DIO-mCherry). After four weeks, rats were submitted to the following place conditioning (CPA) protocol: on the first day, rats freely explored both chambers, each with specific visual and tactile cues, of a two-chamber apparatus. During ensuing conditioning sessions, in an alternating order across days, rats were confined to one of the two chambers and systemically injected (i.p.) with the DREADD agonist clozapine-n-oxide (CNO). Each individual rat was repeatedly injected with the same single dose of CNO (0, 2, 4 mg/ml/kg BW) throughout the experiment. On alternating days, all rats were administered a vehicle (20% DMSO in saline) injection (1 ml/kg BW) in the other chamber. After 6 conditioning days (3 CNO and 3 vehicle), rats were tested for time spent in the two chambers and a post-test minus pre-test score was calculated for each rat. The conditioning (3 CNO injections/3 saline injections; one per day) and post-test (one day) procedures were repeated twice more (3 weeks for the entire procedure). Preliminary results

suggest that chemogenetic activation of CRF+ cells supports conditioned avoidance behavior in males, but not female rats. These findings suggest that activation of CeA CRF cells is aversive for male but not female rats. Results from this study suggest there are sex differences in the role of amygdalar CRF in mediating aversion and perhaps in mediating traumatic stress effects on behavior.

Title: Vasopressin has sex-specific effects on short-term potentiation in CRH neurons after stress

Authors: *S. P. LOEWEN, J. S. BAINS;
Hotchkiss Brain Inst., Univ. of Calgary, Calgary, AB, Canada

Abstract: A single stress primes glutamate synapses onto corticotropin-releasing hormone (CRH) neurons in the hypothalamic paraventricular nucleus (PVN). This priming allows these synapses to undergo robust short-term potentiation (STP) in response to tetanic stimuli. We have recently shown that the presence of a partner decreases STP following a single stress in female, but not male mice. These findings indicate that social interactions have sexually dimorphic effects on the long-term synaptic consequences of stress. How this occurs, at the cellular level, is not known. Increasing evidence suggests that neurons in PVN are sensitive to neuromodulation by locally released substances. Here, we examined the effects of vasopressin (AVP) on stress-induced STP in CRH neurons. Hypothalamic slices were obtained from male and female Crh-IRES-Cre; Ai14 mice subjected to a footshock protocol (0.5 mA for 2 s delivered every 30 s over 5 min). A subset of slices were incubated in 100 nM AVP dissolved in artificial cerebrospinal fluid for 30 min. Following AVP incubation, whole-cell recordings were obtained from CRH neurons. AVP significantly reduced STP in CRH neurons from females (non-incubated, 152.2 ± 8.2%, n=17; AVP-incubated, 120.2 ± 5.7%, n=16; p=0.003), but not males (non-incubated, 137.1 ± 7.6%, n=12; AVP-incubated, 126.1 ± 8.0%, n=9; p=0.3). The effects of AVP on STP in female mice were prevented by pre-incubation in a V1a receptor antagonist (SR 49059, 147.5 ± 9.0%, n=10). Furthermore, the AMPA:NMDA ratio was significantly reduced in cells following AVP incubation compared to cells from non-incubated control slices (non-incubated, 3.8 ± 0.5, n=9;

AVP-incubated, 2.2 ± 0.4, n=5; p=0.04). These findings indicate that AVP may reduce STP in CRH neurons by enhancing NMDAR-mediated currents and/or decreasing AMPAR-mediated currents in these cells, and implicate this neuropeptide as a potential mediator of social stress buffering in female mice.

Title: Fear and anxiety in the hypothalamus

Authors: *T. FUZESI, D. G. ROSENEGGER, N. DAVIU, T. CHOMIAK, L. A. MOLINA, N. P. RASIAH, J. S. BAINS;
Hotchkiss Brain Inst., Calgary, AB, Canada

Abstract: In addition to controlling the endocrine response to stress, corticotropin-releasing hormone (CRH) neurons in the paraventricular nucleus of the hypothalamus (PVN) also regulate specific stress-related behaviors. Evidence suggests these two processes may be controlled independently, but precisely how these neurons encode both rapid behavior and slow hormone release is not known. Here, we used *in vivo* single fibre photometry and the genetically encoded Ca reporter, GCaMP6s to assess real-time calcium changes in PVN CRH neurons in freely behaving mice. We examined PVN CRH activity in conditions with increasing degrees of negative valence (homecage, novel environment and footshock). Consistent with recent reports, CRH neurons show a rapid, transient increase in $^{Ca2+}$ in response to an acute footshock stress. By contrast, exposure of the animal to a mild stress (placement in a novel environment) elicits an increase in the GCaMP signal (compared to homecage). This increase persists for the duration of the exposure to the novel environment. Repeated exposure (4 days) to the same novel environment had no effect the amplitude of this persistent increase. Exposure to an environment associated with footshock also induced a sustained elevation, however with a higher amplitude. These observations indicate that PVN CRH neurons show distinct activity profiles that reflect the duration and intensity of the stressor.

Title: PVN-CRH neurons control innate escape behaviors

Authors: *N. DAVIU, T. FUZESI, D. ROSENEGGER, N. RASIAH, T.-L. STERLEY, G. PERINGOD, J. BAINS;
Univ. of Calgary, Calgary, AB, Canada

Abstract: Flight or freeze are instinctive responses to threat. These behaviors are one component of a broader stress response that includes the recruitment of hypothalamic PVN CRH neurons. Here we reveal an unexpected role for these neurons as a modifiers of the flight response to threat. We used single fiber photometry to record *in vivo* calcium responses in PVN CRH neurons during different situations that require mice to engage in an innate escape behavior. Our results demonstrate that flight /escape responses to an advancing shadow are preceded by an increase in calcium in CRH neurons. In addition, inhibition of this cell population decreases the probability of escape, suggesting a permissive role for CRH neurons. Further, we show that these behaviors, although instinctive, are also trainable. We show a differential entrainment of CRH neurons to an uncontrollable (learned helplessness) vs controllable (learned avoidance) stress training protocol. Following controllable, but not uncontrollable stress, CRH neurons show associative learning. When challenged with a looming shadow, controllable stress subjects show an increase in CRH calcium and a flight response, but uncontrollable stress subjects show a bias toward freezing and no increase in CRH calcium. These findings provide evidence that CRH neurons encode a preparatory signal for an innate survival behaviors to a threat and demonstrate that behavioral training can alter this signal and modify instinctive behavior.

Title: An *in vivo* electrophysiology study of neurons in the paraventricular nucleus of the hypothalamus responding to stress

Authors: *A. ICHIYAMA[1], K. SCOTT[2], B. L. ALLMAN[2], W. INOUE[1];
[2]Anat. and Cell Biol., [1]Univ. of Western Ontario, London, ON, Canada

Abstract: A hallmark of the stress response, the activation of the hypothalamic-pituitary-adrenal (HPA) axis, starts with the release of corticotropin releasing hormone (CRH) from neuroendocrine neurons in the paraventricular nucleus of the hypothalamus (PVN). Although it is generally believed that CRH release is encoded by the firing activities of PVN-CRH neurons, the *in vivo* firing activity of these neurons remain unknown as traditional electrophysiology methods are unable to distinguish neurons intermingled in the PVN by their neurochemical identities. To investigate this, we used a combination of optogenetics and electrophysiology to "tag" the *in vivo* firing activity of CRH neurons by expressing light-activated channelrhodopsin (ChR2).
In anesthetized, head-fixed mice, we first recorded the spontaneous single unit firing activities of unidentified PVN neurons during a no stress baseline and following stressful sensory stimuli (sciatic nerve stimulation). Using off-line wave form analysis, we found that sciatic nerve stimulation elicits heterogeneous responses from PVN neurons. While most units increased firing frequency, we found units that were non-responsive or even decreased firing.
We then used optogenetics to identify the spontaneous activity of PVN-CRH neurons. Light stimulation of ChR2-expressing CRH neurons elicited time-locked increases in firing activity, which provided fingerprint waveforms of light-responding PVN-CRH neurons. This allowed us to identify the activity of PVN-CRH neurons from spontaneous recordings. Finally, we observed both light and sciatic nerve stimulation induced increased activity in the same recording. This is the first demonstration of firing activities of identified PVN-CRH neurons *in vivo*.

Abstract: Activation of the hypothalamic-pituitary-adrenal (HPA) axis is a hallmark of the stress response conserved across vertebrates. Although adaptive in the short-term, protracted recruitment of this energetically costly response can be maladaptive. Indeed, the HPA axis is flexible and can habituate after repeated stress exposures. Despite the biological and clinical importance of HPA axis habituation, surprisingly little is known about the neural plasticity mechanisms through which repetition of stressful experiences refines the sensitivity of the stress axis to the stressor. Here we report a neural correlate for HPA axis habituation. Using a mouse model of repeated restraint and slice patch-clamp electrophysiology, we studied hypothalamic corticotropin-releasing hormone neurons that form the apex of the HPA axis. We found that the intrinsic excitability of these neurons substantially decreased after daily repeated stress in a time course that coincided with their loss of stress responsiveness *in vivo*. This intrinsic excitability plasticity co-developed with an expansion of surface membrane area, resulting in an increase in input conductance with minimal changes in conductance density. Moreover, repeated stress augmented ruffling of the plasma membrane, suggesting an ultrastructural plasticity that may efficiently accommodate membrane area expansion. We report a novel structure-function relationship for intrinsic excitability plasticity that correlates with habituation of the neuroendocrine stress response.

Title: Synaptic sensitization to stress mediated by hyperpolarization-activated cyclic nucleotide-gated (HCN) channels

Authors: *J. K. SUNSTRUM[1,2], E. W. SALTER[3], W. INOUE[4,2];
[1]Neurosci., The Univ. of Western Ontario, London, ON, Canada; [2]Robarts Res. Inst., London, ON, Canada; [3]Physiol., Univ. of Toronto, Toronto, ON, Canada; [4]Physiol. and Pharmacol., Univ. of Western Ontario, London, ON, Canada

Abstract: The hormonal and behavioural response to stress can habituate (diminish its responsiveness) to repeated familiar stressors while maintaining its responsiveness to unfamiliar (novel) stressors. A prevailing theory of stress habituation predicts two opposing forms of plasticity, one that diminishes and another that sensitizes the stress response. While this may involve plasticity in segregated populations of neurons, whether a single population of neurons can accommodate the opposing forms of stress-induced changes remains unknown. The hormonal and behavioural response to stress is controlled by corticotropin releasing hormone (CRH) neurons in the paraventricular nucleus of the hypothalamus (PVN). Our recent study found that, in a mouse model of repeated stress, the intrinsic excitability of CRH neurons decreases, a mechanism in line with habituation. Here, we investigated a mechanism that enables a sensitized response to an unfamiliar stressor in the same stress model. Considering that afferent glutamatergic synapses are the major excitatory inputs onto CRH neurons, we hypothesized that potentiation of these excitatory synapses represents a neural correlate for sensitized responses to an unfamiliar stressor. Crh-IRES-Cre;Ai14 mice underwent the well-established repeated restraint stress paradigm (21 days of 1 hours per day restraint). We then used *ex vivo* whole-cell patch clamp electrophysiology to study CRH neuron synaptic activity. We found that pharmacologically stimulating cAMP (either by activating adenylyl cyclase or blocking cAMP breakdown by phosphodiesterase) potently increased the frequency of spontaneous excitatory postsynaptic currents (sEPSCs) in CRH neurons ($p < 0.0001$ and $p = 0.0006$, respectively). In line with our hypothesis, this cAMP-induced increase in sEPSC frequency was even greater following our repeated stress paradigm ($p < 0.0001$), suggesting CRH neurons are sensitized to cAMP facilitation of glutamate release following stress. Furthermore, this cAMP-induced facilitation was dependent on presynaptic hyperpolarization-activated cyclic-nucleotide-gated (HCN) channels. This work identifies a novel homeostatic mechanism that supports sensitization of the stress response in the same model known to show habituation to repeated stressors.

Title: Inhibition of corticotropin-releasing factor (CRF) neurons in the oval nucleus of the bed nucleus of the stria terminalis does not affect anxiety-like behavior in adult male rats

Authors: *R. CHUDOBA[1,2,3], V. OLIVERA[1,2,3], P. LIS[1], C. EDMONSON[1], S. OLSON[1,2], J. A. DABROWSKA[1,2,3,4];

Pharmacol., North Chicago, IL; [4]Chicago Med. Sch. RFUMS, North Chicago, IL

Abstract: Corticotropin-releasing factor (CRF) is a neuropeptide responsible for regulating autonomic, endocrine, and behavioral responses to stress. A significant population of CRF-producing neurons is found in the oval nucleus of the bed nucleus of the stria terminalis (BNSTOV), a brain region that mediates behavioral responses to stressors such as fear and anxiety. Here, we used a Cre-CRF transgenic rat model that expresses Cre-recombinase driven by the CRF promoter to investigate the role of CRF neurons in the BNSTOV in modulating anxiety-like behavior and contextual fear. We infused male adult rats bilaterally with Cre-dependent adeno-associated viral vector driving expression of inhibitory designer receptors exclusively activated by designer drugs (DREADD) to selectively silence CRF neurons in the BNSTOV and investigate the corresponding behavioral effects. Four weeks after stereotaxic AAV injections in Cre-/- and Cre+/- rats, we investigated if silencing CRF neurons with DREADDs selective ligand, clozapine-N-oxide (CNO), affected anxiety-like behavior using the elevated plus maze (EPM) and open field test (OFT), or contextual fear conditioning (CFC) and acoustic startle response (ASR). In the EPM, percentage time spent in open arms of the maze did not differ between Cre-/- (n = 18) and Cre+/- (n = 13) rats after CNO injection (P = 0.3678). Similarly, in the OFT, percentage time spent in the area center did not differ between Cre-/- (n = 9) and Cre+/- (n = 11) rats (P = 0.8319) nor did silencing CRF neurons affect locomotion (P = 0.4807), suggesting that inhibiting CRF neurons does not affect baseline anxiety-like behaviors. In another experiment, CNO was injected before CFC to determine if silencing CRF neurons affects acquisition of contextual fear in a fear-potentiated startle experiment. Although all rats displayed significant potentiation of the ASR during exposure to context previously paired with foot-shocks (P = 0.0004), there was no genotype effect (P = 0.9218) nor interaction between trial

type and genotype (P = 0.7637, n = 21). Next, we tested ASR where all rats were first tested for their baseline ASR (pre-test) and ASR after CNO injection (post-test). Although time (pre-test vs. post-test, P = 0.6093) and genotype (P = 0.7425) did not affect ASR, we observed a significant interaction between time and genotype (P = 0.0397), suggesting that IP injection before post-test affected startle amplitudes differently in Cre-/- (n = 19) and Cre +/- (n = 14) rats. Overall, our results suggest that although silencing CRF neurons in the BNST$_{OV}$ does not affect baseline anxiety-like behavior in male rats, it might attenuate anxiety triggered by exposure to stress.

Title: Stress experience and hormone feedback tune distinct components of CRH neuron activity

Authors: *J. S. KIM, K. J. IREMONGER;
Univ. of Otago, Dunedin, New Zealand

Abstract: Neural circuits in the hypothalamus are essential for coordinating organism's responses to real or perceived threats. These experiences can evoke a cascade of hormonal and synaptic changes to promote adaptation and reshape future responses. However, the plasticity mechanisms driving these adaptations following stress remain poorly defined. Hypothalamic corticotropin-releasing hormone (CRH) neurons orchestrate behavioral and endocrine responses to stress and are themselves highly sensitive to corticosteroid (CORT) stress hormones. Using fibre photometry in freely behaving mice, we recorded the CRH neuron activity dynamics to understand how their excitability and stress responses can be tuned. We observed that CRH neurons are tonically active and rapidly activated in response to stress (5min loud white noise). Stress-evoked CRH neuron activity robustly habituated to repeated presentations of the same stressor. This habituation was observed following inter-stress intervals as early as 30 min (65.4% of novel response) and lasting at least 24 hours (63.8% of novel response). This adaptation was dependent on stress familiarity as CRH responses failed to habituate against sequential presentations of unfamiliar threats (white noise vs footshock). To address the role of CORT feedback in tuning CRH neuron activity, peripheral administrations of CORT or metyrapone were used to manipulate feedback milieu. Negative feedback inhibited stress-induced ACTH release (Veh 178.8 ±29.7 pg/mL vs CORT 91.9 ±19.0 pg/mL, p=0.04) but had no discernable effects on the magnitude of CRH neuron activation in response to acute stress and the ability to

habituate to repeated stress remained surprisingly unchanged. Instead, CORT was found to slowly (>60 min) inhibit tonic CRH neuron activity in the absence of stress stimuli. These findings reveal how stress experience and stress hormones modulate distinct components of CRH neuronal activity to mediate stress-induced adaptations and challenge the notion that rapid CORT actions are involved in the CRH neuron "shut-off".

Title: Ultradian and circadian rhythms in hypothalamic CRH neuron activity and their relation to home cage behavior

Authors: *C. M. B. FOCKE, K. IREMONGER;
Ctr. for Neuroendocrinology, Univ. of Otago, Dunedin, New Zealand

Abstract: Corticotropin-releasing hormone (CRH) neurons control the hypothalamic-pituitary-adrenal (HPA) axis and thereby the circulating levels of corticosterone (CORT). CORT secretion occurs with a prominent circadian and ultradian rhythm. However, the neural activity patterns in the CRH neuron population which drive these rhythms are unknown. In addition, it is also unknown whether CRH neuron responsiveness to stress varies as corticosterone fluctuates across the circadian cycle.
Using GCaMP6s fiber photometry we have optically measured the activity patterns of CRH neurons in the paraventricular nucleus of awake behaving adult male mice. Photometry recordings were performed across the 24-hour day along with simultaneous monitoring of home cage behavior. In addition, we tested if the CRH neural responses to a 5-minute white noise stress differed at the circadian peak or nadir of CORT (evening versus morning respectively). CRH neuron population activity was found to be highly dynamic across the 24-hour day. However, we found no differences in event frequency or amplitude across the day-night cycle. Most notable however, was the presence of distinct ultradian oscillations (up-states) which occurred every 54 ± 7.8 min (n=7 mice). These up-states were significantly longer in duration over the night (active phase; 23.8 ± 1.2 min) as opposed to the day (inactive phase; 19.9 ± 1.0 min; p=0.01). Furthermore, behavioral analysis revealed that increases in CRH neuron activity were closely related to home cage activity (n=5 mice).
In response to a 5-minute white noise stressor, CRH neuron population activity quickly and robustly increased. However, both the average (AM: 26.2 ± 5.8%, PM: 30.1 ± 7.7%; p=0.1; n=7) and peak responses (AM: 63.6 ± 8.2%, PM: 71.6 ± 10.2%; p=0.1) were the same if the stress was

delivered in the evening versus the morning.
Taken together, these data reveal ultradian and circadian rhythms in CRH neuron excitability across the day with a strong link to home cage activity. However, CRH neural responses to stress were not found to be different across the day.

Abstract: Corticosteroid stress hormones drive a multitude of adaptations in the brain. Hypothalamic corticotropin-releasing hormone (CRH) neurons control the circulating levels of corticosteroid stress hormones in the body and are themselves highly sensitive to corticosteroids. CRH neurons have been shown to undergo various adaptions in response to acute stress hormone elevations. However, the changes in excitability under chronically elevated corticosterone are less clear. To address this, we have used in vitro electrophysiology and calcium imaging to study the changes in neural excitability in CRH neurons in the paraventricular nucleus of the hypothalamus following 14 days of corticosterone treatment (25µg/ml) in the drinking water. We find that prolonged corticosterone elevation in male mice reduces CRH neuron intrinsic excitability as measured by summation of subthreshold postsynaptic depolarisations and spiking output. Calcium imaging in brain slices from male mice revealed that CRH neurons fire with a bursting pattern of activity under control conditions, however, exposure to chronic corticosterone significantly reduced the number of neurons exhibiting this bursting pattern. While basal activity was found to be similar in brain slices from control female mice, corticosterone treatment failed to inhibit neural excitability and occasionally induced elevations in excitability. Blood corticosterone measurements revealed that while the drinking water treatment protocol elevated plasma corticosterone in males, it failed to elevate plasma corticosterone in females. Together these data reveal the functional adaptations in hypothalamic CRH neurons following

corticosterone excess and highlight important sexually dimorphic responses to corticosterone treatment regimes.

Title: Understanding sex differences in neural circuits controlling stress

Authors: *E. M. POWER[1], K. J. IREMONGER[2];
[1]Physiol., [2]Univ. of Otago, Dunedin, New Zealand

Abstract: Males and females respond differently to acute stress and have disparate risks for developing stress-related mental health disorders. Stress evoked release of adrenal corticosteroids are controlled by corticotropin-releasing hormone (CRH) neurons, located in the paraventricular nucleus of the hypothalamus. Corticosteroid release profiles are different between males and females as well as across the estrous cycle. However, it is currently unclear to what extent this is due to differences in CRH neuron intrinsic excitability. Estrogen regulates both the expression and function of multiple ion channels throughout the brain. Specifically, estrogen has previously been shown to modify I_A and I_M potassium (K^+) currents. I_A is a transient outward K^+ current and I_M is a subthreshold, slow delayed rectifier K^+ current. Both I_A and I_M currents are important for CRH neuron function and an increase in either current corresponds to a decrease in neuronal excitability. Here we set out to test if differences in CRH neuron excitability exist between males and females as well as across the estrous cycle and whether these differences are due to disparate K^+ channel function. To investigate this, we performed whole cell *in vitro* electrophysiological recordings of CRH neurons to record intrinsic excitability as well as I_A and I_M currents. Examination of frequency-current (F-I) curves revealed that the gain of CRH neuron firing was significantly higher in males compared to estrous and diestrous females ($P<0.001$ and $P<0.001$ respectively). Interestingly proestrous females had significantly higher F-I gain than estrous ($P<0.001$) and diestrous ($P<0.001$), but were not significantly different from males ($P=0.3325$). Despite the difference in excitability between the groups, action potential parameters, including halfwidth, rise time, amplitude and activation threshold, we remarkably similar.Consistent with the differences in excitability, both I_A and I_M currents were significantly larger in estrous and diestrous females compared to males and

proestrous females (2-way ANOVA, P=0.0006 and P=0.003 respectively, n>7 for each group). As estrous and diestrous females have lower circulating estrogen levels compared to proestrous, this may explain the differences in excitability and K^+ channel function across the estrous cycle. Our findings suggest estrogen driven changes in K^+ channel function may underlie variable CRH neuron excitability levels between stages of the estrous cycle. These differences may also contribute to sex differences in CRH neuron excitability and thus underlie sexually dimorphic responses to acute stress.

Title: Functional characterization of hypothalamic CRF neuron during exposure to appetite and aversive stimuli

Authors: *J. KIM, G. SUH;
Dept. of Biol. Sci., Korea Advanced Inst. of Sci. and Technol., Daejon, Korea, Republic of

Abstract: Corticotropin-releasing factor (CRF) neuron in the Paraventricular nucleus of hypothalamus secretes CRF when exposed to stress. CRF initiates a cascade of events that triggers the release of glucocorticoids from the adrenal cortex. The modulation of the hypothalamic-pituitary-adrenal (HPA) axis is essential for adjusting the neuroendocrine responses to stress, but it does not explain how PVN CRF neurons mediate behavioral changes in response to acute stress. Previous calcium imaging and optogenetic manipulation studies revealed that PVN CRF neurons are immediately activated by aversive cues and are rapidly suppressed by appetitive stimuli and that these neurons are essential for mediating behavioral responses to acute stress and appetitive stimuli (J. Kim, Nature Neuroscience 2019). These findings suggest that there exists a different mechanism independent of HPA axis. To further examine whether the response of PVN CRF neurons to acute environmental stimuli is independent of HPA axis, we surgically removed adrenal glands (adrenalectomy) in CRF-ires-cre mice and tested these mice with optogenetically activating or inhibiting PVN CRF neurons in different behavioral paradigms.

Title: Depressive-related behaviors are modulated by crf neurons of the bnst

Authors: *S. E. HAYNES[1], H. SEO[2], D. G. RAINNIE[3], M.-H. HAN[4];
[1]Icahn SOM At Mount Sinai, New York, NY; [2]Emory, Atlanta, GA; [3]Emory Univ., Atlanta, GA; [4]Mount Sinai Sch. of Med., New York, NY

Abstract: Chronic stress is a key risk factor for the development of Major Depressive Disorder (MDD), yet it is unknown why some people develop MDD as compared to others, despite reporting similar levels of stress. Corticotrophin-Releasing Factor (CRF) has emerged as a molecular substrate that may play a critical role in the etiology of stress-related depression. While many preclinical and clinical studies implicate its role in depression etiology, the relationship between stress, MDD, and CRF neurotransmission is not well understood. The limbic forebrain region, Bed Nucleus of the Stria Terminalis (BNST), encodes the nature and chronicity of stressful stimuli and mediates behavioral/physiological adaptive responses and is thus thought to play a role in depression. Importantly, the oval nucleus of the BNST contains an enriched population of CRF ($BNSTov^{CRF}$) neurons that are stress responsive and thereby may provide a source for the molecular link between CRF and depression. In this study, we seek to elucidate CRF neural mechanisms that underlie depression onset that arises from unmitigated exposure to chronic stress. We hypothesize that the time course to depression-onset is influenced by neuroadapative genetic changes in $BNSTov^{CRF}$ neurons, and that individual differences in crf gene expression may correlate with an individual's vulnerability to depression. To test this, we employed the Chronic Social Defeat Stress paradigm in mice that reliably produces stress-resilient (RES) or depressive-like (DEP) phenotypes on the basis of social interaction and sucrose preference. We have discovered a discrete time window where mice rapidly diverged from baseline behavior to RES or DEP phenotypes, unmasking a temporal dimension to stress-susceptibility. Importantly, gene expression, electrophysiological, and *in vivo* fiber photometry measurements have been conducted to correlate circuit level neuroadaptive changes with those observed behaviorally. Optogenetics and chemogenetics have been used to show necessity and sufficiency for $BNSTov^{CRF}$ neurons for the timing, onset, and severity of depressive behavior. Altogether, these findings provide evidence of a temporal domain to stress adaptation where alterations in CRF neurotransmission may shift the predisposition of mice toward either stress-

resiliency (RES) or stress-induced depressive-like (DEP) phenotypes. This discrete period of neuroadaptation may present a window of opportunity for targeting molecular mechanisms with the possibility of preventing the onset of depression in stress-susceptible populations.

Abstract: Corticotropin-releasing factor (CRF) is a neuroendocrine peptide produced in the paraventricular nucleus of the hypothalamus (PVH), but CRF is also expressed in brain regions outside the PVH and may function as a neurotransmitter or neuromodulator. We generated previously the CRF-modified yellow fluorescent protein (Venus) knock-in mouse (*CRF-Venus,* $CRF^{Venus/wt}$), and then the *CRF-VenusΔNeo* mouse ($CRF^{VenusΔNeo/wt}$) was generated by deleting the pgk-1 promoter-driven neomycin phosphotransferase gene (Neo cassette) from the former genome using the *Actb-FLPe* mouse; the FLP recombinase expressed in the *Actb-FLPe* recognizes the Neo cassette flanked by the flippase recognition target sites and excises it from the *CRF-Venus* genome. We reported that the intensity of Venus expression in the *CRF-VenusΔNeo* was much more prominent than that in the *CRF-Venus*. In the present study, we sought to examine whether the presence or the absence of the Neo cassette in CRF driver mouse genome may also affect expression of a reporter gene. First, the morphological features of the EGFP-expressing neurons in the *CRF-iCre;EGFP*, which was generated by crossing the *CRF-iCre* ($CRF^{iCre/wt}$) with an EGFP-reporter mouse ($Tg^{CAG\text{-}floxed\ CAT\text{-}EGFP/wt}$), was similar to those of the Venus-expressing neurons in the *CRF-VenusΔNeo,* even in the presence of the Neo cassette in the *CRF-iCre* driver mouse genome. Next, distribution and intensity of EGFP expression were not different clearly between the *CRFiCre;EGFP* and the *CRFiCreΔNeo;EGFP*, which was generated by crossing the *CRF-iCreΔNeo* ($CRF^{iCreΔNeo/wt}$) with the EGFP-reporter. Thus, deletion of the Neo cassette from the *CRF-iCre* driver mouse genome did not affect expression of the

EGFP reporter gene explicitly. Finally, intensity of the Cre immunofluorescence was much more prominent in the *CRF-iCreΔNeo* than that in the *CRF-iCre*. From these results, it was assumed that the presence of the Neo cassette may have interfered with the *CRF* promoter, and reduced the expression of *Venus* or *iCre*, in either the *CRF-Venus* or the *CRF-iCre*. However, iCre-induced recombination may have been efficient enough for the full EGFP expression in the *CRF-iCre;EGFP*, even with much smaller amount of iCre expressed in the *CRF-iCre* compared with that in the *CRF-iCreΔNeo*.

Title: Corticotropin releasing factor (CRF) does not influence basal or depolarized GABA or glutamate release from a midbrain defense area

Authors: *J. A. CARR, C. M. PRATER;
Biol. Sci., Texas Tech. Univ., Lubbock, TX

Abstract: The 41 amino acid peptide CRF reduces food intake and related behaviors by acting on tectal CRFR1 receptors in the African clawed frog *Xenopus laevis*. Precisely how CRF acts within the optic tectum to inhibit food intake is unclear but may involve inhibitory GABAergic interneurons. We predicted that if tectal CRFR1-induced inhibition of food intake is mediated via inhibitory GABAergic interneurons, that exogenous CRF would increase basal and evoked GABA release from tectal explants *in-vitro*. Tectal explants from *X. laevis* were depolarized with 60 mM K^+ and GABA was measured in the medium after derivatization using high-performance liquid chromatography coupled to electrochemical detection. GABA secretion from *X. laevis* tectal explants increased under depolarizing conditions and this evoked release was eliminated in calcium-free medium. Exposure of tectal explants to ovine CRF doses ranging from 1 nM to 1 micromolar (AnaSpec, Inc., Fremont, CA; 0, 0.001, 0.01, 0.1, 1 µM) had no effect on either basal or depolarization-induced GABA release. We conclude that our *in-vitro* assay measures calcium-dependent evoked GABA release from tectal explants and that CRF does not appear to influence basal or evoked GABA release *in-vitro*. These findings do not support a role for

GABAergic interneurons in mediating tectal CRFR1 inhibition of food intake. Supported by a grant from National Science Foundation IOS #1656734.

Title: Ketamine rescues behavior and plasticity through dopamine systems

Authors: *M. WU[1], Y. KOZOROVITSKIY[2];
[1]Neurobio. Dept., [2]Neurobio., Northwestern Univ., Evanston, IL

Abstract: Major depressive disorder (MDD) is a prevalent, recurrent mental illness linked to diminished quality of life. Ketamine and its S-enantiomer esketamine, which act as antagonists of the glutamatergic N-methyl-D-aspartate (NMDA) receptors, demonstrate rapid onset anti-depressant effects in clinical trials. However, which neural circuit dynamics mediate the effects of ketamine is still currently unknown. Here, we demonstrate that activity of dopaminergic (DA) neurons in the ventral tegmental area (VTA) changes in an aversive learning paradigm. Ketamine normalizes the impaired dynamics of VTA activity after aversive learning, leading to behavioral symptom relief. The behavioral effects of ketamine require DA signaling, which modulates cortical synaptic plasticity across behavioral states. Together, our data demonstrate a link between DA activity dynamics, synaptic plasticity, and ketamine's behavioral effect in a context of aversive learning.

Title: Prolactin reduces chronic stress-induced depression-like behavior and increases tyrosine-hydroxylase expression in ovariectomized female rats

Authors: *J. MEDINA, D. BESWICK, R. M. DE GUZMAN, J. L. WORKMAN;
Psychology, Univ. at Albany, State Univ. of New York, Albany, NY

Abstract: Postpartum depression (PPD) afflicts approximately 15% of new mothers with debilitating symptoms. The lack of or early cessation of breastfeeding is a unique risk factor for PPD. For instance, women who bottle-feed exclusively are more likely to develop PPD and prospective studies suggest cessation of breastfeeding often precedes depressive symptoms. Thus, certain aspects of lactation may buffer against the development of PPD. Breastfeeding promotes the release of the peptide hormone, prolactin (PRL). Beyond its role in supporting lactation, PRL influences multiple aspects of physiology and behavior including social behavior, neural plasticity, and stress responses in rodent models. Stress is a significant risk factor for depression and abnormalities in the hypothalamic-pituitary-adrenal (HPA) axis have been implicated in the etiology of depression, including PPD. We sought to determine whether prolactin reduces stress-induced depression-like behavior in female rats. Ovariectomized rats were either non-stressed or received chronic variable stress (CVS) and received daily subcutaneous injections of ovine PRL (1 mg/kg) or saline vehicle. Anhedonia was assessed with the sucrose preference test (SPT) at 3 time points during the study: the first day of PRL treatment, 9 or 10 days after the initiation of CVS, and after 20 days of CVS. Passive-coping behavior was assessed with the forced swim test (FST) across two consecutive days (days 23 and 24 of CVS): FST 1 for 15 minutes and FST 2 for 5 minutes. Blood samples from the tail vein were taken 30 minutes after FST 2 to assess stress-induced corticosterone concentrations. Chronic prolactin treatment prevented the development of stress-induced sucrose anhedonia in CVS females. In conjunction with these data, sections of the ventral tegmental area (VTA), a region critical in anhedonia, were labelled for tyrosine hydroxylase (TH) expression to determine whether CVS or PRL alter dopamine-producing cells. Regardless of stress condition, chronic PRL treatment significantly increased TH-immunoreactive cell density in the rostral VTA. Taken together, these findings have critical implications for neuroendocrine mechanisms by which lactation confers resilience against depression.

Title: Ultrastructural analysis of corticotropin-releasing factor regulation of dopaminergic signaling in the midbrain of the macaque

Authors: *E. A. KELLY[1], J. L. FUDGE[2];
[1]Neurosci., Univ. of Rochester Med. Ctr., Rochester, NY; [2]Neurosci., Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: Dopamine (DA) is involved in stress and stress related illnesses, including many psychiatric disorders. Corticotropin-releasing factor (CRF) plays a role in acute and prolonged stress responses by integrating endocrine, autonomic and neural systems. DA is a key target of CRF in the ventral midbrain, providing a fundamental link between stress and altered monoamine function. In the primate, it is now recognized that DA neurons are physiologically heterogeneous with respect to both intrinsic firing and coding properties. Mapping DA subpopulations onto rodent systems is difficult because of a number of differences including: 1) the anatomical expansion in main subpopulations (A10, A9, A8) in primates, 2) relative changes in the size of DA subpopulations, and 3) varying ratios of DA to non-DA cells across A10, A9 and A8 groups. We recently found that a key source of CRF to the DA subpopulations, the central extended amygdala, sends terminals to DA subpopulations that lie mainly outside the midline VTA, preferentially targeting DA subpopulations in the parabrachial pigmented nucleus (PBP) of A10 and the A8 group. We therefore sought to characterize CRF terminals on DA and non-DA cells in the PBP and A8 regions at the ultrastructural level as a first look at understanding CRF dynamics in these subpopulations. A10-PBP and A8 DA neurons are calbindin (CaBP)-positive. Using CaBP and the distribution of CRF-containing fibers in adjacent sections, we prepared blocks from the PBP and A8 subpopulations in a 3-year old male macaque and performed ultrastructural analysis following double immunoperoxidase (CRF) and immunogold reactivity (tyrosine hydroxylase, TH) for electron microscopy (EM). We then determine the synaptic interactions between CRF-containing axons and TH positive (DA+) and TH negative (NON-DA+) neurons in each region. We found CRF immunoreactivity present mostly in axon terminals establishing either symmetric or asymmetric synapse onto dendrites within both the PBP and A8. CRF axons made preferential connections onto NON-DA+ cells in

both regions that were largely symmetric (inhibitory) in nature. Among the DA+ cells, CRF+ contacts were mostly symmetric in PBP while asymmetric (excitatory) in A8. Our preliminary findings suggest similar CRF regulation of non-DA cells in PBP and A8. DA+ cells, however appear to be differently regulated across region.

Title: Inactivation of the deep layers of the superior colliculus disrupts prepulse inhibition in macaques

Authors: *H. F. WAGUESPACK[1], B. L. AGUILAR[2], L. MALKOVA[1], P. FORCELLI[1]; [1]Pharmacol., Georgetown Univ., Washington, DC; [2]Univ. of California, Davis, Davis, CA

Abstract: Sensorimotor gating as measured by prepulse inhibition of the acoustic startle (PPI) is impaired in various disorders, including autism, schizophrenia, and PTSD. The acoustic startle is an unconditioned motor response to a startling stimulus. This response can be reduced when a prepulse of smaller intensity precedes the startling pulse stimulus, a paradigm known as PPI. While the circuitry mediating PPI is well characterized in rodents, it is almost completely unexplored in the primate brain. A recent study from our lab found opposite effects of inhibition of substantia nigra pars reticulata (SNpr) on PPI in rodents and primates (Aguilar et al., 2018). Inactivation of SNpr in rodents disrupted PPI, whereas inactivation in primates facilitated PPI. The SNpr sends direct inhibitory projections to the deep layers of the superior colliculus (DLSC) in both the rodent and the primate. In rodents, lesions to the DLSC reduce PPI and stimulation of the DLSC has the same effect as a prepulse to dampen startle (Fendt & Schnitzler, 1994; Li & Yeomans 2000). The goal of the present study was to compare the effects of DLSC manipulations in macaques to those previously done in rats, to determine if our prior finding was due to divergence at the level of the DLSC. We transiently inhibited the DLSC in four rhesus macaques by bilateral microinfusion of the $GABA_A$ agonist, muscimol (9nmol). Whole-body startle responses were measured with startle pulses between 95-105dB and prepulses between 4-12dB above background noise. Bilateral inhibition of the DLSC significantly disrupted PPI without altering baseline startle amplitude. In contrast to the divergent roles for SNpr between the two species, here we found a similar effect for the DLSC inhibition to that in rodent. These results suggest that the species divergence at the level of the SNpr *is not* due to downstream

differences at the level of the DLSC. These data also underscore the role of the DLSC as a multimodal integrator of sensory information and an important modulator of sensorimotor gating across species.

Title: Effects of altitude on depressive-like behavioral responses in adult male and female rats

Authors: K. NGUYEN[1], C. A. GATES[2], *J. E. HASSELL, Jr[1], C. L. CHO[1], A. ARNOLD[1], A. ELSAYED[1], S. SALAZAR[1], A. LUTHENS[1], M. LEBLANC[4], S. C. ADAMS[4], C. A. LOWRY[3], J. D. REUTER[2];
[1]Integrative Physiol., [3]Dept. of Integrative Physiol. and Ctr. for Neurosci., [2]Univ. of Colorado Boulder, Boulder, CO; [4]Salk Inst., La Jolla, CA

Abstract: Major depression is one of the most prevalent mental illnesses in the United States with an estimated 16.1 million people suffering from a depressive episode every year. The prevalence of major depressive disorder (MDD) among females (8.5%) is nearly twice that of males (4.8%). In addition, states at high altitude in the Intermountain West report higher suicide rates compared with the national average. However, little is known about the effects of acute vs chronic exposure to high altitude on the risk of development of depression or the persistence of depressive symptoms, and there are no previous studies that examine the effects duration of acclimation to high altitude on anxiety- and depressive-like behavioral responses in animal models. We hypothesize that exposure to hypobaric hypoxia at high altitude can increase vulnerability to depression in a gender-specific manner. To determine if high altitude has effects on depressive-like behavioral responses, males and females of two different strains of rats (Sprague Dawley and Long Evans) were tested in the sucrose preference test. Testing took place at sea level or 5,328 feet above sea level (mid- to high altitude) following acclimation for 1, 2, 3, 4, or 5 weeks (n = 8 per group; using a 2 (high altitude versus sea level) x 2 (male versus female) x 2 (Sprague Dawley versus Long Evans) x 5 (1, 2, 3, 4, or 5 weeks) experimental design; N= 320). Rats were euthanized 24 hours after behavioral testing. Here we demonstrate that rats acclimated to 5,328 ft displayed lower sucrose preference, relative to rats housed at sea level, at 1, 2, and 5 weeks of acclimation. Additionally, male rats acclimated to 5,328 ft displayed lower

sucrose preference than female rats acclimated to 5,328 ft, while no sex differences were observed at sea level. Physiologically, using data from both male and female rats, rats tested at 5,328 ft had increased plasma hemoglobin and red blood cell concentrations compared to rats tested at sea level. For red blood cell concentrations, the effect of altitude was evident after 1 and 2 weeks of acclimation. In contrast, for hemoglobin concentrations, the effect of altitude was evident after 1, 2, 3, 4, and 5 weeks of acclimation. These data are consistent with the hypothesis that hypobaric hypoxia at higher altitudes increases vulnerability to development of anhedonic-like behavioral responses.

Title: Manganese enhanced MRI (MEMRI) imaging and changes in cardiovascular reactivity implicate the dorsal raphe in modulating anxiety like behavior in DOCA/salt hypertension

Authors: J. M. WATKINS[1], M. FEBO[2], M. POMPILUS[2], *L. F. HAYWARD[1];
[1]Physiol Sci., [2]Psychiatry, Univ. of Florida, Gainesville, FL

Abstract: Changes in the brain's serotonin and corticotropin-releasing factor (CRF) systems are strongly associated with anxiety and depression. Anxiety/depression and the development of high blood pressure (HBP) are also thought to be interconnected. In the current study, we evaluated whether chronic HBP alters regional baseline brain activity and anxiety related behavior in adult male Sprague Dawley rats. HBP was induced by subcutaneous implantation of a slow-release pellet containing the aldosterone precursor DOCA (150 mg/21 days) and 13 days of elevated salt consumption via voluntary intake of a 1%NaCl/0.2%K+ solution (182 ± 31 vs 22 ± 6 ml/day, DOCA vs control, respectively). One group of rats underwent MEMRI imaging (4.7 T Magnex MR scanner; 25 mg/kg manganese, ip, n=5-7/group). Imaging identified basal activity was significantly reduced in three specific brain regions in the DOCA/salt versus control, including the dorsal raphe, dorsomedial hypothalamus and nucleus accumbens shell (P=0.05). A second group of animals were chronically instrumented with arterial pressure (AP) telemetry probes (Stellar TSE). Resting AP was 151± 10 mmHg in the DOCA/salt group compared to 110 ± 5 mmHg in the controls (P=0.005; n=5/group). On day 13, DOCA/salt and control animals

were placed on an elevated plus maze (EPM) for 5 min. DOCA/salt rats spent significantly more time transitioning between the closed arms and center zone compared to controls (P=0.01). During EPM testing both AP and heart rate (HR) increased, but the rise in both AP and HR was attenuated in the DOCA/salt group, paralleling the reduction in anxiety-like behavior. The average change in AP during EPM testing in the DOCA/salt group was 11± 2 vs 28 ± 3 mmHg in the controls (P=0.001). The rise in HR was 80 ± 4 in the DOCA/salt group vs 103 ± 14 bpm in the controls (P=0.07). These findings support previous work in a genetic model of hypertension, the spontaneously hypertensive rat (SHR) which was identified to have both reduced anxiety and cardiovascular reactivity, and suggest that chronic HBP can attenuate anxiety related responses in rodents. Furthermore, a comparison of whole brain MEMRI imaging from the SHR (Zubcevic J et al., 2018) and the current DOCA/salt model identifies one common brain region potentially involved in attenuating anxiety related behavior in hypertension, the dorsal raphe. Preliminary data shows DOCA/salt hypertension modulates gene expression of both tph2 (serotonin system) and CRF-R1 in the dorsal raphe. The results of this study demonstrate a novel link between tonic dorsal raphe dysregulation and reduced measures of anxiety in chronic HBP.

Title: Identifying glucocorticoid receptor mediated mechanisms of polygene-environment interactions involved in stress sensitivity

Authors: *S. PENNER-GOEKE, S. RÖH, M. JAKOVCEVSKI, E. B. BINDER;
Max Planck Inst. of Psychiatry, Munich, Germany

Abstract: Despite the significant social and economic costs of stress related psychiatric disorders, the molecular mechanisms underlying these diseases remain poorly understood. Using an eQTL approach, previous research from our group successfully identified common functional genetic variants mediating stress sensitivity by altering the transcriptional response of stress-related genes (Arloth, 2015, Neuron). These variants are enriched in long-range enhancer regions in genes targeted by the glucocorticoid receptor (GR), a key transcription factor in the stress response system. Using the variants, a genetic risk score (PRS) was calculated describing transcriptional sensitivity to glucocorticoids (GR-PRS). Importantly, a derivative of this score

could predict risk for major depressive disorder (MDD) and changes in neural circuit activity related to emotion-processing, highlighting the clinical importance of understanding the molecular mechanisms by which these variants alter transcriptional activity at GR target genes. We speculate that under stress conditions, these variants alter a number of different molecular mechanisms, namely GR binding and chromatin interactions between transcriptional start sites and GR-driven enhancer regions, resulting in transcriptional changes in stress relevant networks. MDD patient and control derived lymphoblastoid cell lines harboring high and low GR-PRSes were selected. RNA-sequencing was performed to assess whether there were transcriptional differences in stress relevant networks in LCLs with high vs. low GR-PRSes upon treatment with the GR agonist, dexamethasone. Clustering of samples into high and low polygenic risk was observed when stress relevant genes were analyzed, but not when all differentially expressed genes were included. Next, the mechanisms by which these variants cause this altered transcriptional response upon activation of the stress response system will be identified, using GR-ChIP and a high throughout enhancer screen (STARR-seq). Identification of specific mechanisms mediating stress sensitivity may represent new therapeutic targets for stress-related disease, such as MDD.

Title: TRPA1 KO mice show increased HPA axis sensitivity to chronic variable mild stress

Authors: *V. KORMOS[1], J. FARKAS[2], T. GASZNER[2], A. KECSKES[1], Z. HELYES[1], B. GASZNER[2], E. PINTER[1];
[1]Pharmacol. and Pharmacotherapy, [2]Anat., Pécs Univ., Pécs, Hungary

Abstract: Transient receptor potential cation channel subfamily A member 1 (TRPA1) is an ion channel expressed primarily in the sensory nervous system. The receptor is sensitive for numerous chemical substances and for temperature changes, therefore, its involvement in nociception and inflammatory responses is in the center of interest. TRPA1 knockout mice were shown to display reduced response to nociceptive stimuli. This phenomenon was attributed to functional changes in the sensory peripheral nervous system. Little is known however about the possible role of TRPA1 receptors in longer term environmental challenges that would require

complex adaptation response. Therefore, our aim was here to test the stress adaptation response of the TRPA1 knockout (KO) mice in chronic variable mild stress (CVMS) model. We hypothesized that mice lacking the functional TRPA1 will show altered response to the stressor. Sixteen TRPA1 KO mice and wildtype (WT) counterparts were subjected to CVMS for three weeks. The paradigm consisted of a short term daytime stressor (i.e. 30 mins restraint, shaker, tilted cage or behavioral test) and an overnight mild stress exposure (i.e. wet bedding, social isolation). Control TRPA1 KO and WT mice were not exposed to stress, except behavioral testing by marble burying (MBT), tail suspension (TST) and forced swim (FST), sucrose preference (SPT) tests. Trunk blood samples were collected, and also thymus and adrenal glands were removed and weighed. Control TRPA1 KO mice showed reduced weight gain compared to WT animals. CVMS attenuated the bodyweight gain in both genotypes. Both control and CVMS exposed KO mice showed slightly reduced anxiety levels in MBT. A similar tendency was observed in TST for depression level also, however without statistical power. In FST, control TRPA1 KO mice exerted increased depression level which did not increase upon CVMS, in contrast to that of WT mice. The anhedonia level in SPT was increased by CVMS exposure, but the genotype did not influence the consumption of sweetened fluid. Similarly, blood corticosterone was elevated by CVMS exposure in both genotypes. Control relative adrenal weights did not differ, but upon CVMS, TRPA1 KO mice had larger relative adrenal weights. Interestingly, the relative thymus weight was reduced by CVMS in WT mice only. These data suggest that TRPA1 knockout mice show altered behavioral phenotype in depression and anxiety tests. Altered dynamics of thymus- adrenal- and bodyweight in TRPA1 KO mice upon CVMS exposure suggests the long-term change in the activity of hypothalamus-pituitary-adrenal axis. In our ongoing experiments we study the underlying central mechanism in the brain.

Title: Stress-dependent plasticity of glutamatergic afferents to the locus coeruleus

Authors: *K. BARCOMB[1], C. FORD[2];
[1]Univ. of Colorado Anschutz Med. Campus, Aurora, CO; [2]Pharmacol., Univ. of Colorado, Aurora, CO

Abstract: The locus coeruleus (LC) is the primary source of norepinephrine (NE) to the brain and acts as a major regulator of arousal and attention. The LC is strongly activated by stress and LC dysfunction can lead to psychiatric disorders such as post-traumatic stress disorder. Because of its prominent role in brain function and dysfunction, it is essential to understand the circuitry of the LC. However, while the projection targets of LC-NE neurons have been well studied, little is known about the excitatory LC afferents driving LC activity. In particular, it is unknown if and how glutamatergic inputs are mediated by stress and whether or not they exhibit stress-dependent plasticity. These questions were addressed here using an optogenetic approach combined with whole cell electrophysiology in mice. First, the overall glutamatergic synaptic strength was assessed by recording spontaneous excitatory postsynaptic currents (sEPSCs) either basally or after a 30 minute restraint stress. No change was found after stress in either the frequency or amplitude of events. This lack of an effect of stress on global glutamatergic strength was verified using a reporter mouse that expressed channelrhodopsin-2 (ChR2) in all excitatory (CaMKII-expressing) neurons. In these animals, EPSCs were optically evoked (oEPSCs) and glutamatergic strength was measured using AMPAR/NMDAR ratios and paired pulse ratios (PPRs). Neither measure differed between control and stress conditions. Having observed no change in global synaptic strength post-stress, we finally asked whether stress-dependent modulation may occur at isolated LC afferents by expressing ChR2 in specific regions. A cre-dependent ChR2 was stereotaxically injected into the prefrontal cortex (PFC), periaqueductal grey (PAG), or lateral hypothalamus (LH) of CaMKII-Cre mice, allowing for the expression of ChR2 in just the glutamatergic neurons in those regions. Again, AMPAR/NMDAR ratios and PPRs were measured using oEPSCs in LC-NE neurons of control or stressed mice. While no change was found in the inputs from PAG and LH, there was a significant reduction in the PPRs of PFC inputs. These results suggest a presynaptic increase in the strength of PFC afferents to the LC after stress, which is not observed in other afferents or when looking globally at all excitatory inputs. Further experiments will determine the physiological relevance of this stress-dependent plasticity.

Title: Regulation of VTA GABAergic microcircuitry by chronic variable stress

Authors: *C. BOUARAB, B. THOMPSON, N. FERN, A. POLTER;
The George Washington Univ., Washington, DC

Abstract: Chronic exposure to stress interferes with hedonic processing and plays a significant role in the development of mood and anxiety disorders. While numerous studies have shown the post-hoc consequences of stress, very little is known about the processes that occur during the transition from acute to chronic stress and how they contribute to the emergence of anhedonic behavioral sequelae over the course of stress. GABAergic neurons of the ventral tegmental area (VTA) are uniquely situated to be a powerful regulator at the intersection of stress and reward. VTA GABA neurons exert strong control over the activity of VTA dopamine neurons. Inputs from throughout the brain that carry neuroendocrine, homeostatic, stress-related and social information synapse onto VTA GABA neurons. Thus, these neurons receive diverse information about an animal's internal and external state and integrate this information to tune dopaminergic neuron activity and thus reward-seeking behavior. Moreover, VTA GABA neurons are robustly activated by aversive stimuli or acute stress, perfectly positioning them to regulate changes in reward-related behavior in response to stressful or aversive experiences. However, few studies have measured the effects of chronic stress on VTA GABAergic neurons.
In this study, we set out to characterize changes in the activity of VTA GABA and dopamine neurons following subchronic and chronic variable stress and uncover synaptic mechanisms mediating these changes. We find that subchronic variable stress, which induces behavioral changes in females but not males, is associated with an increase in inhibitory tone in both female and male mice. However, we observe a decrease in the firing rate of dopamine neurons in female, but not male mice. This suggests that a parallel protective mechanism prevents stress-induced decreases in dopaminergic neuron firing in males. Likewise, we find that chronic variable stress induces changes in inhibitory transmission onto dopamine neurons in both males and females. Our future studies will use fiber photometry and slice recording to characterize the sex-specific changes in VTA inhibition that occur over the course of chronic stress. Taken together, our data indicate a significant role for VTA GABA neurons in mediating the switch from physiology to pathology in depression-like behavior.

Title: VTA GABA neurons mediate sex-specific social interaction deficits after subchronic variable stress

Authors: B. THOMPSON[1], C. BOUARAB[3], *A. M. POLTER[2];
[1]Pharmacol. and Physiol., [2]George Washington Univ., Washington, DC; [3]The George Washington Univ., Washington, DC

Abstract: Women are roughly twice as likely as men to be diagnosed with a mood or anxiety disorder. Given that stress plays a significant role in the development of these disorders, sexual dimorphisms in the response to stress are likely to be a critical factor in the enhanced vulnerability of females to mood and anxiety disorders. Across both human populations and animal models, males and females exhibit divergent responses to stress at all levels, from molecular signatures to behavioral adaptations. Subchronic variable stress (SCVS) is a model of depression and anxiety in which female mice develop anhedonia and anxiety, but males do not (LaPlant et al, *Biological Psychiatry*, 2009; Hodes et al, *J. Neuroscience*, 2015). In this study, we use this model to investigate the role that VTA GABA neurons play in sex-specific social interaction and in the response to stress.
Dysregulation of the mesolimbic reward circuitry is implicated in the pathophysiology of stress-related illnesses such as depression and anxiety. VTA GABAergic neurons are poised to be a critical node in the regulation of female-specific maladaptive behavior following SCVS. These neurons regulate activity of the mesolimbic dopaminergic pathway, both by gating the activity of neighboring dopamine neurons and through a projection to the NAc. VTA GABA neurons modulate reward and anxiety-related behaviors and are activated by acute stressors; however, little is known about neuroadaptations in these neurons in response to chronic or repeated stressors. We hypothesize that SCVS increases activity of GABAergic neurons in the VTA in female animals, and that reversing this will decrease SCVS-induced social interaction deficits. Here, we show that SCVS causes sex-specific social deficits in female mice. Stressed female mice spend less time interacting with a naïve male mouse, however, they show no decrease in interaction with another female. In contrast, stressed males show no social deficits. Chemogenetic inhibition of VTA GABAergic neurons after stress reverses this deficit in females, but has no significant effects on sociability in males. Future studies will address the ability of inhibition of GABAergic neurons during stress to prevent stress induced neuroadaptations. Taken together, our data shows that regulation of the VTA microcircuitry in response to stress is sexually dimorphic and may play a role in the development of maladaptive behavioral responses.

Title: Stress drives deliberative tendency via influences on vicarious trial-and-error and monoaminergic systems

Authors: *S. AMEMIYA[1,2], M. ISHIDA[2], N. KUBOTA[2], T. NISHIJIMA[2], I. KITA[2];
[1]RIKEN CBS, Saitama, Japan; [2]Tokyo Metropolitan Univ., Tokyo, Japan

Abstract: Extensive evidences have indicated that stress influences decision making even under familiar choice situations. However, how stress affects decision-making processes is still unclear. Previous studies have reported that vicarious trial-and-error (VTE), rat's head-orienting behavior toward possible options at choice points, reflects decision-making processes. Other series of studies have reported that monoaminergic neurons, including dopamine neurons in the ventral tegmental area (VTA DA), serotonin neurons in the dorsal raphe nucleus (DRN 5-HT), noradrenaline neurons in the locus coeruleus (LC NA), play roles in decision making by regulating reward evaluation, impulse control and attentional control. The monoaminergic neurons are also known to be sensitive to various stressors.
Here, in order to examine effects of stress on decision making, we examine the effects of restraint stress on subsequent decision-making behaviors and neural activity of DRN 5-HT, LC NA, and VTA DA neurons in T-maze task in rats. In the T-maze choice task, an arm has 3 pellets (high-reward side) and the other arm has 1 pellet and the high-reward side was constant throughout the maze test for each rat. Rats ran the task under the same reward condition three consecutive days. Before starting the 3rd day session, rats in the stress-treated group received mild restraint stress for 30 min, and rats in the control group were left in the home cage. On the 3rd day session, we recorded the number of choice of high-reward side, and spending time and VTE at the T-shaped choice point. In addition, we quantified neural activity of the monoaminergic neurons, using c-Fos/5-HT or c-Fos/TH (tyrosine hydroxylase) immunohistochemistry. Acute restraint stress did not affect the number of choice of high-reward side, but increased spending time and the number of VTE at the choice point. The DRN 5-HT and LC NA, but not VTA DA neurons, activated in the stress-treated group compared to the control group. These results suggest that stress increases a deliberate tendency in decision making via increasing VTE and activity of monoaminergic neurons related to impulse control and attentional control.

Title: Noradrenergic modulation of large-scale brain networks in response to acute stress

Authors: ***M. KRENTZ**, H. MURALI MAHADEVAN, Z. REPPMANN, R. TOUTOUNJI, F. KRAUSE, E. J. HERMANS;
Donders Inst. For Brain, Cognition and Behaviour, Radboud Univ. Med. Ctr., Nijmegen, Netherlands

Abstract: Introduction
Acute stress elicits adaptive cognitive and behavioral changes. These are hypothesized to be supported by rapid changes in the interplay between large-scale brain networks. While the salience network (SN) is upregulated after stress, executive control network (ECN) and default mode network (DMN) appear to be downregulated. This shift is thought to be triggered by rapid noradrenergic activation originating from the locus coeruleus (LC), the sole source of cortical norepinephrine. Here, we combined the assessment of large-scale brain network dynamics with functional imaging of LC, which is highly challenging given its small size. Due to increased LC activity under stress, we expect (1) stronger LC-SN coupling, and (2) stronger negative LC-ECN and LC-DMN coupling, after acute stress.
Methods
In the first of three sessions, high-resolution structural imaging, including an LC (neuromelanin)-sensitive T1-weighted TSE sequence, was performed. Two subsequent sessions consisted of resting-state functional assessments following a standardized stress-induction (SECPT) or control procedure. Time courses for network activity were extracted using individualized network masks based on Shirer et al. (2012). LC time courses were extracted using individual segmentations, created by interleaving differently positioned TSE-sequence acquisitions to increase vertical resolution while maintaining SNR. Connectivity measures were corrected for movement, physiological noise (RETROICOR), and compartment signals (e.g., ventricular noise).
Results
Pre-liminary data (n=16) does not suffice to test connectivity hypotheses, but shows that using an interleaved TSE sequence with neuromelanin contrast allows for accurate LC segmentation.

Furthermore, LC BOLD signal exhibits reasonable SNR and resting connectivity, using a set of carefully selected covariates. Moreover, network templates allowed for successful identification of individualized core networks of interest for connectivity analysis. Finally, physiological measures point toward robust stress induction effects.

Conclusion

Preliminary results show that our interleaved TSE sequence can successfully localize LC and data quality and validity assessments point toward testability of the hypotheses upon completion of data acquisition.

Title: Electrophysiological characterization of the stress response in the intact adrenal medulla

Authors: *J. R. LOPEZ RUIZ[1], N. PALLAS[1], S. ERNST[2], R. W. HOLZ[3], E. L. STUENKEL[1]; [1]Mol. & Integrative Physiol., [2]Cell and Developmental Biol., [3]Pharmacol., Univ. of Michigan, Ann Arbor, MI

Abstract: The stress response has a major role in survival and prepares the body to deal with different challenges, however if prolonged, often drives adverse health consequences. A key pathway of the stress response is through the adrenal medulla, in which architecturally clustered and electrically coupled chromaffin cells secrete catecholamines to the general circulation affecting multiple distant target organs. Nonetheless, the in vivo dynamics and interactions within the intact adrenal medulla still remain unknown. Therefore, the goal of this project is to continuously and precisely monitor the electrophysiological responses from the adrenal medulla in the living animal during normal and under stress conditions, to topographically dissect the chromaffin cells population and their interactions. To achieve this, a high density silicon probe was slowly inserted into the immobilized left adrenal gland while recording, then the system was challenged first by electrically stimulating the splanchnic nerve with different intensities, frequencies and train durations, and thereafter by inducing hypoxia to assess the evoked stress response at a cellular level. During basal conditions, spontaneous single as well as compound action potentials with distinct firing rates that ranged from 0.3 to 4.5 Hz were recorded from

multiple anesthetized subjects, >90% of the recorded cells displayed a stable firing rate of under 3Hz. By locally applying TTX to the splanchnic nerve we were able to reversibly block this activity. When lined up and correlated with adjacent channels, the action potential's waveforms, revealed submillisecond interactions that most likely reflect the activity from highly synchronized neighboring chromaffin cells that fire in a specific sequence, each cluster or group of cells fired independently from one another. The electrical stimulation of the splanchnic nerve evoked the firing of the same units and clusters that were spontaneously recorded during basal conditions, with latencies from 2 to 20 ms after the stimulus. The recorded units were able to follow up to 40Hz trains. To assess the physiological stress response, hypoxia by respiratory arrest was induced through an anesthesia overdose. The result was a generalized 1.5-3x increase in the firing rate of the recorded units at the moment breathing stopped, reaching a maximum several seconds after and then gradually dropping to a complete silence. For the first time we were able to document the internal dynamics of the intact adrenal medulla, showing the extend and interactions of the local circuitry that drives the adreno-medullary stress response in the living animal.

Title: Neuromedin U-8 involvement in stress modulation

Authors: *W. ALLAOUI, A. DE PRINS, A. VAN EECKHAUT, S. BALLET, I. SMOLDERS, D. DE BUNDEL;
Vrije Univ. Brussel, Brussels, Belgium

Abstract: Neuromedin U (NMU) is a neuropeptide that is highly conserved across mammals, suggesting strong evolutionary pressure to maintain its structure and function. The C-terminal amidated octapeptide NMU-8 exerts the same biological effects as its longer endogenous isoforms NMU-23 and NMU-25. NMU interacts via two G-protein coupled receptors known as NMUR1 and NMUR2. Studies have shown the involvement of NMU in the stress response, demonstrating increased stress-related behavior following central NMU administration in rodents.

In the present study we evaluated the effects of NMU-8 on stress-related behavior in male C57BL/6J mice. Mice received intracerebroventricular (i.c.v.) administrations of NMU-8 or saline and were evaluated on stress-related behavior in a safe environment, being their home cage, or after forced swim stress. We subsequently evaluated c-Fos expression in the paraventricular nucleus of the hypothalamus (PVH) and arcuate nucleus (ARC) to assess neuronal activation. Additionally, we measured plasma corticosterone using an enzyme-linked immunosorbent assay.
I.c.v. administration of NMU-8 resulted in increased grooming in a safe environment, while no effects on digging or locomotor activity were observed. When mice were exposed to the forced swim test, NMU-8 increased immobility compared to control mice. Furthermore, when mice were pre-exposed to additional forced swim stress one day prior to the forced swim test, NMU-8 was still able to significantly increase immobility. In line with these observations, we observed elevated c-Fos immunoreactivity in the PVH and ARC in naïve mice. When mice were subjected to a single forced swim test, NMU-8 did not significantly increase c-Fos levels in the PVH but increased c-Fos levels in the ARC. However, NMU-8 increased c-Fos expression in both PVH and ARC when mice were pre-exposed to forced swim stress. Interestingly, central NMU-8 administration lowered plasma corticosterone significantly in both mice subjected to a stressful experience and in naïve mice. However, when mice were pre-exposed to forced swim stress, NMU-8 did not significantly decrease plasma corticosterone.
In conclusion, i.c.v. administration of NMU-8 increases neuronal activity in the hypothalamo-pituitary-adrenal axis in baseline and stressful conditions, in line with what we observed at a behavioral level. The exact mechanism through which central NMU-8 administration lowers corticosterone plasma concentrations remains unclear. We suggest that central NMU-8 administration elicits a negative feedback signal towards peripheral corticosterone release, while stress-related signaling in the brain increases.

Title: Predator odor stress on stress and metabolic endocrine outcomes in male and female c57bl6 mice

Authors: *M. L. BLOCK[1], K. WILK[1], E. I. M. FLANDREAU[2];
[2]Psychology, [1]Grand Valley State Univ., Allendale, MI

Abstract: It has long been known that the brain and gut 'talk' to each other and this bidirectional communication is important for both physical and mental health as demonstrated by associations between metabolic syndrome and mental illness in humans. Neuropeptides found in both the gastrointestinal tract and the central nervous system are instrumental in brain / gut communication and may mediate links between stress, metabolism, and psychopathology. The present study is designed to determine whether a single exposure to predator odor is sufficient to produce longer-term changes in the endocrine system as measured by plasma concentrations of the "stress hormone" corticosterone (CORT) and the "hunger hormone" ghrelin. While numerous studies implicate CORT in stress-induced psychopathology, we are just beginning to appreciate the influence of ghrelin in this process. Male and female mice were exposed to one hour of predator stress. Blood was collected 48 hours, 7 days, or 14 days later to assess plasma concentration of these hormones. In addition, body weight and food intake were recorded throughout the study to determine the impact of stress on metabolic efficiency (body weight gained per gram of food intake). Results from this study are important to better understand how stress can contribute to both metabolic syndrome and / or mental illness.

Title: Timeline for impact of high sucrose diet on plasma corticosterone and ghrelin and caloric efficicency in male and female mice

Authors: *T. N. DESJARLAIS[1], E. I. M. FLANDREAU[2];
[2]Psychology, [1]Grand Valley State Univ., Allendale, MI

Abstract: An unhealthy diet is known to increase risk for metabolic syndrome but may also be a risk factor for mental illness. The present study examined the influence of a high sucrose diet (50% sucrose) on two hormones that are both implicated in stress and metabolism: corticosterone, and ghrelin. Control mice were fed a matched diet with less than 1% sucrose or standard chow. We've previously found that 10 days of a high sucrose diet increased negative-valence behavior related to anxiety and also increased plasma corticosterone and ghrelin concentrations 30 days later. The present study measures caloric efficiency weekly and collected blood 24 hours, 7 days, 14 days, or 21 days after starting the special diet to establish a timeline for changes in these endocrine systems, which may explain the links between metabolic and mental illness.

Title: Inhibitory effect of glucose infusion on restraint stress-induced elevation of plasma adrenaline level in rats

Authors: *N. YAMAGUCHI[1], Y. KAKINUMA[3], K. MIMURA[1], T. YAKURA[2], M. NAITO[2], S. OKADA[1];
[1]Dept. of Pharmacol., [2]Dept. of Anat., Aichi Med. Univ., Aichi, Japan; [3]Dept. of Physiol., Nippon Med. Sch., Tokyo, Japan

Abstract: Exposure to stressor causes various systemic responses such as activation of the sympathetic nervous system and the hypothalamus-pituitary-adrenocortical (HPA) axis. Stress-induced sympathetic activation increases plasma levels of catecholamines (noradrenaline and adrenaline), resulting in elevations in blood pressure and heart rate. In addition, facilitated secretion of adrenaline from the adrenal medulla and pancreatic glucagon associated with sympathetic activation increase blood glucose level. We have previously reported that stress-related neuropeptides such as corticotropin-releasing factor and acute exposure to restraint stress increase the plasma levels of catecholamines, and that prostanoids such as prostaglandin E_2 and thromboxane A_2 in the brain, especially in the paraventricular hypothalamic nucleus (PVN), regulate the elevation of plasma catecholamine levels. Therefore, there is a high possibility that

brain prostanoids are involved with stress-related changes in glucose dynamics. In the present study, we examined effects of intravenous glucose infusion on sympathetic activation, that is elevations of plasma catecholamine levels and changes in brain prostanoid levels, under restraint stress exposure in male rats. There were no significant differences in blood glucose levels between vehicle-treated stressed group and glucose-treated stressed group. However, intravenous infusion of 5% glucose solution effectively suppressed stress-induced elevation of plasma level of adrenaline, but not noradrenaline. Similarly, intracerebroventricular infusion of glucose solution also prevented the stress-induced elevation of plasma level of adrenaline, but not noradrenaline. Furthermore, we found that exposure to restraint stress increased thromboxane B_2, a stable metabolite of thromboxane A_2, in PVN dialysates, and the increase in thromboxane B_2 level was suppressed by intravenous glucose infusion. Our results suggest that glucose infusion can inhibit stress-induced sympathetic activation, and that prostanoids in the PVN are involved with this mechanism.

Title: Thromboxane A_2 in the paraventricular nucleus of the hypothalamus participates in 2-deoxyglucose-induced sympathetic activation in freely moving rats

Authors: *S. OKADA, M. TACHI, N. YAMAGUCHI;
Depatment of Pharmacol., Aichi Med. Univ., Aichi, Japan

Abstract: Glucose is the major source of energy for the cells in higher organisms and its homeostasis is essential for maintaining physiological activities. 2-deoxyglucose (2-DG), a non-metabolizable glucose analog, competitively inhibit glucose utilization, resulting in a state of intracellular glucoprivation. Several lines of evidence indicate that 2-DG activates markedly the sympathetic adrenergic system, in contrast with relatively mild sympathetic noradrenergic responses. In addition, 2-DG stimulates noradrenergic system in the brain. We previously reported that release and/or secretion of plasma adrenaline and noradrenaline are separately regulated in brain prostanoid- and adrenoceptor-dependent manners. In this study, we examined the possibility that intravenously administered 2-DG stimulates noradrenaline release in the

PVN, the major integrative center for sympathetic activation, and then released noradrenaline and produced prostanoids in the PVN are involved with the 2-DG-induced elevation of plasma catecholamine levels in freely moving rats. Intravenously administered 2-DG dose-dependently elevated noradrenaline release in the PVN and plasma levels of catecholamines. Central pretreatment with phentolamine suppressed the 2-DG-induced elevation of plasma level of adrenaline, but not noradrenaline. In contrast, central pretreatment with propranolol suppressed the 2-DG-induced elevation of plasma level of noradrenaline, but not adrenaline. Pretreatment with indomethacin attenuated the-2-DG-induced elevation of both noradrenaline and adrenaline levels. Pretreatment with furegrelate, a thromboxane synthase inhibitor, attenuated the 2-DG-induced elevation of both noradrenaline and adrenaline levels, while pretreatment with L-798106, a prostaglandin E_2 receptor subtype EP_3 antagonist, did not alter the 2-DG-induced elevation of plasma catecholamine levels. Furthermore, 2-DG infusion elevated thromboxane B_2, a metabolite of thromboxaneA_2, but not PGE_2 in the PVN microdialysate. Our results suggest that glucoprivation stress increases noradrenaline release in the PVN and then causes TxA_2 production in the PVN, which are essential for the 2-DG-induced elevation of both of plasma adrenaline and noradrenaline.

Title: Evaluation of systemic corticosterone and VEGF in a diabetes-CUSB model

Authors: *D. B. PAZ-TREJO[1,4], K. M. NAVARRETE-VELÁZQUEZ[2], P. ZARATE GONZALEZ[5], H. SANCHEZ-CASTILLO[3], R. ZAMORA ALVARADO[6], L. D. OCHOA DE LA PAZ[7,6];

Abstract: Diabetes is a metabolic disease with several health complications mainly related to poor glucose control and time with the disease, however it's possible that stress serve as a modulator for them.
Stress has been defined as a trigger for many mental diseases including depression and anxiety, also diabetic patients present more depression symptoms than no diabetic population. Besides metabolic alterations, it has been described that diabetes induces endocrine deregulation including disturbance in the HPA axis, one of the main regulators of stress response. In those findings, cortisol has been proposed as an indicator of health complications severity.
The aim of the present work was to evaluate effects of exposure to a chronic unpredictable stress battery (CUSB) to subjects with induced diabetes.
Ablation of pancreas is commonly use as type 1 diabetes model. Streptozotocin (STZ) induces chemical partial ablation of pancreas reducing insulin production and generating hyperglycemic conditions.
We administered a single dose of i.p. 65 mg/kg of STZ to 200-250g male Wistar rats. Subjects were divided in 4 groups: vehicle, vehicle+CUSB, STZ, STZ+CUSB. Six weeks after STZ administration, rats were sacrificed and trunk blood was collected for corticosterone and VEGF-A analyses.
After diabetes induction subjects were exposed to a 10 days CUSB. Body weight was daily measured, meanwhile glucose levels were measured after CUSB and near to the end of the experiment. Results didn't show statistical differences in corticosterone nor VEGF-A levels. Not according to other findings, corticosterone levels of the STZ (hyperglycemic) group were similar to both normoglycemic groups; however there was a great increase in variability in corticosterone levels of the STZ+CUSB group. This data suggests that in early stages of diabetes, the negative feedback regulating corticosterone levels may not be affected and its impairment could be modulated by stress. This can be interpreted as an accelerated deterioration in the presence of stress and could be proved with a continuous measurement of corticosterone and evaluation of other elements of the HPA axis.
Under stress conditions both groups of CUSB decreased their weight and a lower glucose level in the STZ+CUSB was obtained compared to STZ group. The absence of effect in VEGF could be due to the fact that evaluation was systemic and previous evidence shows that VEGF levels variate differentially in particular structures of the system in diabetes and stress conditions.
We observe a relationship between stress and diabetes, however more data is needed in order to establish stress as a risk factor in diabetes for health complications.

Title: Life course contribution of prenatal stress in modulating the prepulse inhibition of the acoustic startle reflex in an AD mouse model

Authors: *Z. JAFARI[1,2], B. KOLB[3], M. MOHAJERANI[3];
[1]Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [2]Basic Sci. in Rehabil., Iran Univ. of Med. Sci., Tehran, Iran, Islamic Republic of; [3]Neurosci., Univ. of Lethbridge, CCBN, Lethbridge, AB, Canada

Abstract: The prepulse inhibition (PPI) of the acoustic startle reflex (ASR), as an index of sensorimotor gating, is one of the most extensively used paradigms in the field of neuropsychiatric disorders. Few studies have examined how prenatal stress (PS) regulates the sensorimotor gating during the lifespan, and also how PS modifies the development of Aβ pathology in brain areas underlying the PPI formation. We followed alternations in corticosterone levels, learning and memory, and the PPI of the ASR measures in $APP^{NL\text{-}G\text{-}F/NL\text{-}G\text{-}F}$ offspring of dams exposed to gestational noise stress. In-depth quantifications of the amyloid-beta (Aβ) plaque accumulation were also performed at six months. The results indicated an age-dependent deterioration of sensorimotor gating, long-lasting PS-induced abnormalities in PPI magnitudes, as well as deficits in spatial memory. The PS also resulted in a higher Aβ aggregation predominantly in brain areas associated with the PPI modulation network. The findings suggest the contribution of a PS-induced HPA-axis hyperactivity in regulating the PPI modulation substrates leading to the abnormal development of the neural protection system in response to disruptive stimuli. The long-lasting HPA axis dysregulation appears to be the major underlying mechanism in precipitating the Aβ deposition, especially in brain areas contributed to the PPI modulation network.

Title: Therapeutic effects of dihydromyricetin on anxiety disorders induced by social isolation in mice

Authors: A. SHAO[1], X. M. SHAO[2], Y. OUYANG[3], J. SILVA[3], D. L. DAVIES[3], R. W. OLSEN[1], *J. LIANG[3];
[1]Dept. of Mol. & Med. Pharmacol., UCLA, Los Angels, CA; [2]Neurobio., David Geffen Sch. Med. at UCLA, Los Angeles, CA; [3]USC, Los Angeles, CA

Abstract: Anxiety disorders are one of the most common mental illnesses in the US. Many patients exhibit treatment-resistance or substantial side effects to available therapies. New treatment strategies are critically needed. Using a mouse model of social isolation stress, we examined the anxiolytic effects of dihydromyricetin (DHM) with elevated plus-maze (EPM) and Open Field (OF) tests. Mice were singly housed with opaque walls for 2 or 4 weeks (Iso2w or Iso4w). Control mice of group housing (social-group) spent 126± 5 seconds (sec) of total 300 sec in open arm of EPM, 153± 2 sec in closed arm. Iso4w-group spent substantially shorter time (37± 1 sec) in open arm, 242± 10 sec in closed arm. DHM (2mg/Kg, oral, daily) treated-iso4w group spent 94± 3 sec in open arm, 183± 5 sec in closed arm. DHM treated-iso2w group spent 146± 10 sec in open arm, 137± 10 sec in closed arm. Diazepam (DZ, 10 mg/Kg oral, daily) treated iso4w group spent 50±19 sec in open arm, 217± 12 sec in closed arm. These EPM results suggest that social isolation increases anxiety levels and can be improved with DHM treatment. Meanwhile, DZ treatment displayed no effect. To quantify changes in locomotor activity, we analyzed the running distance of our mice models in the square OF apparatus. Social-group ran 3950 ± 58 cm during 10 min. iso4w-group ran 2800 ± 231 cm. DHM treated iso4w-group ran 3300 ± 58 cm. DHM treated Iso2w-group ran 3433± 88 cm, indicating DHM treatment improves social isolation-induced reduction in locomotor activity. In contrast, diazepam does not improve locomotor activity (2683 ± 148cm). Social-group showed frequent rearings (54 ± 3 times during 10 min), exploratory behavior and remained at the center area for 0.5 ± 0.3 min. Iso4w-group showed rearing 33 ± 4 times, and remained at the center for only 0.02 ± 0.01 min. DHM treated iso4w-group increased rearing to 55 ± 4 times and 63 ± 7 times for Iso2w-group. DZ-group did not change rearing frequency (35± 2 times). Interestingly, when iso4w-group mice got into OF,

they began with slow movements for 25 ± 2 sec, and then slowly started running. Iso4w-mice also showed lifting tail up after placement into OF for 168 sec. DZ-group took 26 ± 2 sec to start running and displayed a lifted tail for 72 sec. In contrast, Social- and DHM treated- groups did not show these signs. The results suggest that isolation decreases exploratory/locomotor activity and that DHM treatment improves changes in behavior of socially isolated mice. The data indicate that DHM ameliorates the behavioral deficits of anxiety induced by social isolation, providing pharmacological evidence that DHM can potentially be used to treat anxiety disorders.

Title: Low estradiol protects female mice from the memory-impairing effects of multiple concurrent acute stresses

Authors: ***R. E. HOKENSON**[1], A. K. SHORT[2], Y. CHEN[2], A. L. PHAM[2], S. P[2], T. Z. BARAM[1];
[1]Anat. and Neurobio., [2]Pediatrics, Univ. of California Irvine, Irvine, CA

Abstract: Rationale: When multiple, concurrent acute stresses, involving physical, emotional and social, stressors, simultaneously disturb an animal, lasting effects are seen in the brain. In males, this stress impairs spatial memory, reduces the number of thin spines on dendrites of dorsal CA1 of the hippocampus, and inhibits synaptic potentiation of these hippocampal synapses. Sex and estrous cycle differences have been acknowledged in stress responses and spatial memory. Here we investigate if sex and cycle influence the consequences of concurrent acute stresses on memory, and probe the molecular mechanisms.

Methods: Adult female C57BL6 mice were exposed to multiple acute stresses (MAS) for 2 hours. After a recovery period of 2 hours, they were trained for 10 minutes on an object location memory (OLM) task, then tested for memory 24 hours later. In a separate cohort, brains were perfused immediately after stress to determine estrous cycle effects on dendritic spine integrity or neuronal activation indicated by c-fos. For estrous cycle stage classification, vaginal smears were taken and stages were categorized by proportions of cell types. To quantify circulating estradiol levels, trunk blood was collected and serum was analyzed with a commercial estradiol enzyme-linked immunoassay (ELISA) kit.
Results: Females subjected to MAS during proestrus had impaired spatial memory in the OLM task, associated with reduced density of thin spines in CA1 (similar to findings in males). When stressed during estrus, however, memory and spine densities did not differ from those in control mice. Assessments of the circuitry activated by MAS also revealed striking differences between proestrus and estrus mice: the stress-vulnerable proestrus group had higher activation of the basolateral amygdala, a region with monosynaptic projections to CA1. Cell-type proportions of vaginal smears taken prior to serum collection were aligned with measured estradiol concentration, confirming that the proestrus female group had high levels of circulating estradiol and the estrus group had low levels.
Conclusions: In females during high estradiol cycle phases multiple concurrent acute stresses impair hippocampus-dependent memory through loss of spines/ synapses. This may be a result of stronger excitatory input to CA1 from stress-activated afferents including the amygdala. Ongoing experiments are looking to determine estrogen receptor contribution to both spine disruption and circuit activation in male and female mice.

Title: Chronic unpredictable stress results in decreases in dendritic complexity within the medial prefrontal cortex

Authors: *S. E. BULIN[1], J. B. NERIOS[2], D. A. MORILAK[3];
[1]Univ. of Texas Hlth. At San Antonio, San Antonio, TX; [3]Pharmacol. and Ctr. for Biomed. Neurosci., [2]Univ. of Texas Hlth. at San Antonio, San Antonio, TX

Abstract: Stress-related mood and anxiety disorders, like depression and posttraumatic stress disorder (PTSD), are highly prevalent yet poorly treated. Relapse and residual symptoms remain problematic, and a poor understanding of the neurobiology underlying these illnesses has limited the development of new treatments. Imaging studies have shown reduced activity in the mPFC in both depression and PTSD, associated with deficits in executive functions, including impaired cognitive flexibility, that not only represent symptoms of these illnesses, but also contribute causally to their development and maintenance. Such changes presumably involve aberrant forms of neural plasticity in the mPFC. Similarly, chronic stress compromises cognitive flexibility, and is likely to disrupt the plasticity that normally underlies this executive process. Cognitive flexibility mediated in the mPFC can be measured using the attentional set-shifting test, and chronic unpredictable stress (CUS) induces a deficit of cognitive flexibility on this test. Further, we have previously shown that CUS attenuates the response of the mPFC to stimulation of the excitatory afferent from the mediodorsal thalamus (MDT). Alterations in evoked responses as well as reduced plasticity could be mediated by stress-induced changes in dendritic morphology. Chronic restraint stress has been shown to reduce dendritic complexity and synaptic spine density in the mPFC (Liston et al., 2006; Moench & Wellman, 2017.) However, effects of CUS on such morphological parameters in mPFC are not known. To test this, male and female rats were subjected to CUS and sacrificed via pericardial perfusion three days after their last daily stressor. Vibratome sections containing mPFC were transferred individually into the wells of a 6-well cell culture plate containing PBS. DiI-coated gold bullets were delivered ballistically into the tissue using a pressurized gene gun. Pyramidal cells in layers II/III in the mPFC were acquired via Z-stack confocal images and total dendritic length, branch number and complexity were analyzed by Sholl analysis. Spine density in both apical and basal dendrites was also measured via 100x images acquired through the confocal images and reconstructed with Neurolucida. We found that CUS treatment resulted in decreased dendritic length over distance from the soma in layer II/II mPFC neurons, the location of MDT afferent synapses. Spine density and phenotype analysis is ongoing

Title: Stress effects on neuronal connectivity in the orbitofrontal cortex

Authors: *S. M. ADLER[1], M. GIROTTI[1], D. A. MORILAK[2];
[1]Univ. of Texas Hlth. At San Antonio, San Antonio, TX; [2]Pharmacol. and Ctr. for Biomed. Neurosci., Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Depressed patients often experience impairments in cognitive flexibility, a symptom dimension that may underlie illness maintenance and is poorly treated by classic antidepressants. One major risk factor for depression is chronic stress, which has frequently been utilized in rodent models to cause a depression-like phenotype. We have shown previously that chronic intermittent cold stress (CIC) induces a deficit in reversal learning on the attention set-shifting test (AST) in Sprague-Dawley rats, and this deficit can be corrected by antidepressants like citalopram, vortioxetine, and ketamine. We hypothesize that cold stress causes an aberrant potentiation of afferent-driven response in the OFC, leading to dysregulated reversal learning. We wanted to examine if increased activity in the OFC is necessary and sufficient to cause deficits in reversal learning. We used optogenetics by delivering the ChETA variant of channelrhodopsin in an AAV viral vector into the MDT. We first demonstrated that we were able to successfully induce long-term depression (LTD) and long-term potentiation (LTP) using a laser-induction protocol in rats expressing ChETA.
Next, we examined the effects of LTD on reversal learning. In our experiment, we induced opto-LTD 1 hour prior to reversal learning. Our preliminary data indicate a trend for LTD induction to reverse a CIC-induced deficit in reversal learning. Furthermore, there was a significant interaction of virus and stress ($p<0.05$). We will also soon examine if induction of opto-LTP is able to mimic the CIC-induced deficit in reversal learning in non-stressed animals.

Title: Effects of stress on impulsivity measured by the 1-choice serial reaction time test

Authors: *M. GIROTTI[1], C. M. GEORGE[3], F. R. CARRENO[4], D. A. MORILAK[2];
[1]Pharmacol., [2]Pharmacol. and Ctr. for Biomed. Neurosci., Univ. of Texas Hlth. Sci. Ctr. at San

Antonio, San Antonio, TX; [3]Physiol., Univ. Hlth. Sci. Ctr. At San Antonio, San Antonio, TX; [4]Pharmacol., UT Hlth. San Antonio, San Antonio, TX

Abstract: Impulsive behavior, or the tendency to act in response to internal or external stimuli without planning and without regard to potential negative consequences, is a symptom dimension shared by several psychiatric conditions such as bipolar disorder, ADHD, OCD and chronic substance abuse. Stress is known to exacerbate many symptoms in these psychiatric conditions, including impulsivity. However, in many tests of impulsive responding, it is difficult to discriminate pure behavioral inhibition/disinhibition from attentional processes, therefore the effects of stress purely on impulsive responding have not been well characterized. In this work we employed the one-choice serial reaction time (1-CSRT) task to measure the effects of stress on behavioral inhibition. The 1-CSRT task is a variant of the 5-CSRT task where only a single stimulus light and nose poke hole are used, therefore requiring less processing of visuospatial attentional cues. The rat needs only to wait a defined period of time for the stimulus to appear, after which a nose poke into the lit hole will provide a sugar pellet. Rats were food restricted and trained to respond to brief flashes of light presented in the center hole that is illuminated for 5 sec (the limited hold period, LH). Nose-poke responses in the center hole while the light is on are 'correct responses' rewarded by the delivery of a single pellet. A failure to respond within the limited hold period ('omission') is punished by the house light being extinguished for 5 s (time-out period, TO). Premature responses made during the inter-trial interval (5 sec) before the presentation of the visual stimulus are a measure of behavioral disinhibition/impulsivity. Premature responses are punished by a 5s time-out period. Rats were trained to a criterion of 80% correct responses and fewer than 20% omissions with ITI= 5s, LH= 5s and TO= 5s, maintained over the course of 5 days. Under these conditions a "baseline" impulsivity score was measured. Rats were then challenged in one session where the ITI was set to 8s. Following 4 days of reminder sessions at ITI= 5s, rats were subjected to 2 days of inescapable footshock, two weeks of chronic intermittent cold (CIC) stress, or two weeks of chronic unpredictable stress (CUS) and measures of impulsivity at baseline and after challenge (ITI = 8 s) were taken again. We found that impulsive responding was increased at baseline after footshock or after CIC stress, and was increased at baseline and challenge after CUS. These data suggest that stress directly increases impulsive responding in the absence of confounding attentional biases.

Title: Gut-brain actions underlying comorbid neuropsychiatric disturb associated with inflammatory bowel disease

Authors: *S. CUZZOCREA, E. GUGLIANDOLO, M. CORDARO, R. SIRACUSA, R. D'AMICO, A. PERITORE, R. FUSCO, R. CRUPI, D. IMPELLIZZERI, R. DI PAOLA; Univ. of Messina, Messina, Italy

Abstract: Inflammatory bowel disease (IBD) is a chronic relapsing and remitting disorder characterized by inflammation of the gastrointestinal tract and its associated with different neurological and psychiatric disorders, which are integrated among the extra-intestinal manifestation of this disease. In fact, epidemiological studies have shown an increased incidence of depression in patients with colitis, in which strong inflammation in the gut occurs. The possible mechanisms connecting gut inflammation and neuroinflammation in the brain could be via an increase in peripheral cytokines or via damaged nerve terminals in the gut.Recent evidence demonstrated that the gut-brain-axis has a central function in the perpetuation of IBS, and, for this reason it can be considered as a possible therapeutic target.N-Palmitoylethanolamine-oxazoline (PEA-OXA) possesses anti-inflammatory and potent neuroprotective effects. Although, recent studies have explained the neuroprotective properties of PEA-OXA, nothing is known about its effects on gut-brain axis during colitis.The aim of this study is to explore the mechanism and the effect of PEA-OXA on gut brain axis in rats subjected to experimental colitis induced by allowing rats to a free access to drinking water containing 5% DSS for 7 days.Daily orally administration of PEA-OXA 10 mg/kg daily o.s. was able to decrease body weight loss, macroscopic score and colon length and histology alteration after DSS induction. Additionally, we demonstrate that PEA-OXA administration significantly promoting neurotrophic grow factor release and decrease astroglial and microglial activation DSS-induced. Moreover, PEA-OXA,was able to restore tight junction in both hippocampus and colon. In conclusion, in our work, we demonstrate for the first time the action of PEAOXA on gut-brain axis during in a model of DSS induced colitis.

Abstract: Major depression induces memory deficits which have been associated with neuronal alterations in the hippocampus. Neural alterations could be observed at three levels: dendritic arborization, spine density and type of spine. Moreover, olfactory system dysfunction have been associated with major depression in humans and olfactory bulbectomy (OBX) is a well-known model of depression-related behavior in rodents. OBX also induces major neurochemical alterations in various brain regions including the hippocampus and prefrontal cortex (PFC). In the present study, we aimed to investigate whether OBX induced memory and learning deficits and evaluate possible neuronal rearrangement in the hippocampus. To measure spatial memory, we used the classical Morris Water Maze (MWM) task. To characterize neuronal remodeling, we used the Cox-Golgi staining to evaluate possible modifications in dendritic arborization, spine density as well as dynamics of dendritic spines in the CA1 and CA3 region of the dorsal hippocampus and PFC. The present results show that OBX rats required longer time to find the hidden platform of the MWM during the phases of learning and reverse memory. Moreover, the OBX rats also presented a retention deficit as the OBX rats performed less crosses when the platform was removed. OBX induced dendritic atrophy in pyramidal neurons of the CA1 subregion of hippocampus and PFC. These results add further support to the validity and usefulness of the OBX rat as a model of depression.

Title: Anxiety and exploratory behaviors in heterozygous SERT knockout mice exposed to enriched vs. standard housing

Authors: *B. M. KILLE[1], T. WOO[2], E. SOLIDUM[1], J. CUI[3], C. M. GREENLIEF[4], D. Q. BEVERSDORF[5];
[1]Psychological Sci., [2]Interdisciplinary Neurosci. Program, Univ. of Missouri, Columbia, MO; [3]Path & Ana Sci. Dept., U of Missouri-Columbia Sch. of Med., Columbia, MO; [5]Dept Radiol, Neurol, Psychol Sci, DGS of INP, [4]Univ. of Missouri Columbia, Columbia, MO

Abstract: Housing conditions for mouse models greatly affect behavior. Mice, which are social creatures, housed in isolation show increased anxiety when presented with a novel environment. Social housing decreases these anxiety behaviors. There is also evidence that enriched home cages, environments that encourage exploration and novel interaction, decrease anxiety behaviors when compared to typical barren home cage environments. However, the interaction of genetic variability and housing in susceptibility to stress is not known. Knockout of one copy of the SERT gene in mice have similar alterations in stress reactivity to humans with a deletion in the promoter region of SLC6a4, which results in increased risk for mood disorders in association with stessors in humans. Therefore, we wished to examine the effects of enriched environment in mice with increased stress reactivity due to heterozygous KO of of SERT (SERT(+/-)). SERT KO mice have previously shown benefits of enriched housing. However, the mice most commonly used for this research are homozygous knockouts (SERT(-/-)). SERT(-/-) mice present a much more extreme stress-reactive phenotype both behaviorally and physiologically when compared to the heterozygous SERT(+/-). Since SERT(+/-) is most similar to humans with the short SLC6a4 variant,, the current study set out to explore the potential benefits of enriched housing for SERT (+/-) mice. 24 SERT(+/-) and 18 wildtype C57bl6 mice were assigned to two housing types at weaning—half in standard/barren housing, half in enriched housing. Anxiety behaviors were evaluated using an open field test and exploratory behaviors using a novel object paradigm. Preliminary analysis shows a main effect of housing environment, but no main effect of or interaction with genotype on anxiety behaviors, with enriched housing decreasing anxiety behaviors. Exploratory behavior shows an interaction of gene x housing, with heterozygous animals showing no change in novel-object interaction, and enriched wild-type animals actually exploring the object less than their non-enriched counterparts. This project was supported by the University of Missouri Research Council Grant and Mission Enhancement Fund.

Title: Inheritable vs. acquired genetic effects of chronic unpredictable variable stress on cognition and the relationship to stress resilience and vulnerability

Authors: *S. H. JUNG, N. BECHMANN, R. MOORE, C. HATCHER-SOLIS;
Applied Neurosci., U.S. Air Force Res. Lab., Wright-Patterson AFB, OH

Abstract: Stress affects cognitive processes, but the degree of stress-induced changes in cognitive performance is dependent on an individual's genetics and the environments that they have been exposed to. In general, chronic distress induces negative changes in neuronal morphology that are associated with negative effects on cognition, especially memory performance. However, chronic distress can have no effect or even enhance cognition. Thus, individuals can present vulnerability, resilience, or enhancement by stress. However, no scientific explanations for these phenomena are available yet. In this study, we used recombinant inbred BXD strains (64 strains, total n = 3805 mice) to elucidate the molecular mechanisms of these phenomena by identifying genetic candidates that are associated with inheritable and acquired effects of chronic unpredictable variable stress (CUVS; 4 weeks) on cognitive performance measured by the Morris water maze (MWM) test. Quantitative trait loci (QTL) analysis was conducted to identify cognition-associated, inheritable genetic candidates from the MWM performance of sham mice. Our analysis resulted in no significant QTL genetic region. Genetic factors acquired by stress environments were identified in CUVS mice. QTL results from sham and CUVS groups were compared to identify potential interactions of genetic factors of cognition and stress environments. Results show that likelihood ration statistics (LRS) in some genetic regions are greatly increased (chromosomes 1, 2, 5 & 18) and decreased (chromosomes 7, 9 & 19) by CUVS. Moreover, all strains were ranked based on their average latency to the platform during the MWM test, and their ranks were compared between sham and CUVS strains to identify which strains showed negative (susceptibility), no (resilience) and positive (enhancement) changes by CUVS. Seven strains showed positive changes in their ranks (range of rank change: -47 to -19 ranks; range of time change: -16.1 to -8.9 seconds), and 13 strains showed minimal changes (-3 to +3 ranks; -5.5 to 0.01 seconds). Eight strains showed negative changes (20 to 31 ranks; 2.7 to 5.4 seconds). Hippocampal transcriptomes of selected mice were analyzed and we identified signaling pathways and genes that are significantly associated with cognitive performance and stress susceptibility, resilience and enhancement. Therefore, our results provide a genetic explanation for inheritable factors for cognition, acquired factors for stress environment and their interacting factors. Moreover, we suggest that certain hippocampal genes may underlie stress resilience, susceptibility and enhancement of cognition.

Title: Cognitive flexibility and mood disorders after chronic stress exposure

Authors: *M. VARGAS-GÓMEZ[1], P. TORRES CARRILLO[1], K. M. NAVARRETE VELAZQUEZ[1], O. ZAMORA AREVALO[2], D. B. PAZ-TREJO[3,5], H. SANCHEZ-CASTILLO[4]; [1]Psychology Sch., [3]Sistema de Univ. Abierta, Facultad de Psicología, [4]Neuropsychopharm. Lab., Psychology Sch., [2]Univ. Nacional Autónoma de México, Mexico City, Mexico; [5]Sociedad Iberoamericana de Neurociencia Aplicada, A.C., Mexico City, Mexico

Abstract: Deficits in cognitive flexibility and emotional regulation as seen in mood disorders are associated with stress-related neuropsychiatric disorders such as depression and anxiety disorders.
Specifically, impaired cognitive flexibility contributes to the onset and maintenance of these illnesses.The chronic unpredictable stress battery (CUSB) consists of repeated and unpredictable exposure to stressors over a period of time that could modulate behavioral deregulations as anxiety-like and depression-like behaviors.The aim of this study was to examine the phenotypic behaviors of mood disorders and cognitive flexibility in rats.
Twenty two male Wistar rats between 250-300 g were divided into control group and CUSB group.
CUSB stressors include 45°cage tilt, wet bedding, lights on overnight, water deprivation, cold water immersion and movement restrictor. The behavioral evaluation started the next day after the last stressor. The sequence of the behavioral tests were randomized. The CUSB group was exposed to to the sequence of mild stressors for 10 days. While the control group was left undisturbed.
Cognitive flexibility was evaluated by the attentional set shifting task (ASST), depressive-like behaviors were evaluated by the saccharine preference test and anxiety-like behaviors were assessed by the open field test. Rats exposed to the CUSB exhibit an impairment on the extra dimensional (ED) set-shifting phase at the ASST and not in other phases of the task. The impairment was seen as an increase in the number of trials required to achieve six consecutive correct responses.CUSB-exposed animals presented a reduction in locomotor activity and in crosses at the center area of the open field compared with the non-stressed group.
Besides, CUSB group had a reduction of consumption of saccharine and more consumption of

water in comparison with the non-stressed group.In conclusion, the chronic unpredictable stress battery induced anhedonia, anxiety-like behaviors and impairments in cognitive flexibility. These results could be related with the pro-inflammatory profile that has been described as one of CUSB main effects. Therefore, a non-steroidal anti-inflammatory drug (NSAID) with anti-inflammatory properties could be used as a therapeutic alternative to prevent the behavioral changes seen after stress and could be used as an alternative for the treatment of depression and mood disorders diseases.

Title: Interaction prenatal and postnatal stress in anxiety-like behavior and recognition memory of male and female offspring

Authors: *C. ORIZABA-HUERTA[1], D. B. PAZ-TREJO[1,2,3], H. SÁNCHEZ-CASTILLO[1,3]; [1]Facultad de Psicología, Univ. Nacional Autónoma de México, Ciudad de México, Mexico; [2]Sistema Univ. Abierta, Facultad de Psicología, Univ. Nacional Autónoma de México, Ciudad de México, Mexico; [3]Sociedad Iberoamericana de Neurociencia Aplicada A. C., Ciudad de México, Mexico

Abstract: It has been described that offspring exposed to prenatal stress present long-term disturbances and reexposure to stressors promote behavioral changes with greater ease and magnitude. Previous researches focused on evaluating males, their results showed that stress reexposure decrease anxiety-like behaviors and improve the memory deficit. However, no data is available for females. The aim of this study was to evaluate effects of pre and postnatal stress interactions in male and female animals. The subjects were 102 Wistar rat offspring (51 females and 51 males) of 10 pregnant females divided in five groups (a) control, (b) prenatal stress, (c) prenatal and postnatal stress, and (d) postnatal stress. Predator odor (PO) exposure (bobcat pee) was used as stressor. Prenatal stress took place during the second half of rats pregnancy and postnatal stress occurred in PND90, corresponding to adulthood. Open Field (OF) and Elevated Zero Maze (EZM) were used to assess anxiety-like behaviors and Novel Object Recognition

(NOR) test was used to evaluate recognition memory in adult rats. Behavioral markers for anxiety-like behaviors in OF and EZM indicate that prenatal stress increases anxiety in offspring, however, it attenuates anxiety-like behaviors when stress was limited to adulthood. This indicates that *in utero* stressful environment could cause long-term changes in the fetus, these changes remain in adult life and may function as adaptations for environment. The recognition memory in NOR test din't show differences between experimental groups although males obtained higher discrimination index. In some parameters, differential effects were observed between males and females. These effects could be a result of differences in the hypothalamic-pituitary-adrenal (HPA) axis function which involves the activation of gonadal hormones linked to sexual dimorphism in susceptibility to stress effects. 2 out of 3 pregnant stressed rats presented decrease or absence of affiliative care towards their pups. This generated, in the offspring, a decrease in anxiety-like behaviors in adulthood. These findings indicate that absence of affiliative care may increases "resistance" to stress for generating anxiety-like behaviors. This data gives us information of the importance of taking maternal care into account since exposure to stress not only disrupts fetal development but maternal caring; affiliative care also have an impact on the development of the offspring.

Nacional Autónoma de México, Facultad de Medicina, Ciudad de México, Mexico

Abstract: Stress impairs recognition memory, whereas acute stress seems improvement recognition memory. On the other hand, studies have demonstrated sex differences in

neuroendocrine and behavioral responses to stress, where females have showed more impairment than males, which could explain the higher prevalence in females to develop stress related disorders. Additionally, most neural and behavioral studies not include females, however, the pattern suggest that stressed males have down-regulation on neural activity while stressed females have not alter or have up-regulation of neural activity. The above supports the idea of sex specific stress effects on behavior. The aim of this study was to compare female and male responses to different stressors vs. no-stress condition: Chronic Unpredictable Stress Battery (CUSB), Predator Scent Stress (PSS), and control group. Male and female Wistar rats 12 weeks old were used (n=10 per group). Animals of CUSB group were exposed to a battery of stressors for ten days. The stressors that made up the battery consisted of 1) put animals in movement restrictors for 20 min. (3 times per day), 2) swimming in cold water for five minutes (16°C), 3) overnight light exposure (12 hours), 4) placing the rats for 12 hours (overnight) or 3 hours (on day) in their home cages with wet bedding, 5) placing the rats for 3 hours in their home cage that was tilted at 45°, and 6) overnight water deprivation (12 hours). The exposure to each stressor was randomized according to the CUSB protocol. Animals of the PSS group were exposed for 10 minutes in an exposure box that contained a bottle with scent tag impregnated with predator urine. Behavior was assessed with Novel Object Recognition Test 24 hours after the final stressor exposure. The results obtained were CUSB-exposed females had negative values in the recognition index than control females and CUSB-exposed males. PSS-exposed females also had negative values in the recognition index but more higher than CUSB-exposed females. Furthermore, CUSB- and PSS-exposed males had a lower recognition index than control males but they had not negative values. The above suggests that CUSB and PSS induced impairment on recognition memory in females and males but not in the same way. That impairment could be associated with sex-specific alterations in areas important for learning and memory like the prefrontal cortex and hippocampus and for areas mediating mood and anxiety such amygdala.

Abstract: The use of cephalopods for research in neurosciences goes back to almost a century. This model has attracted the attention of several researchers thanks to the great complexity of behaviors, comparable even with those of some vertebrates, as well as the anatomical and physiological difference when compared with vertebrates, proof of a very different evolutionary history that diverged from ours about 550 million years ago. These characteristics offer us an opportunity to study and compare completely different nervous systems but that converge in some capacities such as learning, decision making, use of tools and even emotions. Despite the great advantage of neuroscience research in cephalopods and its great progress in recent years, it has not grown to the level of other models such as arthropods or vertebrates. This delay in research is due to several problems, one of which is the lack of a standardized species for daily use and shared by several laboratories. In the present project we propose the use of *Octopus maya*, a species reared in captivity, in the facilities of the UNAM in Sisal, Yucatán. As the first part of this proposal, the atlas of the *O. maya* brain ganglion is presented. To this end, we extracted the "brains" of 4 adult specimens. Sagittal and coronal sections were made every 80µm to make Hematoxylin-Eosin stains. From the coronal slices, 42 lamellae were obtained, while from the sagittals 75 were obtained. In addition, the lobe connectivity was tracked by the injection of DiL (1,1'-Dioctadecyl-3,3,3 ', 3 '-Tetramethylindocarbocyanine). It was determined that the brain of *O. maya* has a structure similar to that of sister species such as *O. vulgaris* and *O. mimus*, with 14 main structures, divided into more than 60 subregions. However, *O. maya* presents differences regarding the size and communication of the structures. Considering the plasticity of the nervous system, associated with the different behaviors observed along phylum Mollusca, it is feasible to hypothesize that these differences in the brain of O. maya are related to the development of particular behaviors in the habitat of the species (shallow waters with grasses and rocky bottoms).

Abstract: Chronic stress induces several alterations in cognition, behavior and physiological function. After chronic unpredictable stress exposure, animals may develop depression-like behaviors and cognitive deficits. These negative effects of stress are related to alterations in sensitive-stress structures like the hippocampus. Patients with depression and stress-related pathologies have deficits in hippocampus-dependent tasks besides several hippocampus alterations such as neuronal atrophy, reductions in size and volume. There have also been described inflammatory and neuroinflammatory dysregulations in these patients. The aim of this experiment was to evaluate stress-induced depression-like behaviors and cognitive deficits. Stress and control groups were constituted with male Wistar rats with 200-250 gr bodyweight at the beginning of the experiment. Stress exposure took place with a 10-day Chronic Unpredictable Stress Battery (CUSB). This battery consisted in six stressors (restraint, wet bed, water deprivation, tilt cage, cold water immersion and lights over the night) randomly presented. Behavioral phenotype was assessed after stress. Barnes maze and Novel object recognition test were used for memory assessment. Meanwhile, forced swim test and saccharin preference were used to explore depression-like behavior. Stressed animals showed decreased bodyweight gain. Depression-like behavior was more prevalent in contrast to non-stressed animals as data have shown in forced swim test and saccharin preference. However, adipsia was observed in stressed animals. This last effect could explain the absence of statistical significance in saccharin preference. Memory deficits were observed in stress group since rats had higher escape latencies and made more total errors in Barnes Maze. In accordance to previous data, chronic unpredictable stress induces depression-like behaviors and deficits in cognition. After 10 days in CUSB, rats exhibited depression-like behaviors and deficits in hippocampal-dependent tasks.These results support the hypothesis of stress as a risk factor to mood disorders development and hippocampal-dependent cognitive alterations. Depression-like behaviors may be modulated by chronic and higher levels of proinflammatory markers and reactive microglia in the central nervous system.

Title: Effects of the exposure to alcohol and stress during adolescence in the behavioral response of adult rats

Authors: *M. D. VERGEL-MUNGUÍA[1], U. TORRES-LÓPEZ[1], J. E. RAMÍREZ-SÁNCHEZ[1], P. TORRES-CARRILLO[1], D. B. PAZ-TREJO[2,3], H. SANCHEZ-CASTILLO[1];
[1]Lab. de Neuropsicofarmacología, Univ. Nacional Autónoma de México, Facultad de Psicología, Ciudad de México, Mexico; [2]Sistema Univ. Abierta, Univ. Nacional Autónoma de México, Facultad de Psicología, Mexico City, Mexico; [3]Sociedad Iberoamericana de Neurociencia Aplicada AC, Ciudad de México, Mexico

Abstract: The increase in alcohol consumption in adolescents has become an important public health concern. The adolescence is a crucial stage, in which occur several plasticity processes in the central nervous system, that bring to the ability to adapt to the environmental demand, however, they also make the organism vulnerable to other factors, such as drug abuse or stress. It is known that the alcohol consumption at high doses during adolescence causes damage to brain areas undergoing maturation. Previous studies have suggested that alcohol consumption starts as a form of self-medication to stressful events. In addition, it is known that acute alcohol consumption produces anxiolytic effects, however, with prolonged use of alcohol, levels of anxiety and depression rise. Nowadays, the long-term effects of adolescent exposure to alcohol in combination with stress in the behavioral response, and particularly in the development of depression and anxiety remain largely unknown. For this reason, the purpose of this study was to investigate the effects of exposure to alcohol and chronic unpredictable stress during adolescence in the development of anxiety and depressive like behaviors in adult stage. Male Wistar rats at the postnatal day 21 were used under standard laboratory conditions and divided in 3 control conditions (No Alcohol + No Stress, No Stress + No Alcohol and Naive) and 4 experimental groups (Alcohol + Stress, Stress + Alcohol, Alcohol and Stress). The Alcohol + Stress group was administered with alcohol at 10% v/v for 21 days and then exposed to Chronic Unpredictable Stress Battery (CUSB), the Stress + Alcohol group was exposed to CUSB and then alcohol consumption; the Stress group was exposed to CUSB only and the Alcohol group was exposed to alcohol only. In all conditions, depressive effects were evaluated with forced swimming test and anxiogenic effects with open field test. Also, alcohol consumption of the Stress + Alcohol,

Alcohol + Stress and Alcohol groups was measured, as well as the water consumption in control groups. The results indicate that the order of exposure to alcohol and stress has repercussions in the development of depressive and anxiety like behaviors. Furthermore, alcohol consumption was also affected by a consequence of this exposure order. This research highlights the importance of early life events in the proper development of subjects in the adult life.

Nacional Autonoma De Mexico. Fac Psicologia, Mexico City, Mexico

Abstract: The stress response allows individuals to increase the probability of survival in the face of a real or perceived situations that may put in danger an individual, its offspring or the entire species, therefore, the stress response is conserved throughout different phyla. The study of the stress response has focused mainly on the murine model, where studies have shown that chronic and acute stress exposure causes changes in the neurobehavioral response. The research model in octopus is a model that is gaining strength in Neurosciences due to the complexity of the behaviors that these animals presents, nevertheless, the stress response in this model as well as the effects that different stressors cause in octopuses behavior have not yet been understood and is usually known only by anecdotic descriptions. The absence of a standardization in the evaluation of the stress response in the octopus model causes that the welfare of the specimens influences the behavioral results obtained in the research. So, the aim of this study was to behaviorally assess the changes in the octopus behavior during and after acute exposure to an environmental stressor. Four specimens of *Octopus maya* were used from the Multidisciplinary

Unit of Teaching and Research UNAM, located in Yucatan, Mexico. They were divided into 2 groups: a group exposed to a low intensity red light (Control) and a Group exposed to high intensity light (Experimental) for 24 hours. The acute stress exposure causes an increase in activity and exploration behavior with respect to the control group during the stressor. The above suggests that acute exposure to an environmental stressor, modified the behavior of the octopuses, being a precedent for future investigations where the environment is considered in the welfare of the specimens as well as their influence on the behavioral results of the model.

Title: Behavioral effects of exposure to stress in different life times

Authors: *K. B. VALENCIA[1], Y. VIDAL-DE LA O[1], O. GALICIA-CASTILLO[2], D. PAZ-TREJO[3,4], H. SANCHEZ-CASTILLO[1];
[1]Lab. de Neuropsicofarmacologia, UNAM, Ciudad de Mexico, Mexico; [2]Facultad de Psicologia, UNAM, Ciudad de Mexico, Mexico; [3]Sistema de Univ. Abierta; Sociedad Iberoamericana de Neurociencia Aplicada, Univ. Nacional Autonoma de Mexico, Facultad de Psicologia, Ciudad de Mexico, Mexico; [4]Sociedad Iberoamericana de Neurociencia Aplicada AC, Mexico City, Mexico

Abstract: Stress is a systemic response for a real or perceived threat, that enhance the survival probability of an organism. Several mechanisms have been proposed as modulators of this response, however, when these mechanisms are not enough, and the stress response is sustained over time (chronic stress), that response could be nocive. Research in humans has demonstrated that a history of adverse experiences specifically during childhood, adolescence (both considered critical development periods) or adulthood could be a risk factor to develop psychiatry disorders as anxiety or depression. In basic research, it has been suggested that exposure to chronic stress during adolescence could vulnerability the system, and the negative effects remains to adulthood. On the other hand, exposure to chronic stress during adulthood induce anxiety-like behaviors (increased thigmotaxis, decreased rearing, etc.), depression-like behaviors (decrease in

saccharine intake, increased immobility) or cognitive deficits (specifically on spatial and recognition memory). Therefore, animal models mostly explore the effects of chronic stress during adolescence or adulthood alone, but there are few reports in which the exposure to stress take place during different moments of life course, as occurs in most cases. Due this, the aim of this research was to evaluate the behavioral effects of a double exposure to chronic stress (first in adolescence and after in adulthood) in order to study a possible incubation, potentiation or adaptation effects. For that, we use a chronic unpredictable stress battery (CUSB) and we evaluate depression-like behaviors with saccharine preference (SP) and anxiety-like behaviors with open field test (OFT). Results showed a decreased saccharine intake in SP in groups exposed to stress only in adulthood (CUSB alfa) and in adulthood and adolescence together (CUSB beta) compared to control suggesting an anhedonic state. In OFT CUSB beta showed a decreased time spend in center, decreased rearing, increased immobility and grooming compared to control, suggesting an anxiety behavioral phenotype. CUSB alfa only showed a decreased rearing. This data suggests that an exposition to stress during adolescence could potentiate a second exposition during adulthood resulting in a more intense anxiety behavioral phenotype.

Title: Investigation of second-order conditioning as a potential mechanism of the maintenance of fear memories in a rodent model of post-traumatic stress disorder

Authors: *J. M. JUDD, E. A. SMITH, J. KIM, D. PEAY, B. S. BADARUDDIN, F. SANABRIA, C. D. CONRAD;
Psychology, Arizona State Univ., Tempe, AZ

Abstract: Post-Traumatic Stress Disorder (PTSD) is characterized by the presence of robust and intrusive fear (American Psychiatric Association 2013). In PTSD, second-order conditioning may contribute to the maintenance of traumatic memories into environments where the trauma did not occur (Wessa and Flor 2007). We use chronically stressed rats to produce a vulnerable phenotype that, when combined with fear conditioning, leads to overly robust fear memories to model PTSD (Conrad et al. 1999; Hoffman et al. 2014; Miracle et al. 2006). Recently, we found

that implementing a delay between chronic stress and fear conditioning improves fear extinction (Judd et al. 2018). In the current study, we tested whether second-order conditioning contributes to impairments in fear extinction in rats that do not experience the post-stress delay. Male Sprague Dawley rats were chronically restrained by wire mesh (6hr/d/21) or assigned to a non-stressed control group (CON). Fear conditioning occurred within a day (i.e., immediately, STR-I) or 6 weeks (i.e., delay, STR-D) after chronic stress ended. Prior to the start of fear conditioning, rats were acclimated to two different contexts (A & B) for 10 min/day 3 days/context to attenuate the likelihood of chronic stress potentiating context fear learning during the training session. Day 1 of fear conditioning involved the presentation of 3 tone (20 s, 75 dB)-footshock (1 s, 0.8 mA) pairings in context A. On day 2, half of the rats were exposed to 3 tone presentations in context B, while the other half were exposed to context B for an equal duration without the tones. On day 3, rats were returned back to context B and their freezing to context was measured. All groups (CON, STR-I-STR-D) that received the tone in context B on Day 2 froze more to context B on day 3 than did their counterparts who never received a tone presentation in context B. These results suggest that CON, STR-I, and STR-D all show some level of second order conditioning, and this fails to explain the heightened freezing during extinction by STR-I in past work.

Title: A novel chronic unpredictable intermittent restraint stress paradigm disrupts spatial memory in male, but not female rats

Authors: *D. N. PEAY[1], B. S. BADARUDDIN[1], P. A. PARADA[2], J. M. JUDD[1], M. E. DONNAY[1], C. D. CONRAD[1];
[1]Psychology, Arizona State Univ., Tempe, AZ; [2]Univ. of Texas at El Paso, El Paso, TX

Abstract: In rodents, chronic stress typically impairs spatial memory in males, but has no effect or can even enhance spatial memory in females. Recently, a study found that an intermittent restraint (IR) paradigm over 9 days produced more robust effects on the stress response and anxiety profile than did a daily restraint paradigm. We investigated whether such an IR paradigm

could be applied to an extended duration over several weeks or more to impair spatial memory in both sexes. Results presented at last year's meeting showed that IR for six hours/day for three weeks was potentially effective in impairing spatial memory in male rats. Here, we tested whether the IR paradigm would impair spatial memory in both male and female rats (IR-M, IR-F) when extended to six weeks before spatial memory testing commenced. After six weeks of IR, rats began behavioral testing on days when IR was not administered. Consequently, IR allowed for a continuation of the stressor, while permitting multiple behavioral assessments on the Y-maze, object placement (OP), novel object recognition (NOR), and open field (OF). We found that the IR paradigm failed to impair spatial memory in either males or females at 6 weeks and 9 weeks, suggesting that when extended, the IR paradigm may have become less stressful. Therefore, we modified the IR to be unpredictable (UIR) in the following ways: changing the time of day for restraint (ranging from 7:00 to 19:00), the number of consecutive days of IR before a day off (ranging from 2 to 6), and changing the duration of restraint combined with gentle orbital shaking (30min, 60 min). Despite these changes, UIR still impaired Y-maze performance in males, but not in females. All groups (males, females, CON, UIR) demonstrated memory on the 1-min and 1-hr NOR task. We also included an additional stressor seven days after the last UIR session to determine whether this novel stressor would impact Y-maze performance, but spatial memory remained intact. Together with other reports, these findings support the interpretation that chronic stress negatively impairs hippocampal-dependent function in males, but not in females. This and other reports raise the question as to whether females are resilient to chronic stress-induced spatial memory deficits.

Title: Stress-induced multi-system metabolic reprogramming in mice vulnerable to post-traumatic stress disorder (PTSD)-like behavior

Authors: *G. PRESTON, E. MORAVA-KOZICZ, T. L. KOZICZ;
Clin. Genomics, Mayo Clin., Rochester, MN

Abstract: Mitochondrial dysfunction has been increasingly implicated in several psychopathologies, including post-traumatic stress disorder (PTSD), a debilitating psychiatric disorder induced by exposure to a traumatic event. We recently showed that mitochondrial function was significantly impaired in the brains of mice affected by PTSD-like symptomatology. Here we investigate multi-system metabolic effects of trauma exposure and PTSD-susceptibility in these animals. We previously induced PTSD-like symptomatology in a cohort of 48 WT FVB mice, identifying 7 PTSD-vulnerable animals and 16 PTSD-resilient animals. These animals displayed disrupted mitochondrial energy metabolism in the brain, which is often associated with diverse metabolic disruptions. To elucidate the metabolic and biochemical disruptions associated with PTSD vulnerability in the animals, as well as to identify novel biomarkers and potential therapeutic interventions, we subsequently performed targeted high-performance liquid chromatography and gas chromatography/mass spectrometry, and nuclear magnetic resonance for metabolites including acylcarnitines, amino acids, TCA metabolites and organic acids Trauma-exposed animals and PTSD-vulnerable animals displayed metabolic changes associated with increased oxidative stress, disrupted fatty acid oxidation, and impaired phospholipid synthesis in the brain, as well as disrupted fatty acid oxidation in the liver. Conversely, PTSD-resilient animals displayed evidence of increased consumption of branched chain amino acids (BCAA's). Ultimately, metabolites associated with energy metabolism, including ketone body production, glucose metabolism, and BCAA consumption were sufficient to fully delineate stress-naïve, PTSD-resilient, and PTSD-vulnerable animals. Subsequent LASSO analysis identified concentration of plasma acetylcarnitine (C2) as the most significant predictor of PTSD-vulnerability within this cohort of animals. Our data illustrate a profound stress-induced metabolic rewiring in mice susceptible to PTSD-like behavior. The metabolic changes observed are consistent with the mitochondrial dysfunction identified in these animals, as well as with epidemiological evidence observed in human patients with PTSD. Furthermore, these data identify several novel biomarkers for stress exposure and PTSD-vulnerability, as well as potential therapeutic interventions for the prevention and treatment of PTSD. Further studies will focus on confirming the predictive power of these novel biomarkers, and investigating the efficacy of the potential therapeutic interventions identified.

Title: Comparison of single or combined early life stress - Immune challenges on long term behavioral outcomes in male and female rats

Authors: L. SAAVEDRA[1], M. G. HERNÁNDEZ[1], A. OCHOA - ZARZOSA[2], *L. TORNER[3]; [1]Biomed. Res. Ctr., Inst. Mexicano del Seguro Social, Morelia, Mexico; [2]Ctr. de Estudios Multidisciplinarios en Biotecnología, Univ. Michoacana de San Nicolás de Hidalgo, Morelia, Mexico; [3]Biomed. Res. Ctr. of Michoacan, Inst. Mexicano Del Seguro Social, Morelia, Mexico

Abstract: Early life stress (ELS), including maladaptive family environments, low socioeconomic status or childhood maltreatment, creates a greater risk to suffer psychopathologies such as major depression and anxiety in adulthood. Early life severe infections can also alter affective and cognitive processes. Here we compared the effects of a neonatal single or combined stress - immune challenge on several behavioral parameters in adult male and female rats. Four groups of male and female Sprague Dawley rats were used: 1) control + vehicle, 2) maternal separation (MS, 3 hours/day on postnatal days [PN] 1 to 14) + vehicle, 3) control + Lipopolysaccharide (LPS, 0.5mg / kg, PN14), 4) MS + LPS. Starting at PN120, the emotional state of the groups was analyzed utilizing elevated plus maze (EPM), open field (OF) and forced swimming (FS) tests. To evaluate spatial and non-spatial memory, the object recognition (OR) and object placement (OP) tests were used following the emotional tests. Only female rats in diestrous were selected before each test. LPS, but not MS, increased anxiety like-behavior in the EPM and OF tests in male rats. In females both LPS and MS increased anxiety like- behavior. Combined MS+LPS increased anxiety in both males and females. MS, but not LPS, resulted in increased depressive like - behavior in the FS test in males. LPS or MS increased depressive like- behavior in females. Combined MS+LPS increased depressive - like behavior in both genders. MS and LPS challenges had no effects on spatial (OP) and non-spatial (OR) learning in males; in females, LPS decreased their performance in the OP test. Combined MS+LPS did not affect the execution of male and female rats in OP and OR tests. We conclude that behavioral responses to early life challenges depend on gender, suggesting a sexual dimorphism, and also on the nature of the adverse event faced.

Title: Basal and stress-induced cortisol and anxiety-like behavior after cannabidiol (CBD) injection in male and female zebrafish (*Danio rerio*)

Authors: *N. A. OPIOLA, M. L. PETRUNICH-RUTHERFORD;
Dept. of Psychology, Indiana Univ. Northwest, Gary, IN

Abstract: Anxiety disorders are becoming more prevalent every year, with almost 19% of the adult population suffering from some sort of anxiety disorder within the past year. Due to a variety of biological and social factors, females are more likely to be diagnosed with anxiety disorders than males. Thus, it is imperative that investigations into therapeutic options examine possible sex-dependent differences in treatment efficacy. Cannabidiol (CBD) has recently gained popularity for treatment of various disorders, including stress-induced conditions like anxiety. CBD is the one of the main non-hallucinogenic components found in the *Cannabis sativa* plant, and acts on the endogenous cannabinoid (eCB) system in the body. The eCB system plays a role in many brain and behavioral functions, including the stress response. A key factor in the stress response is the activation of the hypothalamic-pituitary-adrenal (HPA) axis. Anxiety disorders are often associated with dysfunction of the HPA axis, leading to unpredictable responses to stress. Although CBD elicits anxiolytic effects in human and animal models, more studies are needed to determine whether these effects are mediated by HPA normalization. Very few studies have examined the effects of CBD on stress-induced neuroendocrine responses, namely cortisol. Vertebrates such as zebrafish (*Danio rerio*) share a high degree of functional and genetic homology with mammals, and thus are appropriate research subjects when studying the eCB system and neuroendocrine pathways governing stress. In the current study, an intraperitoneal injection paradigm was employed to expose zebrafish to either CBD (0.2 μg/1 μl) or a vehicle (1 μl 2% Tween-80 in saline). One hour after CBD or vehicle injection, zebrafish were exposed to either an acute net stress or control condition. Acute stress was induced using a 9-minute net stressor while control subjects were placed into 1L fresh water for 9 minutes after injection. Immediately after the stressor or control condition, anxiety-like behavior was recorded for 15 minutes in the light-dark test. Subjects were then sacrificed to assess whole-body cortisol levels. Acute stress increased whole-body cortisol levels in both male and female fish; this stress-induced increase in cortisol was not as pronounced in the CBD-treated animals. CBD treatment elicited generally anxiolytic behavior in both males and females. The results from the current study suggest that CBD does not appear to influence male and female zebrafish differently; however, these results support the use of CBD as a general anxiolytic compound that has the potential to influence neuroendocrine stress regulation.

Title: Acute effects of N-acetylcysteine on basal and stress-induced anxiety-like behavior and whole-body cortisol levels in zebrafish (*Danio rerio*)

Authors: *M. L. PETRUNICH-RUTHERFORD, A. APONTE;
Dept. of Psychology, Indiana Univ. Northwest, Gary, IN

Abstract: Anxiety disorders are highly prevalent today; however, many of the common treatment options for anxiety-related disorders have an elevated risk for potential abuse. Thus, safer alternative treatment options are needed. N-acetylcysteine (NAC), a drug used to prevent liver damage resulting from acetaminophen overdose and often used as a cough suppressant, has recently surfaced as a potential compound that could be repurposed to treat anxiety disorders. Although promising, evidence supporting the anxiolytic potential and mechanism of action of NAC is limited. Animal models, such as the zebrafish (*Danio rerio*), are critical for investigations into pharmacological potential of anxiolytic compounds, as neural structures and biochemical pathways regulating stress responses are highly conserved between zebrafish and mammals. The aims of the current study were to determine whether NAC would mitigate the anxiogenic effects of an acute (9-minute) net stressor on (1) anxiety-like behavior and (2) the neuroendocrine stress hormone response in zebrafish. Adult zebrafish were exposed to a net stressor following an acute 10-minute NAC treatment (1 mg/L) and were subsequently subjected to the light/dark preference test. The light-dark test is a well-validated paradigm used to measure scototaxis behavior as a result of anxiety. It was expected that the acute stressor would increase anxiety-like behavior and whole-body cortisol levels, and that NAC pretreatment would prevent stress-induced increases in these measures. NAC blunted the increase in whole-body cortisol levels elicited by the acute stressor; however, NAC did not appear to influence stress-induced freezing and scototaxis behaviors observed in the light-dark test. The results of the current study provide evidence that brief NAC exposure has potential to regulate the neuroendocrine responses elicited by acute stress; however, chronic exposure of NAC may be required to have an impact on anxiety-like behavior. Thus, NAC may be of potential clinical use to treat neuropsychiatric conditions associated with significant neuroendocrine dysfunction. Further studies are necessary to examine the long-term impact of chronic NAC, particularly on behavioral and neuroendocrine alterations observed in response to chronic stress exposure.

Abstract: High-intensity interval training (HIIT) is associated with better physical performance, but there is limited information about the effects of HIIT on redox state of cerebellar tissue, cerebral cortex, and cognition. The aim of this study was to evaluate the effects of HIIT on redox state parameters in cerebellar tissue, cerebral cortex, and cognitive function of wistar rats. Forty-three young male wistar rats were housed under controlled environmental conditions with food, and water *ad libitum*. Animals were assigned to HIIT or Non-trained groups. HIIT protocol was performed during six weeks. Speed was determined through the assesstment of the maximum oxygen consumption (VO_{2max}). HIIT consisted of short bouts (1 minute) running on a treadmill at 10º inclination (85-100% of VO_{2max}) with 2 minutes of active recovery (60% of VO_{2max}, 10ºC inclination). Non-trained group was daily exposed to a disconnected treadmill for the same amount of time as HITT group. Both groups were submitted to the open field, and novel object recognition tasks after six weeks. Malondialdehyde concentration (MDA), superoxide dismutase (SOD) activity, and non-enzymatic antioxidant capacity (FRAP) were quantified to determine the redox state. HIIT presented increased levels of MDA, SOD, and FRAP ($p<0.05$) in the cerebellar tissue, but no differences were seen in cerebral cortex. These results indicated an improved antioxidant capacity, despite increased MDA levels in the cerebellar tissue. Both groups did not present impairment in locomotor activity, development of anxious behavior or

cognitive decline. HIIT enhanced the antioxidant defenses on cerebellar tissue with no deleterious effects on rats' cognition.

Sch. Med., Winston Salem, NC

Abstract: Early life stress (ELS) is a major risk factor for anxiety, mood and substance use disorders (SUDs). A form of ELS, infant maltreatment (MALT), occurs during rapid brain development, leading to long-term neurobehavioral effects. The developmental trajectory and underlying mechanisms are not well understood and difficult to address in humans due to limitations of prospective, longitudinal designs. Here, we used translational macaque model of

infant MALT and a cross-fostering design with random assignment to caregiving group at birth. Rates of MALT in macaques are similar to human populations, with similar long-term psychopathology outcomes as in children. We studied longitudinal brain structural alterations underlying increased stress/emotional reactivity and risk for SUDs, focusing on regions controlling these processes: amygdala, hippocampus, prefrontal cortex (PFC), and nucleus accumbens (NAcc). We collected (1) MRIs in 42 rhesus monkeys (20 CONT -11F, 9M-, 22 MALT -8F, 14M-) at 3 and 6 mos (infancy) and 12 mos (juvenile period), and (2) hair samples at 6 and 12 mos to measure cortisol (CORT) accumulation as index of stress exposure during infancy or the juvenile period, respectively. We used regression models to examine if higher CORT exposure predicted alterations in neurodevelopment. We also examined if MALTs were more vulnerable than CONTs to psychostimulant escalation during adolescence using a cocaine (COC) self-administration extended access (EA) paradigm. We used a fixed-ratio 20 schedule of reinforcement with daily 4hr sessions and two COC doses: a "high" dose of COC, 0.1 mg/kg/inj, and a second dose (ranging from 0.003 to 0.1 mg/kg/inj), which elicited the highest response rate in each subject (EDMax). Our findings suggest bigger amygdala ($F_{1,30}$ =5.96, p=0.021) and NAcc ($F_{1,29}$ =6.63, p=0.015) volume growth with age in MALTs compared to CONTs. Although higher CORT exposure did not explain these results, higher CORT levels predicted blunted PFC volume growth from 3 to 12 mos (total, grey and white matter (e.g. Total PFC: right: r=-0.604, p=0.003; left: r=-0.472, p=0.027). CONTs showed stable COC intake during EA and did not "escalate" intake at either COC dose. Our findings are consistent with previous reports in macaques and in contrast to rodent studies, which increase response rate ("escalation") under EA compared to limited access (1hr sessions). We are currently analyzing if MALTs show differences in EA drug intake compared to CONTs. Our findings suggest ELS alters structural development of cortico-limbic circuits. We are currently examining if these neural changes underlie increased vulnerability for psychostimulant escalation.

Abstract: The stress response has been described as a systemic response in real or perceived conditions of treat. Current literature shown that the stress exposure alters the levels of corticosterone in different brain structures such hippocampus (Hip) amygdala (Am) and prefrontal cortex (PFC). However such changes not necessarily has been reported simultaneously. The aim of this research was to evaluate simultaneously the corticosterone leves in three brain structures related with the stress response (Hip, Am and PFC). 14 Wistar male twelve weeks old rats were exposed to a chronic unpredictable stress battery (CUSB). 30 minutes after the end of the stress exposure the brains were removed and the Hyp, Am and PFC were dissected and corticosterone levels were measured with ELISA protocol. Results showed great variability in the corticosterone leves of the control condition, by the other side, the stressed group showed a decrease in the variability. This data suggests that an exposition to stress alters differentially in different brain structures.

Title: Sigma-1 receptor antagonist effects on sucrose reinforcement driven by intra-accumbens opioid and dopamine agonist administration

Authors: *M. TAPIA[1], J. R. LEE[2], M. CESSAC[3], K. MASON[1], L. RIVERA[4], J. BODEEN[1], D. K. MILLER[1], M. J. WILL[1];
[1]Psychological Sci., [2]Interdisciplinary Neurosci. Program, [3]Nutr. and Exercise Physiol., [4]Biol. Sci., Univ. of Missouri, Columbia, MO

Abstract: Feeding behaviors can be influenced by a multitude of factors including one's demographic and socioeconomic status, biological tendencies, nutritional knowledge, food preference, and portion size (Scaglioni et al., 2018). As the intersectionality of these factors have important implications as it relates to the prevention and treatment of one's risk of obesity, it is important to investigate pharmacological methods in which feeding behaviors can be altered. Sigma 1 receptors have been investigated for their involvement in learning, rewarding and motivational processes. PD144418 1,2,3,6-tetrahydro-5-[3-(4-methylphenyl)-5-isoxazolyl]-1-propylpyridine], a potent and selective sigma 1 ligand exhibiting a high affinity and selectivity for sigma 1 receptors, has been found to produce a dose-dependent attenuation of locomotor activity induced by cocaine. Moreover, PD144418 decreases motivational effort of food-reinforced operant behavior, without altering locomotion, appetite or food palatability in rats. However, it remains unknown whether PD144418 can alter the motivational effort of food-reinforced operant behavior in response to altered modification to hedonic or dopaminergic driven feeding behaviors. The present study examined the effects of PD144418 on hedonic and dopaminergic driven motivational aspects of feeding, via central administration of a mu opioid agonist, DAMGO, or d-amphetamine, a dopamine uptake inhibitor and releaser, in male and female rats using a progressive ratio (PR) schedule of reinforced operant task. Male and female rats (*n*=24) were first trained on a fixed ratio (FR) schedule of reinforcement. Following FR training, rats were tested under a PR schedule of reinforcement. 15-minutes prior to testing, each rat received a single dose of PD144418 (0, 3.16 or 10 μmol/kg, ip). Immediately prior to being placed in the operant chamber, each rat received an infusion of either DAMGO (0.25μg/0.5 μl/side bilaterally), d-amphetamine (10μg/0.5 μl/side bilaterally), or saline. Results determined that pretreatment with PD1444418 did influence operant responding under these conditions of opioid and dopaminergic manipulations, raising intriguing possibilities and questions regarding the mechanism underlying the interaction of sigma 1 receptors and these motivational processes.

Title: The interaction of astrocytes and medium spiny neurons in dorsomedial striatum regulates adenosine-dependent reward-seeking behaviors

Authors: *S. KANG[1], S.-I. HONG[1], H. LEE[3], D.-S. CHOI[1,2];
[1]Dept. of Mol. Pharmacol. and Exptl. Therapeut., [2]Dept. of Psychiatry and Psychology, Mayo Clin. Col. of Med., Rochester, MN; [3]Dept. of Cancer Biomed. Science, Grad. Sch. of Cancer Sci. and Policy, Natl. Cancer Ctr., Seoul, Korea, Republic of

Abstract: The maladaptation in reward-value dependent shifting between goal-directed and habitual actions may underlie multiple psychopathologies such as addiction, obsessive compulsive disorders, impulsivity and some decision-making disorders. Dorsomedial striatum (DMS) has been spotlighted because of its role in goal-directed behaviors orchestrated by neurons within the DMS via adenosine signaling. However, how astrocytes, the major modulator of extracellular adenosine levels, contribute to the neuronal synaptic activities and the sequential behavioral shifts remains largely unknown.
Utilizing the Inscopix endomicroscopy/fiber photometry *in vivo* calcium imaging and the cell type specific activation of designer receptors exclusively activated by designer drugs (DREADDs), we confirmed that GFAP-driven activation of hM3Dq DREADDs increases intensity and frequency of calcium signaling in the DMS astrocytes of ALDH1L1-GCaMP6s expressing mice. We found that this chemogenetic activation of the DMS astrocytes increase and decrease neuronal excitability of direct pathway Medium Spiny Neurons (dMSNs) and indirect pathway Medium Spiny Neurons (iMSNs), respectively. Specifically, it reduced the frequency of spontaneous excitatory postsynaptic currents (sEPSCs) in dMSNs, whereas it increased the amplitude of the sEPSCs and decreased the frequency of spontaneous inhibitory postsynaptic currents (sIPSCs) in iMSNs. The changes in sEPSCs and sIPSCs induced by astrocytic activation were significantly inhibited in the DMS of mice lacking ethanol-sensitive adenosine transporter, ENT1 (equilibrative nucleoside transporter 1, *Slc29a1*). NBTI, an ENT1-specific blocker, also reduced the chemogenetic-evoked synaptic events, suggesting that ENT1 is, at least partly, required for astrocytic adenosine release.
In the devaluation tests of reward seeking by within-subject instrumental nose-poking paradigm, which mice shift between goal-directed and habitual actions according to outcome value change, the chemogenetic activation of DMS astrocytes shifted the habitual behaviors to the goal-directed actions in sucrose-reward seeking in the ENT1 WT mice, but not in the ENT1 KO mice. When the ENT1 expression in the DMS is rescued by injection of GFAP-driven ENT1 expressing AAV into the DMS of the ENT1 KO mice, the behavioral shift was restored by the chemogenetic activation.
Together, our results indicate that astrocyte-mediated adenosine signaling in the DMS determines goal-directed and habitual actions by selectively regulating specific synapses suggesting that reward-seeking behavior results from the interaction of neurons and astrocytes.

Title: Measurement of response vigor in a progressive ratio task in common marmosets

Authors: *T. ENOMOTO[1], N. KONOIKE[2], K. NAKAMURA[2], K. IKEDA[1];
[1]Platform Technol. Res. Unit, Drug Res. Div., Sumitomo Dainippon Pharma Co., Ltd., Osaka, Japan; [2]Primate Res. Institute, Kyoto Univ., Inuyama, Japan

Abstract: Motivational deficits are common symptoms in a wide range of neuropsychiatric disorders. However, there are no approved medicines for motivational deficits. In the drug discovery for this symptoms, translational methods to measure the motivation are essential. Since the prefrontal cortex has played a crucial role on motivation, non-human primates with the developed prefrontal cortex would be useful in this field. We previously developed a novel effort-based decision making task in common marmosets (*Callithrix jacchus*). In the present study, we measured response vigor and persistence, another aspect of motivation, in a progressive ratio task in common marmosets. We used the same touch-panel system and food reward (a piece of cakes) as the effort-based decision making task. Marmosets were trained to touch the picture in the panel to get the reward. The required numbers of touch responses to get one reward were progressively increased. A test session was terminated after 30 min or earlier if 3 min elapsed after a response. The breakpoint, which was the last ratio obtained, was measured as an index of response vigor and persistence. Animals were treated with compounds or vehicle in a counter-balanced way. A vesicular monoamine transporter-2 inhibitor tetrabenazine, which has been known to deplete the dopamine in the synaptic vesicles, was administered 120 min before the test. Tetrabenazine (1 and 3 mg/kg s.c.) decreased the breakpoint. Either a dopamine D_1 receptor antagonist SCH-39166 (0.01 and 0.03 mg/kg i.m.) or D_2 receptor antagonist raclopride (0.01 and 0.03 mg/kg i.m.) also decreased the breakpoint. Therefore, the decrease of D_1 and/or D_2 receptor signaling may be related with the effects of tetrabenazine on motivation. On the other hand, methamphetamine (0.1 mg/kg i.m.), which has been known to elevate the extracellular dopamine levels in the brain, increased the breakpoint. Clinical studies have shown that tetrabenazine induces some motivational deficits, while amphetamine elevates the motivation in humans. Therefore, our progressive ratio task in common marmosets would have predictive validity. This behavioral task could be a simple and useful assay to measure the motivation in translational research.

Title: Varenicline, a nicotinic acetylcholine receptor partial agonist, alters reward network functional connectivity during an alcohol incentive delay task in heavy drinkers

Authors: *B. W. STEVENS[1], A. L. COWAND[1], V. VATSALYA[3], J. L. GOWIN[4], S. E. BARTLETT[5], M. HEILIG[6], R. MOMENAN[2], V. A. RAMCHANDANI[1];
[1]Section on Human Psychopharmacology, [2]Clin. NeuroImaging Res. Core, Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD; [3]Dept. of Med., Univ. of Louisville, Louisville, KY; [4]Dept. of Radiology and Psychiatry, Univ. of Colorado Denver, Denver, CO; [5]Sch. of Clin. Sci., Queensland Univ. of Technol., Brisbane, Australia; [6]Dept. of Clin. and Exptl. Med., Linköping Univ., Linköping, Sweden

Abstract: Varenicline is a nicotinic acetylcholine receptor (nAChR) partial agonist approved for smoking cessation. Clinical trials also suggest that varenicline can reduce alcohol drinking. Varenicline has been shown to reduce activation in brain reward regions to nicotine cues in smokers, and our lab found this effect for alcohol cues in heavy drinkers. These studies however did not examine the dynamics of these activations across brain networks. This analysis sought to extend these findings by studying the effects of varenicline on neural dynamics using functional connectivity in non-treatment seeking heavy drinkers (>14 standard drinks/week for females and >20 for males). Following randomization to varenicline (VR; N=17; Female=3) or placebo (PL; N=12; Female=1) for 2 weeks, participants underwent an MRI scan while performing the Alcohol-Food Incentive Delay (AFID) task which included alcohol (Alc), neutral (Neut) or food cues followed by a target response phase, and then feedback. After the task they rated how excited, happy, fearful and unhappy they were to each cue type. fMRI data were analyzed using seed to voxel generalized psychophysiological interactions including all the task phases as regressors. Seed regions included the left (L) and right (R) nucleus accumbens (NA), putamen, medial and lateral OFC. Analyses focused on comparing Alc and Neut trial types at $p<0.05$ FDR cluster-corrected. The VR group reported feeling less excited ($p= 0.004$) during Alc trials. In the Alc>Neut cue contrast, the VR group had greater connectivity between 2 seed regions (R NA and L putamen) with the right posterior cingulate (PCC). A similar pattern emerged for the

Alc>Neut winning feedback contrast, with the VR group showing higher connectivity between the R medial OFC and L NA with the L angular gyrus. Given the emerging role of PCC in regulating whether attention is internalized or externalized, these results suggest that VR may be interacting with the reward regions reducing internalization of alcohol cues. The angular gyrus has been shown to play a role in emotional regulation, helping signal the PFC to exert control, and therefore VR could be downregulating the emotional response to winning feedback. These findings provide additional insights into the neural dynamics underlying VR's effect on alcohol drinking and efficacy in alcohol use disorder in that VR might influence regulatory mechanisms that act upon reward networks.

Title: Histone demethylase KDM6B mediates heroin craving

Authors: *S. MITRA[1], P. H. GOBIRA[3], J. A. MARTIN[4], S. THOMAS[5], C. T. WERNER[2], D. M. DIETZ[6];

Inst. on Addictions; Program in Neurosci., State Univ. of New York At Buffalo, Buffalo, NY; [5]Pharmacol. & Toxicology, The State Univ. of New York at Buffalo, Buffalo, NY; [6]State Univ. of New York, Buffalo, NY

Abstract: Opioid use disorder is a chronic relapsing disease. Following prolonged drug cessation, relapse events are often triggered by drug-associated cues. Nucleus accumbens (NAc) acts as a hub for convergence of reward-related pathways and therefore forms a critical region for enduring neuroadaptations implicated in cue-evoked maladaptive behaviors. One intriguing mechanism underlying neuroadaptation leading to relapse vulnerability is the epigenetic modification of DNA and histones. These unique epigenetic signatures constitute the backbone for chronic alterations in genomic landscape and cellular dysregulation leading to aberrant behaviors such as compulsive drug craving. Lysine-specific demethylase 6B (KDM6B) is a histone demethylase that modifies histone tails and is at the nexus of mechanisms known to be

dysregulated in the addicted state. Bone morphogenetic proteins (BMPs) are a member of the TGF beta superfamily of proteins that serve as important mediators for a wide array of cellular functions. With emerging evidence for overlapping roles of BMP pathway and KDM6B and limited understanding of their role in addiction, we aimed at investigating if there is a potential cross-talk between KDM6B and the BMP pathway underlying behavioral and cellular plasticity inflicted by drugs of abuse. Here, we show that following prolong abstinence (abstinence day 14 [AD14]) from heroin self-administration, a time point characterized by enhanced drug craving, both canonical BMP pathway intermediates SMAD 1/5/8 phosphorylation and histone demethylase KDM6B is potentiated in the NAc. Pharmacological manipulation of canonical BMP pathway and KDM6B by noggin and GSK-J4 respectively, reduced cue-induced heroin seeking with evidence of potential cross-talk between KDM6B and BMP pathway. Our findings demonstrate that KDM6B mediates cue-induced heroin seeking following prolong abstinence, potentially through a transcriptional mechanism involving canonical BMP pathway.

Title: Influence of physical activity on diet preferences in male and female rats

Authors: *J. R. LEE, M. A. TAPIA, V. N. WEISE, E. L. BATHE, V. J. VIEIRA-POTTER, F. W. BOOTH, M. J. WILL;
Univ. of Missouri, Columbia, MO

Abstract: Palatability driven feeding and voluntary physical activity are mediated by and influence similar neural mechanisms, notably through the actions of opioids within the nucleus accumbens. Recent studies suggest that access to a voluntary running wheel results in sex dependent behavioral and physiological adaptations related to opioid mediated palatability-driven feeding. However, experimental parameters such as testing environment and composition of diet may also influence these results. To explore this relationship, male and female Wistar rats were given either access to a voluntary running wheel (RUN group) or no access (SED group) for one week prior to being stereotaxically implanted with bilateral cannulae targeting the nucleus accumbens. Following 7 days of recovery, with RUN or SED conditions continuing the duration of the experiment, all rats were assessed daily (2h/day) for feeding behavior of concurrently accessible high-carbohydrate and high-fat diet for one week. Following this week, all rats were administered the μ-opioid receptor agonist D-Ala2, NMe-Phe4, Glyol5-enkephalin

(DAMGO) (0.0025µg, 0.025µg, or 0.25µg/0.5µl/side) or the opioid antagonist naloxone (20µg/0.5µl/side) into the nucleus accumbens and given concurrent access (2h) to both diets.

Title: Naltrexone does not alter willingness to exert effort in a monetary reward task

Authors: *J. K. HOOTS[1], M. C. WARDLE[1], H. DEWIT[2];
[1]Univ. of Illinois At Chicago, Chicago, IL; [2]Univ. of Chicago, Chicago, IL

Abstract: Background: The opioid system contributes to the hedonic or "liking" experience of rewards such as foods and drugs. Opioidergic "hot spots" governing hedonic experience are important for reward learning and goal-directed behavior. Here, we used the mu-opioid receptor antagonist naltrexone to examine the role of opioids in determining effort expenditure for rewards in healthy adults. We hypothesized that naltrexone would reduce willingness to exert effort for monetary rewards. Specifically, we expected effort levels to be equivalent at the start of each session, but we predicted that effort expenditure would decrease over the naltrexone sessions, as individuals would experience less pleasure from "wins" during opioid blockade and alter their effort accordingly.
Methods: Healthy adults (N = 34) participated in a 3-session within-subjects double-blind study in which they received oral doses of placebo or naltrexone (25 and 50 mg). Subjects completed the Effort Expenditure for Rewards Task, a 50-trial computerized game in which they were given an opportunity on each trial to choose between two task difficulty levels. In the easy task, participants could receive $1 after completing a relatively easy button-pressing task. In the hard task, they could receive between $1.24 and $4.20 by completing a more difficult button-pressing task. Subjects were informed of the reward amount for the hard task and the probability of receiving any reward upon task completion (12%, 50%, or 88%) before choosing the easy or hard task for each trial. Participants received feedback about the amount of money won after each trial. The outcome variable was the number of times each subject chose the hard task.
Results: In a Generalized Linear Mixed Model, naltrexone dose (0, 25, and 50 mg) had no significant effect on willingness to exert effort for monetary rewards. Willingness to exert effort decreased over the course of the 50 trials in each session in all conditions, but this decline in

effort was also not affected by naltrexone. Further, the effect size observed for even the highest dose of naltrexone was small (d = 0.23).
Conclusions: We demonstrated that acute opioid antagonism did not significantly alter willingness to exert effort for monetary rewards. Although individuals decreased their willingness to exert effort during the session, this did not vary across drug conditions. While naltrexone at these doses has shown an effect on evaluation of social stimuli, these findings suggest that blockade of the opioid system has little effect on willingness to exert effort for monetary rewards.

Title: Endocannabinoids are released in the VTA of male rats during copulation to satiety and activate CB1 receptors to induce a long-lasting sexual inhibition and drug hypersensitivity

Authors: *E. GONZÁLEZ-MORALES, R. GARDUÑO-GUTIÉRREZ, G. RODRÍGUEZ-MANZO;
Pharmacobiology, Cinvestav-Sede Sur, Mexico, Mexico

Abstract: A male rat with unlimited access to a receptive female will ejaculate repeatedly until becoming sexually satiated. This process induces the appearance of two long lasting (72h) phenomena: a sexual behavior inhibition and a generalized hypersensitivity to drug actions. During copulation to satiety, the mesolimbic dopaminergic system is constantly activated. The dopaminergic neurons of this system synthesize and release endocannabinoids (eCB) in the ventral tegmental area (VTA), in response to its repeated stimulation. Blockade of CB1 receptors during copulation to satiety, prevents the appearance of both the sexual inhibition and the drug hypersensitivity in sexually satiated rats. We hypothesized that eCBs, which have been associated to brain plasticity processes, might be involved in the induction of these phenomena by acting at the VTA. To test this hypothesis we examined the effects of the direct infusion of the CB1 receptor antagonist AM251 into the VTA of male rats prior to copulation to satiety on sexual behavior inhibition and hypersensitivity to the 5 HT1A receptor agonist, 8 OH DPAT, measured by the appearance of one sign of the serotonergic syndrome, the flat body posture. In addition, we searched for changes in VTA CB1 receptors' density and activation of male rats that copulated to satiety 24h earlier. Results showed that antagonism of CB1 receptors in the VTA

blocked the appearance of the sexual behavior inhibition and the hypersensitivity to 8 OH DPAT in the sexually exhausted male rats. VTA CB1 receptor's density did not differ between sexually experienced and sexually satiated rats. However, we found a significant increase in the CB1 receptors that co localized with beta arrestin2 in the sexually satiated males in comparison to the sexually experienced animals. CB1 receptor and beta arrestin2 co localization reflects receptor internalization, indicative of its activation. It is concluded that during copulation to satiety eCBs are released in the VTA, where they activate CB1 receptors. Blockade of this eCBs action at VTA CB1 receptors interferes with the appearance of the two plasticity phenomena that characterize sexually satiated male rats

Title: The CRH-expressing projection pathway from the basolateral amygdala to the nucleus accumbens contributes to neurobiological mechanisms of anhedonia

Authors: *M. T. BIRNIE[1,2], A. K. SHORT[1,2], Y. CHEN[1,2], C. A. ITOGA[2], X. XU[2], T. Z. BARAM[1,2];
[1]Pediatrics, [2]Anat. and Neurobio., Univ. of California Irvine, Irvine, CA

Abstract: Rationale: Disruption to the operations of the reward circuitry underlies many aspects of affective disorders. A major manifestation of disrupted function of the reward circuitry is anhedonia, the reduced ability to experience pleasure. Anhedonia is an important dimensional entity linked to depression, schizophrenia, and other emotional disorders, yet its origins and underlying mechanisms remains unclear. We have previously identified augmented expression of the stress-related neuropeptide corticotropin-releasing hormone (CRH) within the amygdala as a cause of anhedonia in experimental models. More recently we identified a CRH-expressing projection pathway from the basolateral amygdala (BLA) to the nucleus accumbens (NAc). Therefore, we aim to understand how this molecularly-defined CRH-expressing pathway impinging on the nucleus accumbens might contribute to anhedonia. Methods: We utilized novel viral-genetic approaches to map CRH^+ pathways using Cre-dependent viruses injected into CRH-Cre mice. Further, we assessed chemogenetic targeting of CRH^+ neurons using excitatory

and inhibitory Designer Receptors Exclusively Activated by Designer Drugs (DREADDs), as well as excitatory optogenetic tools paired with behavior analysis. Results: We show that CRH-expressing neurons project from the basolateral amygdala to the nucleus accumbens. Preliminary data indicates anhedonia was observed when targeting these CRH^+ neurons with excitatory DREADDs and optogenetic stimulation, as measured by the sucrose preference, scent of a mouse and three-chamber social interaction tasks. Conclusions: These findings suggest that aberrant connectivity of the CRH^+ BLA-NAc pathway results in anhedonia and further identifies a mechanistic role for CRH-expressing neurons in stress-related major neuropsychiatric disorders.

Title: Dopamine receptor independent actions of dopamine on medium spiny neuron synaptic transmission in the nucleus accumbens

Authors: *D. A. BURKE[1,2], V. A. ALVAREZ[1];
[1]Lab. on Neurobio. of Compulsive Behaviors, Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD; [2]Neurosci., Brown Univ., Providence, RI

Abstract: The nucleus accumbens (NAc) is a brain region that subserves healthy motivated behaviors and is an important site of dysfunction in psychiatric diseases, such as addiction and depression. Acting as a “limbic-motor interface,” projection neurons in the NAc, medium spiny neurons (MSNs), integrate excitatory glutamate signals from cortex, amygdala, and hippocampus along with dopamine (DA) signals from midbrain to facilitate motivation and reward learning. However, NAc also contains an extensive network of inhibitory GABA synapses between MSNs, which remains understudied. It is currently unknown how DA interacts with this network of MSN GABA synapses. We hypothesize that by modulating synaptic strength within this network of lateral inhibition, DA influences NAc information processing by shifting the balance of excitation/inhibition at the micro circuitry level. MSNs express either Gs coupled D1 receptors or Gi coupled D2 receptors (D2MSNs). Due to the link between D2 receptor (D2R) signaling and multiple psychiatric disorders, we begin by focusing on D2MSNs. Here we ask: how does DA acutely affect GABA transmission from D2MSNs onto neighboring MSNs? We hypothesize that endogenously released DA from the midbrain can inhibit local GABA

transmission from D2MSNs to MSNs. Using a dual optogenetic approach to test this hypothesis in mouse brain slices, we show that DA neuron stimulation that precedes D2MSN GABA release can acutely depress GABA transmission from D2MSN synapses. To further probe this DA inhibition of D2MSN synaptic transmission, we applied exogenous DA at different concentrations and found the IC50 to be in the micromolar range, an order of magnitude higher than previous studies using heterologous systems. We next hypothesized that this DA depression of D2MSN GABA transmission is mediated presynaptically by D2Rs expressed on D2MSNs. We found that indeed this depression is driven by a presynaptic mechanism, but surprisingly it is only partially explained by D2R activation. Genetically deleting or pharmacologically blocking D2Rs only attenuates DA mediated depression by ~50%. Moreover, D1 receptor antagonists did not block this remaining depression, suggesting a novel target of DA. Taken together, these results shed light on the actions and mechanisms by which DA acutely modulates the lateral inhibitory network in the NAc. This insight is necessary for understanding how DA shapes NAc circuitry and information processing to promote motivated behaviors, both in health and disease.

Title: Methadone administered immediately after ejaculation do not inhibit the sexual behavior of the male rat

Authors: *J. ROJAS-HERNÁNDEZ[1], J. JUAREZ[2];
[1]Univ. De Guadalajara, Guadalajara, Mexico; [2]Univ. Guadalajara, Guadalajara, Jalisco, Mexico

Abstract: Release of endogenous opioids during the execution of male sexual behavior, particularly after ejaculation, has been related to the reinforcing and rewarding properties of sexual performance. On the other hand, the literature show evidence that opioids agonists administered before mating, suppress the sexual behavior in male rats. This supports the notion that opioids are responsible for the sexual inhibition that occurs after ejaculation. However, the literature indicates that sexual inhibition occurs when opioid agonists are administered before sexual intercourse, and there is no evidence of this effect when the opioid activity is enhanced immediately after ejaculation. On this basis, the aim of this work was to investigate whether the methadone, administered immediately after reaching ejaculation, facilitates or inhibits, both the subsequent copulatory event, and the sexual intercourse 24 h after its administration. In addition, qualitative changes in the copulatory pattern were studied. Methods: Three groups of sexually expert male rats were treated with either, 1) methadone 2.5 mg/Kg immediately after ejaculation;

2) saline solution 1 mL/Kg immediately after ejaculation, and 3) No any treatment. Thirty minutes after injection, all males were exposed to the same female with whom ejaculation was previously executed. The results showed that there was no difference in the proportion of males able to resume intercourse immediately after methadone injection, as well as 24 h after receiving the treatment. But there was an increase in the number of mounts, intromissions and in the ejaculatory latency of the copulatory serie following methadone injection when compared with control group. These results show that an increase in the opioid activity after ejaculation do not inhibit the forward progress of sexual execution, rather increases, apparently, the stimulation threshold to reach the next ejaculation. This finding contrast with the described sexual inhibition, when opioid agonists are administered before sexual intercourse.

Title: Sign tracking is predictive of suboptimal behavior in a rodent gambling task

Authors: M. C. SWINTOSKY, J. T. BRENNAN, J. P. PAULUS, *S. E. MORRISON; Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Cues that are repeatedly associated with rewards can exert a powerful influence over behavior. They can elicit approach or interaction with the cue even when such behavior is maladaptive: e.g., the flashing lights of a slot machine might prompt approach by a patient in recovery from gambling disorder. Notably, the ability of reward-associated cues to produce approach and/or interaction varies widely among individuals. In a Pavlovian conditioned approach protocol, for example, if a cue (e.g., extension of a lever) predicts a reward in a different location (e.g. a sugar pellet delivered to a food cup), some rats will preferentially approach and interact with the lever - a behavior known as sign tracking (ST) - and others will approach the site of reward delivery, a behavior known as goal tracking. A propensity towards ST has been linked to susceptibility to addiction and relapse, as well as various forms of impulsive behavior.
The neurobiological basis of ST has much in common with brain processes underlying addiction

and relapse, including pathological gambling. Both ST and gambling disorder, among other forms of addiction, are dependent on dopaminergic transmission in the mesocorticolimbic circuit. However, little is known about the relationship between ST and risky decision-making. Therefore, we characterized the performance of sign trackers and goal trackers on a rodent gambling task (rGT) incorporating win-associated cues (modified from Barrus & Winstanley, 2016). We found that rats with a propensity towards sign tracking, as compared to goal trackers, collected significantly fewer rewards during the rGT, which resulted from two forms of suboptimal behavior: an increase in premature nosepokes (impulsive action) and increased choice of the high-risk, high-reward option. Administration of dopaminergic agents, including a D2 agonist (quinpirole) and a D3 agonist (PD128907) exacerbated this suboptimal performance in a manner that was dependent on the individual's baseline behavior. These results suggest that individual differences in cue reactivity, as represented by sign tracking behavior, may be an important factor underlying individuals' susceptibility to pathological gambling, perhaps arising from enhanced engagement of the mesolimbic dopamine system by reward-associated cues.

Title: The role of the serotonin 1B receptor in impulsivity and related behavioral constructs

Authors: *S. S. DESROCHERS[1], V. M. MAGALONG[2], J. LEE[1], P. D. BALSAM[2], K. M. NAUTIYAL[1];
[1]Psychological and Brain Sci., Dartmouth Col., Hanover, NH; [2]Barnard Coll Columbia Univ., New York, NY

Abstract: The serotonin 1B (5-HT1B) receptor is implicated in a number of psychiatric disorders involving dysregulation of impulsive behavior, including ADHD and conduct, gambling, and substance use disorders. Prior work has shown that the absence of 5-HT1B receptor expression in adult mice (tetO1B model) causes increased impulsivity. Our studies here examine the effects of 5-HT1B on other phenotypes, theoretically related to impulsivity, including motivation, reward sensitivity, effort, and habitual-like behavior using operant paradigms. Mice lacking 5-HT1B expression in adulthood showed increased motivation assessed

on several reinforcement schedules, including random ratios (about 50% higher than controls) and progressive ratio (about 141% higher than controls). Interestingly, over repeated testing on a progressive ratio schedule, the effect of 5-HT1B on increased responding was no longer evident. This was not likely due to differences in extinction, as there were no group differences in a classic three day extinction test. To test the effect of 5-HT1B in a high-effort choice task, we used a concurrent choice paradigm; mice could freely consume milk reward or lever press on a random ratio 20 schedule for the same reward. An absence of 5-HT1B receptor expression resulted in increased lever pressing compared to controls. Though this potentially suggests habitual behavior, these mice showed normal decreases in lever pressing following satiety-induced devaluation, as well as normal contingency degradation. During free feeding, mice lacking 5-HT1B receptors consumed more reward but not more chow, suggesting 5-HT1B may influence reward sensitivity. Current work aims to assess the effect of 5-HT1B on reward sensitivity and additional measures of habit using lithium chloride devaluation. To examine how these various behaviors correlate with impulsivity, we performed an exploratory factor analysis using behavioral measures of impulsive action (Go/No-Go), motivation (progressive ratio), low and high-effort responding (random ratio 5 and 20 schedules), feeding (free chow consumption), and reward intake (free milk consumption) from one group of 41 mice. A two-factor model described the data well, accounting for almost 70% of the variability. Impulsivity, motivation, and high-effort responding loaded strongly onto one factor while feeding and low-effort responding loaded onto another factor. Reward intake loaded significantly onto both factors. These factors seem to differentiate between highly motivated and low-effort related behaviors. Together, these data point toward a more complex role of the 5-HT1B receptor in modulating motivated behavior.

Title: Distinct effects of psychostimulant drugs on the regulation of class IIa HDACs in the mouse mesocorticolimbic and striatal systems

Authors: *M. A. BERNARDI[1], O. V. TORRES[2], M. SOSA[1], J. MUNIZ[1], F. J. URBANO[3], E. E. GARCIA-RILL[4], J. L. CADET[5], V. BISAGNO[6];

Abstract: Some psychostimulant drugs cause neuroplastic changes leading to addiction and cognitive deficits while others enhance cognition. Epigenetic mechanisms are known contributory factors to drug-induced neuroadaptations. These epigenetic changes include dysregulation of histone deacetylases (HDACs) thought to participate in maintaining aberrant transcriptional programs associated with altered cognitive functions and behaviors. HDACs are divided into zinc-dependent [class I (HDAC1,2,3,8), class IIa (HDAC4,5,7,9), class IIb (HDAC6,10), and class IV (HDAC11)] and NAD-dependent [class III (sirtuins1-7)] enzymes. Our laboratories have previously reported that psychostimulants differentially influence the acetylation status of histones 3 and 4 at promoters of HDACs in the prefrontal cortex (Addiction Biology, 2019. doi: 10.1111/adb.12737). In the present study, we injected methamphetamine (1mg/kg), modafinil (90mg/kg), caffeine (10mg/kg) or methylphenidate (10mg/kg) in C57BL/6 mice to investigate potential changes on the mRNA expression of HDACs 4, 5 and 7 in the medial prefrontal cortex (mPFC) and dorsal striatum (DS). All psychostimulants increased locomotion at these doses. Modafinil decreased HDAC7 and HDAC5 mRNAs in DS but increased their levels in mPFC. Methylphenidate increased HDAC5 mRNA in mPFC but decreased it in DS. Methamphetamine increased HDAC4 and HDAC5 mRNA levels but decreased HDAC7 expression in mPFC. Caffeine did not effect HDAC expression. Interestingly, HDAC7, which is linked to inflammation, showed modafinil-dependent effects in both brain areas. Importantly, class IIa HDACs are phosphorylated and exported from the nucleus to cytoplasm, a process that is mediated by $^{Ca2+}$-dependent signals via association with CaMKII via protein-protein interactions. We thus measured CaMKII-alpha mRNA levels after drug administration. Unexpectedly, only methylphenidate induced changes in CaMKII-alpha mRNA in the mPFC, suggesting that other phosphorylation pathways may be involved in stimulant-induced regulation of class IIa induced within the mesocorticolimbic and striatal systems.

Title: Endocannabinoid regulation of cue-induced incentive motivation in mesoaccumbal circuits of male rats

Authors: *M. P. K. LEIGH[1], M. FEJA[2], A. N. BAINDUR[1], K. T. WAKABAYASHI[3], M. NIPHAKIS[4], B. CRAVATT[4], C. E. BASS[1];

Inst. on Addictions, Univ. at Buffalo, SUNY, Buffalo, NY; [4]The Skaggs Inst. for Chem. Biol., The Scripps Res. Inst., La Jolla, CA

Abstract: The endocannabinoids (eCBs) 2-arachidonoyl glycerol (2-AG) and anandamide (AEA) are metabolized by the enzymes monoacylglycerol lipase (MAGL) and fatty acid amide hydrolase (FAAH), respectively. Our previous work shows that enhancement of 2-AG levels with a systemically active MAGL inhibitor, MJN110, leads to a robust increase in operant responding to reward predictive incentive cues (ICs) in male rats, while rimonabant dose-dependently decreases responding. The current study sought to determine brain regions that mediate these effects by microinfusing the drugs directly into the ventral tegmental area (VTA) or nucleus accumbens (NAc) before testing. Initially, free-fed rats are trained to nosepoke during discrete 8-sec audiovisual ICs to obtain 64µl of 10% sucrose. Once stable (average responding ~85-90%) the rats are switched to a decreasing reward IC task in which the sucrose volume delivered is progressively decreased every 15 min (from 64µl, 48µl, 32µl, to 16µl). During this task variant, overall response ratio decreases (~65-70%), with choice and vigor to respond to ICs and collect reward decreasing proportionately across the volumes of sucrose delivered. Intra-VTA MJN110 attenuates the decrease in IC responding, resulting in overall enhancement in the choice (response ratio) and vigor of responding (decreased latency to nosepoke, and enter the reward cup) to ICs. However, while intra-VTA infusions of rimonabant did not alter operant responding, intra-NAc infusions decreased responding to ICs. Intracranial infusions of the FAAH inhibitor PF3845 into either the VTA or NAc did not alter responding. Our data further suggests that intra-VTA infusions of the CB2 antagonist SR-144528 enhances the vigor of the response (e.g. decreases the latency to nosepoke) without affecting response ratio. Our results suggest normal endocannabinoid tone in the NAc, but not the VTA, can be suppressed to attenuate cue-induced reward-seeking behaviors. Increasing 2-AG, but not AEA, in either the VTA or the NAc, enhances cue-induced reward-seeking. In addition, our results indicate a potential specific role of CB2 receptors in mediating the vigor of responding to the cue. Together our data demonstrates heterogeneous regulation of reward seeking by eCBs in mesoaccumbal circuits.

Title: The effects of ketamine on sexual behavior and anxiety in female rats

Authors: *S. H. MEERTS[1], F. A. GUARRACI[2], C. M. F. GONZALEZ[2], M. ALI[2], D. LUCERO[2], M. BROYLES[2];
[1]Psychology, Carleton Col., Northfield, MN; [2]Psychology, Southwestern Univ., Georgetown, TX

Abstract: Most antidepressants disrupt sexual function. Ketamine administration is a new approach for treatment resistant depression and effects on sexual function are not known. The present study characterized the effects of chronic ketamine administration on sexual motivation and anxiety in female rats. To more closely mimic the treatment of ketamine in humans, ketamine was administered once per week for a total of 4 injections over 4 consecutive weeks. Sexual motivation was measured each week using the partner preference paradigm. Briefly, female subjects were first given the opportunity to spend time in the vicinity of a sexually receptive female stimulus or a sexually vigorous male stimulus, with restricted physical contact (NO-Contact). Immediately after, subjects were permitted unrestricted access to the stimulus animals (CONTACT). Female subjects received ketamine (10.0 mg/kg) or saline 30 min prior to each partner preference test. One week after the last partner preference test, subjects received ketamine or saline again, but then were tested for anxiety on the elevated plus maze (EPM). Ketamine consistently increased time spent with the male stimulus animal across the first three tests, with no differences observed during the last test. Effects were most robust during tests that permitted physical contact. On the first test, ketamine treated subjects were less likely to leave the male after mounts and faster to return to the male after intromissions than saline treated subjects. Ketamine had no effect on anxiety as measured by the EPM, although very low levels of anxiety were observed in both groups. These data demonstrate that rather than causing sexual dysfunction, ketamine exposure enhances sexual motivation as measured by time spent with the male during the partner preference test. Sexual motivation also increased across the 4 tests in saline treated rats to eventually match the levels of sexual motivation observed in the ketamine treated rats. Ketamine is a promising new treatment for depression particularly if, as shown here, effects on sexual function are positive and not disruptive.

Title: An examination of the effects of selective serotonin receptor stimulation or blockade of the ventral tegmentum on progressive ratio performance in the rat

Authors: *Z. PIERCE-MESSICK, R. VACA-TRICERRI, W. E. PRATT;
Dept. of Psychology, Wake Forest Univ., Winston Salem, NC

Abstract: Serotonin signaling has long been linked to satiety and motivation. Recent work from our laboratory has shown that stimulation of some, but not all, serotonin receptor subtypes within the meso-accumbens pathway affects food intake of both pabulum and palatable diets. In these experiments, we assessed whether ventral tegmental activation or blockade of selective serotonin receptor subtypes would impact the appetitive motivation for sugar pellets as assessed in a progressive ratio (PR) task. Separate groups of rats (N = 12/group) were food-deprived and trained to lever press for sugar pellets on a PR2 schedule, where the first lever press was reinforced and further reinforcement required the rat to increase responding by two additional lever presses for each subsequent pellet delivery. Once trained, standard aseptic surgical procedures were used to implant indwelling stainless steel guide cannulas (23 gauge) bilaterally above the VTA (with the skull flat; -5.6 mm posterior and 0.6 mm lateral to bregma, 7.3 mm ventral to skull surface). Upon recovery, rats were returned to the operant chambers and retrained on the task without food deprivation. Separate groups were then tested following stimulation or blockade of ventral tegmental serotonin 1A, 1B, 2A, 2B, 2C, or 3 receptors. Individual rats in each drug group were tested on all doses of a single drug across three test days, separated by at least 48 hours. Consistent with their effect on modulating food intake, significant effects on progressive ratio performance were observed following stimulation of ventral tegmental serotonin 1A receptors with 8-OH-DPAT [0, 2, 4, 8 micrograms/side; $F(2,18)= 4.04$, $p = .036$] or stimulation of serotonin 3 receptors with mCPBG [0, 10, & 20 micrograms/side; $F (3,33)= 5.61$, $p = .003$], with high doses of both agents generally decreasing break point. Additionally, stimulation of serotonin 2C receptors with RO-60-0175 (at 0, 2, and 5 micrograms/side) reduced total lever presses [$F(2,16)= 3.89$, $p = .04$] and demonstrated a trend towards reducing breakpoint [$F(2,16)= 3.09$, $p = .07$]. There were no significant effects from stimulating ventral tegmental serotonin 1B, 2A, or 2B receptors on break point; neither was there any impact of antagonism of any of the serotonin receptor subtypes examined here. These data provide additional evidence of

a role for serotonergic signaling in the mesolimbic pathway on motivated behavior, and suggest that individual serotonin receptor subtypes serve separable roles within the ventral tegmentum.

Title: An examination of the impact of nucleus accumbens cocaine- and amphetamine-regulated transcript on palatable food intake in rat

Authors: *W. E. PRATT, A. CARNEY;
Dept. of Psychology, Wake Forest Univ., Winston Salem, NC

Abstract: Cocaine- and amphetamine-regulated transcript (CART) is a neuropeptide that promotes satiety through its actions within hypothalamic and other neural circuitry that regulate energy homeostasis. Interestingly, CART-containing fibers are also found in the nucleus accumbens, which is a brain region that has been implicated in promoting food intake in the presence of palatable diets. Prior work from other laboratories have examined the impact of nucleus accumbens CART on food intake of rat chow in ad libitum or food-restricted animals, but to our knowledge there has been no investigation of the impact that nucleus accumbens CART signaling might have on feeding that is promoted by a palatable diet. This project compared the effects of nucleus accumbens injections of cocaine- and amphetamine-regulated transcript on the intake of a palatable diet in non-deprived animals. Male Sprague-Dawley rats underwent surgery to implant two stainless steel, 23 gauge guide cannulas bilaterally above the anterior medial nucleus accumbens shell (+3.1 mm anterior & 1 mm lateral to bregma; 5.0 mm ventral to skull surface; nose bar set at 5 mm above aural plane). After one week of recovery, all animals were presented with a high fat/sucrose diet for daily 2-hr feeding sessions. Food intake, water intake, and locomotor measures were monitored throughout the sessions. Once the animals were acclimated to the feeding chambers and the injection procedures, each rat (N= 7) received bilateral nucleus accumbens injections of 0, 0.1 µg, or 1.0 µg of CART in 0.5 µl of saline immediately prior to being placed into the chambers. On separate treatment days, the rats also received injections of the mu-opioid receptor agonist DAMGO (at 0.025 µg/side), with or without CART co-administration. All rats received each of the six drug combinations, with each test day separated by at least 48 hours. Injections of 1.0 µg of CART reduced feeding on the palatable diet, and caused a significant reduction in body weight after 24 hours. CART also inhibited the effects of mu-opioid receptor stimulation on palatable feeding, although there was no significant interaction between mu-opioid receptor stimulation and CART administration into

the nucleus accumbens. Injections of 1.0 µg of CART into the brain 2 mm anterior to the nucleus accumbens had no impact on palatable feeding in a separate group of animals, demonstrating that the effect was site-specific. These data suggest that CART signaling in the nucleus accumbens directly impacts the motivation to consume palatable diets.

Title: Administration of Zolmitriptan, a 5-HT1B receptor agonist, on the rewarding effects of methamphetamine in male and female adolescent rats

Authors: R. A. CABRERA[1], B. COYNE[1], N. PENTKOWSKI[2], *A. R. ZAVALA[1];
[1]Psychology, California State Univ., Long Beach, CA; [2]Univ. of New Mexico, Albuquerque, NM

Abstract: Preclinical research demonstrates the involvement of 5-HT_{1B} receptors in the rewarding effects of cocaine, alcohol, and methamphetamine in adult rats. The role of 5-HT_{1B} receptors in modulating drug reward has not been previously examined in adolescent rats. In the present study, we examined whether Zolmitriptan modulates the acquisition of methamphetamine-induced conditioned place preference (CPP), a validated model of reward, in male and female adolescent rats. We hypothesized that administration of Zolmitriptan will reduce the preference for methamphetamine in both male and female rats. Beginning on postnatal day (PD) 28, male and female adolescent rats underwent a 10-day methamphetamine CPP procedure. On days 1 and 10, rats were tested for their pre-conditioning and post-conditioning place preferences, respectively, during 20-min sessions. On days 2-9, rats were conditioned for 30-min with saline or methamphetamine (0, 0.125, 0.25, 0.5, 1.0 mg/kg), on alternating days. To examine the role of 5-HT_{1B} receptors in the acquisition of meth-induced CPP, Zolmitriptan (0 or 10 mg/kg) was administered 15 min before the start of every drug conditioning session. Results indicate that activation of 5-HT_{1B} receptors decreases the effects of methamphetamine in male and female adolescent rats in a dose-dependent manner. These

findings add to a growing body of literature that suggests the 5-HT_{1B} receptor system may be a useful target for developing treatments for drugs of abuse.

Title: Early-life ketamine administration attenuates the rewarding effects of ethanol in adolescent Sprague Dawley rats

Authors: *D. FRANCO, J. ZAMUDIO, A. R. ZAVALA;
California State Univ., Long Beach, CA

Abstract: The prevalence of depression in juvenile populations has increased in the past decades. Recently, ketamine, a non-competitive NMDA receptor antagonist, was approved by the Food and Drug Administration for the treatment of depression. Nevertheless, the long-term effects of early ketamine administration in juvenile populations remain unclear. Moreover, since ketamine is also a drug of abuse, ketamine exposure may inadvertently alter developing brain reward systems and thereby increase the vulnerability to abuse drugs that function within these circuits (e.g., ethanol). Thus, we examined the hypothesis that early ketamine administration increases the rewarding effects of ethanol in adolescent rats using the conditioned place preference (CPP) paradigm, a validated animal model of reward. Male and female rats received daily ketamine injections from postnatal day (PD) 21-30. One day after the last ketamine injection, rats were assessed for ethanol-induced CPP on PD31. CPP was established by conditioning rats with either ethanol (0.0-2.0 g/kg) or saline on alternating days during 15-min conditioning sessions across eight days, respectively. CPP was assessed on PD 40 in a drug-free state. Saline pretreated male rats demonstrated ethanol-induced CPP with the lowest dose of ethanol (0.125 g/kg), whereas saline pretreated female rats demonstrated ethanol-induced CPP with a moderate dose of ethanol (0.5 g/kg). In contrast, ketamine pretreated male rats no longer demonstrated ethanol-induced CPP at the lowest dose (0.125 g/kg). Similarly, ketamine pretreated female rats did not exhibit ethanol-induced CPP at any dose. Contrary to our hypothesis, early-life ketamine administration attenuated the rewarding properties of ethanol in

male and female adolescent rats. These findings suggest that early-life ketamine may have therapeutic potential for the treatment of alcohol use disorder. Future studies will need to be done to examine this hypothesis further.

Title: Mice optimize switching behavior through cost-benefit evaluation

Authors: *N. A. SCHNEIDER, J. LISMAN, H. J. PI;
Brandeis Univ., Waltham, MA

Abstract: Avolition is a negative symptom of schizophrenia (SZ) characterized by a lack of motivation to initiate and sustain activities as well as an impairment of effort-choice evaluation. This symptom is debilitating in everyday life and few treatments are available. We have developed a quantitative behavioral paradigm for mice as an assay for motivation and effort-related choice behavior in order to mechanistically investigate neural circuits involved and their implication in avolition.
We hypothesized that mice can make economic decisions by evaluating cost and benefit of a given task and designed a neuroeconomic choice task by combining progressive ratio (PR) and fixed ratio (FR) lever pressing. Water-restricted mice can freely choose either PR or FR associated with a large and small volume of water respectively, and collect water reward by completing the required number of presses. Initially the mice prefer the large reward, but as the PR gets higher mice switch to preferring the small reward. A novel component of our design is a 2-dimensional parameter space of lever press ratio and reward amount which confers more quantitative and sensitive behavioral readouts. Based on the results from pilot experiments, we have chosen a 2x2 parameter space where large reward volume is either 2x or 5x larger than small reward and the FR schedule is either 6 or 12 (abbreviated as 2xFR6, 2xFR12, 5xFR6 and 5xFR12). By manipulating the FR requirement and large reward volume between sessions, we have been able to successfully influence effort-related choice behavior.
Seven adult mice (5 female, 2 male) of the strain C57BL/6J were trained on the task. The parameters and the sides of FR and PR were pseudo-randomly chosen. Consistent with our hypothesis, mice's preference of larger reward progressed as the parameters changed. The

average percentages of large reward choices during a session were 6.8 ± 0.6%, 13.9 ± 1.5%, 7.7 ± 0.6% and 20.4 ± 1.6% for 2xFR6, 2xFR12, 5xFR6 and 5xFR12 respectively. We also determined the indifference point at which the subjective values of both sides becomes equal and the mouse switches from preferring the large reward to preferring the small reward. The indifference points also progressed with different parameters (31 ± 2 for 2xFR6, 40 ± 1 for 2xFR12, 33 ± 1 for 5xFR6 and 46 ± 2 for 5xFR12). Taken together, the results suggest that our mice are able to assess the effort and reward associated with the task given changing parameters and adjust decisions accordingly. We will collect data from more WT mice and are currently evaluating Df1/+ mice, a SZ model of the 22q11.2 deletion, to determine if this SZ model shows effort-cost evaluation deficits similar to patients with avolition.

Title: Highly opioid-sensitive inhibitory afferents from the periaqueductal gray to the ventral tegmental area drive immobility

Authors: *R. ST. LAURENT[1], A. C. TSUDA[2], J. A. KAUER[2,1,3];
[1]Dept. of Neurosci., [2]Dept. of Mol. Pharmacology, Physiology, and Biotech., Brown Univ., Providence, RI; [3]Dept. of Psychiatry & Behavioral Sci., Stanford Univ. Sch. of Med., Stanford, CA

Abstract: The ventral tegmental area (VTA) encodes information about both rewarding and aversive stimuli and is required for the addictive properties of drugs of abuse. In the VTA, opioids inhibit GABAergic nerve terminals that normally regulate dopamine cell firing, increasing their firing rate. The VTA receives inhibitory input from local interneurons, but also from numerous extrinsic brain areas. However, the synaptic physiology and behavioral output for all afferent connections have not been extensively characterized. The periaqueductal gray (PAG) sends both glutamatergic and GABAergic projections to the VTA. Longitudinal columns of the PAG dictate connectivity and behavioral outputs associated with pain, stress, and threats: dorsal subdivisions are associated with the generation of both active and passive responses while

ventral PAG subdivisions (vPAG) are generally associated with coordination of passive behaviors and opioid analgesia. Despite these intriguing and seemingly interrelated properties of the PAG and VTA, the functional relevance of PAG_{GABA} to VTA synapses is unknown. We used an optogenetic approach to investigate synaptic plasticity, opioid effects, and behavior at the PAG_{GABA} to VTA pathway in male and female mice. We found that an increase in synaptic strength was triggered by low frequency stimulation (LFS) of PAG GABAergic synapses in the VTA. This long term potentiation was not dependent on NMDA receptor or neurotensin receptor 1 activation. PAG inhibitory synapses were profoundly depressed by opioid receptor activation. Finally, activating PAG_{GABA} to VTA synapses increased immobility in a real time place preference procedure. Preconditioning with LFS in vivo resulted in an increase in immobility. Additionally, exposure to morphine blocked the effects of photostimulation on immobility. In conclusion, we characterized an unusual form of synaptic plasticity that occurs at inhibitory PAG to VTA synapses that are also strongly depressed by opioids. We also report that activation of this projection in vivo induces a phenotype of immobility, a behavior that is typically associated with ventral portions of the PAG.

Title: Ventral pallidum GABAergic projections to the VTA support reinforcement that is attenuated by CB1 receptor blockade

Authors: *K. Z. PETERS, K. R. CRUZ, D. P. COVEY, J. F. CHEER;
Anat. and Neurobio., Univ. of Maryland, Baltimore, MD

Abstract: Intra-cranial self-stimulation (ICSS) is reinforcing in rodents and involves activation of the mesolimbic pathway. Dopaminergic projections from the ventral tegmental area (VTA) to the nucleus accumbens (NAc) are activated in response to natural rewards and drugs of abuse. Within the VTA, endocannabinoids and CB1 receptors modulate patterned dopamine release via disinhibition of presynaptic input. However, the afferent structures that are subject to CB1 receptor modulation and how this modulation influences reward and reinforcement is not clear. The VTA receives GABAergic inputs from the ventral pallidum (VP) that synapse onto dopamine and local GABA neurons. Here we report that GABAergic VP neurons projecting monosynaptically to VTA dopaminergic neurons express CB1 receptors on their terminals and

may be modulated by endocannabinoids. We assessed whether activation of GABAergic VP neurons projecting to the VTA supports ICSS and to what extent this is regulated by endocannabinoids. VGAT cre mice were injected with channelrhodopsin (ChR2) into the VP and implanted with optical fibers in the VTA. GABAergic terminals within the VTA originating from the VP were then stimulated using an ICSS protocol. We also assessed real-time place preference (RTPP) for optical stimulation of these terminals to further establish whether activation was reinforcing. We found that optogenetic stimulation of VP GABA terminals in the VTA supports ICSS, as stimulation was robustly reinforcing. This was corroborated by a significant place preference for the optically stimulated side in RTPP in all mice. In addition, ICSS was greatly reduced by the CB1 receptor antagonist rimonabant in a dose-dependent fashion. Thus, we demonstrate that optical stimulation of VP GABAergic terminals in the VTA is reinforcing and systemic CB1 antagonism attenuates ICSS supported by this projection. Future experiments will use intra-cerebral injections of rimonabant and cell type and pathway-specific genetic deletion of CB1 receptors to assess the contribution of endocannabinoids and CB1 receptors within the VTA specifically to these effects. We will also assess the downstream consequences of this pathway activation for dopamine release in the NAc using in vivo fast-scan cyclic voltammetry.

Abstract: Maintaining the internal temperature within a narrow range optimal for cellular and molecular functions is critical for animals to survive. In face of a thermal challenge, the brain prompts an array of autonomic and behavioral responses to defend thermal homeostasis. Unlike

stereotyped autonomic responses, behavioral responses are flexible goal-directed behaviors that manifest in many forms, such as seeking warmth, building nests, or turning on heaters. While the circuit mechanisms of autonomic thermoregulation have been extensively studied, their counterpart in behavioral thermoregulation remains poorly understood. Here we identify a subpopulation of neurons in the lateral hypothalamus (LH), a region essential for diverse motivated behaviors, as a critical circuit node for behavioral thermoregulation. Chemogenetic inhibition of these neurons confirmed their role in diverse thermoregulatory behaviors. By recording *in vivo* calcium dynamics, we show LH neurons bidirectionally encode the motivational value of thermal stimuli. Furthermore, anatomical tracing revealed that the LH neurons receive projections from thermosensory relay structures. Our data establish the LH subpopulation as a key circuit node in thermoregulatory behaviors. Further investigations will uncover the neural mechanisms by which sensory information is integrated and transformed into the motivational value and trigger thermoregulatory behaviors.

Title: Cocaine-induced increases in motivation require CB1 receptor activation in the ventral tegmental area

Authors: *E. J. BEEBE, V. M. AYVAZIAN, J. M. WENZEL, N. E. ZLEBNIK, J. F. CHEER; Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: A large body of evidence supports an integral role for mesolimbic dopamine in motivation. Indeed, drugs that increase dopaminergic transmission, such as cocaine, increase motivation for a number of reinforcers as measured by elevated breakpoints under a progressive ratio (PR) schedule of reinforcement. Conversely, dopamine receptor antagonism decreases PR breakpoints. Our laboratory and others have shown that phasic mesolimbic dopamine is under the control of midbrain endocannabinoids (eCBs). Relatedly, antagonism of cannabinoid type-1 (CB1) receptors decreases PR breakpoints for food reinforcers, likely through downstream effects on dopaminergic function. However, it remains unclear if drugs that increase dopamine effectively increase motivation through eCB-dependent processes. To test this, we trained male

and female rats on a PR task for a food reinforcer. Once breakpoints stabilized, each rat underwent a series of test days in which they were pretreated with either cocaine (10mg/kg or 15mg/kg, IP), the CB1 receptor antagonist rimonabant (1 or 3mg/kg, IP), or both cocaine and rimonabant. Each test session was interleaved with non-drug baseline sessions until breakpoints re-stabilized. As expected, acute cocaine increased breakpoints, while rimonabant dose-dependently decreased breakpoints. Importantly, rimonabant, at a dose that on its own did not decrease breakpoints, blocked the ability of cocaine administration to increase breakpoints. These data suggest that cocaine-induced gains in motivation are dependent upon eCB signaling. However, because rimonabant was administered systemically, these effects could not be localized. Given the essential role of dopamine in motivated behavior, we hypothesized that rimonabant acts within the ventral tegmental area (VTA) to block phasic activation of DA cells and attenuate cocaine-potentiated motivation. Therefore, we implanted bilateral cannula in the VTA for rimonabant administration via intracranial (IC) injections. As expected, cocaine (IP) on its own increased breakpoints, and rimonabant (IC) dose-dependently decreased breakpoints. Crucially, rimonabant (IC), at a dose on its own that did not decrease breakpoints, when administered into the VTA, blocked the ability of systemic cocaine administration to increase breakpoints. These data suggest that cocaine-induced gains in motivation are dependent upon eCB signaling in the VTA.

Title: Ventral pallidum output pathways in cue-elicited reward seeking, reinforcement and choice

Authors: *C. A. CAYTON, D. M. FRAZEE, I. D. LIN, J. M. RICHARD;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: The ventral pallidum (VP) is critical for both reward processing and responses to reward-related cues. We previously showed that excitations in many VP neurons are predictive of the latency and likelihood of cue-elicited reward seeking behavior, and that disruption of VP activity at cue onset disrupts reward-seeking. VP activity has also been shown to track the value of rewards during consumption, and to be reinforcing in the absence of other rewards. Here, we

aimed to determine whether these functions are assigned to distinct output pathways, focusing first on VP neurons projecting to the ventral tegmental area (VTA) versus the mediodorsal thalamus (mdThal). We used an intersectional virus strategy to express channelrhodopsin in VP-VTA or VP-mdThal neurons in rats and tested if stimulation of these populations was sufficient to invigorate cue-elicited reward-seeking behavior and alter reward value. Rats were trained with two auditory cues: a discriminative stimulus (DS) and a neutral stimulus (NS). Entering the reward port during the DS results in liquid sucrose delivery (10%), whereas port entries during the NS have no programmed consequences. After learning the task, rats received blue light stimulation in VP (20 Hz, 1s or 10s) during 50% of cue presentations. Stimulation of VP-VTA or VP-mdThal neurons during the cues failed to alter reward-seeking likelihood or latency. This suggests that activation of these neurons is not sufficient to invigorate cue-elicited reward seeking. To determine whether stimulation of these projection populations is reinforcing, we gave rats the opportunity to nose poke for stimulation (20 Hz, 1s). We found that, as expected, VP-VTA stimulation supported operant responding. In contrast, VP-mdThal stimulation did not. Finally, we tested whether stimulation of these projection populations would potentiate the value of a primary reward in a choice test. Presses on either of two levers resulted in delivery of equivalent liquid sucrose reward, but presses on one of the levers results in stimulation during sucrose consumption (20 Hz stimulation during continuous licking up to 8s). Rats receiving stimulation of VP-VTA neurons, but not VP-mdThal neurons, preferred the lever that produced sucrose paired with stimulation. Yet, when rats were tested in the absence of sucrose delivery they did not maintain responding, despite the continued availability of stimulation. Together these results suggest that while VP-VTA stimulation is capable of acting as a primary reinforcer and potentiating the value of other rewards, stimulation of these neurons is not sufficient to potentiate cue-elicited reward seeking.

Title: Circuit directionality for motivation: Lateral accumbens-pallidum, but not pallidum-accumbens, connections regulate motivational attraction to reward cues

Authors: *E. SMEDLEY[1], A. DILEO[3], K. S. SMITH[2];
[2]Psychological and Brain Sci., [1]Dartmouth Col., Hanover, NH; [3]Tufts Sackler Sch. of Grad. Biomed. Sci., Boston, MA

Abstract: Sign-tracking behavior, in which animals interact with a cue that predicts reward, provides an example of how incentive salience can be attributed to cues and elicit motivation. The nucleus accumbens (NAc) and ventral pallidum (VP) are two regions involved in cue-driven motivation. The VP, and NAc subregions including the medial shell and core, are critical for sign-tracking. Further, connections between the medial shell and VP are known to participate in sign-tracking and other motivated behaviors. The NAc lateral shell (NAcLSh) is a distinct and understudied subdivision of the NAc, and its contribution to the process by which reward cues acquire value remains unclear. The NAcLSh has been implicated in reward-directed behavior, and has reciprocal connections with the VP, suggesting that NAcLSh and VP interactions could be important mechanisms for incentive salience. Here, we use DREADDs (Designer Receptors Exclusively Activated by Designer Drugs) and an intersectional Cre-dependent viral delivery strategy, in adult male Long Evans rats, to produce a biased inhibition of NAcLSh neurons projecting to the VP (NAcLSh to VP, N=8), and vice versa (VP to NAcLSh, N=10). Each of the pathway inhibition manipulation groups were compared to their own respective controls given a control virus lacking the DREADD receptor and CNO delivery. We find that disruption of connections from NAcLSh to VP reduces sign-tracking behavior while not affecting primary motivation to consume food rewards. In contrast, VP to NAcLSh disruption affected neither sign-tracking nor reward consumption, but did produce a greater shift in animals' behavior more towards the reward source when it was available. These findings indicate that the NAcLSh to VP pathway plays an important role in guiding animals towards reward cues, while VP to NAcLSh back-projections may not and may instead bias motivated behavior towards rewards.

Title: Translatome analysis of ventral pallidum projection neuron subtypes

Authors: *H. NAM, M. ENGELN, R. CHANDRA, M. LOBO;
Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The ventral pallidum (VP) is a structure within the basal ganglia that is classically known to participate in the canonical indirect pathway. However, its targets are diverse, as the VP also sends dense projections to regions outside the basal ganglia, such as the lateral hypothalamus (LH), the mediodorsal nucleus of the thalamus (MDT) and its neighboring region of the lateral habenula (LHb). Therefore, the VP is not just an internal nucleus of the basal ganglia but also an important output structure of the system. As expected from its complex connectivity, the VP is important in many behaviors, such as the processing and execution of motivated behaviors. Despite its position within the basal ganglia and its involvement in many behavioral processes, the VP remains an understudied brain region, with limited knowledge about the cellular-level characteristics. In this study, we sought to provide knowledge into the circuitry and cell subtypes of the VP by identifying translatome profiles of discreet VP projection neurons. We used the RiboTag mice, which have a Cre-inducible HA-tagged ribosomal protein that allows for isolation of ribosome-associated mRNA. We injected a retrograde AAV5-Cre virus into the VP projection targets, the ventral tegmental area (VTA), the LH, the LHb, and the MDT. Additionally, added to our analyses was NPAS1-Cre crossed with RiboTag mouse, which identifies VP neurons that sends projections to the nucleus accumbens, VTA, and LHb. As a control, we used animals that were injected with Cre directly into the VP. RiboTag-isolated mRNAs were used for RNA-seq and clustering analysis confirmed that samples clustered well within its VP projection neuron subtype relative to controls. Out of about 16,000 genes analyzed, we found 1,628 genes to have at least 2-fold change in either direction in any of the VP neuron subtypes. 32 genes were commonly changed in all groups, and 1,036 genes were uniquely enriched or downregulated in each group. We observed changes in specific GABA, glutamate, and cholinergic receptor subunits, as well as neuronal transporters in subsets of VP neurons, which could serve as potential markers or be related to specific functions of the projections. We also saw upregulation of transcription factors in specific VP neuron populations, which may regulate transcripts that give rise to their neuron subtype identity. Results from our study will provide a comprehensive genetic signature for each VP neuron subpopulation which can have important ramifications to interpret studies of behavioral functions of VP and its functional role in disease.

Title: Optogenetic stimulation of the lateral preoptic area drives apparent paradoxical reward and aversion

Authors: *A. G. GORDON[1], N. MITTAL[2], C. DUVAUCHELLE[2], M. MARINELLI[1];
[1]Neurosci., [2]Pharm., Univ. of Texas at Austin, Austin, TX

Abstract: The lateral preoptic area (LPO) is a hypothalamic brain region interconnected with limbic brain regions critical for reward and aversion. Despite previous research into the LPO, the emotional valence of LPO activity remains to be understood. We conducted a series of experiments to determine the emotional valence of LPO neuron stimulation using optogenetics and neuronal recording using fiber photometry in awake-behaving male Sprague-Dawley rats. In our first set of experiments, we found that optogenetic stimulation of the LPO (40 Hz, 1s, 15mW) supported intracranial self-stimulation (ICSS) on a fixed-ratio 1 schedule, and that optogenetic stimulation of the LPO-VTA projection also supported ICSS, but to a lesser extent. Furthermore, we found that optogenetic stimulation of the LPO supported ICSS in a progressive ratio test in which rats responded for stimulation periods up to 5 minutes in duration. The highest break-point was observed for stimulation durations of 10s and 60s, compared with shorter (1s) or longer (5 min) durations. In our second set of experiments, we unexpectedly found that optogenetic stimulation of the LPO and the LPO-VTA projection drove real-time place aversion (RTPA) in a real-time place testing procedure (RTPT) in the same rats that demonstrated ICSS. During the RTPA procedure, entry into the laser-paired side of the chamber was coupled with an increase in 50kHz ultrasonic vocalizations, which are typically associated with positive affect. To determine if rats that avoided the optically-paired side of the chamber were still willing to enter that side of the chamber in the face of adversity, we electrified the floor of the laser-paired side of the chamber (0.05-0.15 mA). We found that rats receiving LPO stimulation upon entering the electrified side of the chamber persisted entering the side of the chamber, whereas control rats stopped entering. This indicates that rats found LPO-stimulation rewarding enough to overcome adversity. Finally, we conducted an experiment to record the LPO during positive and negative Pavlovian conditioning. Preliminary results from these experiments indicate that LPO activity correlates with positive and negative unconditioned stimuli. Altogether, these results indicate that activation of the LPO is rewarding, despite producing an apparent real-time place-aversion; these results also challenge the assumption that time spent on each side in the RTPT procedure indicates reward or aversion.

Title: Lateral habenula projecting hypothalamic neurons govern food preference in a leptin dependent manner

Authors: *R. M. O. O'CONNOR[1], M. V. MICIONI DI BONAVENTURA[2], M. ISHIKAWA[3], K. DEVARAKONDA[4], V. MATHIS[5], P. J. KENNY[6];

Abstract: Obesity rates are on the rise worldwide, resulting in a growing threat to public health. Pharmacotherapies that safely reduce body weight in obesity remain elusive, partially due to our incomplete knowledge of the complex neuronal mechanisms that control food choice (palatable high-calorie versus less palatable low-calorie food). The lateral hypothalamus (LH) is considered a critical node in the maintenance of energy homeostasis and prominently expresses the receptor for leptin, an adipocyte derived anorectic hormone. The development of obesity in rats is associated with deficits in LH sensitivity to rewarding stimuli, a switch in preference towards palatable calorically dense food items yet a seemingly paradoxical deficit in food-related motivation measured by the willingness of obese rats to deploy instrumental responding to receive food rewards. A major output of the LH terminates in the lateral habenula (LHb) which has been described as a “preference center”. We tested the hypothesis that leptin signaling on LHb innervating LH neurons plays an important role in food-related motivation. We found diphtheria toxin induced ablation of this pathway decreased levels of instrumental responding, and shifted preference towards palatable calorically dense food, phenotypes conspicuously similar to that seen in rats with diet-induced obesity. Interestingly, inhibition of leptin activity in LHb projecting LH neurons of obese rodents led to similar increases in preference for palatable food and rejection of standard chow. Furthermore, electrophysiological recordings revealed obesity induced disruptions to leptin mediated glutamatergic and GABAergic LH innervation of the LHb suggesting the involvement of leptin in communication between the LH and LHb. Based on these findings, we hypothesize that deficits in leptin mediated communication between the LH and LHb may emerge during weight gain contributing to obesity-associated behavioral abnormalities.

Title: Lateral habenula contributions to dynamic effort-based decision-making using a plus maze motivational task

Authors: E. N. BRYANT, J. P. SEVIGNY, *P. M. BAKER;
Psychology, Seattle Pacific Univ., Seattle, WA

Abstract: The lateral habenula (LHb) has been studied regarding memory and motivation especially in association with depression. Thought to be a modulator of motivation within the LHb-rostromedial tegmental nucleus circuit, the LHb likely affects an animal's ability to make optimal survival decisions especially during dynamic tasks. Therefore the LHb may play a role in effort-based decision making by changing the way motivation is integrated into choices between high and low reward. To determine the role of the LHb in effort-based decisions, an ethologically relevant task was utilized to test choice patterns using male and female Sprague Dawley rats. The task measures the subjects' willingness to climb up a ramp in order to receive a high reward (two 45mg sucrose pellets) when a low reward (one 45mg sucrose pellet), low effort option is available. Two arms of a plus maze were designated start arms with opposing arms holding rewards. Subjects encountered a series of effort-based stages presented in the form of progressively taller ramps (short = 15cm, medium = 20cm and tall = 30cm). They advanced to the next effort stage once two consecutive days of high arm preference above 80% were shown. The task proceeded using the highest ramp rats were willing to traverse. We conducted a within subjects inactivation experiment using an ABBA design with A being a saline treatment and B representing inactivation of the LHb by administration of the GABA agonist, muscimol (50ng/0.2µL) via cannula injection. After completing all trials with the ramp, rats ran two control trials, one with no ramp and drug treatment and another with no treatment and no ramp, to verify subjects' ability to discriminate between low and high rewards without an effort component. Preliminary results showed that prior to surgery the average preference for high reward on the 30cm ramp was 71.8 ± 2.7%. This indicates that the reward to effort ratio was balanced between required effort and reward salience, demonstrating the validity of this task design to examine the LHb in effort-based decision making. Preliminary results suggest disruption of willingness to exert effort following LHb inactivation. These results support LHb involvement of weighing effort in choice behavior.

Title: Novel population of nucleus accumbens direct-pathway MSNs express stress-associated neuropeptide corticotropin releasing hormone

Authors: *J. J. STOLLEY[1], V. A. ALVAREZ[2], J. C. LEMOS[1];
[1]Neurosci., Univ. of Minnesota, Minneapolis, MN; [2]Lab. on Neurobio. of Compulsive Behaviors, Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD

Abstract: The neuropeptide corticotropin-releasing hormone (CRH) has been shown to increase dopamine and acetylcholine transmission in the nucleus accumbens (NAc). These effects are accompanied by facilitation of appetitive behaviors. The endogenous source(s) of CRH to the NAc remain unclear. While recent evidence points to CRH containing afferents to the NAc from several limbic regions, there is also an uncharacterized population of CRH-expressing cells that resides in ventral NAc. Using fluorescent *in situ* hybridization, we characterized the cellular identity of neurons positive for Crh mRNA within the NAc of male mice using markers for both medium spiny projection neurons (Drd1, Pdyn, Drd2, Penk) and distinct interneuron classes (Chat, Npy, Th, Sst, Nos1, Pthlh). After analyzing the entire rostro-caudal and medial-lateral expanse of the NAc, we found that CRH-expressing cells make up 2.4% of all cells in the NAc and that there is a distinct rostro-caudal gradient, with greater numbers in the caudal aspect of the NAc. Interestingly, the results indicate that CRH-expressing cells in the NAc are predominantly direct pathway medium spiny projection neurons (dMSNs) (86.1% Drd1+, n=2338 Crh+ cells, 4 mice; 75.1% Pdyn+, n=1493 Crh+ cells, 4 mice). A smaller percentage were either Drd1/Drd2 co-expressors or only positive for Drd2 indicating that they were indirect pathway medium spiny projection neurons (iMSNs) (25.2% Drd2+, n=2234 Crh+ cells, 3 mice; 33.5% Penk, n=1493 Crh+ cells, 4 mice). Our findings suggest that interneurons account for little of NAc CRH expression (% of Crh+ cells: 0.13% Chat+, 0.10% Npy+, 0.93% Th+, 1.22% Sst+, 1.79% Nos1+) with the exception of Pthlh+ interneurons (10.3% of Crh+ cells). This work adds insight into the conditions in which endogenous CRH is released to regulate NAc circuitry. Next steps underway include examining the role these cells play in motivation and exploration using behavioral assays with conditional knockout mice.

Title: Optogenetic stimulation of nucleus accumbens circuits elicits behavioral and synaptic plasticity

Authors: *A. TAYLOR[1], K. M. MANZ[1], J. C. BECKER[2], B. A. GRUETER[1,2];
[1]Vanderbilt Brain Inst., Vanderbilt Univ., Nashville, TN; [2]Anesthesiol., Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: The nucleus accumbens (NAc) is important for integrating sensory information and coordinating motor output. The main neuronal cell types in the NAc are GABAergic medium spiny neurons (MSNs). Stimulation of either dopamine 1 (D1) receptor expressing or dopamine 2 (D2) receptor expressing MSNs result in activation of distinct pathways that differentially modulate reward behavior. In addition to MSNs, GABAergic interneurons (INs), although sparse in number, critically regulate timing of principle cell firing. In particular, parvalbumin expressing fast-spiking INs (PV-INs) regulate MSN firing via a feedforward mechanism. Action potential generation in both NAc MSNs and PV-INs is dependent upon excitatory drive from cortical, limbic and thalamic inputs. In order to understand how NAc PV-IN to MSN circuits function and this circuit's contribution to pathological conditions such as drug addiction, it is critical to understand the nature of excitatory and inhibitory control exerted onto MSNs. In this study, we utilized optogenetics to determine if NAc PV-INs are necessary and/or sufficient to induce associative learning. Specifically we investigate PFC to MSN and PV-IN to MSN synaptic and behavioral plasticity. We find that 1Hz and 30Hz stimulation of PFC terminals in the NAc induced long term depression (LTD) of optically evoked excitatory post synaptic currents. 1Hz and 30Hz stimulation of PV-INs caused LTD of optically evoked inhibitory post synaptic currents. *In vivo*, 1Hz stimulation of PV-INs caused place aversion, whereas 30Hz stimulation induced place preference. Investigation of the mechanisms underlying this plasticity will contribute to our understanding of how glutamatergic inputs and PV-INs shape NAc circuit function in both health and disease.

Title: Sex differences in optogenetic self-stimulation of prefrontal and hippocampal inputs to the nucleus accumbens shell

Authors: *E. B. LARSON, N. M. LOPRESTI, A. D. CHAPP, K. A. SILVIS, M. J. THOMAS, P. G. MERMELSTEIN;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Sex differences in addictive behavior are well-documented in humans and animals, yet the neural circuitry mediating these differences remains unclear. Given that plasticity at excitatory inputs to the nucleus accumbens shell (NAcSh) has been implicated in addictive behavior in male rodents, we hypothesized that males and females may exhibit different sensitivities to reward-related excitatory transmission in this this region. To investigate this, we utilized a novel context-based open-field spatial task to examine the sensitivity of drug-naïve male and female mice to self-administer optogenetic stimulation of glutamatergic inputs to the NAcSh. Male and female mice were injected with AAV2-CamKIIa-ChR2-eYFP into either the medial prefrontal cortex (mPFC) or ventral hippocampus (vHPC) to express the blue-light sensitive channelrhopdosin2 (ChR2) selectively in glutamatergic neurons. An optical fiber was implanted above mPFC or vHPC projection terminals in the NAcSh to selectively activate mPFC-NAcSh or vHPC-NAcSh circuits during behavioral testing. For this, mice were first habituated to the self-stimulation arena, which consisted of four spatially-restricted and contextally-distinct corner zones. Next, one of the corner zones was made active and the propensity to self-administer 10 Hz optogenetic stimulation was assessed (acquisition). The location of the active stimulation zone was then changed to further assess behavioral flexibility (reversal). We found that females were more likely to acquire mPFC-NAcSh self-stimulation behavior compared to males, while males were more sensitive to vHPC-NAcSh self-stimulation than females. For vHPC-NAcSh inputs, female also showed impaired reversal at higher frequencies (20 Hz), despite being able to acquire the task. Interestingly, although males and females exhibited different sensitivities to mPFC-NAcSh and vHPC-NAcSh stimulation, the reward-directed strategies exhibited across these two inputs was conserved. Together, these data suggest that sex differences in input-specific transmission to the NAcSh may be an important factor influencing reward-related behavior, and also implicates the mPFC-NAcSh and vHPC-

NAcSh circuits as potential sites of sex-dependent plasticity relevant for drug addiction and motivated behavior.

Title: Accumbal endocannabinoids attenuate impulsive choice

Authors: *J. F. CHEER[1], J. M. WENZEL[2], N. E. ZLEBNIK[1];
[2]Anat. & Neurobio., [1]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Impulsive choice is characterized by preference for smaller immediate rewards over larger delayed rewards, and impulsive choice behavior is a determining factor in the development and persistence of drug abuse. However, the neural substrates of impulsive choice are still largely unknown. Emerging evidence from human and animal studies suggests frontal cortical regions exert influence over ventral striatal reward processing areas during decision-making in impulsive choice or delay-discounting tasks. Striatal endocannabinoids are powerful modulators of both cortical efferents and local circuitry, but their role in impulsive decision-making is yet to be examined. We used chemogenetic tools to selectively and reversibly inhibit corticostriatal projections and employed targeted intra-NAc pharmacology to interrogate the endocannabinoid system during the performance of a delay-discounting task. Inactivation of the PFC-NAc projection elicited a robust increase in impulsive choice, demonstrating a critical role for PFC afferents to the NAc during controlled choice behavior. Furthermore, blocking accumbal CB1 receptor signaling potentiated impulsive choice, whereas enhancing endocannabinoid signaling attenuated impulsive choice in a CB1 receptor-dependent manner. Together, these findings highlight new ways in which ventral striatal processing contributes to impulsive decision-making. Results such as these may have important implications for the pathophysiology and treatment of drug addiction and impulse control disorders such as attention deficit/hyperactivity disorder.

Title: Projections from oxytocin-releasing cells in paraventricular nucleus of hypothalamus to nucleus accumbens in male and female rats

Authors: *L. R. HAMMERSLAG[1], E. D. DENEHY[1], K. E. SAATMAN[2], M. T. BARDO[1]; [1]Psychology, Univ. of Kentucky, Lexington, KY; [2]Spinal Cord & Brain Injury Res. Cntr, Univ. Kentucky, Lexington, KY

Abstract: Purpose: Recent preclinical studies have highlighted the potential for the neuropeptide oxytocin (OT) to reduce drug seeking and drug-induced activation of the nucleus accumbens (NAc) through activation of OT receptors in NAc (Cox et al., 2017, Biol. Psychiatry, 81(11):949–958). Although magnocellular OT-releasing cells (magnOT), located in the paraventricular nucleus of the hypothalamus (PVN), are known to project to forebrain structures, it is unclear if there are direct PVN to NAc projections that may mediate these effects. It is also unclear if parvocellular cells (parvOT), which are thought to innervate primarily the spinal cord and brain stem, also project to NAc. In the present study, we used the retrograde tracer cholera toxin b (CTb) to identify and characterize projections from the PVN to the NAc in virgin male and female rats.
Method: Adult male (n=4) and female (n=4) Sprague-Dawley rats underwent surgery for infusion of CTb into NAc. One week later, they were perfused with 4% paraformaldehyde and brains were processed using fluorescent immunohistochemistry to identify CTb^+ cells in NAc and PVN, as well as OT^+ cells in the PVN. Images were captured at 20x and OT^+ cells were classified as either magnOT (soma semiaxis > 13 µm) or parvOT (soma semiaxis < 10 µm), then further classified as CTb^+ or CTb^-. Whole slice images were captured to verify the accuracy of NAc CTb injections.
Results: We identified NAc projections among both the magnOT and parvOT OT-releasing cells in the PVN in both males and females; no sex differences were noted. These projections were more common among magnOT cells than among parvOT cells. There were also a large number of CTb^+ cells in the PVN that were not OT immunopositive, indicating that other cells within the PVN also send projections to NAc.
Discussion: Our results demonstrate direct projections from OT-releasing cells in PVN to NAc in virgin male and female rats, consistent with the results of a previous study that had been

conducted in lactating females (Knobloch et al., 2012, Neuron, 73(3):553-566). Interestingly, we identified both magnOT and parvOT projections to NAc, adding to the evidence that parvOT cells, once thought to innervate primarily the spinal cord and brainstem, also project sparsely to forebrain. We are currently testing the hypothesis that OT may modulate drug seeking and drug-induced NAc through these monosynaptic connections from PVN.

Title: Effect of an aversive stimulus on sexual motivation depends on the susceptibility to the induction of the motivated state

Authors: *C. SOTELO-TAPIA[1], A. C. MEDINA[2], M. HERNÁNDEZ-GONZÁLEZ[1], R. M. HIDALGO-AGUIRRE[1], M. GUEVARA[1];
[1]Inst. de Neurociencias, Univ. de Guadalajara, Guadalajara, Mexico; [2]Neurobiologia Conductual y Cognitiva. Inst. de Neurobiologia-UNAM, Queretaro, Mexico

Abstract: Sexual motivation results from the adequate processing of sexually-relevant stimuli that trigger approach behaviors to a potential partner. The efficacy with which sexual stimuli induce this motivational state depends on several factors, including the individual's physiological condition, which can be affected by an aversive stimulus such as an electrical shock applied to the foot. The changes produced by aversive stimuli can reduce or suppress behaviors, depending on their intensity and duration. Given that sexual motivation is a physiological state of activation that drives the individual to seek sexual interaction, and that it can be affected by aversive stimuli, the aim of this study was to determine the effect of electric foot shocks on sexual motivation in male rats. To this end, 33 male rats were used, divided into two groups, a control group (CG, n = 11) that did not receive shocks, and an experimental group (EG, n = 22) that received electric foot shocks *en route* to a compartment holding a receptive female. The parameters of sexual motivation (mount, intromission and ejaculation latencies) were recorded 48 hours before, immediately after, and then 48 hours after, receiving an electric shock. Only 11 male rats in EG copulated with the female 48 hours after receiving the shocks, and they took longer to enter the compartment with the female. Also, they had longer mount and intromission latencies immediately after receiving the aversive stimulus. The rats in EG that did not enter the compartment with the female rat after receiving the shocks had a high ejaculation latency 48 before receiving the aversive stimulus. These results show that the effect of an aversive stimulus

on sexual motivation depends on the time elapsed from the moment that the stimulus was received, and on the individual's susceptibility to the induction of sexual motivation. It is likely that this effect on sexual motivation depends on differences in the functionality of brain structures, and the levels of hormones related to sexual motivation and the processing of aversive stimuli.

Title: Evidence for distinct populations of D1 spiny projection neuron in NHP striatum

Authors: *J. HE[1], M. KLEYMAN[4], A. ALIKAYA[2], E. OZTURK[2], K. ROTHENHOEFER[2], M. WIRTHLIN[5], L. BYRNE[2], A. R. PFENNING[5], W. R. STAUFFER[3];
[1]Systems Neurosci. Inst., [3]Neurobio., [2]Univ. of Pittsburgh, Pittsburgh, PA; [4]Carnegie Mellon, Pittsburgh, PA; [5]Computat. Biol. Dept., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: The striatum is the major input nucleus of the basal ganglia and is critical for learning, cognition, movement, reward, and emotional responses. The striatum can be anatomically and functionally divided into three subregions: the caudate, putamen, and ventral striatum. The caudate forms circuits with association and oculomotor cortical regions. The putamen is interconnected with sensorimotor cortical regions. The ventral striatum, which includes the Nucleus Accumbens (NAcc), is integrated within limbic circuits and processes information about rewards and emotions. Multiple neurodegenerative and mental health disorders, such as Parkinson’s disease, Autism spectrum disorder, and addiction, are characterized by abnormal function in neural circuits that involve specific striatal subregions. To identify molecular access points to enable cell type and circuit specific investigation and therapeutic strategies, it is critical to understand how gene expression in different regions of the striatum regulates structure and function. Here, we set out to investigate the transcriptional architecture of the striatum in non-human primates (NHPs). We dissected caudate, putamen, and NAcc regions from 5mm thick coronal sections, immediately rostral to the anterior commissure, from two Rhesus monkeys. We isolated nuclei from the three striatal subregions and performed single nucleus RNASeq. Bimodality constrained hierarchical clustering of the resulting 80,000 RNASeq profiles identified D1 and D2 spiny projection neurons (SPNs), striatal interneurons, and marker genes

for each neuron type. Strikingly, the hierarchical clustering algorithm split D1 SPNs into two distinct cell-types ($p < 0.05$, Hartigan's Dip test, Bonferroni corrected). The first type of D1 SPN was distributed across all three striatal subregions. However, the second type of D1 SPN was preferentially located in the NAcc. Further analysis revealed that gene expression in the NAcc-specific D1 SPNs was enriched for genes associated with dopamine signaling, learning, and higher cognitive functions. These result reveal genetic, and putative functional, heterogeneity in D1 SPNs in the NHP striatum, and they will provide a foundation for investigating cell type specific contributions to higher cognitive functions.

Title: Intermittent access to the opioid fentanyl induces amultifaceted addiction-like phenotype that is associated with an increased number of orexin/hypocretin neurons

Authors: *J. E. FRAGALE[1], M. H. JAMES[1,2], R. GENERALI[1], G. ASTON-JONES[1];
[1]Rutgers Univ., Piscataway, NJ; [2]Florey Inst. of Neurosci. and Mental Hlth., Parkville, Australia

Abstract: Clinical data indicate that human addicts, including opioid addicts, rarely maintain stable drug use patterns over extended periods. To better model abuse patterns in human addicts, the IntA self-administration paradigm (IntA; Zimmer et al., 2012) was established and has since emerged as a powerful preclinical model of drug addiction. IntA to cocaine results in a robust escalation of cocaine intake, increased motivation for cocaine in a behavioral economics (BE) procedure, increased compulsive responding, and greater cued and drug-primed reinstatement compared to traditional short (ShA) and long-access (LgA) models. Despite the utility of the IntA model, it has yet to be applied to the study of opioid addiction. Here, we extend our characterization of the IntA model to the widely abused opioid fentanyl. Male rats were either given ShA (1h, n=12), LgA (6h, n=8) or IntA (n=12) to fentanyl for 14 consecutive days. Like IntA to cocaine, we found that IntA to fentanyl causes escalation of fentanyl intake, increased

motivation for fentanyl on a BE procedure, persistent drug seeking during abstinence, and increased cue-induced reinstatement compared to rats given ShA or LgA to fentanyl. We have previously shown that IntA to cocaine is associated with a persistent increase in number and activity of lateral hypothalamic orexin neurons (James et al., 2018). To determine if IntA to opioids produces similar changes in orexin expression, rats previously given ShA (n=7) or IntA (n=6) to fentanyl were re-exposed to the drug-taking context (self-administration room) following 3mo of abstinence and sacrificed 90 later. Immunohistochemistry was preformed to assess orexin and Fos (activity marker) expression. Rats given IntA to fentanyl exhibited increased orexin cell numbers and activity compared to rats given ShA to fentanyl. Unlike IntA to cocaine, these differences were apparent in both the lateral and medial hypothalamic orexin cell fields. Together, these results indicate that the IntA paradigm can serve as a strong preclinical model of opioid addiction and that IntA-induced behaviors may develop through persistent changes in orexin expression.

Title: Elucidating the role of a midline thalamus projection to nucleus accumbens in reward and aversion

Authors: *J. K. RIVERA IRIZARRY[1], K. E. PLEIL[2];
[1]Neurosci., [2]Pharmacol. & Neurosci., Weill Cornell Med., New York, NY

Abstract: Substance use disorders are characterized by progressively uncontrollable drug use despite negative consequences. Repeated drug consumption may evolve into problematic use by precipitating sustained plasticity in glutamatergic synaptic transmission in regions including the nucleus accumbens shell (NacSh). Glutamatergic synaptic transmission in the NAcSh promotes reward-seeking behaviors including drug self-administration and receives dense glutamatergic input from the paraventricular thalamus (PVT), a midline thalamic region also involved in these behaviors and important for the integration of reward and aversion. Interestingly, the roles of the PVT and NAcSh in these behaviors may be topographically organized, and there is conflicting experimental evidence that the PVT-NAcSh projection promotes the rewarding or aversive components of drug-taking depending on the study. Here, we evaluated the hypothesis that

activity of the PVT to dorsomedial NAcSh (dmNAcSh) pathway is rewarding and sufficient to drive reward-seeking behaviors and mitigate behavioral responses to aversive stimuli using a pathway-specific chemogenetic approach. We found that mice expressing a Gq-DREADD specifically in this pathway preferentially self-administered CNO over water, and that systemic CNO activation of the DREADD resulted in increased sucrose consumption and preference, indicating that activation of this thalamo-limbic circuit is involved in promoting reward-seeking behavior. In addition, it delayed Pavlovian fear acquisition without altering pain perception in a sex-dependent manner, suggesting it may attenuate the aversive component of fear conditioning. Ongoing experiments are evaluating whether this is due to a reduction of aversion *per se* or imbalance between the activation of this and parallel PVT projections. In addition, while we show activation of this pathway is sufficient to drive reward, future studies will evaluate whether it is also necessary for reward-related behaviors.

Title: Molecular and projection-specific dissection of subpopulations in the mouse ventral pallidum

Authors: *S. C. PATE[1], D. KNOWLAND[1], V. LILASCHAROEN[1], B. LIM[2];
[1]UCSD, San Diego, CA; [2]Biol. Sci., UCSD, La Jolla, CA

Abstract: The Ventral Pallidum (VP) is a centrally located nucleus within the ventral striatopallidal circuitry, traditionally considered an output nucleus of the Nucleus Accumbens (NAc). However, studies examining VP function have not been able to benefit from a clear understanding of the molecular and anatomical properties of the cells therein. Here, we distinguish subpopulations of the VP based on their neurotransmitter profile and targeted downstream regions. As the VP contains a mixture of glutamatergic and GABAergic neurons, we selectively target each population by using $Vglut2^{Cre}$ and $Vgat^{Cre}$ transgenic mouse line. In both $VGlut2^{+}$ and $VGat^{+}$ subpopulations, we employ combinations of viral-genetic labeling strategies to answer multiple anatomical questions: first, we characterize the downstream targets, next we examine the spatial organization of VP cells defined by these targets, and lastly we identify input matrices of these neurons on the basis of their target structure. In addition, we employ fluorescent *in situ* hybridization in conjunction with viral-genetic techniques to examine

the molecular identity of NAc neurons projecting to each subpopulation of the VP based on their *Drd1a* and *Drd2* mRNA expression. In all, we provide comprehensive anatomical information regarding the VP which will allow for further interpretation of its function, including in the context of larger subcortical circuits

Title: Muscarinic M5 receptors modulate dopamine transmission and dopamine-dependent exploratory behavior in mice

Authors: J. A. RAZIDLO, *J. C. LEMOS;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Dopamine transmission in the nucleus accumbens (NAc) is a driving force for important behaviors involving motivation and reward learning. Dopamine dysregulation in the NAc is associated with a plethora of disorders that include Parkinson's disease and depression. Thus, targeting biological substrates that modulate dopamine transmission may have important therapeutic potential. The muscarinic acetylcholine type 5 receptor (M5) is the only muscarinic subtype with detectable mRNA in the dopaminergic neurons of the midbrain. We replicated and extended that finding using RNAscope *in situ* hybridization and multiplexing technology. There is evidence that the M5 receptor can modulate dopamine transmission. However, since the discovery of the M5 receptor there has been a paucity of information on its function in relation to dopamine modulation in the NAc and dopamine dependent behavior. Here we demonstrate that that non-selective muscarinic agonist oxotremorine (OXO-M, 10 μM) potentiates dopamine transmission in the NAc using fast scan cyclic voltammetry in an *ex vivo* slice preparation from wildtype control mice (M5 +/+). This occurs under conditions in which dopamine release resulting from dopamine fiber activation, as opposed cholinergic interneuron activation, is isolated. This effect is reversed with the non-selective antagonist scopolamine (1 μM). Importantly, OXO-M potentiation of dopamine transmission is absent in mice with global deletion of M5 receptors (M5-/-), and a small but significant OXO-M-dependent inhibition is revealed. Interestingly, we did not detect any differences in OXO-M potentiation of dopamine peak transient between control and heterozygous mice (M5 +/-) suggesting that dopamine terminals contain spare M5 receptors. Next, we investigated the role of M5 receptors in

modulating exploratory and locomotor behavior using M5 +/+, +/-, -/- mice. In control animals, exposure to a novel environment transiently stimulates locomotor activity, stabilizing as the animal habituates. Our preliminary data suggests that mice with genetic deletion of M5 receptors show a blunted locomotor response in this initial novelty exposure but did not show a global locomotor impairment. These M5 -/- also show a significant reduction in center exploration, indicative of increased anxiety-like behavior. Interestingly, we detected no differences in exploratory behavior of opened and closed compartments of an elevated zero maze, indicating that deficits in exploratory behavior observed in M5-/- mice are context dependent. Furthermore, disruption of M5 signaling may lead to deficits in motivated behavior typical in mood disorders.

Title: Investigating reward motivation and sensitivity in healthy volunteers with high versus low state anhedonia

Authors: *C. L. SLANEY, M. R. MUNAFÒ, I. PENTON-VOAK, C. J. HOUGHTON, E. S. J. ROBINSON;
Univ. of Bristol, Bristol, United Kingdom

Abstract: INTRODUCTION: Anhedonia is a common symptom of many psychiatric disorders including depression and schizophrenia. Despite this, currently available treatments do not adequately address this symptom. One hindrance in developing new effective therapies is that it is unclear whether anhedonia reflects deficits in motivation for reward and/or reward sensitivity. The aim of this study was to behaviourally examine reward motivation and reward sensitivity in healthy adults who have high vs low state anhedonia.
METHOD: Participants scoring high (25+) or low (below 18) on an online anhedonia questionnaire (Snaith Hamilton Pleasure Scale; SHAPS) were invited to take part in this study. In total, 101 participants took part (66 reliably met criterion at study visit). All participants completed a battery of tasks measuring reward motivation (Joystick Operated Runway Task; JORT and Effort Expenditure for Reward Task; EEfRT) and reward sensitivity (Sweet Taste Test; STT). Following this, they completed questionnaires that measured symptoms of anhedonia, apathy and depression. We predicted differences between groups (high vs low state anhedonia) on both reward motivation and reward sensitivity tasks (*pre-registered;*

https://osf.io/6g5x2/).
RESULTS: Primary analyses were conducted on those who reliably met pre-defined criterion at study visit. Contrary to our predictions, there was no clear evidence of a difference between groups on reward motivation tasks (EEfRT and the JORT; $p>.05$). As predicted, there was a difference between groups in the STT, the high anhedonia group had an overall reduced sensitivity to detect sucrose compared to the low anhedonia group ($p<.05$). Exploratory correlational analyses including all participants revealed that poorer sucrose detection was also associated with other self-report measures (apathy and depression questionnaires). Additionally, performance on the EEfRT was related to anhedonia (measured using the Chapman Physical Anhedonia Scale; CPAS), replicating Treadway et al., 2009.
CONCLUSION: These findings suggest that anhedonia is related to changes in sensitivity to detect a reward (i.e. sucrose) and in effort-based decision making (using the CPAS). Importantly, changes in sensitivity to detect a reward do not appear to be anhedonia-specific.

Title: Structural connectomic mapping of dorsal striatum using antibody-conjugated gold nanoparticles and x-ray microscopy

Authors: L. T. COLLINS, K. A. SILETTI, *M. P. SADDORIS;
Psychology & Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: Many current efforts in cellular connectomics rely upon serial electron microscopy. But even when mapping very small regions of neural tissue (i.e. hundreds of micrometers), this technique can take months or years of work. Nondestructive methods involving X-ray microscopy may represent a far more efficient approach towards imaging connectomes up to the resolution of dendritic spines, but this has so far been limited by imprecise chemical stains. A potential method to move past these limitations is to use a gold nanoparticle-based contrast agent with covalently linked antibodies. To demonstrate this, we employed an antibody against the D1 receptor, conjugated the antibody to 60×27 nm carboxyl-functionalized gold, and performed standard immunohistochemical assays on sections of the rat striatum. Male rats (approximately 350-450g at time of sacrifice) were transcardially perfused with 4% paraformaldehyde, and

brains were postfixed for 24h in paraformaldehyde before being saturated in cryoprotectant (20% sucrose in PB), then frozen to -80C. Sections of 40 μm thickness were taken from the dorsal lateral and dorsal medial striatum with a cryostat. Immunohistochemistry was performed using gold nanorods with covalently linked antibodies (rabbit anti-[rat D1], Abcam, 1:100). Primary antibodies were then reacted with a secondary amplification (goat anti-[rabbit Fab], Alexa Fluor® 488, Jackson ImmunoResearch, 1:100). X-ray microscopic imaging facilitated three-dimensional reconstruction of an approximately 500×500×40 μm region of striatum, revealing neuronal processes and dendritic spines with a 400 nm pixel size. This imaging process took less than 24h. These proof-of-concept data from rat striatum demonstrate the approach's promise for connectomic imaging.

Title: The neural mechanism of reward and punishment modulation on visual working memory

Authors: *Y. SUN[1], X. CAI[2], Y. KU[1];
[1]East China Normal Univ., Shanghai, China; [2]Neurosci., New York Univ. Shanghai, Shanghai, China

Abstract: Human do almost everything under the drive of motivation, but it still remains unclear how incentive information influences visual working memory (VWM) which is a fundamental component of cognition. Furthermore, little is known about how reward and punishment related neural circuits influence VWM related circuits. Here, we address this issue in a human functional magnetic resonance imaging (fMRI) study in which 20 subjects engaged in a free recall VWM task with a monetary incentive cue presented at the beginning of each trial. The subjects needed to remember four Gabor patches with different orientations, then recall one of those orientations after a short delay. Whether they got the monetary reward/avoid the punishment or not was determined by the response error and the specific criterion (which was calculated from the result of a pre-experiment). The cue could be low, medium or high monetary reward or punishment, and we manipulated the reward and punishment across blocks and the amount of money across trials. Behaviorally, there was no interaction but a main effect of the level of reward/punishment in response error, which indicated that the more the money, the better the performance. A significant difference between low and high punishment was found through paired sample T test.

Imaging data showed that BOLD signals in caudate and putamen tracked the level of incentive cues in both reward and punishment contexts. The frontal parietal network (superior parietal lobule, intraparietal sulcus, inferior frontal junction) showed enhanced activity at the high reward condition than low reward. However the de-activation of the default mode network(posterior cingulate cortex, precuneus, medial prefrontal cortex) signaled the level of punishment. In addition, the results of parametric modulation revealed that at the punishment context, dorsal striatum was negatively correlated with the response error whereas at the reward context the ventral striatum was negatively orrelated with error. These findings suggest, although the behavioral performance was similar at reward and punishment condition, the neural mechanism seemed to be different. We additionally conducted the representational similarity analysis (RSA) to identify regions correlating with responses error at different condition. The results showed that the pattern of activation in the striatum could reflect the response error dissimilarity matrices as early as the cue stage. This study is critical to understand the similarity and difference of reward and punishment and their influence in VWM.

Title: Training squirrel monkeys on cognitive tasks for addiction studies

Authors: *D. EFFINGER, S. O. BROWN, R. A. MONTORO, H. P. JEDEMA, C. W. BRADBERRY;
NIDA Intramural Res. Program, NIH, Baltimore, MD

Abstract: Substance use disorder has become one of the largest and most rapidly growing health concerns in the United States. One of the hallmarks of substance use disorder is an inability to make logical decisions regarding drug use. Given the recent elevation in opiate use disorder, understanding the impact of abuse on neurological structure and cognitive function is of urgent importance. To explore these questions, we designed a longitudinal MR imaging and cognitive assessment study to look at the effects of prolonged remifentanil self-administration on brain structure, functional connectivity, and cognitive performance using non-human primates. Male squirrel monkeys (n=8) were trained to perform a discrimination/reversal task on a touchscreen wherein two abstract images representing a high and low milk reward were presented for the animal to choose between. Once the animal reached a criterion of 80% accuracy (choosing the

higher reward) on the stimulus discrimination over 15 consecutive trials, the contingencies were switched, and the image previously associated with the higher reward would then deliver the smaller reward. After reaching the same criterion performance on the reversal, two new stimuli were presented. Within a set 150 trial session, the average number of trials it took to reach criterion on the stimulus discrimination was 22.9 ± 1.6 trials [range: 17.2 ± .3 to 80.2± 6.8], with an average number of 2.5 ± .2 discriminations completed within a 150-trial session. For the reversal, the average number of trials it took to reach criterion was 30.9 ± 3.3 trials [range: 17 ± 9 to 73.2 ± 7.8], with an average number of 1.8 ± .3 reversals completed within a 150-trial session. On a delayed match to sample task, we found inconsistent results, suggesting this task is more difficult for the squirrel monkey to learn. With this baseline established, the monkeys have received intravenous catheters and baseline structural and functional connectivity MR scans and begun IV remifentanil self-administration in a food/drug concurrent choice paradigm. After a period of prolonged exposure to remifentanil self-administration, cognitive measures on the discrimination/reversal task, as well as a follow up structural and functional MRI scan will be taken and compared to baseline.

Title: Squirrel monkey performance on opioid/food economic choice

Authors: *R. A. MONTORO, S. O. BROWN, D. P. EFFINGER, E. THORNDIKE, H. P. JEDEMA, C. W. BRADBERRY;
NIDA Intramural Res. Program, NIH, Baltimore, MD

Abstract: We seek to understand opioid use disorder in the context of choice between drug and non-drug reward, and to do so, are establishing a squirrel monkey (*Saimiri sciureus*) concurrent choice paradigm using the short acting opioid remifentanil. Male squirrel monkeys, n = 4, were trained to interact with touchscreens and familiarized with quantity-signifying stimuli for a palatable non-drug reward (30% sweetened condensed milk). Animals were initially trained on a milk/milk economic choice task which offered different quantities of milk, via two visual cues on each trial. Animals proved to have the ability to differentiate the quantity-signifying stimuli by choosing the larger of the two stimuli presented (80%, averaged over four sessions). When

presented with stimuli signifying one of four amounts (75 to 300 microliter/kg), animals reached that 80% criterion in 4 or fewer sessions consisting of 100 trials each. After catheterization, animals were familiarized with novel quantity-signifying stimuli for remifentanil (four amounts from 0.08 to 0.32 micrograms/kg). After several sessions in which animals responded for lone remifentanil-signifying cues, animals were presented with a drug/drug choice task, which, like the milk choice task, offered different quantities of drug simultaneously. To reach the same criterion (80% larger reward averaged over 4 sessions) required 7 ± 2.4 sessions consisting of 108 trials each. Animals are now being presented with a milk/drug choice task in which differing milk quantities are offered against differing drug quantities to study choice between drug and non-drug reward. We are currently exploring how economic choice between drug and non-drug reward can be manipulated with various pre-treatments including; milk satiation, substitution of drug by saline, and morphine pretreatment.

Title: Cortex-wide activation of VIP interneurons by reward and punishment

Authors: *Z. SZADAI[1], H. PI[2], Q. CHEVY[3], K. ÓCSAI[4], G. KATONA[4], B. CHIOVINI[1], L. POPARA[4], A. KEPECS[3], B. ROZSA[5];

Abstract: Reward- and punishment are the critical driving forces for behaviors to boost arousal, attract attention and drive learning. This may be important for cortical processing. Previously we found that the VIP+ cortical inhibitory neurons, which specialize in disinhibition, respond to reward and punishment in the auditory cortex (ACx). To test whether other VIP interneurons

across the brain do this, we used two-photon 3D acousto-optic microscopy and fiber photometry to monitor VIP neuronal activity across multiple cortical areas while mice performed an auditory decision task. We show that the majority of VIP interneurons recorded across the cortex were robustly activated by reward and punishment. VIP interneurons were also modulated by arousal, local cortical processes, as demonstrated by orientation- and direction-selective responses in the visual cortex. Our results reveal that VIP interneurons have multiple response modes, with both local and global contributions, and their global model signals reinforcement events, enabling the orchestration of cortex-wide learning mechanisms.

Title: A midbrain-cortical dopamine circuit drives sexually-motivated singing

Authors: *M. BEN-TOV, F. DUARTE, R. D. MOONEY;
Duke Univ. Dept. of Neurobio., Durham, NC

Abstract: Male zebra finches learn to sing as juveniles and use their song in adulthood to court females. An adult male zebra finch sings in two distinct social contexts: an “undirected song” produced when in isolation from other birds, and a “directed song” that it sings to a nearby female. In fact, presenting a female to a previously isolated male finch motivates him to sing abundant directed songs to the female. The neural mechanisms through which social cues motivate and initiate song production are largely unknown. Song production is regulated by a specialized vocal motor network (the “song system”), which receives input from a variety of neuromodulatory regions that are highly conserved in all vertebrates, and which are likely to provide information to the song system about social context and reproductive state that could drive directed singing. To test this idea, we studied adult male zebra finches while they sang in the presence and absence of a female. We used sound recording and video tracking to monitor the bird’s singing and courtship behavior. Using pharmacological methods, we lesioned

dopamine (DA) terminals either in HVC, a premotor nucleus which lies in the apex of the song production circuity, or lesioned DA cell bodies in the midbrain part of the dopaminergic group A11, an area thought to be involved in social behavior and which is the major source of dopaminergic input to HVC. Either type of lesion abolished the ability of the males to produce female-directed songs, even though males in both experimental groups could still produce undirected songs. Furthermore, birds with DA lesions in HVC still showed courtship behaviors regardless of their inability to sing directed songs, including extensive production of introductory notes and orientation to the female. In contrast, birds with DA lesions in A11 failed to orient, call or sing to the female. Finally, we found that when we optogenetically activated A11 terminals in HVC while males were singing in the presence of a female they sang longer bouts and overall increased their singing rate. Together, these results support the idea that dopaminergic inputs from the A11 to HVC in male finches convey a social context-dependent signal important to female-directed singing.

Title: Ultrasonic calling in response to playback of appetitive 50-kHz ultrasonic vocalizations in rats

Authors: *A. C. BERZ, T. M. KISKO, C. H. CHEN, M. WÖHR, R. K. W. SCHWARTING; Philipps-University Marburg, Marburg, Germany

Abstract: Rats emit ultrasonic vocalizations (USV) of different frequencies for communicational purposes. The so-called 50-kHz USV are thought to represent a positive emotional state, which is related to the meso-limbic reward system since both their production and perception, are associated with dopamine release in the nucleus accumbens. In contrast, 22-kHz USV might reflect a negative affective state and serve as alarm calls.To test the signal features of 50-kHz USV, our lab uses playback of these calls on a radial maze. When presenting 50-kHz USV, rats will approach the sound source. Besides this strong social approach, animals may exhibit a response on an ultrasonic level. Some of the emitted calls during and after presenting 50-kHz USV show low frequency features similar to 22-kHz USV, but are shorter and display a slightly higher frequency. These acoustic responses were found in males and females, but seem to depend on development, since they are typical for juvenile but not adult rats. Also during rough-

and-tumble play, juvenile rats may emit these low frequency calls while interacting with a partner. Results from pharmacological interventions with the D2 antagonist haloperidol indicate that the low frequency response calls are not dependent on dopamine D2 receptors. Considering different rat strains like Wistar and Sprague Dawley rats, our data imply that both strains show the phenomenon of low frequency response calls during or after 50-kHz USV presentation. With these studies, we are providing the first comprehensive characterization of the phenomenon of low frequency calls in response to 50-kHz USV playback and during juvenile social play. Besides distinguishing general features like frequency, amplitude and occurrence, we also compare different strains and pharmacological treatments. Our data indicate that these low frequency calls do not reflect aversive states since the animals do not show any avoidance behavior. Rather, it is tentative to assume that they serve as an important adaptive function of juvenile rats in anticipation of or during social interaction with conspecific animals, for example, to decrease the likelihood of aggression.

Title: Identification of forebrain inputs to a midbrain vocalization circuit that promote and suppress the production of social vocalizations

Authors: *K. A. TSCHIDA[1], V. C. MICHAEL[1], J. TAKATOH[1], S. ZHAO[1], B.-X. HAN[1], F. WANG[2], R. D. MOONEY[1];
[2]Dept. of Neurobio., [1]Duke Univ., Durham, NC

Abstract: Vocalizations are an essential medium for communication and courtship in numerous mammalian species ranging from mice to humans. In mammals, the midbrain periaqueductal gray (PAG) serves as an obligatory node in a vocalization-related network that spans the forebrain and brainstem, as bilateral lesions of the PAG result in mutism. Despite the PAG's importance for vocal production, the identity, function, and connectivity of PAG neurons involved in vocalization has remained elusive, in part because the PAG is a functionally and anatomically heterogeneous structure that serves myriad roles including nociception, defensive behaviors, and autonomic regulation. To this end, we previously used a viral genetic strategy to identify and characterize PAG neurons whose activity is necessary and sufficient for the

production of ultrasonic vocalizations (USVs) in the mouse. This work established the identity of the PAG neurons selectively required to gate the production of USVs (i.e, PAG-USV neurons), and an important remaining question is how PAG-USV neurons integrate upstream information to appropriately gate vocal output.
To identify neurons upstream of the PAG vocalization circuit, we performed trans-synaptic rabies tracing from PAG-USV neurons as well as nearby PAG inhibitory interneurons. We found that the PAG vocalization circuit receives inputs from a variety of cortical and subcortical regions implicated in social behavior, including neurons in the preoptic area (POA) of the hypothalamus and in the central amygdala (CeA). We used genetic tools to selectively activate subpopulations of POA and CeA neurons that project to the PAG, revealing that PAG-projecting POA neurons promote USV production, while activation of PAG-projecting CeA neurons halts ongoing vocalization. We then performed in situ hybridization to establish the neurotransmitter phenotypes of PAG-projecting neurons in the POA and CeA. Finally, we monitored the activity of the PAG vocalization circuit, to understand how activity in upstream neurons shapes the activity of PAG-USV neurons during natural social interactions. Taken together, these experiments further our understanding of how the midbrain vocalization circuit is embedded in and recruited by forebrain networks that control social behavior.

Title: Descending control of vocalization in the mouse brain

Authors: *V. C. MICHAEL[1], K. A. TSCHIDA[1], J. TAKATOH[1], S. ZHAO[1], F. WANG[2], R. D. MOONEY[3];
[2]Dept. of Neurobio., [1]Duke Univ., Durham, NC; [3]Duke Univ. Dept. of Neurobio., Durham, NC

Abstract: Vocal communication is a key social behavior by which humans and other mammals form and maintain social bonds, convey information about social status and mating fitness, and engage in cooperative behavior. Successful vocal communication is essential for social affiliation and impairments in vocal communication typify neuropsychiatric disorders. Mice produce complex ultrasonic vocalizations (USVs) in a variety of social contexts, allowing researchers to

study the circuits underlying vocal control using advanced genetic tools. The midbrain periaqueductal gray (PAG) is a critical node in the vocal motor circuit whose activity is obligatory for vocalizations. In previous studies, we used a viral genetic method (CANE, Capturing Activated Neuronal Ensembles) to identify and tag a subpopulation of PAG neurons whose activity are necessary and sufficient to produce USVs (PAG-USV neurons). In the current study we sought to dissect the larger vocal-control circuit in which these neurons reside. We used CANE-based trans-synaptic rabies tracing from PAG-USV neurons as well as from local PAG inhibitory neurons (PAG-GABA) to identify afferents to the PAG vocal control circuit. We found that PAG-USV neurons receive input from a variety of cortical and subcortical regions implicated in social behavior, supporting the idea that PAG-USV neurons integrate information about social context to gate vocal output. We identified subpopulations of neurons in the preoptic area (POA) of the hypothalamus and the medial amygdala (MeA) that project to the PAG. We used genetic tools to show that the activation of GABAergic POA neurons that project to the PAG drives vocal production while the activation of GABAergic MeA neurons that project to PAG stops ongoing vocalizations. We further dissected the circuit mechanisms through which upstream inputs act on the PAG vocal control circuit by conducting *in vitro* whole cell recordings of PAG-USV and PAG-GABA neurons while optogenetically activating terminals from the POA and MeA. Together these experiments demonstrate that inhibitory inputs from forebrain structures with known roles in social behavior are integrated by the PAG vocalization circuit to drive or suppress vocal behavior.

Title: Differing release patterns of dopamine and acetylcholine in the mouse basolateral amygdala in response to emotion-laden vocal sequences

Authors: *Z. GHASEMAHMAD[1], D. PERUMAL[2], B. SHARMA[2], R. PANDITI[2], J. J. WENSTRUP[1];
[1]Dept. of Anat. and Neurobio., Northeast Ohio Med. Univ. (NEOMED), Rootstown, OH;
[2]Northeast Ohio Med. Univ., Rootstown, OH

Abstract: Social vocalizations, reflecting the internal state of a sender, can change the internal state and behavior of listeners. These listener responses are mediated, in part by the basolateral amygdala (BLA), an emotional brain center shaping reactions to salient and valent stimuli and are thought to depend on inputs from neuromodulatory centers. Here, we examine how emotion-laden vocalizations evoke patterns of neurochemical release within the mouse BLA. A liquid chromatography/mass spectrometry (LC/MS) technique allowed simultaneous detection of non-electroactive chemicals (GABA and acetylcholine (ACh)) and catecholamines in the same samples. For playback of highly emotion-laden vocalizations of CBA/CaJ mice, we identified vocal sequences that were characteristic of restraint (aversive) and an intense stage of mating (appetitive). We presented 5 contextual exemplars from each context. Mice were tested in 3 groups: males-mating, males-restraint, and females-mating (w/estrous monitoring). These groups were chosen based on previous results showing sexually dimorphic reactions to mating vocalizations but similar behavioral responses to restraint calls. After experiencing mating and restraint situations in a counterbalanced order on consecutive days, mice were implanted with a microdialysis probe and CSF samples were collected from BLA before, during, and after vocalization playback in 10-min intervals. Probe location in or adjacent to BLA was histologically confirmed. Samples were analyzed using LC/MS and concentrations of neurochemicals were monitored and correlated with behavior. Here we report on the release of ACh and dopamine (DA). During 20-min playback of mating vocalizations, DA increased in both male and female mice and remained elevated after playback for 1 hour. However, ACh concentration decreased during playback and returned to baseline after the mating vocalizations stopped. In contrast, playback of restraint vocalizations decreased DA during and after playback of the vocalizations, while ACh showed a transient increase in concentration during playback and returned to baseline after playback stopped. Our findings suggest interplay between ACh and DA release in the BLA may contribute to distinct behavioral responses to appetitive and aversive vocal sequences.

Title: Muscarinic and glutamatergic regulation of self-grooming behavior and ultrasonic vocalizations in the context of open-field habituation in rats

Authors: *J. C. BRENES[1], J. CHINCHILLA[2], R. LEANDRO[2], J. FORNAGUERA[2], M. ROJAS-CARVAJAL[3];
[1]Inst. for Psychological Res., [2]Neurosci. Res. Ctr., Univ. of Costa Rica, San Pedro, Costa Rica; [3]Neurosci. Res. Ctr., Univ. of Costa Rica, San José, Costa Rica

Abstract: Glutamatergic and cholinergic signaling has been widely associated with spontaneous exploratory activity, non-associative learning, attention, and ultrasonic vocalizations. We tested whether (i.p.) administration of scopolamine (SCP; muscarinic antagonist) or MK-801 (MK; NMDA antagonist) was able to impair or delay open-field test (OF) habituation. In this context we analyzed different behaviors paying special attention to particular grooming subtypes, which have been previously linked to novelty habituation and emotional de-arousal. Both drugs were daily administered during four consecutive days 20-min before a 15-min OF session. On the fifth day, rats were given vehicle (saline, i.p) and tested as previously mentioned. On each testing day, ultrasonic vocalizations of 50-kHz and 22-kHz were analyzed. We found that neither SCP nor MK altered the behavioral kinetics of locomotion. However, SCP and MK strongly inhibited the emission of rearing behavior. Surprisingly, such an inhibition recovered in all groups on the last testing day without drugs. Moreover, MK but specially SCP strongly disrupts grooming syntaxes. Overall, MK and SCP decreased the time spent on grooming behavior, without affecting its frequency. In addition, both drugs increased the emission of short, head-directed sequences of grooming -the so-called cephalic grooming-, but dramatically abolished the most complex forms of this behavior, which have been associated with habituation learning and de-arousal. Interestingly, after drug clearance (day 5), neither MK, not SCP altered grooming emission. Further evidence about OF activity and the emission of ultrasonic vocalizations will be presented and discussed in the context of the glutamatergic and cholinergic mechanism mediating habituation, risk-assessment, and social communication in rats.

Title: Mu opioid receptors in the medial preoptic area govern social play behavior in adolescent male rats

Authors: *C. ZHAO[1], L. CHANG[2], A. AUGER[2], L. RITERS[1];
[1]Integrative Biol., [2]Psychology, Univ. of Wisconsin-Madison, Madison, WI

Abstract: Neural systems underlying important behaviors are usually highly conserved across species. Our research in songbirds has demonstrated a crucial role for opioids in the medial preoptic area (MPOA) in affiliative, non-sexual, social communication and reward. Unlike directed social behaviors (e.g., food-directed, mate-directed, drug-directed), affiliative social behaviors do not result in immediate, obvious extrinsic reward, suggesting that they may be intrinsically rewarded. One such affiliative behavior in mammals is social play. In rodent models, the MPOA is well-known for its role in directed social behaviors such as sexual and maternal reward; however, the role of MPOA in affiliative, intrinsically-rewarded social behaviors has not been well studied. Given that social play in mammals is a highly rewarding, motivated, affiliative behavior, and the MPOA is highly conserved (i.e., it is neuroanatomically, neurochemically and functionally similar) in birds and mammals, we predict that our studies of MPOA in songbirds are uncovering a central nucleus that is part of a core, conserved circuit across species in which opioids act to stimulate and maintain affiliative social behaviors. In this study, we applied our insights from songbirds to rats to determine whether opioids in the MPOA of adolescent rats govern social play behavior. We knocked down gene expression of mu opioid receptor (Oprm1) in the MPOA of Sprague-Dawley rats via adeno-associated viral (AAV) vectors and short hairpin RNA (shRNA)-mediated gene silencing. On postnatal day 21, AAV vectors expressing either rat Oprm1-shRNA (n=12) or scrambled shRNA (n=12) were injected bilaterally into the MPOA. Social play behavior was scored in group-housed animals undisturbed in the home cage on postnatal days 35-39. Animals were video-recorded for two 20-minute trials per day over 5 days for a total observation time of 200 minutes per animal. The frequency of each component of play behavior including pouncing, pinning, wrestling/boxing, biting and chasing was calculated over the entire observation time. We found that knockdown of Oprm1 in the MPOA reduced the number of total play-bouts and the frequency of pouncing, a major index of social play behavior, with little effect on other components of play behavior in adolescent male rats. Taken together, these results demonstrate that knockdown of Oprm1 in the MPOA suppresses social play behaviors in adolescent male rats and support the hypothesis that the MPOA is a central nucleus that is part of a core, conserved circuit across vertebrates in which opioids act to govern affiliative, intrinsically-rewarded social behaviors.

Title: Strain dependent effects of maternal behavior on hypothalamic oxytocin neurons

Authors: J. A. GENTES, ***S. M. SIVIY**;
Gettysburg Col., Gettysburg, PA

Abstract: Oxytocin (OT) modulates a variety of mammalian social behaviors, yet relatively little is known about the role of this neuropeptide in the control of playfulness. The F344 rat is consistently less playful than other strains of rat and we have been investigating whether strain differences in play may be associated with systematic differences in OT functioning. When comparing play between F344 and LEW rats we found that strain differences in play are fairly resistant to cross-fostering (*Physiol Behav*, 2017, 169, 147), suggesting that early postnatal influences have little impact on the levels of play in F344 rats. As part of that study and to determine whether early postnatal experiences may impact OT differentially in F344 and LEW rats, slices were processed immunohistochemically for OT-positive neurons in the paraventricular nucleus of the hypothalamus. Those rats reared by LEW dams were found to have significantly more OT-positive neurons than those reared by F344 dams, which engaged in less licking and grooming (LG) of their pups than LEW dams. This suggests that LG directed to pups is associated with increased hypothalamic OT. To further assess the relationship between licking and grooming received by pups and the number of OT-positive neurons, we did a correlation analysis between % time spent in LG by the dam and the number of OT-positive neurons for those pups that were sampled from each litter. The results are shown in the accompanying figure. A separate analysis was conducted for each strain and there was found to be a strong positive relationship between LG received and OT-positive neurons among LEW rats, with more LG received associated with more OT-positive neurons. On the other hand, there was no relationship between these two variables among F344 rats. This suggests that LEW rats use information provided by the mother (i.e., licking and grooming) and translate this into increased levels of hypothalamic oxytocin. This was not the case with F344 rats and suggests that rats of this strain may be impervious to the effects of early neonatal stimulation on OT structure and/or function.

Title: Nmda-lesions in the prefrontal cortex delay the onset of maternal behavior in adult female, but not infanticidal behavior in male mice (c57bl/6)

Authors: *M. ALSINA-LLANES, D. E. OLAZABAL;
Fisiología, Facultad de Medicina, Univ. de la República, Montevideo, Uruguay

Abstract: There is significant variability in the immediate behavioral response exhibited by inexperienced adult mice when they are exposed to pups for the first time. While most females can display parental behavior (PB) or sensitize rapidly, adult males are infanticidal or non-parental. The prefrontal cortex (PFC) participates in attentional selection, decision making, behavioral flexibility and planning that may be critical in the rapid decision to display PB or infanticidal behavioral (IB). We investigated if excitotoxic lesions in the PFC inhibited PB or IB in naïve adult female and male mice. Adult females and males received bilateral injections into the PFC of 0.2 µl of 25 mM phosphate-buffered saline solution (females: n=6; males: n=6) or 5

μg of N-methyl-D-aspartate (NMDA, females: n=6; males: n=7) dissolved in 0.2 μl of PBS. Two days later, animals were exposed to pups and then tested in an open field. All females with sham-lesions displayed full PB at the first encounter with pups. However, those with NMDA-lesions exhibited partial PB (50%) or were non-parental (50%). Four repeated exposures of 60-min to pups were needed to induce full PB in the NMDA-lesion female group. Sham-lesion males displayed non-PB (17%) or IB (83%), while all NMDA-lesion males were infanticidal. There was no difference in general locomotor and exploratory activity (i.e. peripheral crosses, rearings, immobility time). Nevertheless, both females and males with NMDA-lesions showed a reduction ($p<0.05$) in the number of central crosses and time that remained in the central area respectively, suggesting an increase in anxiety in lesioned groups. Our results suggest that the PFC is engaged in the rapid onset of PB in females, coordinating and planning its rapid execution, or reducing the anxiety to the first encounter with pups. However, IB may be a more stereotyped behavior with minor planning/coordination or increased by anxiety.

Title: Temporal and spatial circuit activity dynamics in the interpeduncular nucleus differentially signal novelty and familiarity

Authors: *S. MOLAS, R. ZHAO-SHEA, P. KLENOWSKI, A. R. TAPPER;
Dept. of Neurobiology, Brudnick Neuropsychiatric Res. Inst., Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: Novel stimuli induce an increase in exploratory response that rapidly decreases as the stimulus becomes familiar upon repeated exposures. Novelty exploration and habituation with familiarity are fundamental for the adaptation to changes in the environment and prime goal-directed behaviors. The brain circuits that control behavioral responses to novelty and familiarity are still poorly understood. Our previous work demonstrated that the interpeduncular nucleus (IPN) of the midbrain represents a neuroanatomical substrate for familiarity signaling. In particular, using c-Fos expression as a read out of neuronal activation, we showed that as novel stimuli become familiar upon repeated exposures activity of IPN GABAergic neurons progressively increases. Here, we have deeply investigated IPN neuronal responses during interactions with novel and familiar stimuli by combining fiber photometry and genetically

encoded calcium indicators. We expressed CAG.Flex.GCaMP6m in IPN GABAergic neurons in the GAD2-Cre mouse line and recorded changes in Ca2+ signals as a proxy for neuronal activity in awake behaving mice during social and object novel preference tests. We have defined clusters of GABAergic neurons distributed throughout IPN sub-regions that exhibit differential responses to either novel or familiar stimuli, as well as clusters with no response. Importantly, changes in activity mainly occur within the second minute of the 5-minute behavioral testing. These results suggest IPN neurons signal novelty and familiarity through a highly dynamic temporal- and spatial-dependent manner.

Title: Transcriptomic regulations underlying pair bond maintenance in the socially monogamous prairie voles

Authors: *F. DUCLOT[1,2], L. SAILER[1,2], P. KOUTAKIS[3], Y. LIU[2,4], Z. WANG[2,4], M. KABBAJ[1,2];
[1]Biomed. Sci., [2]Program in Neurosci., [3]Nutrition, Food and Exercise Sci., [4]Psychology, Florida State Univ., Tallahassee, FL

Abstract: Social affiliation is a core characteristic of human social behaviors and related impairments are a common feature in a multitude of neuropsychiatric disorders including schizophrenia and autism spectrum disorders. As a result, understanding the neurobiology of social attachment is of critical importance. In this context, the socially monogamous prairie vole (Microtus ochrogaster) provides an excellent opportunity to study the molecular mechanisms underlying the formation and maintenance of a pair bond. In prairie voles, prolonged cohabitation with an opposite-sex partner leads to an enduring social bond. Despite the variety of neurotransmitter systems involved in the initial formation of the bond, however, relatively little is known regarding the mechanisms associated with its maintenance. In this study, we thus aimed at identifying the pattern of gene expression related to pair-bond maintenance by analyzing the global transcriptional profiles in the nucleus accumbens (NAc) by RNA-sequencing. To this end, male and female adult prairie voles were cohabitated for 3 weeks with an opposite-sex partner—or a same-sex conspecific as a control—and tested for selective aggression to verify the

establishment of the pair bond. Notably, a third group was cohabitated for 24 hours in order to discriminate regulations specific to the maintenance phase of the bond. At baseline, sex differences in gene expression were widespread and involved many critical biological processes related to neuronal activity and plasticity. In both sexes, however, the early phase of the cohabitation (24 hours) triggered large transcriptional changes whereas few genes were differentially expressed in the late phase (3 weeks) when compared to sexually-naïve controls. Interestingly, the analysis of related biological pathways reveals a sex-specific profile of regulations. Indeed, while the biological pathways associated to the early and late phases were similar in females, but distinct in males. Although the related pathways underline a widespread alteration of several aspects of neurotransmission in both sexes, we observed notable sex-specific regulations. For instance, large regulations of genes related to mitochondrial activity were observed in females but not males, highlighting the mitochondria as a novel candidate for sex-specific regulations underlying pair-bonding in prairie voles. Overall, these data will provide a novel insight into the global transcriptomic profiles underlying the maintenance of a bond in the prairie vole NAc, and thus open the way for the identification of novel candidates mediating enduring social attachment.

Title: Automated analysis of prosocial and aggressive behaviours using computer vision and machine learning

Authors: *S. R. O. NILSSON, J. J. CHOONG, S. A. GOLDEN;
Biol. Structure, Univ. of Washington, Seattle, WA

Abstract: Background. Disrupted social behaviour is a fundamental shared symptom of many neuropsychiatric disorders, including drug addiction, depression and PTSD. However, freely behaving mice are seldom considered in the experimental design of preclinical models. This is predominately due to technical limitations preventing high-throughput, consistent, and unbiased

scoring of freely-moving complex social interactions.
Method. We developed predictive classifiers of social and aggressive behaviors during mouse dyadic encounters. Single C57BL/6J mice were placed into the home-cage of a CD-1 mouse and interactions were recorded in variable lighting conditions and different resolutions/frame-rates. We used DeepLabCut (Mathis et al., 2018, Nat Neurosci) to generate a model that tracks eight body-parts on each of the two mice. We detected and reduced tracking inaccuracies and calculated a battery of diverse features (>100) based on body-part movements, distances, angles, sizes, and their deviations across rolling windows. We used the features in sklearn-based machine learning algorithms against multiple socially-relevant targets (e.g., aggressive events, anogenital sniffing, tail rattling, pursuit, lateral threat display) and we visualized the tracking and the predictions with OpenCV.
Results. Model predictions were in excellent or good agreement with manual human frame-by-frame scoring. For example, random forest implementations based on re-sampled data predicted aggressive and tail rattling events with more than 95% accuracy. The model generalized well to new recording conditions.
Conclusion. The data support that complex social behaviors can be readily quantified in an un-biased, fast, and automated way in unmarked individual mice using DeepLabCut for feature detection and our python modules for machine learning.

Title: Oxytocin-dependent reopening of a social reward learning critical period with MDMA

Authors: *R. NARDOU[1], E. M. LEWIS[1], R. ROTHHAAS[1], R. XU[2], A. YANG[2], E. S. BOYDEN[2], G. DÖLEN[1];
[1]The Solomon H. Snyder Dept. of Neuroscience, Brain Sci. Inst., Johns Hopkins Univ., Baltimore, MD; [2]MIT, Cambridge, MA

Abstract: A critical period is a developmental epoch during which the nervous system is expressly sensitive to specific environmental stimuli that are required for proper circuit organization and learning. Mechanistic characterization of critical periods has revealed an important role for exuberant brain plasticity during early development, and for constraints that are imposed on these mechanisms as the brain matures. In disease states, closure of critical periods limits the ability of the brain to adapt even when optimal conditions are restored. Thus, identification of manipulations that reopen critical periods has been a priority for translational neuroscience. Here we provide evidence that developmental regulation of oxytocin-mediated synaptic plasticity (long-term depression) in the nucleus accumbens establishes a critical period for social reward learning. Furthermore, we show that a single dose of (+/−)-3,4-methylendioxymethamphetamine (MDMA) reopens the critical period for social reward learning and leads to a metaplastic upregulation of oxytocin-dependent long-term depression. MDMA-induced reopening of this critical period requires activation of oxytocin receptors in the nucleus accumbens, and is recapitulated by stimulation of oxytocin terminals in the nucleus accumbens. These findings have important implications for understanding the pathogenesis of neurodevelopmental diseases that are characterized by social impairments and of disorders that respond to social influence or are the result of social injury.

Title: Correlated neural activity and encoding of behavior across brains of socially interacting individuals

Authors: *L. KINGSBURY, S. HUANG, J. WANG, K. GU, P. GOLSHANI, Y. E. WU, W. HONG;
UCLA, Los Angeles, CA

Abstract: Social interactions involve some of the most complex decision-making tasks that animals must navigate to secure their survival and reproductive success, as individuals must integrate internal state variables with real-time decisions of others in a context-dependent manner. In interacting dyads, individuals thus become entrained as they attend to, predict, and react to each other's decisions. To date, social neuroscience has mostly focused on behavior in individual animals to interrogate the neural computations underlying social decision-making. But a full understanding of the social brain, and how circuits are engaged during complex, dyadic interactions, requires a broader picture that reflects the dynamic nature of natural social engagement. An open question is whether and how emergent properties of neural systems, such as interbrain activity coupling, may arise across brains of interacting individuals to shape behavior.
Here, by simultaneously performing microendoscopic calcium imaging in pairs of socially interacting mice, we find that animals exhibit interbrain correlations of neural activity in the prefrontal cortex that are dependent on ongoing social interaction. Interbrain coupling arises from two neuronal populations that separately encode one's own behaviors and those of the interacting partner. Strikingly, interbrain correlations predict future social interactions as well as dominance relationships between animals in a competitive context, suggesting a functional link between neural activity coupling and the evolution of real-time social engagements. They also reflect an asymmetry in encoding of partner behavior across dominants and subordinates, suggesting that brain coupling depends partially on attention of subordinates directed toward dominants. Together, these results demonstrate that interbrain synchrony exists in rodents, indicating generality and conservation of the phenomenon across diverse species beyond what has previously been observed in humans and non-human primates. By uncovering how interbrain synchronization arises from activity patterns at the single-cell level, this work also sets the groundwork for more incisive, circuit-level investigation into the emergent neural properties of multi-individual systems and their role in coordinating social interactions.

Title: Modulation of social behavior by mu opioid receptors in the brain reward network

Authors: *C. T. TODDES[1], L. ZUGSCHWERT[2], P. E. ROTHWELL[3];
[1]Univ. of Minneosta, Minneapolis, MN; [2]Neurosci., Univ. of St.Thomas, Minneapolis, MN;
[3]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: The rewarding aspects of social interaction require activation of mu opioid receptors within the brain reward network. However, it is unclear where in this network mu opioid receptor expression is essential for the regulation same-sex affiliative social interaction. The goal of this study was to determine how global and regional genetic knockout of the mu opioid receptor alters social behavior in male and female mice, using a variety of behavioral assays. Our behavioral battery includes the social conditioned place preference test, the dyadic social interaction test, and the reverse three-chamber social test. The reverse three-chamber test is a novel social assay that examines the social preference of a wildtype "judge" between a "typical" wildtype mouse and an "atypical" mu opioid receptor knockout mouse. These assays focus on different aspects of social behavior including social reward, motivation, and preference. Our data demonstrates that constitutive homozygous and heterozygous deletion of the mu opioid receptor impairs social behavior across tests. Additionally, preliminary data has shown a social impairment in mice following conditional knockout of the mu opioid receptor from cortico-limbic regions that converge upon the nucleus accumbens. These results highlight critical locations within the brain reward network where mu opioid receptor expression is necessary for normal social behavior.

Title: Effect of lOFC lesion on social value unblocking of Pavlovian reinforcement learning in male rats

Authors: *S. VAN GURP[1], J. HOOG[2], T. KALENSCHER[3], M. VAN WINGERDEN[4];
[1]Comparative Psychology, [2]Heinrich Heine Univ., Duesseldorf, Germany; [3]Univ. of Duesseldorf, Duesseldorf, Germany; [4]Heinrich-Heine Univ. Düsseldorf, Düsseldorf, Germany

Abstract: Objectives: Reinforcement learning theory states that when stimuli are added to stimulus that fully predicts reward, learning about those additional stimuli will be blocked (Kamin, 1969). Learning about added stimuli can become unblocked by an increase in reward

value that is then associated to these additional stimuli (Holland, 1984). Here, we hypothesised that unblocking of learning about an added stimulus would occur when additional rewards are delivered to a social partner and that learning about added stimuli is blocked when a social partner is not rewarded. Furthermore, as Lateral Orbitofrontal Cortex (lOFC) neurons have been found to be coding upshifts in reward value during unblocking (Lopatina et al, 2015) we hypothesised that temporary inactivation of the lOFC would impair upshifts in social value. **Methods:** Actor rats (N= 36) and partner (N=36) learned to discriminate between a CS+ and CS-. Consequently, the rats went through compound conditioning consisting of 3 conditions: Both Reward/unblocked, both actor and partner rat were rewarded (Actor CS+, Partner CS-); Own Reward/blocked, only the actor was rewarded (Actor CS+, Partner CS-) and No Reward, both rats were not rewarded (Actor CS-, Partner CS-). Then the rats went through a probe session were the CS+, CS- and the unblocked (Partner CS+) and blocked cue (Partner CS-) were presented to the actor rat in extinction. In a control experiment, the exchange of visual and auditory information between actor and partner during the compound phase was impeded by an opaque wall. Finally, in a third experiment we temporarily inactivated the lateral OFC during the compound phase. **Results:** We found that when actor rats have fully learned a stimulus-reward association producing reward for themselves, delivering an additional reward delivery to a partner rat, in association with an additional a cue delivered in compound to the learned cue unblocked associative learning about this cue in the actor rats. In contrast, additional cues that did not predict additional reward remained blocked from acquiring associative value. In a control experiment where putative social cue exchange between the partnered rats was prevented, the normally unblocked cues now remained blocked as expected. Finally, preliminary data shows that inactivation of lateral OFC did not impair social unblocking. **Conclusions:** These results suggest that social value can drive reinforcement learning in rats, and that the transmission of social cues is necessary for this learning to occur. In addition, these results provide evidence that learning about changes in value derived from reward delivered to a social partner do not require the lOFC.

Title: Hypothalamic vasopressin regulates social behavior in female mice

Authors: *N. RIGNEY[1], J. WHYLINGS[1], G. J. DE VRIES[2], A. PETRULIS[2];
[2]Neurosci. Inst., [1]Georgia State Univ., Atlanta, GA

Abstract: The neuropeptide arginine-vasopressin (AVP) has long been implicated in the regulation of social behavior and communication in diverse taxa, but the source of AVP release relevant for behavior has not been precisely determined. Potential sources include hypothalamic cell populations such as the paraventricular (PVN), supraoptic, and suprachiasmatic nuclei, as well as extrahypothalamic cell groups in the extended amygdala. To address if AVP cells in the PVN are important for mouse social communication in males and females, we deleted PVN-AVP cells using viral-mediated delivery of Cre-dependent caspase-9 suicide construct into the PVN of AVP-Cre positive mice (expressing Cre-recombinase under the control of the AVP promoter) or AVP-Cre negative littermate controls, and assessed their levels of social investigation. Preliminary results indicate that lesions of the PVN-AVP cell population in female mice increase social investigation of both opposite and same-sex individuals. These manipulations had little effect on non-social anxiety-like behaviors in the elevated-plus maze. Conversely, PVN-AVP cell deletion in male mice did not affect social investigation. These results suggest that AVP released from PVN normally inhibits social approach in female, but not male, mice. Parallel experiments will reveal if PVN-AVP influences other aspects of male and female social communication.

Title: Manganese as contrast medium and its effects in the behavior of male rats for longitudinal studies

Authors: *J. A. AGUILAR MORENO, Jr.[1], M. A. VEGA SOLACHE[2], E. CABRERA[2], R. G. PAREDES[3];
[1]Plasticidad y Conducta sexual, Inst. De Neurobiología, Instituto de Neurobiologia, Mexico; [2]Insituto de Neurobiología, Querétaro, Mexico; [3]Inst. De Neurobiologia UNAM, Querétaro, QRO, Mexico

Abstract: In recent years, the use of manganese (Mn) as a contrast medium had increased considerably, due that Mn can be used as a tracer of neural activity in magnetic resonance (MR) studies, for its paramagnetic properties and accumulation in active neurons. Another important characteristic of Mn is that can have toxic effects, inducing motor impairment after the administration, leading alterations in the behavior of the animal. It has been reported the effects of Mn on the motor skill of rats, but it is unknown how it can impact motivated behaviors, such as sexual behavior and wheel activity of male rats. Then, we evaluated signal intensity changes in MR images of male rats with different levels of sexual experience. We used male Wistar rats, 300grs, without sexual experience. We use ovariectomized females as sexual stimulus. The males were randomly assigned to one of the following groups: Control (saline), and MnCl2 16mg/kg. Males were tested for sexual behavior (SB), where they freely control the sexual interaction for 30 minutes. Thereafter, they were exposed to a running wheel for 30min of free activity. Finally, they were evaluated in a Rotarod, in two different modes, regular speed and ramp (10rmp and 10-15rpm, respectively). Subjects were tested in the same behavioral sequence once a week for 10 weeks. MnCl2 was administered s.c. on sessions 1, 5 and 10. An additional group was injected with the same MnCl2 indicated dose and tested for sexual behavior in the same time as the other groups and scanned in weeks 1, 5 and 10. The results show that the performance in the experimental group was decreased in the activity wheel in sessions 1 and 5 ($p<0.05$) respect to control group, but it do not last in the following session, indicating a temporal but not permanent affectation in the behavior. The performance in Rotarod was not affected. SB parameters remain similar in both groups, having statistical differences only in the number of ejaculations in session 1, being lower in the group of SB+MRI ($p<0.05$). The statistical maps of MEMRI showed a significant brain activation in the amygdala, medial preoptic area in the experimental groups in session 5 and 10 ($p<0.05$). The results demonstrate that 16mg/kg of MnCl2 is an adequate dose to study SB with MEMRI without long lasting behavioral alterations.

Title: Brief social isolation increases social interaction and cortical drive of basolateral amygdala activity

Authors: *N. C. FERRARA, M. PADIVAL, J. A. ROSENKRANZ;
Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL

Abstract: Adolescence is characterized by high social drive and ongoing brain maturation. The decline in social drive from adolescence to adulthood coincides with cortical development, which likely influences the age-dependent changes in the regulation of emotions. Increased activity in cortical regions, such as the anterior cingulate cortex (ACC), and the amygdala have been linked to social behaviors, and the projections from the ACC to the basolateral amygdala (BLA) are necessary for socially learned fear. Combined, this work suggests there may be existing developmental changes in the ACC-BLA pathway regulating social drive. Manipulations of social drive can be used to investigate the developmental shifts in social behaviors and uncover role of the ACC and amygdala. Brief social isolation facilitates social drive and promotes the value of social interactions. This can be used as an approach to investigate the influence of the developing ACC-BLA circuits to social behaviors. We found that brief social isolation (2hrs) increases the duration of social interaction, in adolescents and adults, and the overall duration of social interaction was substantially higher in adolescents. We next used anesthetized *in vivo* single unit recordings to determine the impact of brief isolation on BLA activity in adults. We found that brief isolation increased BLA neuronal activity. Further, ACC-evoked BLA activity was preferentially increased in groups exposed to brief isolation. These results suggest that increased social drive, through brief isolation, facilitates ACC drive of BLA activity in adults. These results begin to provide insight to the changes in cortico-amygdala circuitry from adolescence to adulthood that contribute to the refinement of social behaviors.

Title: The motivation to seek social contact versus food differs with age and between rats and mice

Authors: *C. J. REPPUCCI, A. Q. CHAMBERS, L. A. BROWN, A. H. VEENEMA;
Neurosci. Program; Dept. of Psychology, Michigan State Univ., East Lansing, MI

Abstract: For all species, survival depends on the expression of the appropriate behavior depending on an individual's current motivational state and the presence of stimuli in the

surrounding environment. Thus far, most studies have focused on better understanding how the brain regulates the expression of a single behavior or suite of behaviors associated with a single motivational state. However, in everyday life, we often find ourselves in situations of competing motivational states with multiple choices of how we can act. We aimed to develop a novel behavioral paradigm to test the competition between the motivation to seek social contact and the motivation to seek food, which can then be used to delineate the neural substrates that coordinate and support the expression of multiple motivated behaviors. Subjects were placed in a 3-chamber Plexiglas apparatus where a social stimulus (novel age- and sex-matched conspecific) and a food stimulus (standard lab chow) were corralled on opposite sides. To determine how the motivation to seek social contact and the motivation to seek food compete, we altered the motivational states of subjects by exposing them to acute social isolation and/or acute food deprivation. Preference was determined by the relative amount of time subjects spent investigating each stimulus. We first examined whether the competition between social contact-seeking and food-seeking is stable across the lifespan by comparing adolescent and adult male and female rats. Compared to adult rats, adolescent rats exhibited a greater hunger-mediated shift in stimulus preference; neither isolation nor sex affected behavior. Next, we examined whether this effect was conserved across rodent species, by repeating the experiment using adolescent male and female mice. Adolescent mice exhibited a similar hunger-mediated shift in stimulus preference compared to that observed in adolescent rats. However, while adolescent rats exhibited a strong preference for the social stimulus when sated which was attenuated by hunger, adolescent mice did not have a stimulus preference when sated and had a strong food preference when food deprived. Additionally, we found that total stimulus investigation (social + food) was greater in adolescent rats and mice than adult rats, consistent with prior reports that adolescence is characterized by increased motivation for rewarding stimuli. Given their higher investigatory drive and greater sensitivity to homeostatic manipulations of motivation, this behavioral paradigm appears to be ideally suited for future interrogations of the underlying neural systems (e.g., oxytocin, orexin, dopamine) in adolescent subjects.

Title: Sex differences in juvenile social recognition: Role of oxytocin in the bed nucleus of the stria terminalis

Authors: *K. E. YOEST, M. G. HENRY, R. BREDEWOLD, A. H. VEENEMA;
Neurobio. of Social Behavior Laboratory, Dept. of Psychology & Neurosci. Program, Michigan State Univ., East Lansing, MI

Abstract: The ability to recognize and respond to previously encountered conspecifics is crucial for normal social interaction. The neuropeptide oxytocin (OT) and its corresponding receptor (OTR) have been identified as a brain system required for social behavior, and sex differences in the organization of the OT system have been linked to the sex-specific regulation of social recognition in adult rats. Sex differences in the OT system are already present early in development, but the functional implications remain unknown. Here, we sought to determine the role of OTR within the posterior region of the bed nucleus of the stria terminalis (BNSTp) in the regulation of social recognition in juvenile rats. We first determined whether juveniles show similar temporal patterns of social recognition to adults, by testing whether 5-week-old male and female rats were able to recognize a previously encountered same-sex conspecific 30, 60, or 120 minutes following initial investigation. Juvenile males showed social recognition 30 and 60 minutes following the initial encounter, but not after 120 minutes, similar to what has been previously seen in adults of both sexes. Juvenile females, however, did not show social recognition at any time point tested, indicating a developmental difference in social recognition ability in females but not in males. We are currently testing whether OT administered to the BNSTp is sufficient to induce social recognition in females and to prolong social recognition in males. In addition, we are characterizing whether OTR is expressed by neurons or glial cells within the BNSTp of juvenile male and female rats. Finally, we will determine potential sex differences in the extent to which OTR expressing cells within the BNSTp are activated in response to social investigation in juveniles. Together, these results will provide insight into how sex differences in the BNSTp-OT system are involved in the sex difference in social recognition in juvenile rats.

Title: Role of vasopressin in the ventral pallidum in regulating social play behavior in juvenile male and female rats

Authors: *J. D. A. LEE, R. BREDEWOLD, A. H. VEENEMA;
Dept. of Psychology, Michigan State Univ., East Lansing, MI

Abstract: Social play is predominantly displayed by juveniles of many mammalian species, including rats and humans. Engagement in social play helps develop social competence throughout life. Children diagnosed with autism spectrum disorder (ASD) show decrease involvement in social play. Moreover, ASD is more prevalent in males than females. Thus, there is a need to better understand the neural mechanisms underlying social play in both sexes. We recently showed that vasopressin acting in the lateral septum (LS) of juvenile rats regulates social play behavior in a sex-specific manner. Vasopressin projections to the LS originate in the bed nucleus of the stria terminalis (BNST) and medial amygdala (MeA). We further showed that the ventral pallidum (VP) also receives vasopressin projections from the BNST and MeA. Here, we hypothesized that, similar to the LS, vasopressin in the VP regulates social play in a sex-specific manner. We found that the VP and LS show a similar sex difference in vasopressin fiber density, with denser vasopressin fibers in juvenile males. In contrast, VP and LS show a brain region-specific sex difference in vasopressin 1a receptor (V1aR) binding density, with denser V1aR binding in the female LS and male VP. Using a specific V1aR antagonist, we are currently determining the effects of V1aR blockade in the VP on social play behavior in 5-week-old juvenile male and female rats. In addition, by combining retrograde tracing in the VP and LS with RNAscope for vasopressin and Fos mRNA expression, we will determine the extent to which vasopressin neurons in the BNST and MeA project to both the LS and the VP and are activated in response to social play. This study will provide insights into the brain regions recruited by vasopressin for the sex-specific regulation of social play behavior as well as the larger neural network modulated by the BNST/MeA-vasopressin system.

Title: Regulation of social play behavior by oxytocin in the nucleus accumbens of juvenile male and female rats

Authors: *R. BREDEWOLD[1], S. PROANO[2], A. SCAZZERO[1], J. MEITZEN[2], A. H. VEENEMA[1];
[1]Dept of Psychology & Neurosci. Program, Michigan State Univ., East Lansing, MI; [2]Dept of Biol. Sci. and Grad. Program in Biol., North Carolina State Univ., Raleigh, NC

Abstract: Social play is a highly motivated and rewarding behavior that is predominantly expressed by juveniles. Exposure to social play in the juvenile period is important for the development of social competence in humans and rats. Social play deficits are seen in children with autism spectrum disorder (ASD) and these deficits may contribute to life-long impairments in social functioning. The neuropeptide oxytocin (OT) is currently being tested in clinical trials to help normalize social behavior in ASD patients. We aimed to better understand how OT modulates social play in male and female juvenile rats by focusing on its role in the nucleus accumbens (NAc), because this brain region is important for motivated and rewarding social behaviors. We found that injecting the specific OT receptor (OTR) antagonist des-Gly-NH_2,d$(CH_2)_5$[Tyr(Me^2),Thr^4]OVT into the NAc significantly decreased the duration of social play in both sexes, but required a higher dose of the OTR antagonist in males (100 ng/0.5 µl) than in females (10 ng/0.5 µl). This suggests that OT in the NAc facilitates social play in both sexes, but that females are more sensitive than males to disturbances in OTR activation. We further showed that OTR binding density in the NAc is similar in males and females, suggesting that factors other than the OTR contribute to the sex difference in behavioral sensitivity to the OTR antagonist. We are currently using microdialysis to determine the effects of the specific OTR antagonist des-Gly-NH_2,d$(CH_2)_5$[Tyr(Me^2),Thr^4]OVT (OVT) on changes in dopamine, serotonin, glutamate, and GABA release in the NAc while rats are exposed to social play. We also are employing whole-cell patch clamp to test how OVT modulates NAc neuron electrophysiology, and are specifically assessing intrinsic excitability and excitatory synapse properties. We also will be exploring potential sex differences in the type of NAc neurons expressing the OTR of juvenile rats. These experiments may provide insights into the mechanisms by which OT in the NAc facilitates social play in sex-specific ways, with applications for social play deficits and sex-biases seen in ASD.

Title: Probing the neuronal circuitry of social hierarchy

Authors: *E. M. AMELCHENKO[1], D. SMAGIN[2], S. SHUVAEV[3], K. UMADEVI VENKATARAJU[3], P. OSTEN[3], N. KUDRYAVTSEVA[2], A. KOULAKOV[3], G. N. ENIKOLOPOV[1];

Abstract: Establishment of social hierarchy through intermale aggressive behavior helps to deflect excessive violence and injury, protects group's valuable resources, and molds the societal structure. Successful acts of aggression may be rewarding, with a series of wins increasing aggressive motivation and propensity to engage in aggressive behavior, and a series of defeats having an opposite, aversive, effect. Social hierarchy is dynamic and may be altered after encounters between animals of a comparable rank. Several brain regions and circuits involved in aggressive behavior and social dominancy have been identified; however, the global maps of brain networks involved in establishing, maintaining, and reversing social status are not known. We used an animal model of intermale social conflict and applied global mapping of c-Fos expression to determine network activity across the brain regions and infer the circuits involved in aggression, defeat, and reversal of social status. Male mice were trained in a model of chronic social conflicts, and analyzed in several behavioral paradigms: (a) aggression (3, 10 or 20 days of consecutive agonistic interactions in pairs, producing winner and loser animals); (b) deprivation (20 days of agonistic interactions followed by 14 days of fight deprivation); (c) inversion (20 days of agonistic interactions followed by placing the animals in new pairs: winner vs. winner and loser vs. loser). Brains were processed using iDISCO protocol, imaged under the light-sheet microscope, postprocessed using ClearMap pipeline, and analyzed to reveal the interrelations between each of the behavioral states and to infer the connectivity patterns and related neuronal networks. We first analyzed the overall effect of the social status on the position of the activation patterns in a low-dimensional space using principal component analysis of the datasets and found that relative positions of particular patterns allow making conjectures and predictions on how the history of winning/losing defines the neural engram. We next used the data to identify groups of brain regions that show covarying activation upon experimental manipulations and therefore may be functionally related, with strong covariance explained by connectivity, and then asked whether such clustering can be related to the actual neuroanatomical mesoscopic connectivity. Finally, we identify functional subnetworks of coactivated brain regions by computing pairwise correlations between brain regions for animals with a defined social status and comparing these subnetworks to the known connectivity patterns to build mechanistic models of activation in specific subnetworks.

Title: Habenula and periaqueductal gray represent eye contact established by emotional history

Authors: *H. LEE, K. MAEDA, O. HIKOSAKA;
Lab. of Sensorimotor Res., Natl. Eye Inst., Bethesda, MD

Abstract: In the world, numerous animals have been living together, sharing many kinds of emotional history. For an appropriate social recognition beyond species, eye contact is rapid and useful social information seeking behavior. Herein we hypothesized that brain modulates different eye contact patterns, as a precursor of social interaction, based on emotional histories of relationships. For this hypothesis, we tested contextual Pavlovian-foraging task in monkeys by recording neuronal activity in lateral habenula (LHb), amygdala, and periaqueductal gray (PAG). In the task procedure, the monkey experienced three types (Rich, Poor, Dangerous) of visual scenes (i.e., variable faces and landscapes) which were probabilistically associated with distinct types of fractal objects: Big reward objects in Rich scene; Small reward objects in Poor scene; Big reward and Punishment objects in Dangerous scene. We found that eye is a highly salient feature on faces. Although eye contact is not necessary for acquiring reward and is not related to any reward value, eye contact was rapidly getting lower in the poor context than the rich or dangerous context. In neuronal recording, we found that many neurons in PAG and LHb changed their activity strongly in response to the visual scenes. There were different types of neurons in PAG. Some PAG neurons were strongly excited by the poor scenes than the rich or dangerous scenes. Other PAG neurons were excited tonically by the dangerous scenes than the rich or poor scenes. These data suggest that PAG contains different groups of neurons that encode different types of negative mood. On the other hand, many LHb neurons were excited phasically and tonically by the poor scenes than the rich or dangerous scenes. They were also sensitive to the fractal objects that appeared in each scene, depending on their values and dangers. Previously, we reported LHb and dopamine neurons can motivate reward anticipation (Bromberg-Martin ES, Matsumoto M, Hikosaka O., 2010) and amygdala can motivate excitement in dangerous context (Maeda K, Kunimatsu J, Hikosaka O., 2018). Present study suggests that PAG can relay these types of emotional information to control behaviors, including eye contact for social interaction.

Title: Investigation on whether rule-violating behavior can be improved into rule-observing strategy

Authors: *J. BYUN[1,2], A. ALKAHWAJI[1,2], H.-S. SHIN[1,2];
[1]Ctr. for Cognition & Sociality, IBS, Daejeon, Korea, Republic of; [2]Dept. of Basic Sci., Univ. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Following social rule is indeed orderly resolution of social conflict over limited resource. Thereby, most individuals take this as a strong strategy for the best choice. Meanwhile, how one could have decided to cling to a certain strategy is highly complicated. Here, we suggest a behavioral mechanism of strategy establishment in mice in social conflict. First, we trained pairs of mice to compete over wireless brain stimulation reward. Then, as the pairs developed mutual social rule by 'reward zone allocation,' we sorted out the pairs consist of rule-observing- and rule-violating mice. Those pairs went through further identical competition games. By the end, majority of rule-violating mice became rule-observing mice. We found the payoff equity and individual payoff were affected while the violating mice made attempts for following the mutual rule. We observed that mice could risk their own benefit by keeping the rule, enhancing payoff equity between their partners. These results support that altruistic decision can change socio-economic strategy in mice. To figure out what happens in their brain, a wireless EEG recording system is under development to record simultaneously in both of freely-moving mice.

Title: Prefrontal mechanisms for tracking group behavior, reputation, and identity during three-agent itneraction in macaques

Authors: *R. BÁEZ-MENDOZA, E. P. MASTROBATTISTA, A. J. WANG, Z. WILLIAMS; Massachusetts Gen. Hospital-Harvard Med. Sch., Boston, MA

Abstract: Primate group behavior poses the unique challenge of tracking others behavior, their reputation, and social identity. The ability to interact effectively within groups allows individuals to build affiliations and benefit from reciprocation with others. Furthermore, it can lead to dynamical interactions that can be affected by changes in reputation or distribution of wealth. The precise neuronal computations that underlie interactive group behavior, however, remain poorly understood. Here, we obtained multiple-neuronal recordings in the dorsal anterior cingulate cortex (dACC) and frontopolar cortex (FP) of individual rhesus macaques as they performed a structured reciprocity-based social task within a group. We devised a three-agent apparatus and social task in which three macaques interacted with each other over multiple rounds, and in which one individual could offer a food reward to one of the other two. Individuals could reciprocate past rewards that had been delivered to them by other group members in previous trials. Based on this design, we could dissociate computations associated with interactive behavior, social preference, and group dynamics. Within experimental sessions, we controlled for the animals' position and gaze contact between actor and potential recipients. Across experimental sessions, we also controlled for group composition, social hierarchy, and the presence of conspecifics. Behaviorally, we find that the monkeys demonstrated a strategic preference for other individuals and that they favored rewarding those who reciprocated. The rate in which individuals reciprocated within a session and across sessions was reflected in different levels of reputation. Although the more dominant monkey obtained more rewards within a session, the group worked together to reduce inequality. At the neuronal-level, distinct subpopulations of dACC neurons tracked the identity of the current actor and reward recipient. In contrast, the activity of a subpopulation of FP neurons correlated with the current actor's reputation for reciprocity. These findings reveal neurons in the primate prefrontal cortex that encode information about particular individuals, their behavior within social groups and their reciprocity. Together, they also lay the future groundwork for studying social behavior in humans and for testing neurobiology-guided clinical treatments.

Title: Neurons in the primate amygdala simulate decision processes of social partners

Authors: *F. GRABENHORST[1], R. BAEZ-MENDOZA[1], W. GENEST[1], G. DECO[2], W. SCHULTZ[1];
[1]Physiology, Develop. and Neurosci., Univ. of Cambridge, Cambridge, United Kingdom; [2]ETIC, Univ. Pompeu Fabra, Barcelona, Spain

Abstract: Primates observe the choices of social partners to learn about the reward value of objects. Such values learned from observation not only inform own decision-making but may also provide a basis for predicting the decisions of others. Although the neuronal mechanisms underlying these social cognitive processes remain unclear, the amygdala may play an important role: the amygdala is a key component of 'the social brain' and its neurons participate in economic decisions (Grabenhorst et al., 2012, 2016). Here we show that monkeys' amygdala neurons derive object values from social observation and use these values to simulate a partner monkey's decision processes. While two monkeys alternately made reward-based choices, amygdala neurons encoded object-specific reward values learned from social observation. Dynamic activity patterns translated these values into representations of the recorded monkey's own choices. Surprisingly, the same activity patterns unfolded spontaneously before the partner's choices in separate neurons, as if these neurons simulated the partner's decision-making. These neurons encoded signatures of a mutual-inhibitory decision computation, including value comparisons, value-to-choice conversions, and the difficulty of the partner's decision, resulting in accurate predictions of partner's choices. We refer to these neurons as 'simulation neurons' (Grabenhorst et al., 2019) because they dynamically encoded decision-making signatures during social observation, without decision requirements for the recorded monkey. Biophysically realistic modelling of amygdala circuits showed that simulation neurons emerge naturally from convergence between object-value neurons and self-other neurons. Our data and model suggest a

neurobiological account of mental simulation as neural decision computation. The amygdala simulation neurons reported here could allow primates to reconstruct their social partners' mental states and may constitute simple precursors for human mentalizing capacities, such as theory of mind. We speculate that dysfunction or absence of simulation neurons could impoverish social cognition, as is symptomatic in autism.

Title: Chronic stress induces anxiety-associated negative valence behaviors by activating a corticotropin-releasing hormone-related molecular signature in oval bed nucleus of the stria terminalis

Authors: *P. HU[1], I. MAITA[1], C. KWOK[1], E. GU[1], M. GERGUES[1], J. LIU[3], M. PHAN[1], Z. PANG[3], D. F. SWAAB[4], P. J. LUCASSEN[5], T. A. ROEPKE[2], B. A. SAMUELS[1];

Sch., Piscataway, NJ 08854, NJ; [4]Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [5]Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: The bed nucleus of stria terminalis (BNST) is a forebrain region highly responsive to stress that expresses corticotropin-releasing hormone (CRH) and is implicated in anxiety-associated negative valence behaviors. However, little is known about how chronic stress

modulates CRH signaling and neuronal activity in the BNST. We subjected C57BL6/J mice to 6-weeks of chronic variable mild stress (CVMS) and assessed effects on behavior, cellular neurophysiology and CRH-related molecular signaling in the BNST. CVMS elevated plasma corticosterone levels, induced anxiety-associated negative valence behaviors, diminished M-currents (a voltage-gated K^+ current that stabilizes membrane potential and regulates neuronal excitability), and increased mEPSC amplitude in the oval nucleus of BNST (ovBNST). Additionally, the number of c-fos^+, CRH^+, and CRH activator pituitary adenylate cyclase-activating polypeptide $(PACAP)^+$ cells were increased, whereas the number of CRH inhibitor striatal-enriched protein tyrosine phosphatase $(STEP)^+$ cells were decreased in the ovBNST. CVMS also activated PKA in BNST and chronic infusion of the PKA antagonist H89 into ovBNST reversed all electrophysiological and behavioral effects of CVMS. Moreover, optogenetic activation of ovBNST mimicked the behavioral effects of CVMS. Together, these data demonstrate that ovBNST mediates the effects of chronic stress on behavior through alterations in cellular excitability and CRH signaling. These data highlight a novel role for PKA-dependent CRH signaling in the ovBNST, which has important implications for the understanding of the neural circuitry underlying stress-related anxiety disorders.

Title: Dissecting the role of basolateral amygdala CRF neurons in learned and innate fear

Authors: *N. V. LUCHKINA, V. Y. BOLSHAKOV;
Psychiatry, McLean Hospital, Harvard Med. Sch., Belmont, MA

Abstract: Anxiety disorders are among the most commonly occurring mental illnesses, however, they remain difficult to address in clinical practice due to the lack of specificity in available treatments. Recent studies suggest a bidirectional role, i.e. anxiogenic or anxiolytic, for neuropeptide corticotropin releasing factor (CRF) in anxiety. This bimodality is strictly dependent on the participating cell types and neural networks involved and makes CRF an

attractive research topic and a potential therapeutic target. A complete characterization of distinct CRF subpopulations and understanding their roles, specifically within anxiety-related brain circuits, is of paramount importance for the development of treatments with desired anxiolytic effects. Towards this goal, we have identified a previously undescribed population of CRF-expressing neurons in the basolateral amygdala (CRF^{BLA}, constituting ~3% of all BLA Nissl+ cells). CRF^{BLA} neurons demonstrated unique electrophysiological properties, distinguishing them from neighboring non-CRF^{BLA} cells, as identified with patch-clamp recordings in slices from $Crh^{IRES-Cre}$::Ai14(tdTomato) reporter mice. First, CRF^{BLA} neurons showed higher firing rates and input resistance. Second, CRF neurons did not display spike-frequency adaptation, in contrast to BLA pyramidal cells. Third, CRF^{BLA} cells were much more excitable, as indicated by a lower rheobase. Taken together, such properties suggest a possibility of more reliable activation of CRF^{BLA} cells by weaker synaptic inputs, which may result in an increased susceptibility for the induction of long-term plasticity. Furthermore, immunostainings revealed that a majority of CRF^{BLA} neurons are GAD67+ (expressing GABA producing enzyme glutamate decarboxylase) and thus represent a subpopulation of GABAergic cells. Using ex vivo optogenetics, we determined that medial prefrontal cortex (mPFC) fibers form functional synapses on CRF^{BLA} neurons and, as expected, synaptic transmission at inputs to CRF^{BLA} cells is less efficient compared to BLA pyramidal cells. To analyze the functional role of CRF^{BLA} neurons in control of anxiety and fear extinction, we presently use DREADD-based methodologies to selectively manipulate (suppress or promote) the activity of CRF^{BLA} cells during fear extinction and assays of anxiety-related behaviors. Our initial results suggest that CRF^{BLA} cells may gate anxiety circuits in the BLA. In summary, these experiments can give mechanistic insights into the function of individual GABAergic neuronal subtypes in regulation of information flow in anxiety-driving microcircuits.

Title: Serotonin transporter polymorphism (5-HTTLPR) biases neurophysiological response to threatening voices

Authors: *C. CHEN[1], R. M. MARTÍNEZ[1], C.-W. CHAN[1], T.-T. LIAO[1], Y. CHENG[2]; [1]Taipei Med. Univ., Taipei, Taiwan; [2]Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: The 5-HTTLPR polymorphism has been regarded as a genetic contributor to anxiety-related traits and vulnerability to affective disorders. This polymorphism has been associated with the amygdala reactivity in response to threatening faces. However, the association between this polymorphism and the neural response to threatening voices remains unclear. This study genotyped 5-HTTLPR in ninety-five healthy Han Chinese participants, who varied in trait anxiety (STAI-T), as well as recorded their mismatch negativity (MMN), a component of the event-related potential elicited by the unexpected presence of angrily and fearfully spoken syllables embedded in a passive auditory oddball paradigm. Results showed that the short-allele (S) carriers of 5-HTTLPR appear to have significantly reduced fearful MMN than did the noncarriers. The fearful MMN amplitudes were negatively correlated with the STAI-T scores. Path analyses further indicated that 5-HTTLPR explained 4.9% of the variance in fearful MMN, which explained 6.5% of the variance in STAI-T. These findings provide preliminary evidence to corroborate the notion that 5-HTTLPR has a broad impact on social cognition. 5-HTTLPR could affect threatening voice processing already at the preattentive stage. Emotional MMN might shed some light on the emotional vigilance characteristic of trait anxiety.

Title: Increased evoked phasic dopamine release in the nucleus accumbens shell during sustained pain

Authors: *T. A. GEE[1], N. C. WEINTRAUB[1], E. NAVRATILOVA[2], D. LU[2], M. L. HEIEN[1], F. PORRECA[2];
[1]Chem. & Biochem., [2]Pharmacol., Univ. of Arizona, Tucson, AZ

Abstract: Dopamine signaling in the nucleus accumbens (NAc) regulates motivation and behavior through both tonic and phasic signaling. Tonic dopamine levels have been suggested to regulate the phasic dopamine signals in response to neuronal burst firing. We directly tested this hypothesis using fast scan adsorptive voltammetry (FSCAV) and fast scan cyclic voltammetry (FSCV) to measure tonic and phasic dopamine signaling, respectively, in the NAc shell in lightly anesthetized male, S.D. rats. Prior to dopamine measurements, the depth of anesthesia was standardized across animals by establishing a 6.3 +/- 0.2 second latency to a heat-induced tail-flick response. Application of capsaicin to the eye produced a significant increase in phasic dopamine signals as well as a hypodopaminergic state in the NAcSh that persisted for approximately two minutes; tonic dopamine levels were reduced by 22 +/- 8 % in response to capsaicin. Following recovery of dopamine levels to pre-capsaicin baselines, application of capsaicin to the alternate eye again produced a hypodopaminergic state of similar magnitude. Electrical stimulation of the medial forebrain bundle one minute after the instillation of capsaicin on the eye, during the hypodopaminergic state, increased phasic dopamine release by 48 +/- 18%. These data show that phasic dopamine signals can be elicited by noxious stimuli, that ongoing pain produces a hypodopaminergic state, and directly demonstrate that phasic dopamine signals are increased when tonic dopamine levels are low. The data suggest that salient stimuli produce enhanced phasic dopamine signaling that may underlie behaviors such as impulsivity and impaired decisions that are observed in hypodopaminergic conditions including chronic pain.

Title: The effects of delta-9-tetrahydrocannabinol and cannabidiol on anxiety end emotional memory are regulated via dissociable intra-amygdala modulation of neuronal activity and oscillation states in ventral hippocampal and prefrontal cortical projections

Authors: *H. J. SZKUDLAREK, B. PEREIRA, M. DE FELICE, B. RASHEED, T. JUNG, S. N. WHITEHEAD, S. R. LAVIOLETTE;
Univ. of Western Ontario, London, ON, Canada

Abstract: Cannabis produces complex psychotropic effects across various brain circuits. Previous research in our laboratory has demonstrated that the two major phytocannabinoids in cannabis, delta-9-tetrahydrocannabinol (THC) and cannabidiol (CBD) produce highly divergent effects on anxiety-related behaviours, cognition and emotional memory formation. In general, the anxiogenic effects of cannabis are linked to the actions of tetrahydrocannabinol (THC) whereas its anxiolytic effects have been associated with cannabidiol (CBD), the two main compounds produced by the plant. THC interacts with the endocannabinoid system via actions on CB1 receptors while CBD targets multiple receptors including the serotonergic 5-HT1a subtype. The basolateral amygdala (BLA) is a key brain region controlling affective and social behaviors and is functionally connected with other brain regions responsible for modulation of anxiety states like the prefrontal cortex (PFC) and ventral hippocampus (vHipp). In the present study we used behavioral, anatomical and electrophysiological approaches to study the effects of direct intra-BLA infusion of THC, CBD or its combination. We show that infusion of THC (100 ng) induces anxiolytic effects in the light-dark-box test while having no effects on anxiety in elevated plus maze and social motivation or social recognition. Similarly, CBD infusions (500 ng) had no effect on anxiety in the light-dark-box, elevated plus maze or on social behavior. Interestingly, co-infusion of THC (100ng) and CBD (500ng) induced strong anxiolytic effects expressed by longer durations spent in the open arm of the elevated plus maze and in the light compartment of the light-dark-box. Single unit and local field recordings in urethane anesthetized rats revealed that intra-BLA infusion of THC led to increased neuronal frequency, bursting rates and elevated low and high-gamma oscillations in the prefrontal cortex whereas vHipp activity was not affected. In contrast, intra-BLA infusion of CBD greatly reduced firing of vHIPP cells while having no effect in the PFC. Interestingly, THC+CBD induced no change in neuronal firing of PFC neurons while hippocampal cells were still inhibited, suggesting that CBD may counteract THC effects but not the opposite. Moreover, using retrograde tract-tracing with cholera toxin we show that PFC- and Hipp-projecting BLA neurons comprise two non-overlapping populations. These data suggest that intra-BLA THC and CBD target different neuronal BLA populations to affect anxiety behavior via dissociable pathways to the vHipp and PFC.

Title: Fear conditioning regulates endocannabinoid degradation

Authors: *M. A. FAROOQ, J. LIU;
Cell Biol. and Anat., Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA

Abstract: Post-traumatic stress disorder, PTSD, is a debilitating psychiatric disorder that is characterized by a cluster of symptoms that include intrusive memories, avoidance, hyper arousal, and negative mood and feelings. Individuals with PTSD exhibit dysregulation of the fear system and enhanced stress response. Several animal models exist to study this extremely heterogeneous disorder. For instance, a fear conditioning paradigm is used to understand consolidation and extinction of fear memories, whereas predator odor exposure is used to model the psychological stress and emotional learning. The cerebellum, a brain structure traditionally known for motor coordination, is also implicated in emotional learning, and it is required for consolidation of associative fear memory. Endocannabinoid signaling regulates both memory processing and mood. Clinical studies have shown that individuals with PTSD exhibit reduced levels of circulating endocannabinoids. However, the mechanism underlying this decrease in endocannabinoids is unclear. Monoacylglycerol lipase, MAGL, is an enzyme that degrades 2-arachidonoyl glycerol, 2-AG, the major endocannabinoid in the cerebellum. We tested whether fear conditioning and predator odor stress upregulates MAGL activity, which leads to reduction in endocannabinoid tone. We used a fluorescence-based assay to assess MAGL activity. In a fear conditioning paradigm, mice were either subjected to a tone that is paired with a foot shock or an unpaired protocol as control. Twenty-four hours after fear conditioning training, we quantified MAGL enzymatic activity in the lobule V/VI of the cerebellar vermis, a region which is critical for fear memory consolidation and emotional learning. We found that fear conditioning increased MAGL activity by 70 ± 47% as compared to the unpaired control. This learning-induced increase in MAGL activity is predicted to accelerate 2-AG degradation and reduce endocannabinoid signaling. In contrast when mice were exposed to fox urine, MAGL activity remained unchanged as compared to the controls. Therefore an increase in MAGL activity may contribute to associative fear memory formation and the PTSD symptoms of intrusive memories and hyper arousal.

Title: Role of PSD95 and nNOS interaction in gene regulation following fear conditioning and implications for molecular mechanisms underlying PTSD

Authors: *J. PATEL[1], A. I. MOLOSH[4], E. T. DUSTRUDE[2], A. SHEKHAR[3];
[2]Dept. of Psychiatry, [3]Indiana CTSI, [1]Indiana Univ. Sch. of Med., Indianapolis, IN; [4]Psychiatry, IU Sch. of Medicine,, Indianapolis, IN

Abstract: Fear and anxiety are evolutionarily developed responses to perceived or anticipated threats. Normal learning can produce avoidance behavior that promotes survival, but excessive and persistent fear after trauma can lead to development of phobias and post-traumatic stress disorder (PTSD). Involvement of the amygdala in fear acquisition is very well described and requires activation of N-methyl-D-aspartic acid receptors (NMDARs). At a cellular level, NMDAR activation leads to production of nitric oxide (NO) by a process that is mediated by interaction between postsynaptic density protein 95 (PSD95) and nitric oxide synthase (nNOS). Our laboratory has previously shown that fear conditioning enhances PSD95-nNOS interaction and that the small-molecule ZL006 inhibits this interaction. Treatment with ZL006 attenuates rodent cued-fear consolidation, impairs long-term potentiation of neurons, and prevents fear-mediated shifts in glutamatergic receptor current densities in the basolateral amygdala (BLA). In addition, we have demonstrated that treatment with ZL006 avoids adverse effects on cognition that are observed following direct antagonism of NMDARs. To further elucidate mechanisms underlying the role of the PSD95-nNOS-NO pathway in conditioned fear, the current study utilized auditory cue paired-fear conditioning and RNA-sequencing of BLA tissues to examine fear conditioning-mediated gene changes. Expression of 403 genes was altered in the BLA following fear expression, and of these genes, 60 were restored by systemic treatment with ZL006. Network data analysis and gene ontology enrichment analysis of these genes with Ingenuity Pathway Analysis and DAVID software found that cell-cell interaction and cognition-related pathways were significantly altered. Our results reveal novel genetic targets that underlie plasticity of fear-memory circuitry via their contribution of NMDAR-mediated fear consolidation and can inform future strategies for targeting fear related disorders like PTSD.

Title: Adenosine A_{2A} receptors control the extinction of fear memories

Authors: S. L. REIS[1], V. LOURENÇO[1], R. A. CUNHA[2], P. M. CANAS[1], ***A. P. SIMÕES**[1]; [1]Ctr. for Neurosci. and Cell Biol., Coimbra, Portugal; [2]Ctr. for Neurosci. and Cell Biology; Fac. of Medicine-University of Coimbra, Coimbra, Portugal

Abstract: Adenosine A_{2A} receptors ($A_{2A}R$) control the acquisition of fear memories[(1,2)]. Now, we studied the role of $A_{2A}R$ in fear extinction. C57BL/6 mice were contextually fear conditioned (1^{st} day: habituation followed by 3 footshocks) and then subjected to fear extinction (2^{nd}-4^{th} day: re-exposure to the same context without footshock) and their freezing behavior was monitored. The role of $A_{2A}R$ was investigated using a selective antagonist, SCH58261 (SCH) applied either intraperitoneally (ip, 0.1 mg/kg)) or directly (50 nM) in cannulated basolateral amygdala (BLA) or ventral hippocampus (VH), 1h before each extinction session. Extinction memory was tested on the 5^{th} day by re-exposing mice to the conditioning chamber. Electrophysiology was performed at two time periods - during extinction training and after the memory test - in transverse VH slices and horizontal BLA-containing slices from naïve (context exposed), fear conditioned (ACQ), fear conditioned + extinction (EXT) and fear conditioned + extinction in the presence of SCH (EXT+SCH) groups. Field excitatory postsynaptic potentials (fEPSP) were measured in VH CA3-CA1 synapses and population spikes (PS) were evaluated in BLA. Long-term potentiation (LTP) was triggered by high-frequency stimulation. Both ip and local blockade of $A_{2A}R$ accelerated fear extinction: 23h after the first ip injection of SCH, mice already froze less than controls (EXT+SCH: 16.3±2.7% of freezing *vs* EXT: 29.4±4.1%). The same was observed when SCH was administered in VH (EXT+SCH: 14.5±3.9% *vs* EXT: 34.3±5.7%) and in BLA (EXT+SCH: 14.6±2.9% *vs* EXT: 26.2±2.9%). Moreover, SCH administration did not affect locomotion, anxiety or passive extinction of fear. During fear extinction, both ACQ and EXT had lower post-tetanic potentiation in BLA comparing to naïve and EXT+SCH (ACQ: 14.4±5.3% of potentiation and EXT: 19.1±4.5% *vs* naïve: 54.3±13.4% and EXT+SCH: 50.4±10.6%). In VH, LTP in ACQ was lower comparing to naïve and EXT+SCH (ACQ: 16.7±8.5% above baseline *vs* naïve: 48.8±9.5% and EXT+SCH: 48.5±3.3%). After the memory test, basal neurotransmission was increased in BLA of ACQ comparing to EXT and naïve but only the EXT+SCH group was equal to the naïve. In VH, LTP was now increased in ACQ compared to naïve and EXT+SCH (ACQ: 87.0±11.2% above baseline *vs* naïve: 49.2±9.3% and EXT+SCH: 51.4±9.6%). In conclusion, $A_{2A}R$ blockade accelerates fear extinction by altering neuronal plasticity in BLA and in VH.1- Simões et al., Neuropsychopharmacol. 2016, 41: 2862-2871; 2- Wei et al., Biol. Title: Anxiolytic effect of ethanol on locomotor activity in rats

Authors: *L. MANZO[1], A. C. TAFOLLA[2], A. GORDILLO[2], C. TORRES[3];
[1]Univ. Michoacana De San Nicolas De Hidalgo, Morelia, Mexico; [2]Univ. Michoacana de San Nicolas de Hidalgo, Morelia, Mexico; [3]Univ. of Jaen, Jaen, Spain

Abstract: Early-life stress is associated with increased vulnerability to alcohol addiction.The exposure to reward uncertainty typical of training can reduce emocional self-medication (ESM) in rats with high levels of anxiety. We demostred, locomotion and anxiety behavior in Wistar (nonselected) male rats exposed to 32% to 4% sucrose downshift event in a consummatory successive negative contrast (cSNC) situation were given a two bottle, 2 h preference test immediately after consummatory training, and finally to the open field test (50 cm x 50 cm) to assess locomotor activity and anxiety behavior. One of the two bottles contained 2% ethanol or water different groups (the second bottle contained water for all groups). Because ethanol has anxiolytic properties in tasks involving reward loss, oral consumption after extinction sessions was interpreted as anti-anxiety or ESM.Three additional groups received the same postsession preference tests, but were always exposed to 4% sucrose during consummatory training. Rats showed the cSNC effect, suppressing consummatory behavior after the downshift relative to unshifted controls.This effect was accompanied by a selective increase of ethanol oral intake during the initial downshift sessions. Such increased fluid preference did not occur in animales with acces to water or unshifted controls groups with postsession access to the anxiolytic during the postsession test. These results suggest that ESM may reverse symptoms of anxiety in animal model. The effect ESM increased locomotion activity in the open field relative to water controls. The origin of addictive behavior is often linked to the rewarding effects of drugs of abuse.

Title: Neural control of organized escape from multimodal threats

Authors: W. WANG[1], P. J. SCHUETTE[2], B. TOBIAS[1], J. NAGAI[4], F. M. REIS[1], A. L. SEVERINO[5], M. CHAKERIAN[1], L. LIN[1], S. LEONARD[1], M. SEHGAL[6], A. J. SILVA[7], C. J. EVANS[2], C. M. CAHILL[3], B. S. KHAKH[4], *A. ADHIKARI[1];

Ctr., Los Angeles, CA

Abstract: Rapidly escaping from imminent danger is paramount for survival. However, the circuits controlling adaptive escape from threats can also provoke highly debilitating panic attacks in humans. Despite the biological and clinical relevance of panic-related escape, escape circuits are not well-understood. In particular, naturalistic organized escape that takes into account the geometry of the environment to promote flight through optimal escape routes has not been investigated. We optogenetically activated seven brainstem and hypothalamic nuclei that were shown or hypothesized to induce escape. Activation of six nuclei induced escape-related actions, such as jumping and running, but these actions were not coordinated correctly to allow escape from a geometrically complex environment. In contrast, activation of the hypothalamic dorsal premammillary nucleus (PMd) promoted versatile context-dependent flight, as mice jumped to escape only in the absence of a climbing route. In the presence of a climbing route, mice climbed instead of jumping to escape out of a complex environment. Chemogenetic inhibition and excitation of the PMd respectively impaired and increased organized escape from a wide variety of threats, including a live predator, carbon dioxide, a thermal threat and a shocking grid. Fiber photometry recordings show that the PMd is activated prior to escape,

regardless of the threat used or of the specific motor actions involved in flight. As the PMd is the strongest input to the panic-inducing dorsal periaqueductal gray (dPAG), we hypothesized that the PMd induces escape through the PMd-dPAG projection. Indeed, optogenetic inhibition of the PMd-dPAG projection decreased threat-induced organized escape. All results were replicated in 2-5 months old male and female mice (n=7-12 per group), the order of assays and drugs were counterbalanced. We identify the PMd as the first circuit shown to be sufficient and necessary for inducing organized context-dependent escape from numerous threats.

Title: The medial cerebellar nucleus augments IPSC amplitude in the ventrolateral periaqueductal gray freezing circuit by activating local dopaminergic neurons

Authors: *C. E. VAAGA, I. M. RAMAN;
Neurobio., Northwestern Univ., Evanston, IL

Abstract: To avoid predation, mice engage in stereotyped behaviors such as innate freezing in response to threatening stimuli. Freezing requires activation of the ventrolateral periaqueductal gray (vlPAG), and stimulation of glutamatergic neurons in the vlPAG elicits freezing in naïve mice. Lesions of the cerebellar vermis also reduces freezing in rats, suggesting that the cerebellum may interact with freezing circuitry; however, the underlying synaptic mechanisms have not been investigated. Here, using anatomical and slice electrophysiological experiments in mice (male and female; ~p21-p90), we found that the medial cerebellar nucleus (mCbN) directly projects to the vlPAG where it modulates the synaptic efficacy of IPSCs in freezing-specific neurons. We recorded from putative freezing-specific glutamatergic neurons, which express the transcription factor Chx10. Chx10+ neurons project to the ventral gigantocellular nucleus of the reticular formation, which projects to the spinal cord to mediate freezing. Functionally, although the mCbN neurons were glutamatergic, optogenetic stimulation of ChR2-expressing mCbN neurons in slice experiments robustly increased electrically evoked IPSCs in Chx10+ neurons

(control: 180±42 pA; +mCbN optogenetic stimulation: 231±48. pA, n=7). We reasoned that the IPSC augmentation may result from cerebellar activation of local dopaminergic/noradrenergic neurons in the vlPAG. Consistent with this hypothesis, tyrosine hydroxylase (TH) positive neurons in the vlPAG received direct mCbN excitatory input (-31.9±13.1 pA, n=5 of 6 cells). Either bath applying dopamine, or optically stimulating TH-positive neurons mimicked mCbN-dependent IPSC augmentation. Finally, in wild-type mice, bath applying D_1 and D_2 receptor antagonists abolished mCbN-dependent IPSC augmentation (stim without blockers: 135.5±8.6% of control, stim with blockers: 101.9±1.0% of control, n=7, 4). These results suggest that the mCbN modulates IPSC amplitude in freezing-specific neurons, which are thought to be primarily driven through disinhibition following amygdala activation. Furthermore, given the high basal firing rates of mCbN cells, the data suggest that the dopaminergic tone in the vlPAG may be regulated by cerebellar activation.

Title: Dissecting projection-specific contributions of the zona incerta to fear

Authors: *A. VENKATARAMAN[1], B. G. DIAS[2,3];
[1]Neurosci. Grad. Program, [2]Dept. of Psychiatry and Behavioral Sci., Emory Univ., Atlanta, GA; [3]Yerkes Natl. Primate Res. Ctr., Atlanta, GA

Abstract: Fear expression towards threat-associated stimuli is an adaptive behavioral response. In contrast, generalization of fear responses toward non-threatening cues is maladaptive and is associated with psychopathology. Sensorimotor integration is critical to express appropriate and inhibit inappropriate fear responses towards fearful and neutral stimuli, respectively. The mammalian subthalamic region called the zona incerta (ZI), typically considered a sensorimotor relay, has been shown to play a crucial role in modulating fear responses. We have recently shown that the ZI can bidirectionally modulate fear generalization - decreasing ZI activity facilitated fear generalization while increasing ZI activity abolished fear generalization. Furthermore, we demonstrated that GABAergic cells in the ZI could modulate fear generalization. In this study, we were interested in understanding how projections of GABAergic cells in the ZI influence fear-related behavior. GABAergic cells in the ZI send strong projections

to the thalamic nucleus reuniens (RE) and midbrain periaqueductal gray (PAG); regions that play important roles in fear generalization, fear learning and fear expression. More specifically, the RE mediates specificity and long-term maintenance of fear memories, while the PAG generates and orchestrates fear and defensive responses. Using optogenetic manipulations, our preliminary results suggest that GABAergic cells in the ZI that project to the RE and the PAG differentially alter fear responses. Together, our results suggest a prominent role for GABAergic projections from ZI in calibrating fear responses.

Title: Optogenetic manipulation of ventral hippocampal parvalbumin interneurons during innate and learned fear

Authors: *W.-L. CHANG[1], J. C. JIMENEZ[2], E. Z. AKGUNGOR[1], K. S. OTTE[2], J. D. BARBOSA[3], A. Z. HARRIS[1], R. HEN[1];
[1]Dept of Psychiatry, Systems Neurosci. Div., Columbia Univ/New York State Psychiatric Inst., New York, NY; [2]Columbia Univ., New York, NY; [3]Emory Univ., Atlanta, GA

Abstract: Background: Lesion, pharmacological, and optogenetic studies in rodents have shown that the ventral hippocampus is important for the expression of anxiety-like behavior, particularly the output region CA1. The ventral CA1 (vCA1) exhibits increased neural oscillations in the theta frequency range (4-12 Hz) in anxiogenic environments, and this synchronous oscillation is coordinated by interneurons, such as parvalbumin (PV)-expressing interneurons, which target the soma and axons of excitatory cells. In this study, we determine the behavioral effects of acute manipulation of PV cell activity in the vCA1 using optogenetics during innate and learned anxiety-like behaviors. Methods: Male and female PV-Cre c57BL/6J mice received bilateral injections of adeno-associated virus (AAV) into the vCA1 and fiber optic implants. AAV containing Cre-dependent eNpHR3.0 was used for inhibitory experiments, while AAV with Cre-dependent hChR2(E123A) was used for excitatory experiments. Cre-dependent eYFP or mCherry AAV was used for controls. Behavioral tests were performed with 10 mW light delivery in timed blocks. Time blocks consisted of constant light for inhibitory experiments,

while 5 msec pulses at 20 Hz were used in excitatory experiments. Behaviors included the open field, elevated plus maze (EPM), elevated zero maze (EZM), and contextual fear conditioning (CFC). Results: Both excitation and inhibition of PV cells increased avoidance of innately anxiogenic environments. PV cell stimulation during the encoding/conditioning phase of CFC had no effect on freezing behaviors the next day. Experiments of PV cell inhibition during the retrieval/testing day of CFC are ongoing, but preliminary evidence suggests that PV inhibition decreases freezing behavior on Day 2 of CFC. Discussion: Our findings demonstrate that acute manipulation of PV interneurons in the vCA1 is sufficient to alter anxiety-related behavior. Unexpectedly, both stimulation and inhibition of PV cells increased avoidance of innately anxiogenic environments. It is possible that rhythmic stimulation of PV cells at 20Hz increased synchronous activity in the vCA1 to cause increased anxiety-like behavior. Inhibitory experiments were consistent with previous findings from vCA1 pyramidal cell manipulations. Inhibiting vCA1 pyramidal cell activity increases time spent in open arms of the EPM, while stimulation during CFC retrieval disrupts normal expression of conditioned fear. PV cell inhibition would be expected to disinhibit pyramidal cells, and therefore increase their activity. Our results from inhibitory experiments are consistent with that prediction.

Title: Parallel hippocampal-to-amygdala circuits distinct reactions from innate to learned threat

Authors: *Y. GU, M. WU, L. WANG, L. LIN;
Inst. of Brain Functional Genomics, East China Normal Univ., Shanghai, China

Abstract: Innate behaviors are genetically determined and stereotyped. Whereas in the learned circuit, rapid learning of new CS-US association causes rapid overwriting of existing memories. How neural circuits processing innate fear instruct an adaptive learning process (for example, freezing in Pavlovian threat conditioning) in rodent? From a neuroscience perspective, this question might lead us to investigate the neural basis of learning and (inherently) memory. In this endeavor, we propose that distinct brain circuits guide different behaviors underlie

fundamental properties: feedforward, feedback and self-organizing networks. We focused on the hippocampal-amygdala circuits because (i) the extensive knowledge has confirmed their roles in innate and learned defensive behaviors; (ii) both brain regions employ a one-to-many wiring configurations to orchestrate multiple aspects of defensive behaviors; (iii) under certain circumstances, either activate or inhibit the same pathway can promote a broad spectrum of defensive behaviors.
We use different viral strategies for tracing retrograde and anterograde transsynaptic neural pathways within the dorsal hippocampal CA1 area and the basolateral/central amygdala in genetically defined populations of neurons in mice. Then we use chemogenetics and multi-channel recording techniques to manipulate and monitoring the circuits during defensive behaviors. In the mean while combining with CAMPARI to label the "snapshot firing neurons" for distinct behavioral readouts. The results potentially help us to better understand the interactions between hippocampus and amygdala circuits by segregated, integrated or antagonistic mechanisms in a nascent stage.

Title: Encoding fear of heights by single neurons in basolateral amygdala

Authors: *J. LIU[1], L. LIN[2], **D. V. WANG**[3];
[1]Drexel Univ. Col. of Med., Philadelphia, PA; [2]East China Normal Univ., Shanghai, China; [3]Neurobio. and Anat., Drexel Univ., Philadelphia, PA

Abstract: Fear of heights, and related avoidance of heights, are essential for survival and everyday life. However, irrational or excessive fear of heights can lead to acrophobia, which may have a serious impact on people's lives. Unfortunately, the neuronal activities and circuitry of fear of heights, acquired in the absence of any previous aversive experience ("visual cliff", Gibson & Walk, 1960), have not yet been systematically studied. Converging evidence suggests that the amygdala is a key brain region involved in both learned and innate fear. By means of multi-channel tetrode recording and heart rate measurement in freely behaving mice upon high place exposure, we identified a distinct neuronal population in basolateral amygdala (BLA) that encodes the fear of heights. Unlike the prominent rapid habituation effects of amygdala neurons to conditioned fear, the high-place innate fear neurons presented greater resistance to habituation

by exhibiting sustained activation (up to 30 min). Transition between ground and a high platform, the high-place fear neurons exhibited an “all-or-none” responsive pattern, which is likely mediated by visual and/or vestibular inputs. Importantly, contrary to the responsive patterns of BLA anxiety-related neurons we reported before, the high-place fear neurons only respond to heights, but not anxiogenic conditions such as the open-field induced anxiety. To identify regulatory afferents that either activate or inhibit the firing of the BLA high-place fear neurons, we injected AAV viruses that encode Channelrhodopsin-2 (ChR2) into major BLA-projecting regions, including the prefrontal cortex (PFC) and lateral entorhinal cortex (LEnt), which have previously been implicated in fear processing. Then, we implanted an optrode (an optical fiber surrounded by eight tetrodes) into the BLA to examine how photoactivation of these afferents may potentially affect high place-fear neurons’ activities. Our results revealed that photostimulation of the PFC-to-BLA afferents activates a subpopulation of non-high-place fear BLA neurons. More interestingly, photostimulation of the LEnt-to-BLA afferents evokes differential effects on BLA neurons: a subpopulation of BLA neurons can be activated, while the majority of the BLA neurons, including the high-place innate fear neurons, are inhibited, indicating a LEnt-to-BLA neural circuit involved in regulating fear of heights. These findings provide insight into a better understanding of the neural circuits of fear of heights and may have clinical implications for treatment of excessive fear and anxiety disorders, such as acrophobia.

Title: Apical intercalated cell cluster: A novel sensory regulator in the amygdala

Authors: D. ASEDE, D. DODDAPANENI, A. CHAVEZ, J. OKOH, S. ALI, *M. BOLTON; Max Planck Florida Inst., Jupiter, FL

Abstract: It is increasingly appreciated that distinct classes of GABAergic neurons regulate different aspects of information processing in the amygdala. One unique class is the amygdala intercalated cells (ITCs) which are masses of GABAergic neurons organized in clusters around the basolateral amygdala (BLA). Recent evidence indicates that different fear states activate distinct ITC clusters, highlighting the distinct nature and function of each ITC cluster in fear-related behaviors. Although the role of a few of the ITC clusters has been studied, the functional role of apical ITCs (apITCs) is unknown. Here, using optogenetics, we show that apITCs receive direct sensory input from thalamic and cortical areas. Upon fear conditioning and memory retrieval, thalamic inputs undergo pre and postsynaptic plastic changes, indicative of their

involvement in fear behaviors. 3D reconstruction of biocytin-filled apITCs revealed that they arborize extensively within the apITC cluster itself and also innervate the dorsal striatum and LA. We further showed that apITCs provide sensory feedforward inhibition to LA principal cells, a putative mechanism for controlling plasticity during fear learning.

Title: Reshaping fronto-amygdalar circuitry through electrically forced hebbian plasticity

Authors: ***F. J. DA SILVA**, M. J. SCHATZA, E. B. BLACKWOOD, M.-C. LO, A. S. WIDGE; Psychiatry, Univ. of Minnesota, Minneapolis, MN

Abstract: Fronto-amygdalar circuits (IL-BLA in rats, and prefrontal cortex-Amygdala in humans) are implicated in fear learning and fear extinction. Altering the functional connectivity of these circuits may facilitate the extinction of learned fear responses, which may reduce the debilitating effects of fear-related diseases such as post-traumatic-stress-disorder (PTSD). At the neuronal level, when one neuron regularly contributes to the firing of another, the connection between them is strengthened (Hebb's rule). Similarly, at the regional neuronal network level, paired pulse electrical stimulation (the activation of many neurons in one area followed by similarly broad activation of neurons in another) also leads to temporarily increased connectivity between the regions involved in the paired stimuli. However, paired electrical stimulation likely activates both inhibitory and excitatory sub-populations. It is not clear whether such broad alteration of connections will translate to lasting changes in functional connectivity and behavior. Rather than modulating the activity in both regions, a more efficient approach to Hebbian plasticity might be to stimulate a downstream region only after the activity in another has naturally gone above some threshold. This more closely mimics natural activity patterns, and thus might produce more lasting effects. We are currently implementing that protocol in the IL-BLA circuits, inducing Hebbian-like connectivity enhancements by stimulating one BLA region in response to increases in IL activity. We will compare multiple variations on this stimulation, including the definition of an IL activity increase (ensemble spiking rate vs. power in the high gamma local field potential), timing of BLA stimulation relative to IL activity, and amplitude of

the BLA stimulation. We will also explore single pulse BLA stimulation versus stimulation that mirrors the activity recorded in the originating area, to determine which combination of parameters results in the greatest and longest-lasting changes in connectivity. This poster will present the initial results from those experiments, demonstrating that this activity-dependent stimulation facilitates IL-BLA synapses and that facilitation requires precise stimulation timing. Future work will use these protocols to modulate fear extinction in rats, as a step towards translating the technique into humans.

Title: Environmental enrichment reverses anxiogenic-like behavior induced by cohabitation with mice submitted to chronic neuropathic pain

Authors: *I. M. CARMONA[1,2], P. E. CARNEIRO DE OLIVEIRA[1], A. CANTO-DE-SOUZA[1,2,3];
[1]Dept Psychology-Psycobiology group/UFSCar, São Carlos, SP, Brazil; [2]Joint Grad. Program in Physiological Sci. UFSCar/UNESP, São Carlos, SP, Brazil; [3]Grad. Program in Psychology/UFSCar, São Carlos, SP, Brazil

Abstract: AIM: Animal models are fundamental tools for understanding the neurobiological bases implicated in anxiety modulation. Our group recently demonstrated that cohabiting with a conspecific submitted to chronic pain produces enhancement anxiety-like behaviors in observer mouse. Although their anxiety treatment is usually pharmacological, alternative interventions such as environmental enrichment may prevent or reverse psychological disorders. Therefore, the present study aimed to evaluate the effects of environmental enrichment in anxiety-like behavior tested on the elevated plus-maze (EPM) in mice that cohabiting with a cagemate in neuropathic pain. **METHODS AND RESULTS:** Male Swiss mice (n=10-14/group) were submitted to 28 days protocol. On the 21st after birth (weaning) mice were housed in pairs for 14 days to familiarity establishment. On the 14th day, the animals were divided into four groups: cagemate nerve constriction exposed to standard environmental (CNC+SE), in which one animal

from each pair was subjected to sciatic nerve constriction and cagemate nerve constriction exposed to EE (CNC+EE); cagemate sham exposed to standard environmental (CS+SE), one animal from each pair was subjected to the same surgery but without constriction and cagemate sham exposed to EE (CS+EE). On the 28th day all groups were exposed to elevated plus-maze. Two-way ANOVA followed by *post-hoc* Duncan test revealed that cohabitation with mice in sciatic nerve constriction condition induces anxiogenic-like behavior and enriched environment reverted this effect in percentage of open arm entries (CS/SE: 34.6±5.6; CNC/SE: 6.1±1.9*; CS/EE: 16.0±5.4#; CNC/EE: 29.1±5.1*#) and percentage of open arm time (CS/SE: 14.9±3.1; CNC/SE: 1.6±0.7*; CS/EE: 6.7±2.9#; CNC/EE: 13.1±2.8#) and closed arm entries (CS/SE: 6.9±0.7; CNC/SE: 9.1±0.6; CS/EE: 8.9±1.0#; CNC/EE: 12.2±1.4*#) of the EPM. Data are presented as mean ± SEM. *P<0.05 versus respective CS group. #P<0.05 versus respective SE group. **CONCLUSIONS:** These findings suggest that EE reverses anxiogenic-like behavior induced by cohabitation with mice submitted to chronic sciatic nerve constriction.

Title: Inhibition of the left medial prefrontal cortex (mPFC) prolongs the anxiogenic effect induced by social defeat in mice: Modulation by NMDA receptors in the right hemisphere

Authors: *R. L. NUNES-DE-SOUZA[1], N. SANTOS-COSTA[2], D. C. MASCARENHAS[2], G. VICTORIANO[2];
[1]Pharmacol., Univ. Estadual Paulista, UNESP, Araraquara, Brazil; [2]Pharmacol., Univ. Estadual Paulista - UNESP, Araraquara, Brazil

Abstract: Injections of Cobalt chloride ($CoCl_2$, a nonselective synaptic inhibitor) and NOC-9 [a nitric oxide (NO) donor], respectively, into the left and right medial prefrontal cortex (L- and RmPFC) provoke anxiety in mice. Also, LmPFC inhibition immediately followed by a single social defeat stress (SDS) lead to anxiogenesis in mice exposed to the elevated plus maze (EPM) 24 hours later. Given that glutamate NMDA (N-methyl-D-aspartate) receptors are densely present in the mPFC, we investigated (i) the time course of the anxiogenesis induced by the

LmPFC inhibition + SDS and (ii) the effects of intra-RmPFC injection of AP-7 (a NMDA receptor antagonist) on this long-lasting anxiety. Male Swiss mice received intra-LmPFC injection of $CoCl_2$ (1mM) and 10 min later were subjected to a single SDS episode and then (i) exposed to the EPM 2, 5, or 10 days later or (ii) 2 days later, received intra-RmPFC injection of AP-7 (0.05 nmol) and were exposed to the EPM. EPM analysis comprised the spatiotemporal measures [percentage of entries and time in open arms (%OE; %OT) and frequency of closed arms entries (CE)]. Results showed that the combination LmPFC inhibition + SDS reduced the %OE and %OT 2, 5 or 10 days later. In addition, the expected anxiogenic effects induced by the LmPFC + SDS were absent in animals that received intra-RmPFC injection of AP-7 two days later. Importantly, drug injections outside the dorsal region of the mPFC (i.e. prelimbic and cingulate cortex, area 1) did not produce significant behavioral effects on anxiety. These results suggest that the integrity of the LmPFC is important for mice to properly cope with SDS, and that NMDA receptor blockade in the RmPFC facilitates the resilience phenomenon to the anxiogenic effects induced by the SDS in male mice.

Title: Dissimilar activation pattern of the anterior cingulate cortex, insula and amygdaloid complex in the modulation of pain empathy in mice

Authors: *A. CANTO-DE-SOUZA[1,2,3], D. BAPTISTA-DE-SOUZA[1], R. NUNES-DE-SOUZA[3,4];
[1]Psychobiology Group, Dept of Psychology, UFSCar, São Carlos, SP, Brazil; [2]Grad. Program in Psychology/UFSCar, São Carlos, SP, Brazil; [3]Joint Grad. Program in Physiological Sci. UFSCar/UNESP, São Carlos, SP, Brazil; [4]Pharmacol, FCF/Unesp, Araraquara, SP, Brazil

Abstract: The pain experience not only includes nociceptive and nocifensive but also emotional-affective and cognitive components. It has been shown that see a conspecific with pain can increase or decrease the sensation of pain in the observer mouse. Recently, our research group has shown that living with a conspecific in chronic pain increase the nociceptive responses in

animals subjected to the writhing test. In addition, chemical inhibition of amygdala and insula, respectively, enhances and attenuates the hyperalgesia. **Aim:** Here we investigated the activation pattern of the anterior cingulate, insular cortices and amygdaloid complex (e.g., central, lateral and basal nuclei) in mice submitted to sciatic nerve constriction and the cagemates living with a conspecific in chronic pain. Brain activation was recorded through FosB expression in each area of both hemispheres. **Methods:** Male Swiss mice (n=6-7/group) were housed in pairs for 28 consecutive days. On day 14th, pairs of mice were grouped as follow: cagemate nerve constriction [CNC; i.e. one animal from each pair was subjected to sciatic nerve constriction (SNC) surgery] or cagemate sham (CS; i.e. one animal from each pair was subjected to (SS) sham surgery). After that, each pair was returned to its homecage to live together for further 14 days. On testing day (day 28th), all mice were euthanatized and their brains removed for immunohistochemistry assay. **Results:** Two-way ANOVA [Factor 1: condition (SNC or SS), Factor 2: hemisphere (left or right)] revealed decreasing of the activation in the anterior cingulate cortex ($F_{(1,20)}$=18.52; $P < 0.05$) of the SNC group compared to the CS, similarity observed in mice submitted to constriction (F(1,20)=12.86; $P < 0.05$) compared to the sham group. In contrast, SNC group showed an increase of FosB bilaterally in the insular cortex ($F_{(1,20)}$=28.46; $P < 0.05$) as observed in animals on neuropathic pain condition (F(1,20)=24.24; $P < 0.05$). On the same way, for mice submitted to sciatic nerve, we observed the increase of activation in the central (F(1,20)=5.14; $P < 0.05$) and lateral (F(1,20)=11.87; $P < 0.05$) nuclei of the right amygdala. However for cagemates we observed the decrease of activation of the central nucleus in the left amygdala ($F_{(1,20)}$=5.36; $P < 0.05$). **Conclusion:** These results demonstrate that living with a mouse subjected to SNC induces hyperalgesia and alters the activation pattern of the anterior cingulate, insular cortices and amygdaloid complex. Taken together, the present results suggest the involvement of brain areas that are known to play a role in emotional states, such as anterior cingulate cortex, insula and amygdaloid complex in the modulation of pain empathy in mice.

Title: Chemical inactivation of the anterior cingulate cortex produces an anxiolytic-like effect in mice exposed to the model of empathy for pain

Authors: *G. B. CEZAR[1,2], L. M. SILVEIRA[1,2], L. A. ROSA[1,2], I. M. CARMONA[1,3], A. CANTO-DE-SOUZA[1,2,3];

Abstract: AIM: Empathy is expressed by the ability to recognize and respond to the emotional signals of others. This capacity is crucial for social interaction and has valuable adaptive behavior that provides essential skills for the survival of species. Recently, our group have demonstrated that mice cohabiting with a conspecific submitted to chronic neuropathic pain show anxiogenic-like behaviors in the elevated plus-maze (EPM). Evidence has emphasized the role of anterior cingulate cortex (ACC) in modulation of anxiety, pain and emotional contagion. This study investigated the effects intra-ACC injection of cobalt chloride ($CoCl_2$, a reversibly non-selective synaptic blocker), on the modulation of anxiety induced by cohabiting with a cagemate in neuropathic pain in mice exposed to the EPM. **METHODS AND RESULTS:** Male Swiss mice (n=11-12/group) were submitted to a 28 day protocol. On the 21st after birth (weaning) mice were housed in pairs for 14 days to establish familiarity. On the 14th day, the animals were divided into two groups: cagemate sciatic nerve constriction (CNC), in which one animal of each pair was subjected to sciatic nerve constriction and cagemate sham (CS), in which one animal from each pair was subjected to the same surgery without nerve constriction. After surgery, the mice returned to the box with their respective conspecific (cagemate). On the 23rd day, cagemates were submitted to stereotactic surgery for implantation of guide cannulas directed to the ACC. On the 28th day, the CNC and CS groups received bilateral injections of saline or $CoCl_2$ intra-CCA, and the cagemates were submitted to EPM for five minutes. Two-way ANOVA revealed that cohabitation with mice CNC induces anxiogenic-like behavior and demonstrated that temporary chemical inactivation of the ACC increased percentage of open arm entries (CS/Saline: 48.8±4.9; CNC/Saline: 26.7±3.4*; CS/$CoCl_2$: 53.9±7.3; CNC/$CoCl_2$: 55.4±6.4#) and percentage of open arm time (CS/Saline: 41.5±7.0; CNC/Saline: 20.1±5.2*; CS/$CoCl_2$: 47.8±7.5; CNC/$CoCl_2$: 48.3±7.8#), without altering closed arm entries (CS/Saline: 8.7±0.8; CNC/Saline: 8.4±1.1; CS/$CoCl_2$: 9.9±1.2; CNC/$CoCl_2$: 6.7±1.1) of the EPM. Data are presented as mean ± SEM. *$P<0.05$ versus respective group saline. #$P<0.05$ versus respective group CS/saline or CNC/saline. **CONCLUSIONS:** These data suggest that inactivation of the ACC provokes an anxiolytic-like effect in the EPM in mice. Furthermore, it suggests that ACC is essential for exhibition of anxiety-like behaviors induced by emotional contagion, evaluated through cohabitation with conspecific submitted to chronic neuropathic pain.

Title: The inactivation of the anterior cingulate cortex provokes an anxiolytic-like effect and impairs the evocation of the aversive memory in mice exposed to a model of posttraumatic stress disorder

Authors: *L. A. ROSA[1,2], L. M. SILVEIRA[1,2], G. B. CEZAR[1,2], A. CANTO-DE-SOUZA[1,2,3]; [1]Dept Psychology-Psychobiology Group/Universidade Federal de São Carlos-UFSCar, São Carlos, SP, Brazil; [2]Grad. Program in Psychology/UFSCar, São Carlos, SP, Brazil; [3]Joint Grad. Program in Physiological Sci. UFSCar/UNESP, São Carlos, SP, Brazil

Abstract: AIM: Two of the most important aspects of the Posttraumatic Stress Disorder (PTSD) are the stability of a traumatic (aversive) long-term memory, and hypervigilance, which may be associated with higher levels of anxiety. And since the dorsal anterior cingulate cortex has been associated with context representation, and aversive encoding and anticipation, we carried out a study to evaluate the effects of microinjections of cobalt chloride ($CoCl_2$, a reversible non-selective synaptic blocker) intra-anterior cingulate cortex (ACC/Cg2) of male Swiss male mice on anxiety-like behavior and memory by using an animal model of PTSD that employed reexposures to situational reminders (SR). **METHODS AND RESULTS:** The experimental setup consisted of exposing male Swiss mice (n= 16/group) to an inescapable footshock (0.5 mA/10 s) into the dark side of a light-dark box (LDB), followed by three weekly reexposures to the light side of the box for 2 minutes (SR). Forty-eight hours after the last session, all animals were stereotaxically implanted with guide cannulas bilaterally aimed to the ACC/Cg2. On the twenty-eighth day, 10 minutes after bilateral microinjections of vehicle or $CoCl_2$ (1 mM/0.1 µl) intra-ACC/Cg2, all animals were tested in the elevated-plus maze (EPM) for 5 minutes. On the thirty-fourth day, following the same microinjection procedure, the same mice were submitted to explore both sides of the LDB for 5 minutes. Our results demonstrated that temporary chemical inactivation of the ACC/Cg2 in mice increased percentage of open arm entries ($t_{30} = -5.31$, $p < 0.05$) and percentage of open arm time ($t_{30} = -5.53$, $p < 0.05$), while decreased closed arm entries ($t_{30} = 6.20$, $p < 0.05$), percentage of protected head-dipping ($t_{30} = 2.69$, $p < 0.05$), and percentage of protected stretched attend posture (SAP) ($t_{30} = 4.81$, $p < 0.05$). In relation to LDB, the results demonstrated that inactivation of the ACC/Cg2 decreased latency to enter into the dark side of

the box (t_{30} = 4.99, $p < 0.05$), and increased entries (t_{30} = -2.71, $p < 0.05$) and time spent (t_{30} = -6.55, $p < 0.05$) in the dark side of the LDB. **CONCLUSIONS:** Together, these data suggest that temporary inactivation of the ACC/Cg2 provokes an anxiolytic-like effect in the EPM, and impairs the evocation of the aversive memory in the LDB in mice.

Title: N-methyl-d-aspartate (NMDA) receptor activation in the left prelimbic (but not inflralimbic) cortex restores social interaction in cronically defeated mice

Authors: *N. SANTOS-COSTA[1], M. MATTHIESEN[2], R. L. NUNES-DE-SOUZA[3];
[1]Univ. Estadual Paulista - UNESP, Araraquara, Brazil; [2]Unesp, Araraquara, Brazil; [3]Univ. Estadual Paulista, UNESP, Araraquara, Brazil

Abstract: The chronic social defeat stress (CSDS) in mice allows the identification of two subgroups of animals: susceptible [low social interaction (SI)] and resilient (normal SI). A recent optogenetic study showed that while the activation of the LmPFC in susceptible mice restores sociability to control levels, its inhibition leads to social avoidance in resilient mice. Thus, the LmPFC seems to regulate social behavior independent of the activity of the RmPFC, and confers resilience. Besides, recent findings of ours have shown that NMDA activation of the Left (L) mPFC provokes anxiolytic-like effects of mice exposed to the elevated plus maze. Here, we investigated whether the social avoidance induced by CSDS is reversed by NMDA activation in the L mPFC of mice exposed to the SI test. Methods: Male Swiss mice were submitted to SDS for 10 consecutive days (n=7 no-stressed;10 defeated). 24h later, they were individually exposed to the SI test to record the social interaction profile. The SI ratio were calculated as follows: time in the interaction zone with the aggressor / time in the interaction zone without the aggressor. After that, mice were classified as susceptible (SI ratio < 1) or resilient (SI ratio = or > 1). The day after, mice received saline or NMDA (0.04 nmol/0.2 µL) in the LmPFC and were reexposed to the SI test. Results: On the 1st exposure to SI test, no-stressed subjects had SI ratio equal ou higher than 1 (average=1.2; SEM=0.3), what were maintained in the reexposure (average =1.4; SEM=0.3). Ninety percent of defeated mice were classified as susceptible (SI average: 0.3;

SEM=0.09) and than were separated to receive sal (n=4) or NMDA (n=5). On the retest, saline-injected group maintained its SI ratio average (0.3; SEM=0.2). Interestingly, mice who received NMDA within the L prelimbic cortex (n=3) increased SI to resilient levels (SI ratio average: 1.8; SEM=0.1). However, NMDA microinjection into infralimbic subregion of mPFC (n=2) did not change mice phenotype. These results are suggestive that i) CSDS protocol is able to induce high percentage of susceptible mice and ii) the social avoidance induced by CSDS seems to be reversed by activation of Glu-NMDA receptors located in the left prelimbic (but not infralimbic) cortex of mice.

Title: Empathy for pain: Interplay between antagonist 5-HT_3 and benzodiazepine/$GABA_A$ receptors in amygdala modulates nociceptive response in cagemate that cohabited with a mice undergoing neuropathic pain

Authors: *L. R. R. TAVARES[1,2], D. BAPTISTA-DE-SOUZA[1], A. CANTO-DE-SOUZA[1,2,3]; [1]Dept Psychology-Psycobiology Group/UFSCar, São Carlos, SP, Brazil; [2]Joint Grad. Program in Physiological Sci. UFSCar/UNESP, São Carlos, SP, Brazil; [3]Grad. Program in Psychology/UFSCar, São Carlos, SP, Brazil

Abstract: AIM: Serotonergic and GABAergic receptors within amygdala are involved in pain and emotional responses, suggesting that this structure acts in the modulation of empathy for chronic pain models in mice. The study investigated the role of 5-HT_3 and benzodiazepine/$GABA_A$ receptors ($GABA_AR$) on social modulation of pain induced by cohabiting with a mouse submitted to sciatic nerve constriction. **METHODS AND RESULTS:** Male Swiss mice (n=6-12), were housed in pairs for a period of 28 days. On the 14th day, one animal from each pair underwent constriction surgery of the sciatic nerve or not, divided into two groups: cagemate nerve constriction (CNC), in which one animal of each pair was subjected to sciatic nerve constriction; cagemate sham (CS), in which one animal from each pair was subjected to the same surgery but without constriction. On the 24th day, the CNC or CS animal were subjected to a stereotaxic surgery. On the 28th day each cagemates received injections of

vehicle or ondansetron (OD, 5-HT_3 antagonist, 0.3, 1.0 or 30 nmol/0.1µl) intra-amygdala (Experiment 1), saline or midazolam (MDZ, benzodiazepine/$GABA_AR$ agonist, 3.0 or 30 nmol/0.1µl) intra-amygdala (Experiment 2) and pre-treatment with vehicle or OD (0.3 nmol/0.1µl) follow by saline or MDZ (3.0 nmol/0.1µl) intra-amygdala (Experiment 3). After intra-amygdala injections, mice received acetic acid (0.6%, 0.1 ml/10g i.p.) injection and were submitted to the writhing test. For experiment 1, two-way ANOVA revealed significant effects for treatment [$F_{(3,71)}$=19.85; $p<0.05$] and interaction between treatment and cohabitation [$F_{(3,71)}$=8.16; $p<0.05$]. In experiment 2, two-way ANOVA show statistically significant effects for treatment [$F_{(2,44)}$=11.66; $p<0.05$] and interaction between treatment and cohabitation [$F_{(2,44)}$=3.64; $p<0.05$]. In experiment 3, three-way ANOVA show statistically significant effects for cohabitation [$F_{(1,57)}$=5.11; $p<0.05$], pre-treatment [$F_{(1,57)}$=5.10; $p<0.05$], treatment [$F_{(1,57)}$=13.02; $p<0.05$], and interaction effects for cohabitation x pre-treatment x treatment [$F_{(1.57)}$= 4.91; $p<0.05$]. Post hoc test revealed that intra-amygdala OD and MDZ attenuated hypernociception induced by living together with a cagemate in CNC groups. In experiment 3, the attenuation of the hyperalgesia found by MDZ in experiment 2 was impaired by OD. **CONCLUSIONS:** Our results suggest that the amygdaloid complex modulates the hypernociception induced by cohabitation with a pair in chronic pain through the interplay of 5-HT3 and benzodiazepine/GABAA. This evidences confirming the significative role on serotonin and GABA neurotransmitters on affective-emotional components of pain-related empathy.

Title: The effect of glyphosate-based herbicide on locomotion and anxiety-like behavior in rats

Authors: *M. CÁCERES-CHACÓN[1], O. MARTÍNEZ-GUZMÁN[1], M. RIVERA-LÓPEZ[1], D. M. OJEDA-MARTÍNEZ[2], R. Y. RAMOS-SÁNCHEZ[2], C. J. REYES-SEPÚLVEDA[3], P. ALVELO-FERNÁNDEZ[3], D. SIERRA-MERCADO[1];

[1]Univ. of Puerto Rico Sch. of Med., San Juan, PR; [2]Univ. of Puerto Rico Rio Piedras, San Juan, PR; [3]Univ. of Puerto Rico Bayamon, Bayamon, PR

Abstract: Glyphosate-based herbicides (GBH) are the most commonly used herbicides in agriculture. Glyphosate was initially considered safe for mammals because it acts by inhibiting a metabolic route not present in mammals. However, the use of glyphosate has been correlated with an increased diagnosis of neurological diseases such as movement and anxiety disorders. Similarly, recent studies in rodents have shown that GBH causes decreased locomotion and increased anxiety-like behavior through various methods of exposure including intranasal application, oral gavage and intra-peritoneal injections. Additionally, GBH exposure in rats decreased dopamine levels in the striatum. These studies, however, utilized a dose far larger than that to which animals and humans are likely exposed. Also, the experimental methods often used to treat rodents with GBH are unrealistic (i.e. injections and gavage). Therefore, we aimed to evaluate the effect of prolonged oral consumption of drinking water containing low dose GBH on locomotion and anxiety-like behavior. To achieve this, we gave rats access ad libitum to drinking water containing GBH at a concentration of 0.7mg/l, which corresponds to maximum contaminant level allowed by the environmental protection agency, whereas control rats received filtered drinking water. We assessed locomotion and anxiety-like behavior after two weeks of exposure using the open field test. No difference was seen in total distance traveled (control: 28.65, GBH: 31.63; p=0.55), amount of time spent in the center (control: 32.05, GBH: 15.30; p = 0.39), or the amount of entries into the center (control: 14.00, GBH: 9.50; p=0.54). Anxiety-like behavior was reassessed in the elevated plus maze where no difference was seen in the ratio of time spent in the open arm (control: 0.36, GBH: 0.19; p=0.21), ratio of entries into the open arm (control: 0.31 GBH: 0.21; p=0.48), or anxiety index (control: 0.66, GBH: 0.80; p=0.28). In conclusion, GBH did not affect locomotion or anxiety-like behavior through drinking water at a concentration of 0.7mg/l, after two weeks. Future directions include prolonging the exposure time, assessing other emotional memories and performing immunohistochemistry on brain regions involved in locomotion and anxiety-like behaviors.

Title: Effects of atrazine on locomotion and anxiety-like behavior

Authors: *R. Y. RAMOS-SÁNCHEZ[1], M. RIVERA-LÓPEZ[2], M. CÁCERES-CHACÓN[2], O. MARTINEZ-GUZMAN[2], P. ALVELO-FERNÁNDEZ[3], C. J. REYES-SEPÚLVEDA[3], D. OJEDA-MARTÍNEZ[1], D. SIERRA-MERCADO[2];

Abstract: Atrazine (ATR) is a herbicide widely used in agriculture across the globe. Given its excessive use, it has been detected in water systems and has reached drinking water. Intake of ATR has been shown to influence locomotion and anxiety-like behaviors in rodents. For example, recent studies in rodents have shown that ATR consumption can lead to increased locomotion. Therefore, we aimed to evaluate the effect of prolonged oral consumption of drinking water containing the maximum contaminant level of ATR on locomotion and anxiety-like behavior. To achieve this, we gave rats access ad libitum drinking water containing ATR at a concentration of 0.03mg/l, while control rats received filtered drinking water. We assessed locomotion after two weeks of exposure using the open field test. No difference was observed in total distance traveled (Control: 28.65, ATR: 29.98; p=0.76). No difference was seen in the amount of time spent in the center (Control: 32.05, ATR: 7.93; p=0.18. Anxiety-like behavior was assessed using the elevated plus maze, where experimental rats showed 0.66 and 0.72 for controls p=0.62 anxiety-like behavior. Future directions include increased exposure time to drinking water containing atrazine, as well as assessing brain regions important for locomotion and anxiety using immunohistochemistry. These results may help elucidate if prolonged consumption of oral atrazine affects normal behavior.

Title: Perinatal exposure to drugs of abuse causes permanent aberrations in somatosensory circuits

Authors: *J. B. ALIPIO[1], Y. LI[1], C. W. HAGA[2], R. BALAJI[2], M. E. FOX[2], D. EL-METWALLY[1], M. K. LOBO[2], M. PICCIOTTO[3], A. KELLER[1];

Abstract: Perinatal exposure to drugs of abuse during pregnancy and while breastfeeding may cause lasting changes in offspring. Perinatal exposure to nicotine and opioids is associated with—along with other devastating outcomes—permanent changes in sensory processing, suggesting that functional impairments in somatosensory circuits may underlie these neurodevelopmental consequences. We hypothesize that perinatal fentanyl or nicotine exposure permanently alters synaptic transmission in the thalamocortical (TC) and corticothalamic (CT) projections that regulate somatosensory function. Preliminary findings suggest that perinatal fentanyl exposure permanently suppresses excitatory synaptic transmission in both the primary somatosensory cortex (S1) and the ventroposteromedial (VPM) nucleus of the thalamus. This includes a decrease in the probability of evoked glutamate release, a decrease in the frequency and amplitude of miniature excitatory postsynaptic currents (mEPSCs), and a decrease in the ratio of NMDA/AMPA responses. In contrast, perinatal exposure to nicotine caused opposite changes in the TC/CT circuit - an increase in the probability of evoked glutamate release, an enhancement in the frequency and amplitude of mEPSCs, and a decrease in NMDA/AMPA response ratios. Ongoing studies are examining how perinatal drug exposure influences S1 neural activity in vivo, using electrocorticogram (ECoG) recordings of neural oscillations in awake behaving mice. These studies will contribute to our understanding of the enduring consequences associated with perinatal exposure to drugs of abuse, impact on infant neurodevelopment, and potentially inform improved treatment options.

Title: Buprenorphine exposure during gestation results in dose-dependent consequences for the dam and her litter in a translational model of opioid-maintenance therapy

Authors: *C. M. WALLIN, S. E. BOWEN, S. BRUMMELTE;
Psychology, Wayne State Univ., Detroit, MI

Abstract: Significance: The opioid crisis has led to increases in pregnant opioid-dependent women treated with opioid-maintenance therapy (buprenorphine, BUP). However, not much is known about the consequences of gestational BUP exposure on pregnancy outcomes or fetal development. Previous work has not accounted for the critical fact that women are likely already using opioids at the time of conception and continue to use throughout the postpartum. Unsurprisingly, the initiation of drug use in a new user has considerable physiological effects as compared to a regular user, which necessitates consideration. **Method:** Our translational animal model aimed to resemble human BUP treatment therapy by starting vehicle or BUP exposure subcutaneously (s.c.) in adult female Sprague-Dawley rats (N=30) at least 7 days before conception and continuing exposure throughout the postpartum period. We evaluated effects of *therapeutic* (low-dose, 0.3 mg/kg) and *overexposure* (high-dose, 1 mg/kg) BUP exposure against saline-control (1 mg/mL). Females were randomly assigned to exposure groups (n=10/group) and were bred in house with drug-naïve adult male Sprague-Dawley rats. At parturition, successful litters (N=26) were culled to 5 males/5 females per litter. One male and one female from each litter were randomly assigned to various behavioral tests during either the neonatal period (precipitated withdrawal, postnatal day (PN) 2) or during adolescence (anxiety-like behavior, stress-sensitivity, nociceptive response). Pregnancy outcomes, maternal care behavior, neonatal opioid withdrawal syndrome (NOWS), as well as offspring development were evaluated. **Results:** *Overexposure* (high-dose) BUP exposure resulted in increased pup mortality, increased symptoms of NOWS, and decreased maternal care behavior. In fact, most high-dose BUP pups did not survive past PN 2. *Therapeutic* (low-dose) BUP exposure delayed offspring development, decreased body weight, length, and body temperature, as well as increased tolerance to morphine's analgesic effect (p's < .05). **Conclusion:** Overall our results demonstrate that the *therapeutic* (low-dose) level of BUP was relatively safe though it did have subtle effects on exposed offspring. However, the *overexposure* (high-dose) level of BUP interfered with maternal caregiving behavior and thus offspring survival and increased NOWS. More research is needed to validate the translational implication of these findings for human opioid-dependent mothers maintained on buprenorphine-maintenance therapy or other opioids.

Title: Effects of prenatal cocaine exposure in the neurodevelopment of DAT-Cnr2 and Cx3cr1-Cnr2 conditional knockout mice

Authors: *A. CANSECO-ALBA[1], M. A. HAMMOUDA[2], Q.-R. LIU[4], E. S. ONAIVI[3]; [1]CINVESTAV-IPN, Mexico City, Mexico; [2]William Paterson Univ., Carlstadt, NJ; [3]William Paterson Univ., Wayne, NJ; [4]LCI/NIA/NIH, Baltimore, MD

Abstract: The endocannabinoid system (eCB), including endocannabinoids and their receptors (CB1Rs and CB2Rs) has been detected from the earliest stages of embryonic development and throughout pre- and postnatal development. Consequently, the eCB may play an important role in neurodevelopment. The presence of CB2 receptors in microglia cells and neurons of discrete parts of the brain has been demonstrated. Therefore, the functional relevance of the CB2 receptors in the CNS is emerging. Through the use of new genetic strategies like the generation of conditional knock-out mice, new possibilities are open, in studying the role of the components of the ECS system and in particular, CB2 receptors. The objective of this study was to evaluate the postnatal behavioral development of mice which do not express cannabinoid CB2 receptors in dopaminergic neurons and microglia (DAT-*Cnr2* and CX3cr1-*Cnr2* cKO mice), and to evaluate the effect of perinatal exposure to cocaine in these animals on the neurodevelopmental features of the conditional knockout mice in comparison with the wild type (WT) mice. Ultrasonic vocalizations (USVs), physical development, and reflex activities of the pups from postnatal day 1 to the weaning day were analyzed. A separate group of pregnant cKO females received subcutaneous cocaine injections of 20 mg/kg from gestational days 7 through 17. We report that cocaine treatment of pregnant dams decreased their weight gain during pregnancy in all genotypes. CX3cr1-*Cnr2* cKO mice treated with cocaine show a significant decrease in the number of pups, and this group presented the lowest survival rate. DAT-*Cnr2* cKO pups started crawling and walking sooner than the WT mice, but this feature was lost in the group treated with cocaine. We concluded that the deletion of CB2Rs in dopamine neurons and microglia revealed a neuro-immuno- modulatory effects of CB2Rs in the psychostimulant effects of cocaine.

Title: Prenatal exposure to opioid maintenance treatment reduces cognitive performance in young adult rats

Authors: *M. KONGSTORP[1,3], I. BOGEN[1,4], T. STIRIS[3,2], J. M. ANDERSEN[1,5];
[1]Dept. of Forensic Sci., [2]Dept. of Neonatal Intensive Care, Oslo Univ. Hosp., Oslo, Norway; [3]Inst. of Clin. Medicine, Fac. of Med., [4]Inst. of Basic Med. Sciences, Fac. of Med., [5]Dept. of Pharm., Univ. of Oslo, Oslo, Norway

Abstract: Background and aim: Current knowledge concerning cognitive performance in children born to mothers in opioid maintenance treatment (OMT) is limited and conflicting. In humans OMT is associated with multiple confounding factors making it difficult to draw conclusions about prenatal opioid exposure and its subsequent effects. Hence, the aim of this study was to examine the possible effects on learning and memory in young adult rats prenatally exposed to methadone or buprenorphine.
Methods: Female rats were implanted with 28-day osmotic minipumps delivering methadone (10 mg/kg/day), buprenorphine (1 mg/kg/day) or vehicle 5 days prior to mating. To examine possible effects on learning and memory, the offspring were included in three different behavioral tests. At 7 weeks of age, the offspring underwent the simultaneous brightness discrimination (SBD) test, which reflects non-spatial reference memory. At 8 weeks of age, the rats were included in a novel object recognition test. Finally, the Morris water maze (MWM) test was used to investigate spatial learning and memory in 10 weeks old offspring.
Results: Young adult rats prenatally exposed to methadone or buprenorphine exhibited impaired non-spatial reference memory and recognition memory, shown by reduced performance in the SBD and novel object recognition tests. In the MWM, all animals displayed normal learning abilities, however, methadone exposed offspring displayed impaired spatial memory in the retention task performed 8 days after the learning sessions.
Conclusions: Our study shows that prenatal exposure to methadone or buprenorphine causes impaired cognitive performance in young adult rats. This is of major concern given the escalating increase in opioid use and OMT among fertile women.

Title: Transgenerational epigenetic inheritance associated with prescription opioids abuse: How far has the apple fallen from the tree?

Authors: K. ODEGAARD[1], V. SCHAAL[2], D. MOORE[3], A. CLARK[4], G. PENDYALA[2], ***S. V. YELAMANCHILI**[1];
[1]Pharmacol. and Exptl. Neurosci., [2]Dept. of Anesthesiol., [3]Univ. of Nebraska Med. Ctr., Omaha, NE; [4]Creighton Univ., Omaha, NE

Abstract: Recent statistics from the Centers for Disease Control and Prevention (CDC) show that every day, more than 115 Americans die from overdosing on opioids including heroin as well as prescription opioid pain relievers. Adding another layer of complexity is the increased risk of dependency on prescription opioids such as oxycodone (oxy) during pregnancy and postpartum. Although limited studies have linked maladaptive behaviors and cognitive deficits in exposed offspring, a significant knowledge gap remains in understanding how short- and long-term oxy exposure impacts the epigenetic architecture in the exposed offspring and whether these changes persist in the subsequent generations. We, accordingly have developed an animal model using Sprague Dawley rats to mimic oxy exposure *in utero* and in post-natal pups to examine long-term consequences of its abuse on the exposed offspring (F1) as well as on subsequent generations (F2) in the absence of drug exposure. Using RNA-Seq on RNA isolated from the nucleus accumbens (NAc), a region of the brain involved in reward and sensitive to drug abuse, we identified key changes in genes associated with synaptic signaling and neuron differentiation in both the F1 and F2 generations of each group. Western blot experiments done on synaptosomes isolated from the prefrontal cortex of both F1 and F2 P14 pups show differences in the expression of synaptic genes, such as EAAT2, synaptophysin, and PSD95, among the control, *in utero*, and postnatal groups. We also identified phenotypic differences (head size, body weight, and body length) among the groups in both generations. To further elucidate how these changes impact glutamatergic and dopaminergic systems, we conducted behavioral tests to assess repetitive behaviors and social alterations among the experimental groups and between the two generations. Sex differences were also considered during the behavior tasks. Given the increased use of opiates (both medical and non-medical),

understanding the persistent developmental effects of these drugs will delineate potential risks associated with opiate use beyond the direct effects on the user.

Title: Assessing physiological and behavioral changes in rodents following *in utero* opioid exposure

Authors: *S. STEVENS[1,2], S. MOHAN[1];
[1]Manchester Col. of Pharm., Fort Wayne, IN; [2]Dept. of Pharmaceut. Sci. and Res., Marshall Univ. Sch. of Pharm., Huntington, WV

Abstract: As opioid use among pregnant woman increases, the number of infants born with neonatal abstinence syndrome (NAS) continues to rise. Although the short term withdrawal symptoms are well characterized, the neuropathology behind opioid-mediated NAS and the long term effects on behavior and memory are unclear and warrants further research.
Current preclinical models of NAS are limited by short gestational periods, large litter sizes and primary organogenesis occurring after birth. Using a novel mouse model with an extended gestational period, we aim to study the short and long term effects of *in utero* morphine exposure by assessing withdrawal behavior, memory and investigating key cellular mediators underlying neuropathology of NAS. To model maternal opioid use, dams were treated daily with saline or morphine 10 and 30 mg/kg S.C. beginning on G18 until day of birth; this resulted in a cumulative exposure for 19-21 days. Physiological (body weight, body temperature) and withdrawal behaviors (jumps, wet dog shakes and ultrasonic vocalizations) for each pup were recorded daily for the first eight days.
Differences in memory were measured using Y-maze and novel object recognition tests starting at one month of age. Preliminary data from 3 month-old mice born exposed to morphine were found to exhibit increased physiological changes and withdrawal behavior commonly associated with opioid withdrawal. Additionally, decreased Y-maze performance was found in morphine exposed mice compared to saline treated mice.
These data suggests that our method of *in utero* morphine exposure does result in postnatal withdrawal behavior. A decrease in Y-maze performance suggests deficits in learning and memory in adult mice that were prenatally exposed to morphine. Further studies are currently in progress to determine any underlying cellular changes responsible for these differences. These

results coupled with the lengthened gestational period, small litter size and increased prenatal organogenesis make this mouse model of *in utero* opioid exposure an improved translational model of NAS compared to current animal models.
We are hopeful this novel mouse model will further our understanding of the consequences of *in utero* opioid exposure on neurodevelopment and behavior.

Title: Using human brain organoids to model prenatal buprenorphine exposure

Authors: *J. J. DONEGAN[1], H. ELAM[1], V. NIETO-ESTEVEZ[2], C. MCMAHON[2], J. HSIEH[2], D. LODGE[1];
[1]Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX; [2]Biol. and Brain Hlth. Consortium, Univ. of Texas at San Antonio, San Antonio, TX

Abstract: The misuse of opioids has reached epidemic proportions over the last decade, with over 1.5 million people in the U.S. suffering from substance use disorders related to prescription opioid pain relievers. This increase in opioid misuse affects all demographics of society, including women of child-bearing age, which has led to a rise in opioid use during pregnancy. Infants exposed to opioids *in utero* show an increased risk for neurological and behavioral deficits, including neonatal abstinence syndrome, a cluster of withdrawal symptoms that include tremors, diarrhea, fever, irritability, and seizures. Currently, opioid use disorder in pregnant women is treated with long-acting opioid agonists, including buprenorphine. Although buprenorphine is widely considered safe for the developing fetus, few long-term studies have been conducted. The goal of the current experiments was to examine the consequences of buprenorphine on the developing human brain. While prenatal opioid exposure can be modeled in rodents, species differences limit our ability to recapitulate all aspects of human nervous system development. Therefore, we used human induced pluripotent stem cells to grow 3D brain cell cultures that model the cellular diversity, connectivity, and activity of the developing human brain. Specifically, we used patterning factors to generate dorsal forebrain progenitors (cortical organoids) or ventral forebrain progenitors (subcortical spheroids). RNA Sequencing and

immunohistochemistry were used to confirm cortical or subcortical specificity. To then measure the effect of buprenorphine exposure on neuronal network properties, cortical or subcortical spheroids were treated with buprenorphine (2 ng/ml) at various time points during development and multielectrode arrays were used to record neuronal activity. Immunohistochemistry was used to measure markers of cortical development. Finally, to model the developmental process by which inhibitory interneurons migrate tangentially into the cerebral cortex, cortical and subcortical spheroids were fused in the presence of buprenorphine. Interneuron progenitors were labelled with a GFP tag and migration was monitored using a confocal microscope. Together, our results will provide new information about the developmental consequences of buprenorphine exposure during development and may ultimately lead to new therapeutic strategies to treat infants exposed to opioids *in utero*.

Title: Characterizing the impact of prenatal drug exposure on emotion processing: Findings from the ABCD study

Authors: *A. WAGNER[1], A. RAMAKRISHNAN[2], I. IVANOV[3], M. A. PARVAZ[3]; [1]Psychiatry, Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Biomed. Informatics, Rutgers Sch. of Hlth. Professions, Newark, NJ; [3]Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Background: Prenatal drug exposure has shown to alter the trajectory of neurodevelopment and put an individual at risk for impairments long before functional disorders arise. Adolescence is a period where atypical development becomes apparent in behavior and brain function that can lead to psychiatric illnesses including mood and anxiety disorders, and substance abuse. However, the current literature on precise neural underpinnings of prenatal drug exposure and their manifestations on behavior is sparse, ambiguous, and primarily based on small cohort studies. Therefore, here we leverage data from the Adolescent Brain Cognitive Development (ABCD) study to determine the effects of prenatal drug exposure on working memory and emotional arousal and the underlying brain activity. Methods: From 8,829 children with fMRI data in the ABCD cohort, we defined groups by extent of prenatal drug exposure based on mothers' self-report of drug use during pregnancy: continued exposure (CDE; continued use after pregnancy confirmation), limited exposure (LDE; discontinued use after

pregnancy confirmation), and no exposure (NDE). The N-back fMRI task with emotionally-salient stimuli was used to assess emotion processing during a task which demanded working memory. The primary outcomes were task performance, and brain activity of pre-selected (based on a prior systematic review) regions of interest (inferior frontal gyrus, dorsolateral prefrontal cortex, ventromedial prefrontal cortex, and amygdala). Results: After adjusting for the mother's age at birth, task performance showed main effects of Memory [$F(1,8578)=225.7$, $p<0.001$)], Emotion [$F(2,8577)=4.9$, $p=0.007$)], Stimulus [$F(2,8577)=699.7$, $p<0.001$)], and Exposure [$F(2,8578)=5.008$, $p=0.007$)] as well as Stimulus*Exposure [$F(4,17156)=4.6$, $p=0.001$)] and Memory*Stimulus*Exposure [$F(4,17156)=3.2$, $p=0.001$)] interactions. These differences in task performance as well as in regional brain activations are being further explored and will be included in the final presentation. Conclusion: Although previous studies show that prenatal drug exposure is associated with differences in brain function, those findings should be replicated in a larger study. The ABCD study presents an opportunity to answer important questions about the effects of prenatal drug exposure on development.

Title: Alcohol and tobacco use during pregnancy: A Native American perspective

Authors: *R. C. ROSENTHAL[1], K. E. CONNER[2], K. J. HUFFMAN[1];
[1]Psychology, [2]Interdepartmental Neurosci. Program, Univ. of California, Riverside, Riverside, CA

Abstract: Tobacco and alcohol abuse are prevalent among Native Americans. Thus, Native American offspring are at risk for toxic prenatal exposures. Of specific concern are prenatal nicotine exposure (PNE) and prenatal alcohol, or ethanol exposure (PrEE), as these maternal consumptions may induce developmental brain damage leading to cognitive-behavioral deficits (Abbott et al., 2018). A primary goal of this study is to elucidate preconceived ideologies and the significance they play in children's health, in a specific population where tobacco and alcohol abuse is prominent. For example, the U.S. Department of Health and Human Services reports high incidence rates for Fetal Alcohol Syndrome (FAS) in Alaska (1.5 per 1,000 live births) and, within Native Americans and Alaskan Natives specifically, the rate rises to 5.6. Also, considering the prevalence of teenage pregnancy in the Native American population, it is important to gain insight on individuals' beliefs about what is acceptable, customary and safe to

consume during pregnancy. This project examines Native Americans' perceptions of the use of tobacco (ceremonial and recreational smoking), alcohol, cannabis, certain medications, as well as nutritional choices and sweat lodge practices during pregnancy. Using an online survey, we investigate beliefs about consumption safety during pregnancy in young Native Americans, age 18 to 25, throughout the United States. Our results suggest tribal differences in beliefs about tobacco use during pregnancy. Specifically, some tribes view ceremonial tobacco practices as safe, whereas most believe recreational tobacco is unsafe to use during pregnancy. Additionally, survey data suggest individual differences in beliefs about the safety of alcohol consumption during pregnancy; some subjects perceive wine and beer as safe, while others view all alcohol consumption as unsafe. Regional tribal differences were observed concerning the perceived safety of salmon consumption during pregnancy. Salmon contains polychlorinated biphenyls (PCBs) which are known developmental teratogens. Our results indicate that Alaskan Natives consider salmon safe but red meat unsafe to consume during pregnancy, whereas southwestern tribes believe the reverse. It is important to identify populations that consume or use substances that may cause developmental harm. Nicotine, alcohol and PCBs are examples of teratogens that are known to impact brain development and have lasting behavioral effects on offspring. Pregnancy is a sensitive period, understanding how Native Americans view maternal practices during pregnancy will elucidate gaps in awareness and guide educational outreach.

Title: Modulation of polysialated neural cell adhesion molecules (PSA-NCAM) ameliorates learning and memory deficits associated with prenatal cannabinoid exposure

Authors: *P. D. PINKY[1], J. BLOEMER[1], Y. DU[1], S. E. SETTI[1], R. T. HESLIN[1], W. D. SMITH[1], A. DITYATEV[2], M. N. REED[1], V. SUPPIRAMANIAM[1];
[1]Drug Discovery and Develop., Auburn Univ., Auburn, AL; [2]German Ctr. for Neurodegenerative Dis., Magdeburg, Germany

Abstract: Cannabis is currently the most commonly used illicit drug in the United States, and becoming more popular in pregnant women based on its anti-emetic properties in alleviation of morning sickness. The active ingredient of cannabis is delta-9-tetrahydrocannabinol (THC) which crosses blood placental barrier to reach the fetus causing enduring alterations in synaptic circuitry responsible for cognition and behavior. The aim of our study is to investigate the mechanisms of learning and memory deficits in prenatal cannabinoid exposure (PCE) in

adolescent offspring. We hypothesize that PCE induced reduction in neural cell adhesion molecule (NCAM) and its active form polysialated NCAM (PSA-NCAM) are responsible for glutamatergic neurotransmission mediated deficits in learning and memory. We have performed a series of behavioral, electrophysiological and immunochemical studies to identify the mechanisms of memory deficits in PCE. An osmotic pump filled with either vehicle or the cannabinoid receptor full agonist WIN55,212-2 (2 mg/kg body weight/day) was implanted subcutaneously on Gestational Day-3 to deliver the drug at a constant rate until the pups were born. Open field test was performed to determine the effects of PCE on locomotor activity, and found no difference in general motor activity. Contextual fear conditioning revealed a significantly reduced freezing behavior in the PCE group compared to the vehicle exposed group. The hippocampus based spatial memory test, Morris water maze, revealed a preference for the platform quadrant in control animals, while the PCE animals did not show any preference for a particular quadrant. Electrophysiological experiments were performed on acute hippocampal slices to measure synaptic plasticity. Impairment in both long term potentiation (LTP) and long term depression (LTD) were observed. These impairments were mirrored by alterations in expression of glutamate receptor subtype N-methyl-D-aspartate receptors (NMDAR). An increase in cannabinoid receptor type 1 (CB1) expression along with reduced PSA-NCAM expression have been observed in western blot analysis. The LTP in the PCE group was improved when E.coli derived colominic acid sodium salt was applied on acutely isolated hippocampus slices. Based on the previous studies along with our data, it can be postulated that the observed hippocampus based behavioral deficits could be due to altered NMDAR mediated glutamatergic neurotransmission associated with reduction in PSA-NCAM expression. Present study provides evidence that modulation of NMDA receptors as possible therapeutic option to improve PCE mediated memory deficits.

Title: Prenatal ethanol exposure and enduring effects on pyramidal neuron function in the somatosensory cortex

Authors: *L. C. DELATOUR, P. W. YEH, H. H. YEH;
Mol. and Systems Biol., The Geisel Sch. of Med. At Dartmouth, Hanover, NH

Abstract: Fetal alcohol spectrum disorders (FASD) represent the broad range of cognitive and behavioral deficits associated with prenatal exposure to ethanol. Previous work demonstrated the effects of *in utero* exposure to binge-type ethanol on the radial migration of primordial pyramidal neurons and the form and function of pyramidal neurons in the somatosensory cortex of early postnatal mice. Specifically, changes in spontaneous synaptic activity in layer V/VI pyramidal neurons resulted in a shift in the excitatory/inhibitory balance in postnatal day 9-11 mice. However, the mechanisms underlying these changes and whether they would persist are unknown. We therefore asked how prenatal ethanol exposure affects synaptic strength and pyramidal neuron morphology in the somatosensory cortex in the long-term.
Pregnant mice were exposed to either a liquid food diet containing ethanol (5% w/w) or an isocaloric control from embryonic day 13.5 through 16.5 and both male and female offspring were analyzed. Whole-cell patch clamp electrophysiology revealed an increase in the frequency of spontaneous and miniature synaptic activity in layer V/VI pyramidal neurons in the somatosensory cortex of postnatal day 28-32 mice. Furthermore, optogenetic experiments conducted in Emx1$^{\text{IRES } Cre}$-Ai32 and Nkx2.1Cre-Ai32 mice to investigate paired-pulse-evoked EPSC and IPSC responses, respectively, revealed a change in the release probability of neurotransmitter following prenatal exposure to ethanol. These changes in function were found in the absence of any changes in the dendritic morphology of layer V/VI pyramidal neurons in the control and ethanol-exposed cohorts. These data suggest an effect of ethanol on the presynaptic terminal, resulting in a shift in the excitatory/inhibitory balance. However, a prominent presynaptic mechanism does not preclude an effect of prenatal ethanol exposure on the postsynaptic terminal. In fact, we found a significant change in the density and morphology of spines along the apical dendrites in layer V/VI pyramidal neurons following prenatal ethanol exposure. However, a potential postsynaptic mechanism needs to be addressed systematically. Our findings indicate that prenatal ethanol exposure exerts long-term effects on synaptic strength with a prominent effect on the presynaptic terminal. Furthermore, we demonstrate that morphology does not necessarily predict function, especially during development. These data strongly support an enduring effect of prenatal ethanol exposure on the function of pyramidal neurons in the somatosensory cortex and contribute to our understanding of the underlying etiology of FASD.

Abstract: Maternal binge alcohol drinking during the developmental brain stage can produce deleterious effects on the fetus. In the utero, alcohol exposure may lead to a wide range of morphological and behavioral long-lasting consequences known as fetal alcohol spectrum disorders, which the most severe type is the fetal alcohol syndrome. We aimed to assess the effect of prenatal and lactational alcohol exposure (PLAE) on the reinforcing effects of alcohol during the adulthood. Furthermore, we assessed the possible neurobiological mechanisms underlying the addictive effects of alcohol, such as the opioid system in brain areas involved in drug intake. Pregnant C57BL/6 female mice were exposed to binge alcohol drinking throughout gestation up to weaning. Then, male offspring performed the two bottle choice paradigm induced by alcohol, at early adulthood. After that, brain samples were analyzed by qPCR to quantify the mu and kappa opioid receptors. Our findings demonstrate that PLAE produces an increase of alcohol intake in the two bottles choice procedure. The qPCR analysis of the prefrontal cortex, striatum and amygdala did not display changes in the expression of the evaluated receptors. The current study highlights that PLAE animals increased alcohol consumption due to a lower sensitivity to the pleasant effects of alcohol. The pattern of alcohol consumption used in our study may not be enough intense or prolonged to cause changes in the receptors. For future

research, it may be interesting to analyze the opioid peptides as they have been involved in alcohol reward.

Title: Prenatal ethanol exposure affects the development of GABAergic interneurons in the striatum

Authors: *A. R. TOUSLEY, H. YEH, P. YEH;
Mol. and Systems Biol., Geisel Sch. of Med. at Dartmouth, Hanover, NH

Abstract: Fetal Alcohol Spectrum Disorder (FASD) is a neurodevelopmental disorder that presents with varying degrees of cognitive and behavioral dysfunction including hyperactivity and behavioral inflexibility. Imaging studies have found striatal dysmorphology and changes to corticostriate connectivity to be associated with FASD diagnosis and symptom severity. However, less is known about how FASD-related striatal changes develop. Previous work in the lab has shown that prenatal alcohol exposure (PAE) can increase both the number of GABAergic interneurons in the developing cortex and neurogenesis in the medial ganglionic eminence (MGE), where cortical interneurons are born. Here we asked if PAE affects the migration and function of striatal interneurons, which are also born in and migrate from the MGE into the striatum during the same time period.
We chose to assess the density of striatal interneurons on embryonic day 16.5 (E16.5) in Nkx2.1Cre/Tdtomato mice exposed to 5% binge ethanol during the peak of tangential migration (E13.5-16.5). We found that E16.5 animals exposed to ethanol have an altered distribution of GABAergic interneurons compared to control animals, with the density of interneurons in the dorsal striatum increased and that of the ventral striatum unchanged. This observation suggests an accelerated migration of GABAergic interneurons into the dorsal striatum.
Ongoing studies will clarify how this embryonic change in interneuron distribution influences striatal GABAergic circuit formation post-natally. We are assessing the onset, frequency and amplitude of spontaneous GABAergic and glutamatergic activity in Nkx2.1+ interneurons in the developing striatum during the first two postnatal weeks. Preliminary observations point to an

earlier onset of inhibitory and excitatory synaptic activity in the striatum of neonatal mice. Our results indicate that altered interneuron development in the striatum could contribute to PAE-related pathology. Future experiments will allow us to continue to explore the potential role of striatal interneuronopathy and altered inhibitory circuit formation on the development of behavioral and cognitive changes related to PAE.

Title: Long-term consequences of perinatal opioid exposure

Authors: *H. J. HARDER, L. HANUS, C. SEARLES, W. KENKEL, A. Z. MURPHY; Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: The incidence rate of infants born exposed to opioids during gestation has increased over 400% in the last decade. However, current preclinical models of perinatal opioid exposure (POE) lack clinical relevance and translatability such that these models typically utilize a truncated schedule of opioid exposure restricted to the second embryonic week in the rodent (roughly equivalent to the second trimester in humans). In contrast, women with an opioid use disorder do not restrict their use to pregnancy, but rather, are more likely to initiate drug use in adolescence, become pregnant, and continue opioid use throughout pregnancy. As such, the ability to translate the results from preclinical models are limited. We have developed a novel, more clinically-relevant model of gestational opioid exposure that allows for the assessment of potential long-term consequences on the offspring. In this model, female Sprague Dawley rats are implanted with slow release morphine pellets (75 mg; NIDA) beginning in early adulthood (P40), continuing through gestation, and ending following weaning. Morphine pellets are replaced every two weeks allowing for regular exposure to morphine at clinically relevant plasma levels. Pups are indirectly exposed to morphine via the dam for the entire gestational period, including lactation. Following parturition, pups are tested on a battery of behavioral assays known to be influenced by opioids and/or early life experience. These assays include juvenile play, response to acute and chronic anxiety and stress, nociceptive sensitivity and morphine efficacy, and response to an immune challenge. Parallel changes in the neurocircuitry underlying opioid signaling will further delineate the impact of perinatal opioid exposure. Generation of a complete phenotype (behavioral, anatomical and molecular) of domains

impacted by a highly translatable model of perinatal opioid exposure will facilitate the development of new targeted pharmacotherapies for the amelioration of the long-term consequences, which are largely unknown in the human population.

Title: Late maturing influence of immune activation on morphine withdrawal and tolerance in the infant rat

Authors: S. WANG[1], *B. S. EAST, Jr[2], G. A. BARR[1];
[1]Children's Hosp. of Philadelphia, Philadelphia, NY; [2]Nathan Kline Inst., Orangeburg, NY

Abstract: Between 50-80% of infants in the neonatal intensive care unit are dependent on opiates by the end of their medical treatment. Many of these infants have on-going infections. Best current medical practice is to provide declining amounts of opiates to taper the infant patient off the drugs. As such, this prolongs hospitalization and constitutes a significant burden on the health care system, and an emotional burden on the family whose child remains in the hospital, and has unknown consequences for subsequent development of the newborn. We know little about opiate dependence in the neonate, except that it differs in important mechanisms from dependence in the adult. We also know that there is interplay between opioids and the immune system. Whether that immune- chronic opioid interplay is present or not in the infant has not been studied and thus is not known, despite how common infection is in these babies. We tested the effects of activating the immune system with LPS during chronic morphine treatment in the first or third week of life in the infant rat and tested for precipitated withdrawal or analgesic tolerance, mRNA and protein for immune-related markers. Around weaning (PN21) LPS worsened affective (ultrasonic vocalizations) aspects of withdrawal but not the physical (behavioral signs) aspects. The same immune activating treatment in 7 day old (PN07) infant rats had small protective effect on USV and on behavioral signs, reducing both. Fos-positive cells were increased in the PAG and NAcc, in withdrawal at PN21 only. There were no changes induced by LPS on morphine induced tolerance at either age. These behavioral changes were accompanied by age-dependent differences in the expression of immune-related markers in the

spinal cord and brain. Morphine was immunosuppressant for expression of cytokines at both ages in the spinal cord but only in the older animals in the periaqueductal gray. There were no differences between ages in the number of microglia or astrocytes as a result of LPS treatment . Thus, the effects of activating the immune system during development are late developing in altering precipitated withdrawal and in some but not all aspects of immune function.

Title: Effects of early fentanyl exposure on morphine-induced antinociception

Authors: *G. I. PARK, J. A. TAYLOR, J. W. RIOS, J. A. BUNCH, C. A. CRAWFORD; California State Univ. San Bernardino, San Bernardino, CA

Abstract: Opioid use has reached epidemic levels in the United States. There has been a 200% increase in opioid overdose (poisoning) deaths since 2000, and 61% of all drug overdose deaths now involve opioids. An unfortunate consequence of this crisis has been the increase in opioid use in women of childbearing age. Because of the large number of children potentially affected, it is important to understand the long-term consequences of early opioid exposure. While there is an older literature examining the effects of morphine and heroin, there are relatively few studies assessing at the long-term effects of high potency synthetic opioid compounds like fentanyl. Thus, in the present study we examined whether repeated fentanyl during the early neonate period alters later opioid-mediated behaviors. To examine this issue, we assessed the antinociceptive effects of morphine using the tail flick and hot plate tasks. Male and female rats (n =7-8) were exposed to fentanyl (0, 1, 10, 33 or 100 µg/kg, sc) for 6 consecutive days starting on PD 4. On PD 60, rats were habituated to a tail flick apparatus and a room temperature hot plate. On the following day, tail-flick and paw-lick latencies were measured three times in sequence, with a 10 min interval between trials. After these baseline trials, rats were injected with morphine (0, 1.25, 2.5, 5, or 10 mg/kg, sc) and returned to their home cage for 20 min. Rats were subsequently tested three times on the tail flick and hot plate tasks, with a 10 min interval between each test. As expected, morphine caused a dose-dependent increase in tail flick and paw lick latencies. This morphine-induced effect varied according to pretreatment condition, sex, and analgesic task. Specifically, fentanyl (100 µg/kg) pretreatment reduced the effect of morphine (10 mg/kg) on the hotplate task, while potentiating the antinociception effects of morphine (1.25 mg/kg) on the tail flick task. Interestingly, the effects of fentanyl were only significant in female

rats. The present data suggest that early exposure to fentanyl may have long-term consequences on the functioning of the opioid receptor system of adult female rats.

Title: Effects of caffeine and/or ethanol exposure during development on anxiety-like behavior and learning and memory of adolescent mice

Authors: *A. N. FREITAS, A. C. C. CARVALHO-SILVA, P. C. LISBOA, A. C. MANHÃES, Y. ABREU-VILLAÇA, C. C. FILGUEIRAS;
Univ. do Estado do Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: In spite of epidemiological evidence of the concomitant use of caffeine and ethanol by pregnant women, the consequences of this combined exposure during development have received little attention in experimental studies. In this work we investigated the effects of co-exposure to caffeine and ethanol during development on the anxiety-like behavior, learning and memory, and cortical levels of oxidative stress of adolescent mice. Adult female Swiss mice received one of two concentrations of caffeine (0.1g/L; n=14 or 0.3g/L; n=12) in the drinking water during 7 days before mating. Exposure persisted until their pups were 21 days-old. Control mice (n=10) had ad libitum access to tap water. Every other day, from PN2 to PN8, animals in each litter were injected (i.p) with one of the following solutions: 0.25 µl/g ethanol (ETOH25), 0.5 µl/g ethanol (ETOH50) or saline solution (SAL). From PN30 to PN35 mice were submitted to behavioral tests. Anxiety-like behavior was assessed in elevated plus maze test (EPM) and learning and memory in passive avoidance paradigm (PA). On PN9, cortical levels of oxidative stress were evaluated by the measurement of thiobarbituric acid reactive species (TBARS), antioxidant capacity (DPPH) and protein carbonylation. In EPM, ethanol promoted a dose-dependent decrease in anxiety-like behavior, mice from ETOH50 group spent less time and had fewer entries in open arms than those mice from ETOH25 and SAL groups. Interestingly, in the group of mice exposed to 0.3 g/L of caffeine, anxiety-like behaviors were not affected by ethanol exposure. While caffeine did not affect behavior of mice in PA, learning and memory deficits were found only in males exposed to ethanol. In spite of ethanol did not change oxidative stress

levels, caffeine had a marked antioxidant effect in all oxidative stress assays. Our data corroborate other studies that show that early exposure to ethanol promotes a number of neurobehavioral disorders. Furthermore, we suggest that caffeine exposure during development has a protective effect on deleterious effects of ethanol.

Title: Effects of adolescent sucrose consumption on resistance to punished cocaine in adult male and female rats

Authors: R. PARMAR[1], M. M. COBB[3], R. ARANGO[4], J. PARENT[4], M. CRAWFORD[4], C. RAMIREZ[4], I. C. SUMAYA[2], ***A. M. GANCARZ-KAUSCH**[5];
[1]Psychology, [2]Psychology - 24 DDH, California State Univ. Bakersfield, Bakersfield, CA; [3]Psychology, UCLA, Los Angeles, CA; [5]Psychology, [4]California State University, Bakersfield, Bakersfield, CA

Abstract: Environmental challenges during this crucial time of neural plasticity could potentially result in dire neurodevelopment and behavior consequences in adulthood. It is known that exposure to drugs of abuse during adolescence increases future susceptibility to drug addiction in adulthood, yet little is known about exposure to other natural stimuli that may also alter functioning of the mesolimbic dopamine circuitry and their effects on drug abuse in adulthood. Given that natural and drug reinforcers activate the same neural circuitry (Wise & Rompe, 1989), this pathway may also be responsible for such increases in reactivity to natural reinforcers (sucrose) during the adolescent period. Further research is needed to understand exposure to naturally rewarding stimuli during the adolescent period that may alter functioning and behavior. Here, we seek to understand how exposure to sucrose could alter behavior in adulthood. In order to test this, male and female adolescent rats (PND 28-42) were exposed to either 10 % noncontingent sucrose or water delivery in fourteen 30 min sessions in operant settings. In adulthood, rats were fitted with chronic indwelling jugular catheters and allowed to recover (PND 51-53). Rats were then tested for cocaine self-administration (PND 54-60). During this phase, rats emitted an active response to receive 1.0 mg/kg/infusion of cocaine according to a Fixed Ratio 1 (FR1) schedule of reinforcement. The schedule was increased to FR5 across the 7 days of testing. Following this phase, rats were then tested for resistance to punished cocaine self-administration (PND 61-65), which included a cocktail of cocaine and histamine. Histamine

was used to produce an aversive, delocalized itching sensation throughout the body that has previously been shown to act as an aversive stimulus. We hypothesized that rats exposed to non-contingent sucrose solution during the adolescent period would self-administer significantly greater number of infusions of cocaine/histamine compared to rats exposed to water. Sucrose treated adolescent male and female rats self-administered significantly more infusions of the cocaine/histamine cocktail compared to water exposed controls suggesting sucrose exposure increased resistance to punished cocaine in adulthood.

Title: Adolescent nicotine exposure induces long-term depressive and anxiety-like effects through hyper-phosphorylation of the ERK 1-2 and Akt-GSK-3 pathways and neuronal oscillatory dysregulation in the nucleus accumbens

Authors: *S. R. LAVIOLETTE[1], R. M. HUDSON[2], M. GREEN[4], T. D. JUNG[5], J. RENARD[6], C. E. JOBSON[3], W. J. RUSHLOW[7];
[1]Anat. & Cell Biol., [2]Neurosci., [3]Neurosci. - Dept. Anat. and Cell Biol., Univ. of Western Ontario, London, ON, Canada; [4]Brock Univ., St Catharines, ON, Canada; [5]Anat. and Cell Biol., Western Univ., London, ON, Canada; [6]Anat. and Cell Biol., Western Ontario Univ., London, ON, Canada; [7]Dept of Anat. and Cell Biol., UWO, London, ON, Canada

Abstract: Nicotine dependence typically develops during adolescence and is associated with a variety of neuropsychiatric co-morbidities, including mood and anxiety disorders. Neurodevelopmental nicotine exposure has been reported to influence the later development of affective and anxiety-related behaviours in both clinical and pre-clinical studies. The mammalian nucleus accumbens shell (NASh) is critically involved in regulating emotional processing and both molecular and neuronal disturbances in this structure are associated with mood and anxiety-related pathologies. Specifically, aberrant γ-band oscillation patterns, disturbances in extracellular-signal related kinase 1-2 (ERK 1-2), protein kinase B (Akt)-glycogen-synthase-kinase-3 (GSK-3) signaling pathways and dopamine (DA) D1/D2 receptor expression patterns have been linked to both the effects of chronic nicotine exposure as well as mood/anxiety-related

phenotypes. In the present study, we used a rodent model of adolescent neurodevelopmental nicotine exposure to examine the expression of several molecular biomarkers associated with mood/anxiety-related phenotypes. We report that nicotine exposure during adolescence (but not adulthood) induces profound upregulation of the ERK 1-2 and Akt-GSK-3 signaling pathways directly within the NASh that persists into adulthood. These adaptations were accompanied by profound decreases in theta, alpha, beta and gamma-band oscillatory states, hyperactive medium spiny neuron (MSN) activity with depressed bursting rates and anxiety and depressive-like behavioural abnormalities. Pharmacologically targeting these molecular and neuronal adaptations directly in the NASh revealed that the Akt-GSK-3 pathway, high-γ-band oscillatory signatures and spontaneous bursting rates in the NASh are involved selectively in mediating adolescent nicotine-induced depressive and anxiety-like neuropathological trajectories.

Title: Dose- and sex-dependent effects of acute delta^{9}-tetrahydrocannabinol in adolescent rats

Authors: *C. M. RUIZ, J. R. CEVALLOS, E. CASTILLO, E. HARDER, D. N. JUSTESON, J. S. MONTESINOS, S. V. MAHLER;
Neurobio. and Behavior, UC Irvine, Irvine, CA

Abstract: Cannabis legalization is rapidly spreading throughout North America and the world, which is expected to increase the availability of the drug to all age groups, including adolescents whose brains are in a critical neurodevelopmental period. Numerous studies in rodents have shown persistent, perhaps permanent effects of adolescent exposure to cannabinoid drugs including delta(9)-tetrahydrocannabinol (THC), but little attention has been given to the translational relevance of the dosing delivered in these studies. Indeed, most studies employ moderate to large doses that typically cause anxiogenic effects rather than rewarding ones. Here we test the effects of acutely delivered low or high doses of THC (0, 0.5, 5mg/kg, i.p.) on behaviors in male and female adolescent rats. Male and female long-evans rats were acquired at postnatal day (PD) 22 or bred in-house and all testing was conducted from PD27 to PD50, during adolescence. First, the effects of acute THC on elevated plus maze (EPM) and open field

anxiety-related behaviors was tested. Time spent on the closed and open arms of the apparatus was measured in the 5min test. Subsequently, effects of THC on time spent in the center or periphery of a novel open field was measured for 5min, then locomotion in this environment was monitored for an additional hour. Next, the rewarding effects of THC were assayed in a three-chamber conditioned place preference task, where vehicle (5% Tween80 in saline) was paired four times with one chamber and THC paired with a distinct chamber over 8 alternating, daily training sessions. Finally, the effects of acute THC on neural activity was measured by analyzing c-Fos immunoreactivity after acute vehicle or THC injections. Behavioral and neural activity effects of THC in adolescents were dose- and sex-dependent with both anxiogenic and rewarding effects observed and recruitment of several limbic reward- and stress-related regions. Ongoing work will determine mechanisms of these sex- and age-dependent THC effects, in pursuit of a rat adolescent cannabinoid drug dosing protocol that matches key aspects of human teenage cannabis use.

Abstract: Cannabis is the most commonly abused illicit drug among adolescents, and excessive use in this population is associated with the development of psychiatric conditions, including drug addiction. Adolescence is a critical period for the refinement and organization of neuronal connectivity, especially within the mesocorticolimbic dopamine circuity. In particular, dysregulation of the guidance cue receptor, Dcc, in ventral tegmental area (VTA) dopamine

neurons disrupts spatiotemporal targeting of dopamine axons to the nucleus accumbens (NAc) and the medial prefrontal cortex (mPFC). We have previously demonstrated that exposure to amphetamine in early adolescence (PND21-32) disrupts the development of dopamine circuitry development, leading to alterations in cognitive processing and drug seeking in adulthood. Here, we examine whether exposure to the synthetic cannabinoid-1/2 receptor agonist WIN-55,212-2 (WIN) in early adolescence regulates *Dcc* mRNA expression in the VTA and induces alterations in drug-motivated behaviors and in dopamine function in adulthood. Preliminary findings demonstrate that adolescent exposure to WIN downregulates the *Dcc* receptor in the VTA and its ligand, Netrin-1, in the NAc and mPFC, suggesting disruption of pre- and postsynaptic components of mesocorticolimbic dopamine circuitry. Additionally, WIN-treated mice display aberrant responding for cocaine as well as potentiated cocaine-mediated anxiety. Ongoing experiments will elucidate functional changes in cocaine-evoked phasic dopamine release in the NAc and mPFC. Overall, these findings support that repeated exposure to a cannabinoid-1/2 receptor agonist in adolescence impacts mesocorticolimbic dopamine system maturation and may have important implications for dopamine-mediated learning and psychostimulant-motivated behavior later in life.

Title: Adolescent but not adult exposure to nicotine produces long-term effects on anxiety measured in light-enhanced startle

Authors: *R. C. BARNET, D. KOSEREISOGLU;
Col. William & Mary, Williamsburg, VA

Abstract: Chronic adolescent nicotine exposure may cause long-term changes in the brain pathways that mediate anxiety. The Bed Nucleus of the Stria Terminalis has been linked to anxiety as expressed in one animal model known as the Light-Enhanced Startle Effect (LES; Walker & Davis, 1997). Experiment 1 examined whether adolescent nicotine exposure in rats would cause long-lasting changes in anxiety that persist into adulthood. Adolescent Sprague-Dawley rats were exposed to either nicotine (.15 mg/kg, .40 mg/kg) or saline from postnatal days 28-42. On approximately postnatal day 67 the effect of earlier adolescent nicotine exposure on anxiety was assessed in the LES paradigm. Adult males but not females exposed to nicotine as

adolescents showed significant increases in anxiety measured in LES compared to saline controls. In Experiment 2, the same nicotine preexposure administered during adulthood (beginning on postnatal ay 65) rather than adolescence failed to produce nicotine-induced alterations in anxiety. These findings suggest nicotine exposure during adolescence can produce changes in the neural pathways that mediate anxiety and that these changes persist into adulthood. Given anxiety has been implicated with the progression of drug taking in addiction, and relapse, the present findings further extend use of light-enhanced startle as a useful model for examining adolescent liability factors in addiction.

Title: Differences of nicotine-induced locomotor sensitization in adolescent and adult Wistar rats

Authors: *L. A. ORTEGA[1], M. LAMPREA[2], C. NOVOA[2], J. SOLANO[2];
[1]Fundacion Universitaria Konrad Lorenz, Bogota, Colombia; [2]Univ. Nacional de Colombia, Bogota, Colombia

Abstract: Locomotor sensitization is an increased behavioral response to nicotine administration after repetitive drug exposure. Although such reported effects tend to be reliable, little is known about the behavioral mechanisms underlying nicotine-induced locomotor sensitization. In the present study we evaluated the effects of acute nicotine administration on locomotor performance, for adolescent and adult rats, in the context of previous experience with chronic nicotine. Four locomotor activity tests (5 minutes each) were performed in an open field. Behavioral analyses were centered on free exploration, using a virtual division of the peripheral and center areas of the open field. During day 1, the experimental procedure started with a baseline activity test. Immediately after, subjects were randomly assigned to either Nicotine or Vehicle groups, and nicotine (0.14 mg/kg; reported as free base; same dose for all acute and chronic nicotine administrations) or control saline were administered via SC injections. Ten minutes after the injection, animals underwent an acute challenge activity test. From days 2 to 20, animals were assigned to groups receiving one daily injection of chronic nicotine or saline. On day 21, rats underwent a long-term re-exposure activity test. Immediately after, they received an injection of nicotine or saline. Ten minutes after the injection, animals were assessed on a

chronic challenge activity test. Results suggest that chronic nicotine induced locomotor sensitization among adolescent and adult rats. Interestingly, open field area preference was differentially modulated by nicotine among adolescents and adults. These results suggest the importance of (1) developmental age on the interpretation of locomotor sensitization, and (2) the orientation of the rat to potentially dangerous contexts as a mechanism underlying locomotor sensitization.

Title: MK801-induced locomotor activity in preweanling and adolescent male and female rats: Role of the dopamine and serotonin systems

Authors: M. G. APODACA, G. I. PARK, N. R. MONTEJANO, A. TERAN, T. J. BAUM, ***S. A. MCDOUGALL**;
Psychology, California State Univ., San Bernardino, CA

Abstract: Ketamine is a dissociative anesthetic that causes hyperactivity in both rats and mice; however, the strength of this effect varies greatly depending on the age and sex of the animal being tested. MK-801 shares some of the same pharmacological properties as ketamine (i.e., both are NMDA receptor channel blockers) and, like ketamine, MK-801 stimulates locomotor activity in rats. With both drugs, there is evidence that the increased locomotor activity is ultimately mediated by direct or indirect activation of monoamine (MA) systems. Whether the neural mechanisms mediating MK801-induced locomotor activity differ according to age and sex has not been fully determined. The purpose of this study was to examine if MA depletion, dopamine (DA) depletion, and/or serotonin (5-HT) depletion attenuates MK801-induced locomotor activity, and whether this effect differs among male and female preweanling and adolescent rats. Rats were treated with vehicle, reserpine (a MA depleting agent; 1 or 5 mg/kg), α-methyl-$_{DL}$-p-tyrosine methyl ester HCl (AMPT; a DA synthesis inhibitor; 2 × 200 mg/kg), or 4-chloro-$_{DL}$-phenylalanine methyl ester HCl (PCPA; a 5-HT synthesis inhibitor; 3 × 200 mg/kg) prior to an acute injection of saline or MK801 (0.3 mg/kg, ip). Locomotion was then measured for 2 h. MK801 stimulated substantially more locomotor activity in preweanling rats than adolescent rats. Among adolescent rats, females exhibited significantly more locomotor activity than males. Both AMPT and PCPA decreased the MK801-induced locomotion of preweanling rats and

female adolescent rats, but these compounds did not depress the basal or MK801-induced locomotor activity of male adolescent rats. Reserpine (5 mg/kg), on the other hand, reduced the MK801-induced locomotion of rats regardless of age or sex. Preweanling rats were more sensitive to the effects of reserpine than adolescent rats, since the lower dose of reserpine (1 mg/kg) only attenuated the MK801-induced locomotor activity of the younger age group. When considered together, these results suggest that the neural mechanisms underlying MK801-induced locomotor activity vary according to both age and sex. In general, preweanling rats respond like female rats, as both groups are sensitive to the locomotor depressing effects of DA and 5-HT synthesis inhibitors. In contrast, the same synthesis inhibitors did not affect the MK801-induced locomotion of male adolescent rats. Consistent with results from past ketamine studies, it appears that the locomotor activating effects of MK801 weaken in male rats (but not female rats) as they mature, and some of these effects may be due to age- and sex-dependent differences in MA system functioning.

Title: Ketamine-, cocaine-, and amphetamine-induced locomotor activity in preweanling and adolescent male and female rats: Role of the serotonin system

Authors: *J. W. RIOS, J. A. TAYLOR, M. G. APODACA, J. A. M. ROBINSON, S. A. MCDOUGALL;
Psychology, California State Univ., San Bernardino, CA

Abstract: High doses of ketamine (an NMDA receptor channel blocker) cause sedation, analgesia, and anesthesia in both rats and mice. At subanesthetic doses, ketamine causes prolonged periods of hyperactivity. One of the most interesting aspects of this ketamine-induced effect is that it varies greatly according to both age and sex. Specifically, male rats show a progressive decline in ketamine-induced locomotor activity with increasing age, while female rats show a strong locomotor response across all age groups. The neural mechanisms responsible for ketamine's locomotor activating effects are uncertain, but there is substantial evidence that ketamine directly or indirectly modulates monoaminergic system functioning. Indeed, we previously showed that dopamine depletion causes a substantial reduction in ketamine-induced

locomotor activity. This finding does not rule out the possible involvement of other monoamine systems, since serotonin (5-HT) receptor antagonists reduce the locomotor activating effects of MK801 (an NMDA receptor antagonist). The purpose of this study was to determine whether 5-HT depletion attenuates ketamine- and psychostimulant-induced locomotor activity, and whether this effect differs among preweanling and adolescent male and female rats. Rats were treated with vehicle or the 5-HT synthesis inhibitor 4-chloro-DL-phenylalanine methyl ester HCl (PCPA, 3 × 200 mg/kg) for three days prior to the administration of an acute injection of saline, ketamine (20 or 40 mg/kg), amphetamine (2 mg/kg), or cocaine (15 mg/kg). Locomotor activity was measured for 2 h. In all age groups and both sexes, 5-HT depletion caused a modest decline (25%) in the locomotion of rats treated with 40 mg/kg ketamine. Only in female adolescent rats, did 5-HT depletion reduce the locomotor activating effects of 20 mg/kg ketamine. 5-HT depletion did not affect amphetamine-induced locomotion at any age. Interestingly, PCPA dramatically reduced the locomotor activating effects of cocaine in both preweanling and female adolescent rats, but had minimal effect on the cocaine-induced locomotor activity of male adolescent rats. In sum, (a) both age and sex are critical biological constraints that influence whether 5-HT depletion attenuates ketamine- and cocaine-induced locomotor activity; (b) ketamine caused different patterns of locomotion than amphetamine or cocaine, suggesting that ketamine did not function in the same manner as these prototypical psychostimulant drugs; and (c) when considered together with past results, ketamine's locomotor activating properties are primarily dependent on dopamine neurotransmission, but some 5-HT involvement is evident.

Title: Pre-conception vs post-conception exposure to ethanol: Similar effects on the development of hypothalamic hypocretin/orexin neurons and behavior in larval zebrafish

Authors: *A. D. COLLIER, S. MIN, S. CAMPBELL, M. ROBERTS, K. CAMIDGE, S. F. LEIBOWITZ;
The Rockefeller Univ., New York, NY

Abstract: There are clinical and pre-clinical studies showing that exposure of the embryo to ethanol markedly affects neuronal development and stimulates alcohol drinking and related

behaviors. In rodents and zebrafish, our studies show that embryonic exposure to low-dose ethanol, in addition increasing voluntary ethanol intake during adolescence, increases the density of hypothalamic hypocretin/orexin (Hcrt) neurons, a neuropeptide known to regulate reward-related behaviors. The question addressed here in zebrafish is whether maternal ethanol intake *before* conception affects neuronal and behavioral development, phenomena suggested by clinical reports but seldom investigated, and how these effects compare to those of embryonic ethanol exposure. The goal of the present study was to characterize and compare how pre- and post-conception ethanol exposure affects early development of the Hcrt system and behavior, including voluntary ethanol-gelatin consumption and locomotor activity in larval zebrafish. We used both a pre-conception model, involving 14-day maternal ethanol-gelatin (10%) consumption, and a post-conception model, involving embryonic ethanol (0.5% v/v) exposure in the water from 22-24 hours post-fertilization (hpf). We measured the number, distribution and anatomical location of Hcrt neurons, using live imaging and Imaris software in H*crt:EGFP* transgenic zebrafish during early development. We found that pre-conception maternal ethanol intake and post-conception embryonic ethanol exposure have similar effects on the Hcrt neurons and behavior. They both increased the number of Hcrt neurons and caused these neurons to become more widely dispersed, an effect that was persistent throughout early larval development. Also, these effects on Hcrt neurons in both models were found to be asymmetric, occurring predominantly on the left side of the brain, and they both involved a greater dispersion and altered anatomical location, with some Hcrt neurons detected outside their normal position in the anterior hypothalamus, again primarily on the left side of the brain. In addition, both models of ethanol exposure stimulated voluntary ethanol consumption in 12 dpf zebrafish, measured using a new feeding paradigm, which was positively correlated with Hcrt neuron number, and they also caused an increase in locomotor activity. These findings demonstrate that both pre-conception and post-conception ethanol exposure markedly and similarly alter Hcrt development and behavior, producing unnatural asymmetries and altered anatomical locations that may contribute to the increased ethanol consumption and other behavioral disturbances in offspring.

Title: The effect of adolescent intermittent binge ethanol and ethanol challenge on Arc expression in young adult rat brain

Authors: *W. LIU[1], F. T. CREWS[2];
[2]Pharmacol & Psychiat, [1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Underage drinking is the most common form of substance abuse in adolescent humans, it significantly increases the risk of developing an alcohol abuse problem. In the current study, adolescent intermittent binge ethanol was modeled using adolescent male Wistar rats treated with intermittent binge ethanol (AIE exposure: 5 g/kg/day, i.g., 2 days on-2 days off, P25-P54) and assessed in early adulthood (P80). Arc (the activity-regulated cytoskeletal-associated protein) is a member of the immediate-early gene family that acts as an important regulator of synaptic plasticity. To investigate the effect of AIE exposure on Arc expression in young adult rats (P80), four study groups were assigned. At weaning on P21, male offspring were weight matched and pair-housed into two groups, water control and AIE group. At P80 following 26 days without ethanol, both control and AIE groups were separately divided into two groups challenged with water or ethanol (4 g/kg, i.g., groups: control, AIE, control-challenge and AIE-challenge), and then sacrificed 2 hours later. Arc+IR expression in multiple brain regions of the young adult rat was determined using immunohistochemistry (IHC). Our studies found that Arc+IR baseline expression at P80 was remarkably increased following AIE exposure in prelimbic cortex (92%, $p<0.05$), infralimbic (91%, $p<0.05$), insula (93%, $p<0.05$), anterior cingulate 1 and 2 (124% and 123%, $p<0.01$), lateral septal nucleus (369%, $p<0.05$) as well as the nucleus accumbens shell (99%, $p<0.05$) and core (96%, $p<0.01$). These persistent increases in Arc+IR expression suggest AIE exposure may cause persistent hyper-excitability. Acute ethanol (4 g/kg) challenge of controls significantly increased Arc+IR expression in most brain regions of the interest ranging from 2-5 fold (including frontal, entorhinal, ectorhinal, and perirhinal cortex; nucleus accumbens; granular cell layer, amygdala subregions and lateral septal nucleus) except dorsomedial hypothalamic nucleus at P80. Further, AIE exposure rat ethanol-challenge Arc+IR expression was reduced in the shell of nucleus accumbens (29%, $p<0.05$), lateral septal nucleus (44%, $p<0.05$), basolateral (63%, $p<0.001$) and lateral (38%, $p<0.01$) amygdaloid nucleus compared to control ethanol challenge Arc expression in those brain regions. These findings indicate that adolescent intermittent binge ethanol has a long lastly impacts on Arc expression induced neuronal plasticity that varies in different subregions of young adult rat brain (Supported by the NADIA from NIAAA).

Title: Functional role of a human 3'UTR polymorphism (rs2304297) in the alpha6 (α6) nicotinic acetylcholine receptor subunit gene in adolescent Sprague Dawley rats

Authors: *A. CARDENAS[1], Y. BAI[2], S. LOTFIPOUR[3];
[1]Pharmacol., Univ. of California, Irvine, IRVINE, CA; [2]Univ. of California, Irvine, Irvine, CA; [3]Emergency Med. & Pharmacol., UCI, Irvine, CA

Abstract: The alpha-6 (α6) nicotinic acetylcholine receptor (nAChR) subunit exhibits peak expression in the ventral tegmental area and substantia nigra during adolescence. Adolescence is a critical developmental period (12-18 years in humans, postnatal days 28-42 in rodents) where the maturation of brain neurocircuitry is vulnerable to nicotine exposure and coincides with the initiation of drug use. In humans, a single nucleotide polymorphism (SNP), rs2304297, at position 123 in the 3'-untranslated region (UTR) of the α6 nAChR gene, *CHRNA*6^{C123G}, is associated with enhanced smoking and drug use in adolescence. Our lab has developed a humanized mutant rat line via CRISPR/Cas9 genomic engineering replacing the rat *CHRNA*6 3'UTR with the human *CHRNA*6^{123CC} (non-risk allele) and *CHRNA*6^{123GG} (risk allele) 3'UTR. Previously we illustrated that the *CHRNA*6^{123GG} genetic variant is functional within SH-SY5Y cells. We hypothesize that the *CHRNA*6^{123GG} genetic variant is i.) functional *in vivo* and ii.) will significantly influence drug self-administration, but not baseline behaviors. As a first approach to test our hypotheses, we used our humanized CHRNA6^{C123G} 3'UTR rodent line to test the role of the genetic variant in baseline behaviors, including natural food reward, locomotion and anxiety. Given that the α6 subunit does not alter baseline locomotion, anxiety, and food reward, we predicted no differences in these behaviors between the WT and humanized *CHRNA*6^{C123G} 3'UTR rat line. *CHRNA6*^{123GG}, *CHRNA6*^{123CC}, and WT adolescent rats were subjected to food reinforcement at a fixed ratio (FR)1 schedule for 6 days followed by FR2, FR5, and progressive ratio for 2 days at each schedule. Animals then underwent a locomotor assay, light dark box test, and elevated plus maze for 1 day per test (PN 28-42). Our preliminary data shows that male *CHRNA6*^{123GG} rats have enhanced food reward by the end of FR1 and during the FR2 schedule. The responding normalizes across genotype and sex by progressive ratio testing. No sex- or genotype-dependent differences were identified in locomotor activity and anxiety across all groups. Our preliminary data indicates that the *CHRNA*6^{C123G} SNP is functional *in vivo* by influencing the motivation to attain food. Future studies aim to elucidate the role of *CHRNA*6^{C123G} SNP in drug self-administration.

Abstract: Cue-induced cocaine craving intensifies or incubates during withdrawal from extended-access cocaine self-administration. After prolonged withdrawal, the expression of incubated cocaine craving is mediated by GluA2-lacking, Ca^{2+}-permeable AMPARs (CP-AMPARs) that accumulate in the nucleus accumbens (NAc). Less is known about NMDAR plasticity during incubation, especially in the NAc core. It has been shown that elevated levels of GluN2B-containing NMDARs in the NAc shell, during early withdrawal, are important for subsequent incubation (e.g., Wang et al., 2018). Furthermore, incorporation of GluN3- and GluN2B-containing NMDARs accompanies an increase in CP-AMPAR levels in the ventral tegmental area elicited by a single cocaine injection (Yuan et al., 2013). To evaluate NMDAR transmission in NAc core throughout the incubation process, we conducted whole-cell patch clamp recordings in NAc medium spiny neurons (MSN) at various withdrawal times following self-administration. We measured evoked NMDAR-mediated synaptic responses across membrane holding potentials (-80 to +40) in the presence of subtype selective blockers, identifying an increase in GluN2B-containing receptors beginning on withdrawal day 4-5. We also detected atypical NMDARs, not found in saline control animals, that are comprised of GluN3 and GluN2B subunits during a later withdrawal period (day 13-20). These atypical NMDARs persisted in MSN synapses into late withdrawal (withdrawal day 39 and greater). Super-resolution light microscopy immunofluorescence array tomography was used to characterize the expression pattern of NMDAR subunits in both control and incubated

conditions. Differential expression of GluN3-containing NMDARs was found between treatment groups. We then conducted behavioral studies to determine if GluN2B- or GluN3-containing NMDARs contribute to the incubation of cocaine craving. Viral knockdown of GluN3A subunits in early withdrawal disrupted later expression of incubated cocaine craving. Our results indicate that alterations in NAc NMDAR function are dynamic and precede the incorporation of CP-AMPARs during withdrawal from extended-access cocaine self-administration and are maintained throughout the period when incubated drug seeking is maximal.

Title: Defining the role of retinoic acid mediated homeostatic plasticity in nucleus accumbens core medium spiny neurons during incubation of cocaine craving

Authors: *A. M. WUNSCH[1,2], D. T. CHRISTIAN[3,2], J. R. FUNKE[1,2], T. A. GREEN[4], E. S. CALIPARI[5], L. CHEN[6], M. E. WOLF[1,2];

Br., Galveston, TX; [5]Pharmacol., Vanderbilt Univ. Sch. of Med., Nashville, TN; [6]Stanford Inst. of Neuro Innovation and Translational Neurosci, Stanford Univ., Stanford, CA

Abstract: Profound alterations in glutamate-dependent synaptic plasticity accompany incubation of cocaine craving. In rats that self-administer cocaine, calcium (Ca^{2+})-permeable AMPA receptors (CP-AMPAR) accumulate in excitatory synapses of nucleus accumbens (NAc) core medium spiny neurons (MSN) following ~1 month of abstinence and are required for expression of incubation, whereas CP-AMPAR levels are low in drug-naïve rats. Defining signaling

cascades involved in the long-term synaptic plasticity that drives CP-AMPAR accumulation will clarify mechanisms regulating the strength of cocaine craving. Some data support the idea that cocaine withdrawal leads to reduced activity of MSN at baseline, which may trigger homeostatic plasticity leading to incubation. One form of inactivity-induced synaptic scaling (a type of homeostatic synaptic plasticity) involves activity-dependent regulation of dendritic protein translation by retinoic acid (RA). In hippocampal neurons, blockade of neuronal activity reduces intracellular Ca^{2+}, which disinhibits RA synthesis and leads to synaptic insertion of CP-AMPAR. We hypothesize that reduced Ca^{2+} activity during cocaine withdrawal similarly increases RA synthesis in NAc core MSN, leading to increased levels of CP-AMPAR. Several lines of work are underway to test this hypothesis. First, we studied NAc neurons co-cultured with prefrontal cortex neurons and transfected with a RA reporter system. We found that application of the RA synthesis inhibitor DEAB reduced RA activity in MSN, suggesting RA signaling cascades are functional in NAc MSN. Studies are underway to assess whether RA signaling in cultured MSN is dependent on synaptic activity and intracellular Ca^{2+} levels. Second, whole cell patch clamp recordings are performed on NAc core MSN in brain slices from cocaine-incubated rats. Preliminary data suggest that inhibiting RA synthesis with DEAB reduces CP-AMPAR levels in cocaine-incubated rats to those seen in drug naïve rats, suggesting RA may be an important regulator of CP-AMPAR during abstinence. Third, we will use viral vectors to interfere with RA synthesis or degradation to study the role of RA in NAc core in the incubation of craving and regulation of CP-AMPAR levels. Lastly, we are using fiber photometry to directly assess changes in intracellular Ca^{2+} levels in NAc core MSN at baseline and in response to a cocaine-paired cue during incubation of cocaine craving. Ultimately this work has the potential to define novel targets to reduce drug craving and prolong abstinence.

Title: Defining sex differences during incubation of methamphetamine craving

Authors: *J. R. FUNKE, A. M. WUNSCH, M. E. WOLF;
Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: One of the intractable features of methamphetamine (METH) substance use disorder is the high rate of relapse, which occurs even after prolonged abstinence. While relapse can be induced by a variety of stimuli, one established mechanism involves exposure to drug-paired cues leading to craving and subsequent relapse. This form of cue-induced drug craving can be studied in a rodent model of relapse termed 'incubation of drug craving'. In this model, rats undergo extended-access self-administration (SA) of methamphetamine (or saline; control condition) for 6 hr/day for 10 days. A light cue is paired with each methamphetamine infusion. Rats then undergo cue-induced seeking tests during abstinence in which rats nose poke for presentation of the METH-paired light cue but do not receive drug. Cue-induced METH seeking was found to increase steadily (or 'incubate') during the first week of abstinence and remain elevated for at least 45 days following the last METH exposure in male rats. Furthermore, the accumulation of higher conductance calcium (Ca^{2+})-permeable AMPARs (CP-AMPARs) in the nucleus accumbens core mirrors the time course of METH incubation. The overall goal of this project is to establish the rising and falling phases of METH incubation in both male and female rats. In order to define the time course of incubation of METH craving, male and female rats will undergo extended access METH or saline self-administration. Using a within-subject design, experiments are in progress in which cue-induced METH seeking tests are conducted on withdrawal day (WD) 1, WD7, WD30, WD100, and WD180. Estrous cycle is monitored in the female rats around seeking tests. Future studies will determine if CP-AMPAR levels parallel craving during falling as well as rising phases of incubation. Incubation of craving also occurs in abstinent human METH users, so it is important to define its time course and underlying mechanisms.

Title: The role of protein translation in the nucleus accumbens in the expression of incubation of cocaine craving

Authors: *A. B. KAWA, M. E. WOLF;
Behavioral Neurosci., OHSU, Portland, OR

Abstract: In the 'incubation of cocaine craving' model of relapse, rats self-administer cocaine using an extended access procedure, and then experience a prolonged abstinence period. During

abstinence, rats exhibit a progressive intensification (incubation) of cue-induced craving. We have shown that Ca^{2+}-permeable AMPA receptors (CP-AMPAR), comprised exclusively of the GluA1 subunit, accumulate in the nucleus accumbens (NAc) during abstinence and are required for the expression of incubated craving. We have also shown that maintenance of CP-AMPARs in NAc synapses requires active protein translation, as levels are rapidly normalized by general protein translation inhibitors. Also, intra-NAc treatment with a protein translation inhibitor just before the cue-induced seeking test prevents the expression of incubated craving. However, little is known about the specifics of this critical protein translation. In some conditions, inhibition of general protein translation increases the translation of a subset of mRNA with 5' upstream open reading frames, such as Oligophrenin-1 (OPHN1). OPHN1 translation is positively regulated by p-eIF2α. In the hippocampus, OPHN1 is necessary for eIF2α-mediated mGluR-LTD and the removal of synaptic AMPARs. In the VTA, this pathway plays a role in bidirectional CP-AMPAR plasticity in cocaine-exposed animals. Thus, in our NAc studies, treatment with protein translation inhibitors may have increased translation of OPHN1, mimicking mGluR-LTD and removing synaptic CP-AMPARs. In order to learn more about the proteins translated in the NAc of 'incubated' rats and more specifically the regulation of OPHN1 and its role in incubation we are using several strategies. These include puromycin labeling to identify proteins translated during a seeking test in 'incubated' rats and using rats that express Cre recombinase in either D1R or D2R medium spiny neurons to express GFP-tagged ribosomes in a cell specific manner, enabling us to isolate actively translating mRNAs for analysis by PCR. We are also testing the effects of bidirectionally manipulating OPHN1 on incubation and CP-AMPAR expression. The results of these experiments will indicate if OPHN1 is a critical regulator of CP-AMPARs in the NAc after incubation of cocaine craving.

Abstract: Relapse is a major challenge to the treatment of substance abuse disorders. Vulnerability to relapse is exemplified by incubation of drug craving, a progressive increase in cue-induced craving over the course of withdrawal from various drugs of abuse observed in both humans and rodents. We and others have shown that incubation of cocaine craving involves a strengthening of nucleus accumbens (NAc) synapses via post-synaptic accumulation of high conductance Ca^{2+}-permeable AMPA receptors (CP-AMPARs), which enhances medium spiny neuron (MSN) reactivity to drug-associated cues for the expression of incubation. Additionally, impairment of the pre-synaptic regulation of glutamate release occurs after prolonged cocaine withdrawal, through a loss of the DHPG-induced synaptic depression that is normally mediated by mGlu5 and CB1 receptors. Our previous studies suggest that this loss stems from postsynaptic alterations in the mGlu5-endocannabinoid signaling complex, referred to as the 2-AG signalosome. We investigated the mechanisms underlying this impairment. Co-IP studies revealed that, although the 2-AG signalosome was intact, there was an increase in the physical association of Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) and diacylglycerol lipase-α (DGL), which would be predicted, based on earlier studies, to inhibit DGL activity and therefore production of 2-AG. This was confirmed through a DGL activity assay. Future studies will further assess the role of CaMKII in the loss of mGlu5-mediated synaptic depression after incubation of cocaine craving. These studies clarify the nature of impaired mGlu5-mediated synaptic depression during cocaine withdrawal and establish a role for CaMKII in the synaptic alterations associated with incubation of cocaine craving. Title: Incubation of cocaine craving after intermittent access self-administration: Sex differences and estrous cycle

Authors: *C. NICOLAS[1], T. I. RUSSELL[1], A. F. PIERCE[1], S. MALDERA[1], A. HOLLEY[3], Z.-B. YOU[2], M. M. MCCARTHY[3], Y. SHAHAM[1], S. IKEMOTO[1];
[1]Behavioral Neurosci. Res. Br., [2]Mol. Targets and Medications Discovery Br., Natl. Inst. On Drug Abuse-Irp, Baltimore, MD; [3]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Studies using continuous-access drug self-administration showed that cocaine seeking increases during abstinence (incubation of cocaine craving). Recently, studies using intermittent-access self-administration showed increased motivation to self-administer and seek cocaine. We examined whether intermittent cocaine self-administration would potentiate incubation of craving in male and female rats and examined the estrous cycle's role in this incubation. In experiment 1, male and female rats self-administered cocaine either continuously (8 hours/day) or intermittently (5 minutes ON, 25 minutes OFF × 16) for 12 days, followed by relapse tests after 2 or 29 days. In experiments 2 and 3, female rats self-administered cocaine intermittently for six, 12, or 18 sessions. In experiment 4, female rats self-administered cocaine continuously followed by relapse tests after 2 or 29 days. In experiments 3 and 4, the estrous cycle was measured using a vaginal smear test. Incubation of cocaine craving was observed in both sexes after either intermittent or continuous drug self-administration. Independent of access condition and abstinence day, cocaine seeking was higher in female rats than in male rats. In both sexes, cocaine seeking on both abstinence days was higher after intermittent drug access than after continuous drug access. In female rats, incubation of craving after either intermittent or continuous drug access was significantly higher during estrus than during non-estrus; for intermittent drug access, this effect was independent of the training duration. In both sexes, intermittent cocaine access caused time-independent increases in drug seeking during abstinence. In female rats, the time-dependent increase in drug seeking (incubation) is critically dependent on the estrous cycle phase.

Title: Central amygdala PKCδ-expressing neurons are critical to inhibition of incubation of methamphetamine craving after social choice-induced voluntary abstinence

Authors: *M. VENNIRO[1], T. RUSSELL[1], L. R. WHITAKER[1], C. RICHIE[1], R. O. MESSING[2], Y. SHAHAM[1];
[1]Natl. Inst. On Drug Abuse, Baltimore, MD; [2]Univ. of Texas, Austin, TX

Abstract: We recently reported that social choice-induced voluntary abstinence prevents incubation of methamphetamine craving. This protective effect was associated with activation of PKCδ-expressing neurons in central amygdala lateral (CeL) and inhibition of Fos expression in central amygdala medial (CeM). Here we used short-hairpin RNA against PKCδ mRNA

(shPKCδ) and immunohistochemistry to determine the causal role of CeL PKCδ in inhibition of incubation of methamphetamine craving after voluntary abstinence. In Experiment 1 we used immunohistochemistry to validate the AAV virus expressing shPKCδ by injecting it (or shScram control) into CeL either 2 or 4 weeks before novel context exposure to induce Fos. In Experiment 2, we trained two group of rats injected with shPKCδ or shScram into CeL to lever press for social interaction (6 d) and then for methamphetamine infusions (12 d). We then assessed relapse to methamphetamine seeking after 1 and 15 abstinence days. Between tests, the rats underwent social-choice-induced voluntary abstinence. After day 15 testing, we assessed Fos, PKCδ and Fos+PKCδ expression in CeL, and Fos expression in CeM. In Exp. 1, we found that shPKCδ but not shScram decreased CeL PKCδ, Fos, and Fos+PKCδ expression. In Exp. 2, we found that shPKCδ but not shScram restored incubation of methamphetamine craving after voluntary abstinence. This effect was associated with decreased PKCδ, Fos and Fos+PKCδ expression in CeL, and increased Fos expression in CeM. Results demonstrate a critical role of CeL PKCδ in inhibition of incubation of methamphetamine craving after social choice-induced voluntary abstinence

Title: Role of ventral subiculum in incubation of oxycodone craving after electric barrier-induced voluntary abstinence

Authors: *I. FREDRIKSSON[1], S. APPLEBEY[1], A. MINIER-TORIBIO[1], C. CIFANI[2], J. M. BOSSERT[1], Y. SHAHAM[1];
[1]Behavioral Neurosci. Br., IRP-NIDA, NIH, Baltimore, MD; [2]Univ. of Camerino, Sch. of Pharm., Camerino, Italy

Abstract: In humans, abstinence is often self-imposed, and relapse typically involves a conflict situation where addicts choose between the desire to experience the drug's rewarding effects and adverse consequences of drug seeking. To mimic this human condition, we recently developed a rat model of incubation of oxycodone craving after electric barrier-induced voluntary abstinence and showed time-dependent increases in drug seeking on abstinence day 15 and 30 compared to day 1 (incubation of oxycodone craving) that was more pronounced than the classical incubation

of craving after homecage forced abstinence. Here, we examined the role of ventral subiculum (vSub) in incubation of oxycodone seeking after electric barrier-induced abstinence, using the activity marker Fos and muscimol + baclofen (GABA A+B receptor agonists) inactivation. We trained male and female rats to self-administer oxycodone (0.1 mg/kg/infusion, 6-h/d) for 14 days. We then introduced an electric barrier near the drug-paired lever of increasing intensity (0.1 to 0.4 mA) that causes cessation of oxycodone self-administration. Next, we tested the rats (n=6-7/group) for relapse to oxycodone seeking (extinction tests) in the absence of shock and drug on abstinence day 15 and extracted the brains for Fos-immunohistochemistry or tested the rats (n=10-12/group) after vSub injections of vehicle or muscimol + baclofen. Relapse after electric barrier-induced abstinence was associated with increased Fos expression in vSub and local inactivation of vSub decreased "incubated" oxycodone seeking. Together, these data demonstrate a role of vSub in incubation of oxycodone craving after cessation of drug taking due to adverse consequences of drug seeking.

Title: Operant social reward decreases incubation of heroin craving in male and female rats

Authors: *T. I. RUSSELL, M. ZHANG, Y. SHAHAM, M. VENNIRO;
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: Background: We recently reported that operant social choice-induced voluntary abstinence prevents incubation of methamphetamine craving. Here, we determined whether social choice-induced voluntary abstinence would prevent incubation of heroin craving. We also introduce a fully-automatic social reward self-administration model that eliminates the intense workload and rat-human interaction of the original semi-automatic model. **Methods:** In Exp. 1, we trained male and female rats for social self-administration (6 d) and then for heroin self-administration (12 d). Next, we assessed relapse to heroin seeking after 1 and 15 abstinence days. Between tests, the rats underwent either forced or social choice-induced abstinence. In Exp. 2, we developed a fully-automatic social self-administration procedure by introducing a screen between the self-administration chamber and the social-peer chamber; the screen allows physical contact but prevents rats from crossing chambers. Next, we compared incubation of craving in rats with a history of standard (no-screen) or automatic (screen) social self-administration and social choice-induced abstinence. **Results:** The time-dependent increase in heroin seeking after

cessation of drug self-administration (incubation of craving) was lower after social choice-induced abstinence than after forced abstinence. There were no differences in social self-administration, social choice-induced abstinence, and incubation of craving in rats trained in the standard semi-automatic procedure versus the novel fully-automatic procedure. **Conclusions:** Our study demonstrates the protective effect of rewarding social interaction on heroin self-administration and incubation of heroin craving, and introduces a fully-automatic social-choice self-administration procedure that can be used to investigate the role of volitional social interaction in drug addiction and other psychiatric disorders.

Title: Incubation and cocaine cue-induced changes in medial prefrontal cortex parvalbumin and perineuronal nets after long access to cocaine in rats

Authors: *J. ANGUIANO[1], J. M. BLACKTOP[4], J. WINGERT[5], L. CHURCHILL[2], B. A. SORG[3];
[1]Neurosci., Washington State Univ., Vancouver, WA; [2]Program in Neurosci., Washington State Univ., Pullman, WA; [3]Integrative Physiol. and Neurosci., Washington State Univ., Vancouver, WA; [4]Dept. of Integrative Physiol. and Neurosci., [5]Neurosci., Washington State Univ. Vancouver, Vancouver, WA

Abstract: Extracellular matrix aggregations called perineuronal nets (PNNs) surround mainly fast-spiking, parvalbumin (PV)-containing GABAergic interneurons and importantly contribute to plasticity during development, learning and memory. We previously reported that PNNs in the medial prefrontal cortex (mPFC) contribute to cocaine-associated memories (Slaker et al., J Neuro 2015), and that the intensity of PNNs and their underlying PV cells changes after acute and repeated cocaine (Slaker et al., eNeuro 2018). Here we measured changes in the intensity of PV and PNNs (the latter using *Wisteria floribunda* agglutinin, WFA) after 6 hr access to cocaine in rats followed by either 1 or 30 days forced abstinence or 2 hr after cocaine cue-induced reinstatement. Rats were allowed 6 hr access to cocaine (0.5 mg/kg/infusion) for 14 days followed by 1 or 30 d withdrawal or 10 days extinction and then cue-induced reinstatement. The intensity of PV in WFA+ cells was not different for saline controls after 1 d abstinence, but was

increased compared to saline controls after 30 d abstinence. The intensity of WFA around PV+ cells was slightly decreased at 1 d abstinence but increased after 30 d abstinence. Cue-induced reinstatement decreased PV intensity but, paradoxically, increased WFA intensity. These findings indicate a potential incubation effect on both PV cells and their surrounding PNNs as well as conditioned effects of the cue on PV and PNNs. The results suggest that there may be a compensatory increase in inhibitory output from PV to pyramidal cells to dampen enhanced excitatory drive from the mPFC to the nucleus accumbens during incubation.

Title: Decreased N^6-methyladenosine (m^6A) levels in the prefrontal cortex are associated with incubation of cocaine craving

Authors: *D. K. FISCHER[1], S. E. SWINFORD-JACKSON[2], J. STOUTE[3], F. LIU[4], R. C. PIERCE[2];
[1]Grad. Group in Neurosci., [2]Dept. of Psychiatry, [3]Grad. Group in Biochem. and Molelcualr Biophysics, [4]Dept. of Biochem. and Biophysics, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Understanding epigenetic mechanisms, such as RNA modifications, that underlie cocaine relapse-like behavior may lead to the development of new therapies for cocaine addiction. *N*^{6}-methyladenosine (m^6A) is the most prominent mRNA modification. m^6A regulates RNA splicing, translation, and stability which can alter gene expression that dynamically influences neuronal function and behavior.m^6A and its regulatory enzymes, methyltransferases and demethyltransferases,are regulated in the prefrontal cortex by different experiences and stimuli. Neuronal plasticity in the prefrontal cortex, an important region within the mesocorticolimbic reward system, contributes to theincubation of cocaine craving, a rodent model of relapse-like behavior. The extent to which m^6A regulatory enzymes and total levels of m^6A within the prefrontal cortex are associated with cocaine seeking has not been investigated. Here, male Sprague Dawley rats were trained to self-administer cocaine and controls self-administered sucrose or received yoked-saline infusions (14 days, 3 hr/day) followed by 1 day or 30 days of forced abstinence, at which time the prefrontal cortex was harvested. Mass-spectrometry was used to assess m^6A levels and RT-qPCR was performed to measure the

expression of m^6A regulatory enzymes. We observed lower m^6Alevels in the prefrontal cortex of rats that self-administered cocaine and underwent 30 days of forced abstinence compared to saline-yoked controls. Cocaine self-administration and forced abstinence for either 1 or 30 days were both associated with significant increases in the expression of *Fto*, the main demethyltransferase of m^6A, relative to animals that underwent sucrose self-administration. These data suggest that forced abstinence following cocaine self-administration decreases overall levels of m^6A in the prefrontal cortex, which may contribute to increases in cocaine-seeking behavior. The data also suggest that *Fto* may have a reinforcer-specific effect independent of forced abstinence duration. In future studies, we will experimentally alter m^6A levels within the PFC and assess cocaine-seeking behavior to determine whether m^6A contributes to the incubation of cocaine craving.

Title: Accumbal endocannabinoid signaling mediates cocaine craving following prolonged abstinence

Authors: P. H. GOBIRA[1], S. MITRA[2], J. A. MARTIN[3], C. T. WERNER[4], ***D. M. DIETZ**[5]; [1]Univ. of São Paulo, Ribeirao Preto, Brazil; [2]Pharmacol. & Toxicology, [3]Dept. of Pharm and Tox; Res. Inst. on Addictions; Program in Neurosci., [4]Dept. of Pharmacol. and Toxicology; Program in Neurosci., State Univ. of New York at Buffalo, Buffalo, NY; [5]State Univ. of New York, Buffalo, NY

Abstract: Cue-induced cocaine craving is a cardinal characteristic of cocaine use disorder. Cocaine craving progressively intensifies during abstinence leading to perpetual relapse vulnerability. Endocannabinoid signaling in the nucleus accumbens (NAc) mediates synaptic depression associated with rewarding properties and contributes towards cocaine-induced behavioral attributes; however, the role of accumbal endocannabinoid signaling in incubation remains to be investigated. In the present study we found dysregulation of enzymes that mediate synthesis (diacylglycerol lipase-DAGL) and breakdown (monoacylglycerol lipase-MAGL) of endocannabinoid 2-Arachidonoylglycerol (2-AG) following prolonged abstinence from

extended-access cocaine self-administration (SA). DAGL was increased, while MAGL was decreased in the NAc on abstinence day 30 (AD30) but not AD1 following extended-access cocaine SA. Intra-accumbal microinjection of DAGL antagonist DO-34 attenuated, while MAGL antagonist URB-602 increased, cocaine seeking on AD30, demonstrating that 2-AG-mediated endocannabinoid signaling regulates cocaine seeking during prolonged abstinence. Dephosphorylation of eukaryotic initiation factor 2 (eIF2α) was previously shown to mediate cocaine seeking during prolonged abstinence, and we found that inhibiting MAGL resulted in dephosphorylation of eIF2α in the NAc, suggesting that cocaine seeking during prolonged abstinence is mediated through a mechanism involving altered phosphorylation of eIF2α (p-eIF2 α) by 2-AG. Together, these results demonstrate bidirectional regulation of cue-induced cocaine craving by endocannabinoid signaling in the NAc during prolonged abstinence.

Title: Differential microRNA expression in nucleus accumbens shell after prolonged cocaine abstinence in environmentally-enriched rats

Authors: *A. VANNAN[1,2], G. L. POWELL[2], A. M. H. MOKBEL[2], A. L. ESQUER[2], M. DELL'ORCO[3], N. PERRONE-BIZZOZERO[3], J. L. NEISEWANDER[1,2];

Abstract: MicroRNAs (miRNAs) have emerged as “master regulators” of hundreds to thousands of genes, and recent research has linked several miRNAs to substance abuse and addiction. We used a miRNA microarray (nanoString nCounter Rat v1.5) to investigate miRNA expression changes in the nucleus accumbens shell (NAcSh) in relation to incentive motivation for cocaine. Isolate-housed, male Sprague-Dawley rats were trained to self-administer cocaine (0.75 mg/kg/ IV infusion) on a variable ratio 5 (VR5) schedule of reinforcement. After rats achieved stable cocaine intake, they were placed into 21 days of forced abstinence while either remaining in isolation or being placed into environmental enrichment (EE) which is known to attenuate motivation for cocaine. Rats then underwent cue reactivity testing in which a cue light and tone that were previously paired contingently with cocaine were presented on a fixed ratio (FR) 1

schedule in the absence of drug, and these operant responses were used as a measure of cocaine-seeking behavior. Immediately following the cue reactivity test, rats (n=12) were sacrificed and their brains were flash-frozen for RNA analyses. As expected, EE rats showed significantly less cocaine-seeking behavior in the cue reactivity test than isolated rats. Differential expression analysis using nSolver™ Analysis Software identified 16 miRNAs significantly upregulated in EE rats compared to isolated rats. Some of these miRNAs, including several from the let-7 family, have previously been implicated in addiction, while others are novel and predicted to target large number of addiction-related genes (Knowledgebase for Addiction Related Genes, karg.cbi.pku.edu.cn/karg.cbi.pku.edu.cn/). All but one of the upregulated miRNAs were negatively correlated with cocaine seeking behavior. These findings enhance our understanding of the neurobiological benefits of EE and reveal several therapeutic targets for attenuating drug craving.

Title: Altering the gut microbiota affects cocaine-seeking in adult but not adolescent male rats

Authors: *G. J. SUESS, J. KASIAH, B. ANTHONY, B. F. WILLIAMS, B. CHASSAING, K. J. FRANTZ;
Georgia State Univ., Atlanta, GA

Abstract: Research on the gut-brain axis has revealed that gut dysbiosis is associated with several neuropsychiatric disorders, including substance abuse. Using a cocktail of antibiotics in the drinking water of rats, we sought to determine whether antibiotic treatment decreases bacterial abundance in an age-dependent manner and whether antibiotic-induced microbial depletion differentially affects cocaine-seeking in adolescent vs. adult male Wistar rats. After catheter implantation, rats were given antibiotics and self-administered cocaine for two weeks. At the end of self-administration, animals were taken off cocaine and antibiotics, placed into forced abstinence for 30 days, and then underwent extinction testing followed by cue-induced reinstatement. Animals were sacrificed, with brains and abdominal organs collected. Microbial abundance was characterized by conducting qPCR with universal primers. Inflammation in the gut was assessed by quantifying lipocalin-2, a neutrophil marker. During cocaine self-administration, neither age nor antibiotic treatment influenced drug taking. Adults treated with antibiotics reinstated more to cocaine-seeking than water-treated counterparts, however, an effect

not seen in adolescents. In terms of microbial abundance, the antibiotic cocktail depleted microbiota levels in both age groups. In adults, microbiota levels failed to return to baseline over the 30-day forced abstinence, although they did return to baseline in adolescent-onset counterparts. Cecum mass and size were greater in all antibiotic treated animals, compared to age-matched controls, and a further increase was associated with cocaine intake in adults but not adolescents. Neither age, drug, nor antibiotic altered lipocalin-2. Taken together, the present results suggest that microbial depletion is associated with heightened sensitivity to cocaine-related cues in adult rats, but not rats that took cocaine during adolescence. The present results should be complemented by a more thorough investigation of microbial diversity and pro-inflammatory cytokines, perhaps revealing a cocaine-related microbiota profile. These results also suggest that future studies on the impact of probiotics to restore gut health may ultimately suggest adjunct therapies in the treatment of drug addiction.

Title: Cocaine intake dependent plasticity in nucleus accumbens mGluR5 receptor signaling leads to differential regulation of drug seeking

Authors: *M. GHASEMZADEH, D. KRAVTSOV, S. GIWANI, R. VARELA, J. BOROVICKA, O. BURGOS, L. KELBLE;
Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: A major obstacle in the treatment of addiction has been the propensity to relapse, often mediated by drug-associated cues, even after prolonged period of abstinence from drug use. Repeated exposure to cocaine leads to enduring alterations in glutamatergic signaling in the brain reward circuitry that play an important role in long-lasting molecular, cellular and behavioral neuroadaptations. Therefore, glutamate signaling has been investigated as a target for the development of treatment for addiction. Recent studies suggest that group I metabotropic glutamate receptors (mGluR1/5) play important roles in drug reinforcement and drug seeking and, therefore, have been pursued as promising targets for therapeutic development. Here, we examined the role of mGluR1/5 receptors in abstinence drug seeking using animal models of cocaine self-administration. Male Sprague-Dawley rats were trained to self-administer cocaine

(FR1; 1.0 mg/kg/200 µl/inf) during either 2-hr (ShA) or 6-hr sessions (LgA) for 14 days. Subsequently, animals were left undisturbed in the home cage for 3, 10, or 60 days. Following abstinence period, rats were tested under context-primed extinction condition for cocaine seeking after systemic administration of either saline or an mGluR1/5 receptor antagonist (MTEP or JNJ16259685). Following a short abstinence period (3 or 10 days), the blockade of mGluR5 receptor reduced drug seeking only in ShA subjects without affecting the LgA animals, while mGluR1 receptor blockade was effective in reducing drug seeking in both groups. However, after a long abstinence period (60 days), the systemic blockade of either of receptors significantly reduced drug seeking in ShA and LgA rats. Using separate groups of rats, it was demonstrated that intracerebral infusion of MTEP (3µg/side) after 10 days of abstinence into either NAcore or NAshell led to a decrease in drug seeking in ShA rats. However, our preliminary results suggest that it was not effective in reducing drug seeking LgA rats. These results suggest that exposure to cocaine produce a transient intake dependent plasticity in mGluR5, but not in mGluR1, signaling in the brain. Moreover, our data point to Nucleus accumbens as the anatomical substrate contributing to the selective modulation of mGluR5 signaling in LgA rats. Understanding the mechanism of cocaine mediated effects on group I metabotropic glutamate receptors may reveal new molecular targets for the treatment of cocaine addiction.

Title: CRF in the nucleus accumbens core amplifies drug anticipation: Recruitment of CRF-R_2 in cocaine-seeking behavior

Authors: *M. Z. LEONARD[1], H. E. COVINGTON, III[2], K. A. MICZEK[2];
[2]Psychology, [1]Tufts Univ., Medford, MA

Abstract: Dopamine signaling within the nucleus accumbens core (NAcC) is critical to guiding motivated behavior in both appetitive and aversive contexts. The present studies examine accumbens-specific actions of the stress peptide corticotropin releasing factor (CRF) as a candidate mechanism for maladaptive arousal evoked by drug-predictive stimuli. Initial microdialysis studies show that CRF is released in the NAcC when rats are exposed to

environmental contexts that predict an aversive outcome (i.e. social defeat) or drug-reward opportunity (i.e. cocaine availability), and moreover, intra-NAcC infusion of exogenous CRF elicits a robust increase in extracellular dopamine. We subsequently aimed to assess the behavioral impact of NAcC-CRF on instrumental responding directed towards cocaine procurement. To that end, male Long-Evans rats were trained to self-administer cocaine under a chained schedule of reinforcement (FI-FR) in order to dissociate appetitive ('drug-seeking') from consummatory ('drug-taking') behavior. Accordingly, completion of a fixed interval (5 min.) was followed by 5 min of continuously reinforced responding (0.4mg/kg cocaine; FR1) on another lever. Under these conditions, intra-NAcC microinfusion of CRF dose-dependently increased responding during the fixed-interval component of the procedure, but notably did not affect subsequent cocaine intake. Both the behavioral and neurochemical actions of NAcC-CRF were each prevented by selective CRF-R_2 blockade with Astressin-2B, but not the CRF-R_1 antagonist CP376395. However, the CRF-R_2-mediated effects on dopamine and reward-anticipation were absent in drug-naïve animals trained to self-administer saccharin. Taken together, these data suggest a recruitment of CRF-R_2 within NAcC circuits that may contribute to maladaptive cocaine-seeking behavior, perhaps via modulation of dopamine transmission.

Title: Continuous social stress: Individual effects on CRF and cocaine reinstatement in mice

Authors: *D. T. ARENA, M. Z. LEONARD, K. A. MICZEK;
Psychology, Tufts Univ., Medford, MA

Abstract: Vulnerability to the detrimental effects of social stress varies across individuals. In C57BL/6J mice, continuous exposure to social stress can either intensify or suppress behavioral correlates of reward processing, such as sucrose preference, social interactions and cocaine self-administration. It is hypothesized that the divergent changes to social and reward-related behavior after continuous social defeat arise from different plasticity within stress signaling systems, such as corticotropin releasing factor (CRF). The present experiments aimed to characterize pharmacodynamic changes that correspond with stress vulnerability after continuous social defeat. Separate groups of male C57Bl/6J mice were studied after 10 days of either continuous social defeat stress, or no social stress. Following a 10-day period, mice were

examined for social interaction and sucrose preference in order to establish stress phenotype. Mice were then implanted with IV catheters and trained to administer cocaine under a fixed ratio 1 schedule of reinforcement (0.3 mg/kg/inf) for 10 days. After 10 days of self-administration, mice were subjected to 10 days of forced home-cage abstinence, followed by a context-induced reinstatement test. Systemic administration of CP376395 given immediately prior to reinstatement attenuated drug seeking behavior and this was most pronounced in stressed individuals that displayed heightened responding for cocaine during self-administration. Ongoing microdialysis studies indicate effects of CRF on drug seeking after exposure to continuous social stress. These data provide suggestive evidence that the divergent effects of continuous social stress on cocaine-seeking may arise from adaptive changes to CRFR1 signaling in the VTA of mice.

Title: Orexin-A administration in the posterior paraventricular nucleus of the thalamus promotes cocaine-seeking behavior via recruitment of the central amygdala

Authors: *R. MARTIN-FARDON, **A. MATZEU**;
The Scripps Res. Inst., La Jolla, CA

Abstract: Hypothalamic orexin (Orx) neurons that project to the paraventricular nucleus of the thalamus (PVT) have received growing interest because of their role in drug-seeking behavior. OrxA administration in the posterior PVT (pPVT) reinstates extinguished cocaine-seeking behavior in rats that had long access (LgA) to cocaine (6 h/day) after an intermediate period of abstinence (I-Abst, 2-3 weeks). Considering the long-lasting nature of drug-seeking behavior, we examined whether the priming effect of OrxA is preserved after protracted abstinence (P-Abst, 4-5 weeks). Substantial evidence indicates that the central nucleus of the amygdala (CeA) and bed nucleus of the stria terminalis (BNST) are strongly engaged during drug-seeking behavior, and the pPVT projects to both the CeA and BNST. Thus, a secondary objective of the study was to

monitor activation patterns (i.e., Fos^+ cells) of the CeA and BNST following intra-pPVT OrxA injections. Male Wistar rats were trained to self-administer cocaine in LgA sessions for 21 days. After training, the animals were either subjected to 14-21 days of 2 h/day extinction training (I-Abst) or placed for 14 days in the vivarium followed by extinction training for 14-21 days (P-Abst). Once the animals' behavior was extinguished, they received intra-pPVT injections of OrxA (0.5 µg) and were then placed in operant chambers under extinction conditions for 2 h. Immediately following the behavioral tests, the animals were euthanized, and their brains were prepared for Fos immunostaining. The data showed that OrxA reinstated cocaine-seeking behavior at I-Abst but not at P-Abst. The reinstatement of cocaine-seeking behavior was associated with activation of the CeA and BNST. To test whether CeA and BNST activation is necessary for OrxA-induced cocaine-seeking behavior at I-Abst, a separate group of rats was tested at I-Abst. Following extinction, the rats were simultaneously injected with OrxA in the pPVT and a combination of muscimol+baclofen in the CeA or BNST. Transient inactivation of the CeA with muscimol+baclofen prevented OrxA-induced cocaine-seeking behavior, whereas inactivation of the BNST did not affect the ability of OrxA to reinstate cocaine-seeking behavior. Altogether these findings indicate that the HYP->pPVT->CeA circuit is strongly recruited shortly after abstinence in animals with a history of cocaine dependence, and OrxA transmission in the pPVT participates in the reinstatement of cocaine seeking at I-Abst. The differential behavioral outcomes that were observed at I-Abst *vs.* P-Abst suggest that cocaine abuse perturbs the function of Orx receptors and connectivity with the pPVT as abstinence progresses.

Title: Cell type specific role of HDAC3 within the NAc in regulating cocaine-induced plasticity

Authors: *R. R. CAMPBELL[1], E. KRAMAR[1], J. BEARDWOOD[1], A. L. LOPEZ[2], O. CHITNIS[1], J. BANIHANI[1], L. PHAM[1], D. MATHEOS[1], M. WOOD[1];
[1]Univ. of California, Irvine, Irvine, CA; [2]Vanderbilt Univ., Nashville, TN

Abstract: Cocaine engages mechanisms of synaptic plasticity and transcription within the nucleus accumbens (NAc) to promote drug-seeking behaviors. Recent work from the field demonstrates that this occurs in a cell-type specific manner, often differentially affecting

mechanisms of plasticity within the two major output cell types of the NAc: dopamine D1- (D1R) vs D2-receptors (D2R) medium spiny neurons (MSNs). Consistent with this, activation of D1R- and D2R- MSNs drive opposing behavioral responses to cocaine. However, it is unclear how cocaine affects epigenetic mechanisms within D1R- vs D2R- MSNs to promote cocaine-associated behaviors. Prior work from our lab demonstrates that cocaine disengages histone deacetylase 3 (HDAC3) within the NAc to promote cocaine-induced gene expression and cocaine-associated memory formation. Here, we have examined the specific role of HDAC3's deacetylase activity in cocaine-induced behaviors and cellular activity within the NAc. In addition, we have investigated cocaine's cell-type specific effects on histone acetylation within D1R- vs D2R-MSNs. Lastly, we have examined how HDAC3 activity within these distinct cell types regulates cocaine-induced cellular and behavioral responses. Together, these results illustrate how cocaine alters mechanisms of histone acetylation to induce cell-type specific changes in gene expression and synaptic plasticity that promote drug-associated behaviors.

Title: Activity-dependent epigenetic alterations underlying cocaine self-administration

Authors: *A. J. LOPEZ[1], J. E. ZACHRY[1], H. N. HAYNES[1], A. R. JOHNSON[1], M. G. KUTLU[3], L. BRADY[2], K. THIBEAULT[1], E. S. CALIPARI[4];

Abstract: Substance use disorder (SUD) is a behavioral disorder characterized by cycles of abstinence, drug seeking, and relapse. SUD is primarily a behavioral disorder that involves aberrant learning processes after repeated exposure to drugs of abuse. At the core of this

phenotype is the persistence of symptoms long after the cessation of drug use. The neural basis of these behavioral changes has been linked to receptor-based changes in neural circuits across the brain, however, the molecular drivers that allow for these changes to persist beyond the life-span of any individual protein remain opaque. Work from our lab identified a self-administration-induced remodeling of the transcriptome as well as a novel transcriptional signature that is induced by cocaine following a history of self-administration that predicts addictive behaviors. To understand SUD, it will be critical to define the link between neuronal activation, and longer-term changes in transcription that control drug seeking. Epigenetic adaptations - where DNA-protein interactions are modified to alter the probability of targeted transcription - have been implicated in the resilient nature of drug-seeking behavior. Histone acetylation, a generally permissive epigenetic mark, is induced following re-exposure to cocaine and cocaine-associated cues, suggesting that the epigenetic enzymes regulating histone acetylation are key regulators for drug-induced gene networks. KAT2A, a histone acetyltransferase known to regulate activity-dependent transcription and hippocampal memory. While several KAT2A histone targets are modulated by cocaine, the role of KAT2A in drug-associated behaviors remains unknown. As such, we hypothesize cocaine-induced gene networks are underlied by recruitment of various histone modifications, a subset of which are regulated via KAT2A. To test cocaine-induced changes in KAT2A function, mice received cocaine (20mg/kg, I.P.) and NAc collected following 1, 7.5, 15, 30, and 60 min. Using western blot and co-immunoprecipitation, we identified changes in both KAT2A regulation of H3 and subsequent changes in H3 modifications. To further link KAT2A function with cocaine-associated behaviors, mice were implanted with jugular catheters and trained to self-administer cocaine (1mg/kg/infusion, I.V.) or saline. Following IVSA, NAc tissue was collected and analyzed for histone modifications induced by: 1) acute cocaine, 2) repeated cocaine, or 3) persisted 24 hours following IVSA. Together, we find widespread changes in epigenetic modifications across the nucleosome highlighting the complex remodeling that is induced by drug exposure.

Title: Single-cell RNA-sequencing of mouse nucleus accumbens reveals a subtype of D1 medium spiny neurons

Authors: *W. CHEN[1], R. CHEN[1], M. DJEKIDEL[1], A. BHATTACHERJEE[1], L. M. TUESTA[1], Y. ZHANG[2];

Abstract: As one of the most important entry points of the basal reward circuitry, the nucleus accumbens (NAc) has been suggested to play a crucial role in motivational behaviors. However, our knowledge of its cellular heterogeneity is limited. Here, we performed a high-throughput single-cell RNA-seq to reveal the cellular complexity of the NAc. Our results show a rich cellular heterogeneity of interneurons and medium spiny neurons (MSNs) in the NAc. As a proof-of-concept, we focused on the MSNs and found that the tachykinin 2 (Tac2)-positive neurons in the NAc is a molecularly distinct subtype of D1-MSNs. To characterize the Tac2 clusters as a subtype of D1-MSNs, we conducted multi-color FISH, neuronal tracing and behavioral assays, and found that Tac2 is selectively expressed in the Drd1+ MSNs but not in the Drd2+ MSNs. We also found that the NAc Tac2 clusters are preferentially projected to the midbrain. In addition, we manipulated the Tac2 cluster using chemogenetics and found that activation of the NAc Tac2 clusters potentiated, while inhibition repressed cocaine sensitization. However, such manipulation had no obvious effects on anxiety- and depression-related behaviors. Furthermore, we investigated the role of the NAc Tac2 clusters in mediating reinforcement in a mouse intravenous self-administration (IVSA) and found that inhibition of the Tac2 clusters significantly reduced cocaine intakes. Collectively, our results suggested that the Tac2 cluster in the NAc is a D1 MSN subtype that might play a specific role in cocaine addiction.

Title: Extinction of morphine withdrawal-induced place aversion is related to a decrease in mTORC1 pathway in the basolateral amygdala

Authors: *A. FRANCO[1,2], M. V. MILANÉS[1,2], C. NÚÑEZ[1,2];
[1]Group of Cell. & Mol. Pharmacol., Univ. of Murcia, Murcia, Spain; [2]Murcia Res. Inst. of Hlth. (IMIB), Murcia, Spain

Abstract: One of the main issues related to opiate addiction treatment is the relapse in drug intake induced by memories paired with the drug use. Alterations in the traditional memory circuits, including dentate gyrus and basolateral amygdala (BLA), have been shown to be involved in the misleading learning and memory processing in the addicted brain. Several studies have demonstrated that the mammalian (or mechanistic) target of rapamycin (mTOR) complex 1 (mTORC1) participates in synaptic plasticity through several protein synthesis regulation, such as Arc, Homer1, GluR1 and GluR5. The alteration of this pathway seems to be the common physiopathological basis of neurological diseases, including addiction to opiates. We aimed to assess the possible changes in the mTORC1 pathway in BLA during the retrieval of aversive memories associated to morphine withdrawal and their extinction. In order to accomplish our objective, we used the CPA paradigm in morphine-dependent and control rats. After behavioral procedures, brain samples were analyzed by means of western blot and immunofluorescence assays to determine the expression of phospho (p)-mTOR and the mTORC1 target p-S6 ribosomal protein, respectively. Our results revealed a decrease in the levels of p-mTOR in the BLA of rats showing aversion to the morphine withdrawal-associated environment. Likewise, control and morphine dependent rats exhibited lower levels of p-mTOR in BLA after extinction training and test. Accordingly, we observed lower expression of p-S6 in glutamatergic neurons in BLA after naloxone-induced CPA and after extinction training and test. These data agree with recent findings showing that inhibition of S6 phosphorylation promotes neurite outgrowth *in vitro*, which has been related to new memory formation. Further studies are needed to untangle the mechanisms underlying opiates-associated memory formation, retrieval and extinction processes in the addicted brain.

Title: Mu opioid receptors on vGluT2-expressing glutamatergic neurons regulate aversion to oxycodone

Authors: *K. C. JONES[1], M. KUBE[1], B. K. ATWOOD[2], B. MUÑOZ[2], B. FRITZ[1], D. HAGGERTY[1];
[1]Stark Neurosciences Res. Inst., Indianapolis, IN; [2]Dept. of Psychiatry, Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Prescription opioid drugs such as oxycodone produce reward and exert largely through mu opioid receptors (MORs). We previously demonstrated that oxycodone alters the ability of MORs to modulate corticostriatal glutamatergic transmission. We also found that MORs regulate thalamostriatal glutamatergic transmission. Using conditional MOR knockout mice (MORflox-vGluT2cre), we now demonstrate the localization of these MORs as being in vGluT2-expressing thalamic neurons. Whereas our previous work found that MORs are expressed on small populations of cortical glutamatergic neurons, indicating a likely more behavioral restricted role of these receptors, MORs are more broadly expressed in vGluT2 neurons in the brain. Therefore, we decided to explore the role of MORs on vGluT2 neurons in oxycodone-related behaviors. Eight-week-old male and female MORflox-vGluT2cre and wild-type controls underwent behavioral tests including oxycodone-induced conditioned place preference (CPP), home cage 2-bottle choice drinking, and locomotion testing. Whereas wild-type mice showed CPP to oxycodone, MORflox-vGluT2cre mice displayed conditioned place aversion. MORflox-vGluT2cre mice showed decreased locomotor activity compared to controls upon initial oxycodone exposure. In 2-bottle choice drinking, MORflox-vGluT2cre mice consumed less and showed decreased preference for oxycodone compared to controls, but did not differ in their consumptions of sucrose and quinine. These data reveal for the first time that MORs on vGluT2 neurons play a significant role in opioid reward circuitry, specifically modulating aversion to oxycodone. Current work is determining what other opioid-related behaviors are mediated by MORs on this class of glutamatergic neurons.

Title: Heroin-induced respiratory depression and subsequent brain hypoxia are triggered from the periphery

Authors: *E. A. KIYATKIN, D. PEREKOPSKIY, A. AFZAL;
Behavioral Neurosci., NIDA-IRP, NIH, DHHS, Baltimore, MD

Abstract: In this study, we employed high-speed electrochemical monitoring of oxygen in the brain (nucleus accumbens or NAc) and subcutaneous space in freely-moving rats to examine the role of peripheral opioid receptors in mediating respiratory depression and subsequent brain hypoxia induced by intravenous (iv) heroin. As shown previously and confirmed here, heroin administered at a low, human-relevant dose (0.1 mg/kg) induces a biphasic NAc oxygen response, with an initial rapid drop followed by a more tonic increase above baseline. As confirmed by oxygen recording in the subcutaneous space, a highly vascularized location with no metabolic activity of its own, the initial decreasing component of brain oxygen response results from respiratory depression, while the subsequent brain oxygen increase is caused by cerebral vasodilation that enhances diffusion of oxygen into brain tissue independently of its blood levels determined by respiration. Naloxone-HCl, a highly potent opioid antagonist that easily crosses the blood-brain barrier (BBB), fully blocked both components of oxygen response, but naloxone-methiodide, which cannot cross the BBB, fully blocked the heroin-induced NAc oxygen drop but did not affect the subsequent oxygen increase. Naloxone-methiodide also had minimal inhibiting effects on the hyperthermic effects of heroin, which were fully blocked by naloxone-HCl. Therefore, in contrast to the traditional dogma that respiratory depression is mediated via the direct interaction of opioid drugs or/and their metabolites with opioid receptors in the CNS, our study suggests the critical role of peripheral opioid receptors in triggering this adverse effect of opioid drugs.

Title: 6-monoacetylmorphine (6-MAM) but not morphine is responsible for the rapid neural effects of intravenous heroin

Authors: *D. PEREKOPSKIY, E. A. KIYATKIN;
Behavioral Neurosci., NIDA-IRP, NIH, DHHS, Baltimore, MD

Abstract: Although heroin rapidly enters the CNS, it is quickly broken down into metabolites and byproducts.While heroin is metabolized into 6-monoacetylmorphine (6-MAM) and then to

morphine, it is generally believed that morphine interacting with brain mu-opioid receptors is responsible for the neural effects of heroin. However, recent assessments of pharmacokinetics of heroin and its primary metabolites in blood and brain extracellular space questioned this view. While brain levels of 6-MAM increased very rapidly and strongly, peaking at 2-4 min after iv heroin injection, morphine levels increased much weaker, peaking at ~20 min after heroin injection. These data point to 6-MAM as the primary metabolite responsible for heroin-induced neural effects. To clarify this issue, we used oxygen sensors coupled with amperometry to examine changes in NAc oxygen levels induced by heroin, 6-MAM, and morphine delivered intravenously in freely moving rats. Consistent with our previous data we found that iv heroin at an optimal self-administering dose (100 μg/kg) induces a biphasic change in NAc oxygen, with the initial rapid decrease resulting from respiratory depression and more delayed rebound-like increase resulting from cerebral vasodilation. The same biphasic oxygen response occurred when heroin was delivered at a higher dose (400 μg/kg), but with an enhanced initial oxygen decrease. 6-MAM delivered at an equimolar dose mimicked this pattern of oxygen response and its dose-dependent changes, but the effects were slightly weaker and more rapid than those for heroin. This lesser potency of 6-MAM to decrease NAc oxygen levels can be due to the effects of heroin itself before degradation or/and the fast degradation of 6-MAM. In contrast to heroin and 6-MAM, morphine delivered at two equimolar doses failed to decrease oxygen levels, inducing only weak and transient increases. Therefore, it appears that 6-MAM, a primary heron metabolite, is the major contributor for the acute neural effects induced by intravenous heroin.

Title: Opioid withdrawal shifts amygdalar transcriptome and is correlated with gut dysbiosis

Authors: *S. J. O'SULLIVAN[1], E. MALAHIAS[1], J. PARK[1], B. A. S. REYES[2], E. J. VAN BOCKSTAELE[2], R. VADIGEPALLI[1], J. S. SCHWABER[1];
[1]Daniel Baugh Inst., Thomas Jefferson Univ., Philadelphia, PA; [2]Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Opioid withdrawal syndrome consists of severe negative physical and emotional symptoms. Avoidance of these negative physical and emotional symptoms contributes to dependence by negative reinforcement. The amygdala is a well-established set of limbic nuclei

involved in threat detection, fear, panic, and memory that has demonstrated primary involvement in opioid dependence. Moreover, recent findings have connected gut microflora to mood and emotions. We assayed a subset of the transcriptome of single neurons, microglia, and astrocytes in the central nucleus of the amygdala in morphine-dependent and morphine-withdrawn rats using high-throughput microfluidic RT-qPCR. General and cell type-specific transcriptional shifts that lend insight into the underlying substance dependence pathophysiology were observed including increased *Tnf* expression and TNFα protein in withdrawal. Astrocytes, in particular, demonstrated high transcriptional activity. Additionally, opioid withdrawal decreased the *Firmicutes* to *Bacteroides* ratio in gut microflora suggesting gut dysbiosis. We speculate that the transcriptional changes measured in the amygdala and the microfloral changes measured in the gut are related.

Title: Fentanyl abstinence causes structural and molecular changes to nucleus accumbens D1 medium spiny neurons

Authors: *M. E. FOX[1], A. B. WULFF[3], C. A. CALARCO[1], S. A. AMENT[2], M. ENGELN[1], M. LOBO[1];
[1]Anat. and Neurobio., [2]Inst. for Genome Sci. and Dept. of Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD; [3]Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Opioid abuse has risen dramatically over the last decade. Potent, synthetic opioids like fentanyl are responsible for nearly half of opioid-related deaths, yet synthetic opioid abuse remains broadly understudied. Opioids, like other drugs of abuse, engage and alter dopaminergic circuitry to promote continued use and eventual relapse. Neurons in the Nucleus Accumbens (NAc) play a key role in drug abuse and receive dopaminergic input from the midbrain. NAc medium spiny neurons (MSNs) express either dopamine D1 or D2 receptors, and manipulation of their activity can oppositely regulate drug-related behaviors. While it is known that morphine exposure causes a loss of dendritic spines on NAc MSNs, it is unknown if this is true for synthetic opioids like fentanyl, and if the changes are specific to D1- or D2- MSNs. Here we

show that after homecage fentanyl exposure and abstinence, both male and female mice show increased social-withdrawal and reduced dendritic complexity specific to D1-MSNs. To identify the molecular mechanisms behind cell-type specific dendritic remodeling, we used D1- or A2A-Cre mice crossed with RiboTag mice to isolate ribosome-associated mRNA in specific cell types after fentanyl. We performed RNA sequencing of the D1- and D2-MSN translatome and found >1,000 differentially expressed genes. Preliminary weighted correlation network analysis (WCGNA) indicates the most strongly down-regulated genes are associated with Wnt signaling, neurogenesis, and ion channels. Ongoing experiments aim to delineate the precise molecular mechanisms underlying the social behavior deficits and neuron subtype specific atrophy, as well as to characterize changes to NAc function following operant fentanyl self-administration.

Title: Exploring liraglutide as a potential treatment for oxycodone use and abuse

Authors: *C. M. PORTO, III[1], M. M. CLASEN[2];
[1]Program in Neuroscience, Dept. of Psychology, [2]Psychology Department, Program in Neurosci., Williams Col., Williamstown, MA

Abstract: The lack of successful treatments for drug use and abuse has led to a number of novel approaches to study and treat this chronic and relapsing brain disease. One promising therapeutic endpoint lies within a neural system known to regulate food intake, obesity, and type 2 diabetes. In this vein, pharmaceutical drugs designed to enhance the glucoregulatory actions of the incretin hormone, glucagon-like-peptide-1 (GLP-1; i.e., liragutide), have been shown to reduce food intake and adipose tissue in both preclinical and clinical populations, while producing long term improvements in cardiovascular health. Following this initial research investigating the role of the GLP-1 system in food intake and body weight regulation, researchers studying drug dependence hypothesized that GLP-1 agonism might also decrease the consumption of abused drugs given that the modulation of other peptide systems known to regulate food intake, also regulate drug intake. Interestingly, these researchers found that peripheral administration of the

GLP-1 agonist exendin-4 reduces alcohol and cocaine intake in male mice and rats, respectively. While these preliminary investigations suggest that long-term GLP-1 agonism reduces drug intake, additional research is required to evaluate whether this system modulates the intake of other abused drugs (i.e., opioids, nicotine, psychostimulants, cannabinoids, etc.) and whether males and females differ in the magnitude of these effects. To this end, the present research sought to investigate whether the long-term GLP-1 agonist liraglutide modulates the intravenous self-administration (IVSA) of oxycodone in male and female Sprague-Dawley rats. Here, we report that liraglutide (10, 100, 250, 500, 1000 μg/kg; IP) dose dependently reduces oxycodone IVSA (0.056 mg/kg/infusion) and that a single low-dose of liraglutide (250 μg/kg; IP) decreases the reinforcing properties of a number of doses of oxycodone (0.01, 0.032, 0.1, 0.32 mg/kg/infusion) in both male and female Sprague-Dawley rats. Together, these recent data suggest that liraglutide might be a novel target for the pharmacological treatment of oxycodone use and abuse. Ongoing research from our lab is investigating whether liraglutide impacts the escalation of oxycodone IVSA.

Title: Role of orbitofrontal cortex in incubation of oxycodone craving in male and female rats

Authors: *E. S. YANG, M. HAILE, I. R. DAVIS, S. RAZAVI, S. A. COLDREN, X. LI; Dept. of Psychology, Univ. of Maryland Col. Park, College Park, MD

Abstract: Background: Drug seeking progressively increases after withdrawal from drug self-administration (incubation of drug craving). Previous studies have shown that this incubation generalizes across different drug classes in both rats and humans. Here, we examine neural mechanisms underlying incubation of craving to oxycodone, a commonly abused prescription opioid, and we focus on orbitofrontal cortex (OFC), a brain region previously implicated in incubation of heroin craving.
Methods: We trained male and female adult Sprague Dawley rats to self-administer oxycodone (0.1 mg/kg/infusion, 6-h/d for 10 d). Next, we either tested (Relapse-test) or did not test (No-test)

rats for oxycodone seeking (2-h) under extinction condition on withdrawal day 1 or withdrawal day 15. Immediately following the tests, we perfused rats for immunohistochemistry to measure c-Fos, a neuronal activity marker, in OFC.
Results: We found that rats escalated oxycodone intake during training, and exhibited higher oxycodone seeking on withdrawal day 15 than on withdrawal day 1. We observed no sex differences either during the self-administration training or relapse test. Furthermore, c-Fos expression increased in the Relapse-test group compared with the No-test group on withdrawal day 15.
Conclusions and future studies: Results demonstrate that incubation of oxycodone craving occurs in both adult male and female rats after withdrawal day 15 from oxycodone self-administration and is associated with neuronal activation in OFC. Studies are underway to examine the causal role of OFC in incubation of oxycodone craving by pharmacological and chemogenetic approaches.

Title: Effects of acute and chronic morphine on lateral paracapsular amygdala circuitry

Authors: *S. J. WERNER[1], N. LEWIS[2], H. WADSWORTH[2], S. STEFFENSEN[2], N. GRAZIANE[3], Y. SILBERMAN[3], J. YORGASON[2];
[1]Neurosci. Ctr., [2]Physiol. and Developmental Biol., Brigham Young Univ., Provo, UT; [3]Dept. of Neural & Behavioral Sci., Penn State, Hershey, PA

Abstract: Basolateral amygdala (BLA) activity is thought to underlie anxiety-like behavior that may be associated with stress induced drug seeking. Excitatory activity of BLA pyramidal neurons is regulated by local and paracapsular interneurons. The lateral paracapsular interneurons (LPCs) border the external capsule, and are optimally localized for receiving dense cortical input and providing feed-forward inhibition onto BLA principle neurons. The LPCs also uniquely express high concentrations of mu-opioid g-protein coupled receptors (MORs). Therefore, the effects of morphine on LPC activity and local GABA release were examined. Fluorescently double labeled LPCs were observed in GAD65-mcherry/GAD67-GFP transgenic

mice. Whole-cell electrophysiology experiments demonstrated that acute exposure to DAMGO (a synthetic selective mu-opioid receptor agonist), reduced sIPSC frequency in LPCs with no apparent effect on sEPSCs. In VGAT-ChR2 mice, light evoked GABA release onto BLA was reduced with acute application of DAMGO, and reversed with naloxone application. Furthermore, BLA fEPSP amplitude increased in BLA neurons, supportive of reduced inhibition onto BLA principle neurons. Chronic morphine-injected mice (10mg/kg/day, across 5 days, 1-2 days off) had increased sIPSCs compared to saline-injected controls. Current injection induced firing in LPC neurons, but less effectively than in saline controls. Together these data suggest that morphine acutely reduces GABA release onto LPC neurons, but long term opiate exposure results in greater inhibition onto LPCs and subsequent decreases in LPC excitability. These data have implications for increases in anxiety observed during opiate withdrawal.

Title: Increased excitability of PVT neurons following morphine exposure is light/dark cycle-dependent

Authors: *D. S. MCDEVITT, N. M. GRAZIANE;
Pennsylvania State Univ. Col. of Med., Hershey, PA

Abstract: The paraventricular nucleus of the thalamus (PVT) is a midline thalamic nucleus that is reciprocally connected to the major circadian pacemaker of the central nervous system, the superchiasmatic nucleus of the hypothalamus (SCN) and projects to several regions of the greater reward circuit including the nucleus accumbens, amygdala, and medial prefrontal cortex. This anatomical architecture suggests that the PVT is a functionally important relay between arousal and motivated behaviors. In agreement with this, it has been shown that PVT neurons express diurnal variations in activity, that cocaine alters the firing properties of PVT neurons, and that the PVT regulates drug-seeking behaviors. Given this information, we investigated whether i) opioids alter PVT activity, ii) whether opioids alter PVT activity differentially when administered during the day (light cycle) versus at night (dark cycle), and iii) whether opioid administration during the light cycle versus the dark cycle influences the acquisition of

morphine-induced conditioned place preference. Our results show that five day, repeated morphine injections (10 mg/kg i.p.) in mice, during the light cycle, followed by one day forced abstinence, increases the number of tonically firing neurons in the PVT, while the same morphine treatment given during the dark cycle has no effect (due to the already increased tonic firing at baseline). Similarly, morphine treatment during the light cycle elicits increases in excitatory transmission at PVT neuronal synapses (measured using AMPAR/NMDAR ratios), but this effect is not observed following morphine treatment during the dark cycle due to the increased excitatory transmission at baseline. Furthermore, we found that five day, repeated morphine injections (10 mg/kg i.p.) during the light cycle or during the dark cycle elicit a strong conditioned place preference suggesting that the rewarding properties of opioids are intact when administered during the day (light cycle) or during the night (dark cycle). Overall, our results show that morphine-induced changes in PVT neuronal function express diurnal variations. However, there are no diurnal variations observed in the acquisition of morphine-induced CPP.

Title: Interruption of continuous opioid exposure exacerbates drug evoked adaptations in brain function and behavior

Authors: *L. BYSTROM[1], E. LEFEVRE[2], M. T. PISANSKY[2], T. J. Y. KONO[3], P. E. ROTHWELL[2];
[1]Col. of Biol. Sci., Univ. of Minnesota Twin Cities, Minneapolis, MN; [2]Dept. of Neurosci., [3]Minnesota Supercomputing Inst., Univ. of Minnesota, Minneapolis, MN

Abstract: Clinical use of opiate-based analgesics often leads to negative consequences including dependence and addiction. Due to high prescription rates for the treatment of chronic pain, the United States is now faced with an ever rising opioid abuse epidemic. Our central hypothesis posits that maladaptive changes in brain function occur when otherwise continuous opioid exposure is interrupted by brief cycles of withdrawal. To test this hypothesis, male and female C57BL/6J mice were implanted with Alzet osmotic pumps to continuously deliver morphine (63 mg/kg/day), or saline as control, over the course of 7 days. In order to interrupt the continuous morphine administration, mice were given twice daily naloxone (10mg/kg, s.c.) injections (n=18/group). Locomotor activity recorded on the first and last days of treatment revealed that

continuous morphine exposure produced tolerance to the psychomotor activating effects of morphine. In contrast, interruption of morphine exposure with naloxone caused psychomotor sensitization, an addiction-related behavior related to adaptations in the mesolimbic circuitry. A series of low dose (2mg/kg, s.c.) morphine challenges revealed this sensitization to be persistent and enduring up to 4 months withdrawal after initial treatment. We then sought to identify the neurobiological impact of these divergent patterns of morphine administration in key reward-related brain regions. Using our established paradigm, mice (male only; n=6/group) were euthanized on the 6^{th} day of drug treatment and nucleus accumbens and dorsal striatum tissue were collected for next generation RNAseq. After controlling for false discovery rate, we found no genes that were significantly regulated by continuous morphine exposure in either brain region. In contrast, interrupted morphine significantly regulated 687 transcripts in the nucleus accumbens and 407 transcripts in the dorsal striatum. Ingenuity Pathway Analysis identified unfolded protein response, endoplasmic reticulum stress and protein ubiquitination canonical pathways were significantly regulated by interrupted morphine in both striatal subregions. These pathways were all contributed to by the up-regulation of several heat shock proteins. Increased transcription of heat shock proteins therefore represents a unique consequence of interrupted morphine exposure, as previously reported after daily injections of morphine, but not after continuous morphine exposure. This study demonstrates that opioid-evoked adaptations in brain function and behavior are critically dependent on the pattern of drug administration, and exacerbated by interruption of continuous exposure.

Title: Gene by environment interactions influence naloxone precipitated withdrawal in mice

Authors: *D. J. MOORE, C. F. DAVIDSON, T. D. PATTON, A. M. TOORIE, D. N. TECENO, F. M. VASSOLER, E. M. BYRNES;
Dept. of Biomed. Sci., Tufts Univ., North Grafton, MA

Abstract: Drug related deaths involving opioids have increased 200% between the years of 2000-2014. With this continuing rise in opioid use, identifying factors that modify an individual's response to opioids may help both prevention and treatment efforts. Preclinical

models have documented significant strain differences in opioid withdrawal, implicating a genetic contribution to this effect. The extent to which experiential factors interact with genetic vulnerabilities to influence opioid withdrawal remains unknown. The purpose of the current study was to determine the effect of limited exposure to morphine during adolescence on measures of acute opioid withdrawal in adulthood using two mouse strains that demonstrate significant differences in acute naloxone precipitated jumping, a behavioral measure of opioid withdrawal (C57BL/6 - high responder)/ (129/Sv1- low responder). Beginning at 30 days of age females were injected daily with morphine for a total of 10 days using an increasing dosing regimen with doses increased every other day (10, 20, 30, 40, 50 mg/kg, s.c.) with age-matched control animals receiving saline. Animals were then drug-free until testing ~10 weeks later. On the day of testing subjects were injected with either morphine (50 mg/kg, s.c.) or saline; 3h later they received naloxone (30 mg/kg, s.c.). Mice were then immediately placed in test chambers and jumping behavior was recorded for 15 min. One hour later all mice were sacrificed. Trunk blood was tested for glucose and brains were harvested. Significant strain differences in naloxone precipitated jumping and glucose levels were observed. Modest effects of adolescent treatment on naloxone precipitated jumping were observed in C57 but not 129 mice. However, prior adolescent exposure decreased the effects of naloxone on glucose in both strains, although these effects were more robust in C57 mice. Such findings suggest that the effects of endogenous opioids on glucose regulation can be dissociated from effects on behavioral measures of withdrawal. Additional studies examining neuronal activation using cFos labeling in brain regions that regulate naloxone precipitated withdrawal are ongoing. Overall, these findings indicated that prior exposure to opioids in adolescence alters the adult endogenous opioids system and that these effects are moderated by strain.

Title: Generation of knock-in mu opioid receptor-Cre mice

Authors: *J. BAILLY[1], *N. DEL ROSSI[1], M.-C. BIRLING[2], E. DARCQ[1], B. L. KIEFFER[1]; [1]Psychiatry, McGill University, Douglas Res. Ctr., Montréal, QC, Canada; [2]Inst. de Génétique et de Biologie Moléculaire et Cellulaire, Illkirch Graffenstaden, Strasbourg, France

Abstract: The mu opioid receptor (MOR) is the primary molecular target for medicinal opioids, and is broadly expressed throughout the nervous system. Preclinical studies have demonstrated that MOR mediates both the unrivalled analgesic properties of opioids in pain treatment, as well as their numerous adverse effects such as notably their strong addictive potential. Under physiological conditions, MOR is activated by opioid peptides and modulates various physiological systems at the periphery and in the brain, including nociceptive pathways, respiration centers, as well as the processing of natural rewards and mood[1]. Recently, tools have been developed to map and characterize sites of MOR expression at the cellular level [2-4], and identify neuronal populations responding to endogenous and exogenous opioids. These reporter knock-in lines are instrumental to localize the receptor, and speculate about circuit mechanisms underlying MOR function. A further step to better understand MOR physiology, and neural dysfunctions associated to opioid drug use, misuse and abuse, is to study and manipulate the activity of MOR-expressing neurons. To this aim, we have generated a new MOR-Cre line using a knock-in strategy allowing the expression of a detectable and functional eGFP-Cre recombinase under the control of the MOR promoter. Here, we present the characterization of the novel Cre driver mouse line at molecular and behavioral level. We also demonstrate that optogenetic stimulation of MOR-positive neurons in the ventral tegmental area is sufficient to induce strong avoidance behaviour, as anticipated from the literature[5]. This MOR-Cre line represents a unique tool of general interest in areas of pain, addiction and mood disorders.

Title: Whole brain connectivity alterations upon protracted morphine abstinence: A mouse fMRI study

Authors: *L. WELSCH[1], T. M. D. NASSEEF[2], J. PUNEET SINGH[2], E. DARCQ[2], B. L. KIEFFER[1];
[1]Psychiatry, McGill Univ., Montréal, QC, Canada; [2]McGill/Douglas Res. Ctr., Montréal, QC, Canada

Abstract: An opioid epidemic has emerged in North America: overprescribing of opioids pain relievers has led to a rise in overdose deaths at alarming rates. Drug addiction is defined as a chronic relapsing brain disorder, characterized by a cycle of preoccupation, binging, and withdrawal/negative affect [1]. Opioid abstinence enhances negative feelings, resulting in profound dysphoria, irritability, emotional pain and anxiety. Therefore, understanding the neural adaptations occurring during protracted abstinence that drive the negative emotional state is essential to minimize drug craving and social isolation, and prevent relapse. Our previous reports have shown that mice experiencing a 4-weeks period of spontaneous withdrawal from chronic morphine [2] or heroin [3] develop depressive-like behaviors and social withdrawal, and that these emotional deficits can be both prevented and reversed [4] by fluoxetine (5HT-uptake inhibitor) or norBNI (kappa opioid receptor antagonist). Here we study long-term consequences of the chronic morphine treatment on whole brain connectivity using mouse fMRI. As in our previous studies, mice were exposed to escalating doses of morphine or saline during 6 days and underwent 4 weeks of spontaneous withdrawal. Resting-state fMRI was performed on the morphine abstinent and vehicle control mice as described previously [5]. After scanning, mice were tested behaviorally and showed social deficit and more passive coping in the classical forced swim test as we previously reported. We will present both data-driven and seed-based analyses of fMRI datasets. By combining new knowledge on the long-term effects of chronic opioid exposure at behavioral and functional connectivity levels, we hope to elucidate brain networks underlying the negative affect of morphine abstinence at whole brain scale.

Title: Craniofacial mucosal application of NOP agonists for the treatment and prevention of addiction

Authors: *A. HUNTER, M. KLUKINOV, D. YEOMANS;
Anesthesia, Stanford Univ., Palo Alto, CA

Abstract: Activation of the mesolimbic reward system by opioid drugs of abuse is believed to play a major role in the development of addiction and is a target of ongoing research. Past evidence has indicated the role of Nociceptin Orfanin FQ (NOFQ) as an endogenously occurring polypeptide that attenuates addictive behavior when administered directly into the brain by suppression of dopaminergic neuron activity in the ventral tegmental area. However, these previous studies have featured intracerebroventricular injection as the mode of delivery, an immensely invasive technique that does not translate well for wide-spread human use. In order to further explore the potentially “anti-addictive” characteristics of nociceptin with a method that can translate to human treatment, we have developed a method for intranasal application of NOFQ with the end goal of attenuating addictive behavior in opioid-addicted subjects. We used a customized Conditioned Place Preference (CPP) paradigm in order to model addictive behavior. Male adult Sprague Dawley rats were randomly paired with one of two visually and tactilely distinct chambers. Subjects received either morphine (5mg/kg, S.C.) or saline vehicle and were immediately placed in the assigned chamber for 40 minutes every other day for a total of four doses. On days following drug administration rats received an equivalent volume of saline vehicle and were placed in the opposite chamber for 40 minutes. Preference was determined using a combined custom video analysis system and MATLAB analysis program to record and calculate time spent in each chamber. Subjects then received 1 dose of NOFQ (5mg/kg) or saline vehicle via intranasal (I.N.) delivery once per day for a total of 6 doses. IN delivery took place under isoflurane anesthesia with rats in a supine position. 50μL of NOFQ or saline vehicle was delivered via 6.25μL droplets directly into alternating nostrils at two-minute intervals for 16 minutes. Performance on the CPP test was recorded 24 hours following 3 and 6 doses of NOFQ. Our results show that rats subjected to 3 doses of NOFQ, but not saline demonstrated a significant reduction in preference for the morphine-paired chamber compared to rats given I.N. saline under the same addiction regimen. I.N. NOFQ had no significant effect on CPP in the absence of morphine treatments, implying that it is not aversive and does not contaminate CPP results in subjects treated with morphine. This early evidence suggests that I.N.

administration of NOFQ has promise as a viable drug delivery method with therapeutic potential for opioid addiction.

Title: The role of cannabinoid and opioid combinations on pain and respiratory depression in rodents

Authors: *B. M. WIESE[1], E. LIKTOR-BUSA[2], A. LEVINE[1], S. NIKAS[4], A. MAKRYANNIS[4], T. M. LARGENT-MILNES[5], T. W. VANDERAH[3];
[1]Pharmacol., [3]Phamarcology, [2]Univ. of Arizona, Tucson, AZ; [4]Northeastern Univ., Boston, MA; [5]Universty of Arizona, Tucson, AZ

Abstract: With over 100 million Americans suffering from chronic pain each year, and the scope of the opioid epidemic remaining a massive problem with accidental overdose fatalities at an all-time high, it is imperative that a safer alternative for treatment of chronic pain is found. Recent studies have shown that cannabis and cannabinoids may hold the key as a viable analgesic, on their own or in adjunct with opioids, and provide a wider safety profile with the absence of respiratory depression. As more states legalize cannabis for medicinal and recreational use, it is important to understand the mechanisms of action of cannabinoids on pain relief and respiratory depression. In this study we sought to understand the impact of cannabinoid 1 receptor (CB1R) and cannabinoid 2 receptor (CB2R) activation on respiratory depression using both synthetic and available CB1/CB2 agonists alone and in combination with morphine. Furthermore, we sought to evaluate if the analgesic properties of the combinations would remain. Results suggest that CB1 and CB2 activation do not induce respiratory depression on their own. In addition, cannabinoids can mitigate opioid induced respiration depression. Additionally, when tested for antinociception, these combinations retained their analgesic properties. These data support further research of cannabinoids as potential therapeutic analgesics/adjuncts in the face of the opioid epidemic.

Title: Differential effects of various opioids on affect and anxiety-like states

Authors: C. A. MADISON, P. J. WELLMAN, *S. EITAN;
Texas A&M Univ., College Station, TX

Abstract: Opioid misuse and overdose deaths are rising exponentially in the United States, reaching levels characterized by public health officials as an epidemic. This rise in opioid-related adverse outcomes has been driven, in part, by the use of opioids to treat pain disorders in the clinical population. However, the choice of which opioids to be prescribed has largely not been guided by research, due to the assumed inseparability of analgesic functions from adverse outcomes. Recent studies demonstrate that, despite binding to and activating the same receptors, different opioids signal preferentially via differential signaling pathways. This implies that opioids cannot be made equivalent by mere dose adjustment. Our recent research demonstrates that at equianalgesic doses, different opioids could have different benefit/risk outcomes related to drug-specific differences in producing opioid-induced hyperalgesia (OIH), managing burn pain early after injury and in treating/preventing chronic pain. Lastly, various opioids have differential effects on the activity of the D2 dopamine receptors (D2DRs) which have been shown to be related to many disorders, including predisposition to substance abuse as well as mood and anxiety disorders. A connection between substance abuse and mood and anxiety disorders has been well-established in humans; however, there is a lack of experimental research establishing this connection in animal models. For the present study, male mice (PND 27) were tested for baseline levels of sociability, anxiety, and pain sensitivities, as well as for acute opioid-induced locomotion. Then they were administered with escalating doses of various opioids (20mg/kg, 40mg/kg), or saline for two weeks and tested for the development of locomotor sensitization. Levels of sociability, anxiety, and pain sensitivities were retested on the 5th week. This was followed by examining the acquisition, extinction, and reinstatement of conditioned place preference (CPP), and retesting for sociability, anxiety, and pain sensitivities levels. The present data show different effects of various opioids on affect, specifically in inducing anxiety-like states. Differences in the magnitude of inducing sensitization and in CPP were also observed. These results suggest that in a clinical setting a more careful selection of specific opioid drugs over others can provide similar pain relief while reducing opioid-associated risks.

Title: circRIMS2 expression is differentially impacted in acute and chronic oxycodone exposure

Authors: *V. E. LEHMANN, A. LACHMANN, H. KRONMAN, A. RAMAKRISHMAN, P. J. KENNY;
Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Opioid addiction is a major public health crisis in the United States, leading to over 47,000 opioid-related deaths in 2017 alone (CDC, 2018). Additionally, just under one-third of Americans who are prescribed opioid painkillers (such as oxycodone) will eventually become dependent on them. One important facet of addiction research is the function of noncoding RNAs on the development of drug dependence. Circular RNAs (circRNAs) are an emerging class of noncoding RNAs that are formed by backsplicing non-adjacent intronic or exonic sequences. Though circRNAs are expressed throughout the body, they are particularly enriched in the brain. circRNA expression is further localized to synapses, where their mechanism of action is currently unknown. We obtained an RNAseq dataset from isolated DRD1-positive nuclei from the nucleus accumbens, which were further processed using a circRNA analysis pipeline (Circexplorer2), through which we were able to identify raw counts of circRNA transcripts in each individual subject. RIMS2, a synaptic calcium tethering protein, was identified as a host gene for several circRNAs. We chose to further investigate the link between RIMS2 and the striatum, as there is evidence to suggest that RIMS2 is required for dopaminergic exocytosis (Liu et al, 2018). Though a given host gene can have many circular transcripts, the most common RIMS2-derived circular transcript in our dataset has also been identified in other published studies. We chose to investigate the effects of oxycodone withdrawal following 7 days of chronic injections of oxycodone on circRIMS2 expression in striatal synaptosomes as well as total RNA. We observed a significant increase in striatal circRIMS2 expression in synaptosomes 24 hours after the final oxycodone injection. Conversely, a single acute injection of oxycodone was shown to decrease circRIMS2 expression 24 hours post injection. This suggests that circRIMS2 may initially decrease following acute oxycodone exposure, but eventually increase as a compensatory effect of prolonged oxycodone. If circRIMS2 does indeed modulate neural

responses to oxycodone exposure, then manipulation of circRIMS2 *in vivo* could mitigate the addictive properties of opioids.

Title: Optical subcellular pharmacology with fluorescent biosensors of nicotine and opioids

Authors: *A. K. MUTHUSAMY[1], A. V. SHIVANGE[1], P. M. BORDEN[3], A. L. NICHOLS[1], T. M. CHIN[1], C. H. KIM[1], K. BERA[1], A. KAMAJAYA[1], J. JEON[1], J. S. MARVIN[3], E. K. UNGER[4], B. N. Abstract: The chronic effects of neural drugs may be explained in part by multiple modes of intracellular ligand-receptor interactions. Nicotine and some opioids bind to their respective nascent receptors in the endoplasmic reticulum (ER) to increase successful export and trafficking via pharmacological chaperoning. Additionally, some opioid drugs effect G-protein signaling from within organelles. To quantify the extent and dynamics of these drug actions with imaging in live cells, we employ genetically encoded fluorescent biosensors of nicotine and opioids. These data then encourage further studies of molecular and cellular mechanisms that underpin addiction. The visualization of the drug in real-time can be combined with other optical or physiological measurements to achieve a comprehensive picture of cellular responses and

adaptations to the drug.
We began by creating a family of "intensity-based nicotine-sensing fluorescent reporters" (iNicSnFRs) meeting the criterion of $\Delta F/F_0 > 0.3$ at 1 μM. The iNicSnFRs showed directly that nicotine itself enters the ER in clonal cell lines, in primary hippocampal cells, and in human dopaminergic neurons differentiated from iPSCs, within 10 s of application at the sub-micromolar concentrations relevant to CSF levels in a smoker or vaper. Moreover, varenicline, a smoking cessation drug, shows only slightly slower kinetics, potentially explaining its strengths and weaknesses in human use.
Opioids are potent analgesics but pose an inherent risk for addiction and overdose. The cellular mechanisms of tolerance that drive users to take increasing amounts of opioids are not well understood. We screened 16 biosensor mutants with 40+ opioids representing μ, δ, and κ agonists, antagonists, and allosteric modulators. We found biosensor hits for fentanyl, morphine, methadone, and tapentadol among other ligands that we have partially evolved for increased dynamic range and affinity. The data show these opioids entering the ER of HeLa cells within a factor of 4 of the concentration found at the PM. We are now developing AAV-packaged biosensors for use in human iPSC-derived neuronal models for subcellular pharmacokinetic studies of opioids.

Title: Transcriptional regulation of EGR3 in the prefrontal cortex mediates oxycodone-induced pain relief

Authors: S. A. THOMAS[1], *J. A. MARTIN[1], S. MITRA[1], J. WILLIAMS[1], R. CHANDRA[2], M. LOBO[3], F. J. SIM[4], D. M. DIETZ[5];

Abstract: Opiates, like oxycodone (oxy), are extremely effective in their analgesic properties but have also been abused by users for non-medical purposes, highlighting the need to better understand the neurobiology between the pain and exposure to such substances. The goal of this study was to investigate transcriptional changes in the prefrontal cortex (PFC), a region of the mesolimbic dopamine system targeted by drugs of abuse and is involved with pain processing. Oxycodone treatment upregulated EGR3 expression regardless of the pain state. EGR3 overexpression in the PFC was found to potentiate mechanical pain relief with oxycodone. EGR3 expression is mediated in part by the transcription factor NFAT. Pharmacological inhibition of NFAT and subsequent downstream EGR3 expression resulted in decreased oxycodone-induced analgesia. Taken together, this demonstrates a potential role for the NFAT-EGR3 pathway in mediating oxycodone-induced pain relief.

Title: Carfentanil-induced nucleus accumbens hypoxia is inhibited by naloxone

Authors: *E. SOLIS, Jr, M. H. BAUMANN;
NIDA-IRP, Baltimore, MD

Abstract: The United States is experiencing an unprecedented epidemic of opioid overdose fatalities. This crisis is being fueled by the presence of fentanyl and its analogs as adulterants in illicit heroin products and in counterfeit pain pills. Carfentanil is an ultrapotent fentanyl analog that is implicated in hundreds of analytically-confirmed opioid deaths. Preclinical studies show that carfentanil is 10,000-times more potent than morphine as an analgesic agent. Like other mu opioid receptor (MOR) agonists, carfentanil produces respiratory depression which can lead to

death, but the effects of carfentanil on brain oxygen concentrations have not been studied. Here, we employed oxygen biosensors combined with fixed-potential amperometry to measure changes in oxygen concentration in the nucleus accumbens of freely-moving rats. Male rats received surgically-implanted intravenous (i.v.) catheters and intracerebral biosensors under pentobarbital anesthesia. After 4 days of recovery from surgery, rats received i.v. doses of carfentanil at a range of doses. Doses of 0.1 and 0.3 ug/kg carfentanil induced slight increases in oxygen, whereas 1.0 ug/kg carfentanil elicited a slight drop in oxygen followed by an increase. After an i.v. dose of 3 ug/kg, carfentanil induced strong and prolonged brain hypoxia that could be blocked with the MOR antagonist naloxone. The respiratory depressant effects of 3 ug/kg carfentanil mimicked the effects of 6.4 mg/kg morphine, suggesting that the former drug is at least 2,000-fold more potent than the latter. Our studies demonstrate the robust suppression of brain oxygen levels by carfentanil and highlight the risk to drug users who are unknowingly exposed to this ultrapotent opioid agonist.

Title: The effect of traumatic stress on mu opioid receptor dynamics in brain regions associated with emotional learning and addiction

Authors: *N. MOHAMMADMIRZAEI, D. KNOX;
Univ. of Delaware, Newark, DE

Abstract: The onset of post-traumatic stress disorder (PTSD) often precedes and increases the risk for subsequent development of substance use disorder. Individuals with opioid dependence have the highest prevalence of PTSD (33%) compared with all other substance abuse. Hyperarousal and heightened anxiety are common symptoms of PTSD which are frequently addressed through opioidergic drug prescriptions. Opioidergic systems are also implicated in facilitating emotional reactivity, including the modulation of fear, the suppression of affective defense behavior, and anxiolysis. Since, endogenous opioids have inhibitory and modulatory roles in emotional responses, we hypothesized that Mu opioid receptor dysregulation in brain regions associated with emotional learning and memory may be particularly sensitive to the effects of traumatic stress. In order to test this hypothesis, we used the single prolonged stress (SPS) model of PTSD in rats. SPS is a procedure consisting of serial stressors (restraint, forced

swim, and ether exposure) applied over a three-hour window which mimics the behavioral and neurological symptoms of PTSD. Rats were exposed to SPS or control stress, euthanized, and brain tissue were collected 7 days later. The medial prefrontal cortex (mPFC), amygdala, and dorsal hippocampus, were dissected out of coronal brain sections and the cytosolic and membrane proteins from these brain regions separated. We then assayed Mu opioid receptors in all samples using western blot. Other aspects of Mu opioid receptor function were assayed including total Mu opioid receptor expression and changes in cAMP production due to Mu opioid receptor activation. We also examined general changes in neural function in emotional substrates and throughout the reward circuit (e.g. D1/D2 ratios). The study is ongoing, but preliminary data showed decreased membrane Mu opioid receptors in mPFC and dorsal hippocampus with an increase in cytosolic Mu opioid receptors of these regions; a pattern of results indicative of changes in Mu opioid receptor internalization. However, Mu opioid receptors of both membrane and cytosol decreased in amygdala regions, which suggests a down-regulation of the Mu opioid receptors. Thus far, the preliminary data suggests that SPS exposure desensitizes Mu opioid receptor function in brain regions associated with emotional learning and memory.

Title: β-arrestin2 conditional knockout alters morphine-induced excitability changes in D2 spiny projection neurons

Authors: *A. K. PETKO[1], K. A. PORTER-STRANSKY[2], C. LILES[2], D. WEINSHENKER[3], C. A. PALADINI[4];

Abstract: Opiates such as morphine exert their physiological effects by binding to the G protein-coupled (GPCR) μ-opioid receptor (MOR). In addition to transducing canonical G protein signaling, GPCRs also couple to β-arrestin2 (βarr2), which is involved in receptor desensitization and trafficking, and independently signals downstream effectors. Within the nucleus accumbens (NAc), MORs expressed on D1 and D2 spiny projection neurons (SPNs) are subject to

modulation by βarr2. Global deletion of βarr2 alters behavioral sensitivity to morphine, but the cellular subtype and underlying mechanisms responsible are not known. Here, we examined morphine responses in mice with a conditional βarr2 knockout in either D1 or D2 cells. Using slice electrophysiology, we demonstrate that morphine similarly decreases maximum firing rate and slope of the FI curve of D1-expressing SPNs in control and D1 βarr2 KO mice. Morphine also decreases maximum firing rate of D2-expressing SPNs, and this effect is enhanced in those lacking βarr2. Together, these results suggest that MOR-induced inhibition of D2 SPNs, but not D1 SPNs, is modulated by βarr2.

Title: Mu opioid receptors in dopamine D1 expressing neurons are required for oxycodone-induced locomotor sensitization in the presence of chronic pain

Authors: J. A. ALDERETE[1], H. NASEF[1], A. L. SEVERINO[3], S. A. LEE[1], W. M. WALWYN[2], C. J. EVANS[1], ***C. M. CAHILL**[1];

Abstract: Chronic pain affects 1 in 4 Americans, making it a public health crisis and the most common cause of disability in the US. Existing non-addictive treatments are limited, which in part has led to the opioid epidemic. Mu opioid receptor (MOR) expression in the mesolimbic circuitry is responsible for rewarding properties of opioids. Our research aimed to investigate the contribution of MOR in D1 and D2 dopamine receptor expressing neurons via assessment of oxycodone-induced hyperlocomotion in pain naïve and chronic pain (sciatic nerve injury) male and female mice. We ablated MOR in dopamine receptor expressing neurons by breeding D1-cre, D2-cre and A2A-cre with MORloxP mice. Oxycodone produced a dose dependent (1-10 mg/kg, s.c.) increase in locomotor activity, which was not altered by chronic pain. Ablating MORs from D1 or D2 dopamine receptor neurons did not alter dose-dependent increases in locomotor activity in either pain naïve or chronic pain states. Locomotor sensitization (10 mg/kg oxycodone x 4 days) was evident in both pain naïve and chronic pain animals. Ablation of MORs from D2 dopamine receptor expressing neurons (using D2-cre or A2A-cre) mice did not

affect locomotor sensitization. However, oxycodone-induced locomotor sensitization was prevented by ablation of MORs from D1 neurons in chronic pain, but not pain naïve mice. This extended to cocaine-induced effects where cross sensitization to cocaine (5 mg/kg) was blocked by ablation of MORs from D1 but not D2 neurons in pain but not pain naïve mice. Cocaine cross sensitization was enhanced in mice where MOR was ablated from A2A neurons. These studies suggest that chronic pain alters opioid-induced effects in D1 expressing neurons. Since locomotor sensitization is a proxy for changes in reward, future studies will investigate how opioid reward is altered in pain and no pain following manipulations of MOR expression.

Title: Activation of the striatal MAPK-CREB pathway during early withdrawal from escalated oxycodone self-administration

Authors: *C. A. BLACKWOOD, M. T. MCCOY, B. LADENHEIM, J. L. CADET;
Mol. Neuropsychiatry Br., DHHS/NIH/NIDA/IRP, Baltimore, MD

Abstract: The continuing opioid epidemic has prompted research aimed to elucidating potential mechanistic substrates of compulsive oxycodone taking behaviors in rodents. The therapeutic and rewarding effects of oxycodone are both due to its binding to opioid receptors in the brain and periphery. In the present study, we sought to identify biochemical cascades that might be associated with early withdrawal from escalated and non-escalated oxycodone self-administration in rats. To reach that goal, we trained separate groups of rats to self-administer oxycodone using short-access (3h) and long-access (9h) paradigms that lasted for 20 days. Rats were euthanized at 2 hours after the last day of training. Striatal tissues were collected to measure the expression of proteins involved in cellular phosphorylation signaling cascades. Rats given long access to oxycodone escalated their intake of oxycodone to differential degrees, with some rats (LgA-H) taking greater amount of oxycodone than others (LgA-L). Short Access (ShA) rats did not escalate their intake. Biochemical analyses revealed increased abundance of several phosphoproteins of the MAPK-ERK signaling pathway only in the LgA-H animals. Activation of that cascade also led to CREB phosphorylation and histone H3 phosphorylation. These observations suggest that oxycodone SA may cause escalation of drug intake via increased

expression of genes that are downstream targets of this activated cascade. Identification of these genes and their protein products may inform the development of better therapeutic agents to suppress oxycodone abuse and subsequent addiction.

Title: Oxycodone self-administration under punishment: Differential immediate early gene expression in the dorsal striatum of compulsive oxycodone takers and abstinent rats

Authors: *M. T. MCCOY, C. A. BLACKWOOD, B. LADENHEIM, J. L. CADET;
Mol. Neuropsychiatry Br., DHHS/NIH/NIDA/IRP, Baltimore, MD

Abstract: Oxycodone is a prescribed opioid drug that is abused in the USA due to over-prescription. Approaches to treatment of opioid addiction are often difficult because of repeated relapses to drug taking behaviors even after long periods of abstinence. These difficulties in developing successful treatment may be related to lack of understanding of the molecular neurobiology of opioid addiction. To provide partial elucidation of these mechanisms, our laboratory has used footshocks as adverse consequences during oxycodone self-administration (SA) to model one of the criteria of substance use disorders (SUDs). For this presentation, we have used this model to measure potential changes in the expression of immediate early genes (IEGs) in the dorsal striatum of rats during early withdrawal times from oxycodone SA and footshocks.
Male Sprague-Dawley rats were trained to self-administer oxycodone (0.1 mg/kg/injection, i.v.) for 6-9hour training sessions for 22 days. After training, the escalated rats were administered 9-hour foot-shocks with increasing intensity over a period of 6 days. The rats were euthanized 2h after the last session. We then extracted RNA from the dSTR, made cDNA, and ran quantitative polymerase chain reaction (PCR) to measure the expression of Fos-, Jun-, and Egr- IEG families. Rats, given access to 9 hours of oxycodone escalated their intake of oxycodone over the time of the behavioral experiment. The introduction of contingent foot-shocks produced two distinct oxycodone SA phenotypes: (1) shock-resistant (SR) rats that continued to press the lever for oxycodone despite punishment and (2) shock-sensitive (SS) rats that significantly reduced their lever pressing. Quantitative PCR revealed significant decreases in FosB and Egr2 expression in the sensitive group compared to the control and resistant groups. In addition, c-jun and Egr1 mRNA levels were significantly decreased in the SS phenotype in comparison to control rats.

These observations suggest that abstinence from oxycodone self-administration in the presence of contingent punishment may be related to decreased expression of genes that are down-stream targets of several IEGs. This model that mimics the criterion of compulsive drug taking in the presence of adverse consequences may provide greater insight into the molecular neurobiology of oxycodone addiction.

Title: Opioid overdose and rescue impairs risk-based decision-making and behavioral flexibility

Authors: *H. J. CARMON, S. M. THOMPSON, M. S. MCMURRAY;
Psychology, Miami Univ., Oxford, OH

Abstract: The opioid epidemic has become a growing issue throughout the United States. In the year 2016, synthetic opioids such as fentanyl were among the most common drugs involved in overdose deaths in the United States. Fentanyl induces a hypoxic state during an overdose, in which the brain becomes deprived of oxygen and can be damaged. Overdose rescue via naloxone is relatively new and prevents opioids from binding to opioid receptors, saving an overdosing individual. Thus, recent individuals who have overdosed on opioids are more likely to survive due to the increased use of naloxone; however, the consequences of overdose-induced brain damage are unknown. The purpose of this study is to determine the long term neurobehavioral effects of a fentanyl overdose and naloxone recovery on decision-making, which if affected, could explain reports of increased likelihood of relapse following overdose. To do this, we first developed a novel rat model that accurately depicts the timing and extent of physiological events that occur when an individual overdoses on fentanyl. Next, we used this model to compare the effects of overdose and naloxone recovery to naloxone alone on two decision-making paradigms: probability discounting and probabilistic reversal learning. Preliminary results suggest that animals experiencing fentanyl OD demonstrated an elevated risk preference on the probability discounting task, and reduced behavioral flexibility on the reversal learning task. These preliminary results suggest that deficits in decision-making may be associated with fentanyl overdose, increasing the likelihood of a second potential overdose and complicating treatment of addiction.

Title: Neurotoxic consequences of opioid overdose and rescue

Authors: *S. M. THOMPSON[1], D. N. TAPP[1], H. CARMON[1], E. M. BYRNES[2], M. S. MCMURRAY[1];
[1]Psychology, Miami Univ., Oxford, OH; [2]Tufts Univ. Cummings Sch. Vet Med., North Grafton, MA

Abstract: Widespread use of naloxone, an opioid antagonist, has rescued thousands of opioid overdose victims. However, little is known about the long-term effects of opioid overdose. Postmortem studies have indicated neuropathologies in a number of brain regions after lethal opioid overdose, which could complicate treatment if present in survivors. Here, we determine if cell death is present in the rat brain after overdose and naloxone rescue. Regions associated with the maintenance of addiction and reported to be damaged during overdose were specifically investigated, including the prefrontal cortex, ventral tegmental area, and nucleus accumbens. Jugular catheters were surgically implanted into Long Evans rats, who were then administered either subcutaneous naloxone alone (control group), or IV fentanyl (2mg/kg) and subcutaneous naloxone (0.25mg/kg) 10 minutes later (overdose group). Brains were extracted and rapidly and flash frozen for slicing. Neuropathologies (cell death, shrinkage, malformation, etc) were visualized by fluorescent imaging and manually counted with Image J. Damage to these brain regions suggest that they maybe involved in relapse and are permanently affected by overdose in survivors, complicating treatment and contributing to future risks. Additionally, other cognitive domains may also be affected by opioid overdose, including reward processing, decision-making, and potentially memory.

Title: Small molecule inhibitors of PSD95-nNOS protein-protein interactions suppress opioid-induced reward

Authors: *S. A. SABERI[1], C. RANGEL-BARAJAS[1], T. GUTIERREZ[1], V. IYER[1], Y. Y. LAI[1], P. M. KULKARNI[2], S. GARAI[2], G. A. THAKUR[2], J. D. CRYSTAL[1], G. V. REBEC[1], A. G. HOHMANN[1];
[1]Dept. of Psychological and Brain Sci., Indiana Univ., Bloomington, IN; [2]Dept. of Pharmaceut. Sci., Northeastern Univ., Boston, MA

Abstract: Excessive glutamate signaling through *N*-methyl-D-aspartate receptors (NMDARs) is implicated in altered forms of neuronal plasticity including opioid reward and dependence. NMDAR antagonists can block these effects, but their clinical use is limited by adverse side-effects. However, such side-effects can potentially be circumvented by interrupting NMDAR activity downstream. Excessive NMDAR activity activates the enzyme neuronal nitric oxide synthase (nNOS) to produce the signaling molecule nitric oxide (NO). nNOS is tethered to NMDARs via the scaffolding protein postsynaptic density 95 kDa (PSD95). Thus, disruption of the protein-protein interaction between PSD95 and nNOS may provide a viable therapeutic route to inhibit NMDAR-dependent opioid reward without unwanted side-effects of NMDAR antagonists. We previously reported that small-molecule inhibitors of PSD95-nNOS protein-protein interactions (IC87201, ZL006) inhibited NMDAR-dependent NO formation and suppressed pathological pain without impairing memory or motor function (*Neuropharm* 97 (2015) 464-75; *Behav Brain Res* (2016) 305:23-29). However, whether PSD95-nNOS inhibitors themselves lack abuse liability or interfere with NMDAR-dependent opioid reward remains unknown. We used a three-chamber conditioned place preference (CPP) assay to evaluate the impact of IC87201 and ZL006 on opioid reward. Morphine produced robust CPP whereas IC87201 and ZL006 failed to induce either place preference or aversion. Both IC87201 and ZL006 blocked CPP to morphine at doses that lacked intrinsic rewarding or aversive properties. Similar results were observed using CPP paradigms that involved either repeated or single pairings. Our results support the hypothesis that PSD95-nNOS inhibitors exhibit limited abuse liability. Our findings also highlight a previously unrecognized role for PSD95-nNOS disruptors

as a novel non-opioid therapeutic strategy that shows promise for suppressing opioid reward.

Title: Negative allosteric modulation of CB1 cannabinoid receptor signaling suppresses opioid-mediated reward and dopamine efflux

Authors: *V. IYER[1,2], C. RANGEL-BARAJAS[1,2], J. D. CRYSTAL[1,2], A. KULKARNI[4], G. A. THAKUR[4], G. V. REBEC[1,2], A. G. HOHMANN[1,2,3];

Abstract: In recent years, the pervasiveness of the opioid crisis has underscored the urgent need to identify novel compounds that circumvent opioid abuse liability while sparing their therapeutic efficacy. Opioid reward and reinforcement require crosstalk between cannabinoid type 1 receptors (CB1R) and mu-opioid receptors (MOR). While CB1R modulate the motivational properties of opioids via dopaminergic mechanisms and are well-positioned to control critical aspects of opioid abuse, the clinical use of CB1R agonists and antagonists have been limited by adverse side effects. Allosteric modulation represents an indirect strategy to modulate endocannabinoid signaling by targeting a site distinct from that which binds agonists like Delta-9-tetrahydrocannabinol (THC) or the natural ligands (endocannabinoids) of CB1R. Positive and negative allosteric modulators (PAM and NAM) increase or decrease the affinity and/or efficacy of orthosteric agonists, respectively and may produce an optimal and circumscribed spectrum of physiological effects compared to the indiscriminate effects of agonists or antagonists. The present study used GAT358, a CB1-NAM to test the hypothesis that negative allosteric modulation of CB1R would block opioid reward by decreasing dopaminergic

transmission, while bypassing the unwanted side effects of direct CB1R blockade. In vivo voltammetry findings suggest that GAT358, a CB1-NAM can attenuate morphine-induced increases in dopamine signaling in the nucleus accumbens shell, a key component of the mesocorticolimbic reward pathway. GAT358 also blocked morphine mediated conditioned place preference without producing reward or aversion when administered alone. Our results support the therapeutic potential of negative allosteric modulation of CB1R and highlight their role in fine-tuning the undesirable on-target effects of MOR signaling.

Title: Micro-LED optoelectrodes for high-spatiotemporal-resolution *in-vivo* opto-electrophysiology (optoEphys) in freely moving animals

Authors: *K. KIM[1], J. SEYMOUR[1], Y. WU[1], G. BUZSAKI[2], E. YOON[1];
[1]Univ. of Michigan, Ann Arbor, MI; [2]New York Univ., New York, NY

Abstract: Micro-LED optoelectrode, whose first prototype was presented in [1], is a Michigan Probe with monolithically integrated cell-sized (10 × 15 μm) micro-LEDs (μLEDs). Its capability of high-spatial-resolution optical stimulation combined with matching resolution for extracellular electrical recording enables a variety of experiments for the study of micro-circuits inside the brain. A number of improvements have been made to the μLED optoelectrode so that the tool can meet a variety of specifications for an ideal tool for in-vivo optical stimulation combined with electrical recording, or opto-electrophysiology (optoEphys).
Optoelectrodes are currently being disseminated through our NSF funded hub, NeuroNex MINT, and actively utilized in experiments to answer the fundamental neuroscience questions. We present specifications of the μLED optoelectrode and introduce some of the exciting neuroscience experiments that it enables. Furthermore, we are seeking new collaborators to help us guide the design toward greater future impact.

Title: Transcranial radio frequency stimulation (TRFS): A novel noninvasive contactless neuromodulation technique based on radio frequency waves

Authors: *O. YAGHMAZADEH, M. VÖRÖSLAKOS, L. ALON, B. ZHANG, D. K. SODICKSON, G. BUZSAKI;
New York University, Sch. of Med., New York, NY

Abstract: Affecting brain activity by means of external stimuli provides various possibilities for research and clinical applications. In this context, non-invasive neuromodulation techniques sit in a unique position due to their potential low level of side effects. Here we introduce a novel non-invasive contact-less neuromodulation technique based on Radio Frequency (RF) waves. We demonstrate entrainment of neuronal activity, at single cell and neural network levels, by RF exposure in rodent models. We apply RF stimulation at around 1GHz by TEM cell or patch antenna. The RF stimulation intensities that we apply induce electric field and SAR values that are well below the threshold set by safety regulations. We demonstrate that our stimulation paradigm does not induce a significant increase in the body and brain temperature (<0.5°C; n=4 rats and n=2 mice). While applying these 'temperature-safe' intensities, we record in-vivo brain activity in freely moving rodents with silicon probes (hippocampal and cortical regions). Radio-Frequency stimulation is able to modulate the ongoing activity of approximately 30% of neurons, including pyramidal cells and interneurons in both mice and rats. In addition, RF stimulation can affect the ongoing network activity, such as the power and occurrence rate of hippocampal sharp-wave ripples. We demonstrate entrainment of neurons' action potential firing with low frequency (1-20Hz) amplitude modulated RF stimuli. We also provide evidence for RF dose- and direction-dependent response in neural firing in head fixed anesthetized rats. Finite-element physics-based electrodynamic simulations demonstrate the possibility of achieving the induction of similar electric field levels to what we have used in our pilot animal studies into the human brain, suggesting the potential use of this novel method in clinical applications, hence promising the birth of a novel neuromodulation technique: *Transcranial Radio Frequency Stimulation* (TRFS).

Title: Hardware and software for driving high-density optogenetic µLED probes in freely moving animals

Authors: *N. SLAGER[1], A. MENDRELA[1], D. JAMES[1], K. KIM[2], H. YE[1], J. P. SEYMOUR[1], E. YOON[1];
[2]Dept. of Electrical Engin. and Computer Sci., [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Recent advances have allowed for chronic recording and optogenetic stimulation in freely moving animals via high-density monolithically integrated µLED (10 x 16 µm, 460nm peak emission wavelength) probes. In this poster we present an open-source hardware/software implementation for precisely controlling the individual µLEDs independently by user-defined customizable waveforms.
The open source hardware (133 x 93 mm) consists of low cost ($450), discrete, commercially available components. Based on the Texas Instruments' DAC8750 (digital to analog converter), the system includes 12 independent stimulation channels (compatible with a 12 µLED probe), all controllable from field programmable gate array (FPGA) and MATLAB code. The system also incorporates trigger functions (in/out) for external control and communication. All documentation, printed circuit board (PCB) gerber files, and code will be open sourced.
However, as the density of µLEDs increases, it becomes difficult to scale up the number of discrete components on a PCB. Therefore, work has been done to design, build and test integrated circuits for current-based independent driving of 36 µLEDs. Similar to the discrete circuit design, this includes custom waveform generation to avoid artefacts induced by step changes in driving current. In addition, this design features open source FPGA and MATLAB code for complete control, communication and interfacing via trigger functions on all 36 channels.
Future work involves increasing the channel count available for driving high-density µLED probes up to 128 and beyond.

Title: Rapid customization and distribution of carbon fiber array prototypes via the multimodal integrated neural technologies (MINT) hub

Authors: *J. RICHIE[1], P. R. PATEL[1], E. J. WELLE[1], E. DELLA VALLE[1], J. D. WEILAND[1], E. YOON[2], J. P. SEYMOUR[3], C. A. CHESTEK[1];
[1]Biomed. Engin., [2]Biomed. Engineering, Electrical Engin. and Computer Sci., [3]Univ. of Michigan, Ann Arbor, MI

Abstract: The BRAIN Initiative is directed toward accelerating the development and application of innovative technologies to help understand the nervous system. Traditional electrodes are fabricated using silicon based structures. Our group has developed low-cost carbon fiber electrode (diameter = 8um) arrays that are directly mounted to printed circuit boards. While the boards do require many manual fabrication steps, an unexpected benefit to this is the ability to rapidly prototype design changes. Recently, through the NSF funded NeuroNex MINT Hub at University of Michigan, we have established a comprehensive service center for designing and fabricating custom arrays. This center, the carbon fiber core, connects users to the design options and use of this high-density technology. While the basic form factor is similar to previous carbon fiber devices produced (Patel 2015), primary capabilities of the core include changing the number of populated fibers, length of electrodes, tip geometry, and tip coating material. Electrode site numbers are currently limited to up to 16 channels, but can be arranged in varying configurations. The length of the electrode itself can be between 100um-500um and maintain its ability to self-insert into brain tissue without temporary stiffening agents. The shank of the probe can also be selected (10mm or 3mm) depending on the needs of an experiment. Tips coatings can either be optimized for dopaminergic recordings (laser ablation and plasma ashing) or for electrophysiology (PEDOT:pTS or platinum coatings). Users are able to request probes tailored to their experimental needs, troubleshooting assistance, and receive updates about new devices and modifications that can be requested. As of April 2019, our lab has distributed 162 devices to 22 labs in just over a year with successful, reproducible results. Of those labs, 13 are external to University of Michigan and have received roughly 40% of all devices and services provided by our core, with the other 60% having been distributed to labs internal to University of Michigan. Carbon fiber have been requested for use in mammalian (rodent and feline), insect, and *Aplysia* neural systems. Based on a cost analysis study for a batch of 8 probes, a quarter of the cost of the

arrays are labor followed by the combined cost of the Omnetics connector and PCB. This eases customization as the labor per device remains about the same for each modification. In small volume production, a university based service center could allow for these rapid modifications with a relatively low cost of production per device.

Title: Intraoperative large scale extracellular recordings for studying the cellular and microcircuit basis of human cognition

Authors: *V. M. EISENKOLB, J. GEMPT, B. MEYER, S. N. JACOB;
Dept. of Neurosurg., Tech. Univ. of Munich, Munich, Germany

Abstract: The mammalian frontoparietal association cortex is crucial for intelligent behavior. As a center for executive control, these regions are responsible for grouping of sensory stimuli into abstract categories, online storage in working memory and selection of behaviorally relevant over distracting information. It is unknown how individual neurons and neuronal networks in the human association cortex control these higher brain functions. Commonly used methods in human cognitive neuroscience such as EEG or fMRI provide large coverage, but suffer from substantial spatial and temporal summation of neuronal signals which precludes the investigation of cognitive functions at the cellular and microcircuit level. To overcome these obstacles, we have established techniques to implant high-density, multi-channel microelectrode arrays (Utah arrays) into functional parts of the left prefrontal and posterior parietal cortex of awake neurosurgical patients undergoing resection of left-hemispheric brain masses (e.g. tumors). The array can be placed flexibly within the craniotomy allowing us to record with broad cortical access from many locations on the lateral convexity. During sleep and awake phases of the surgery, we record stable local field potentials (LFPs) and spiking activity of individual neurons on up to 96 channels simultaneously. These acute, large-scale extracellular cortical recordings can be combined with cognitive tasks requiring e.g. the categorization of abstract numerical

information. With adequate training, patients achieve satisfactory to very good intraoperative performance in the demanding setting of awake brain surgery. The combination of multi-channel recordings directly from the human association cortex with controlled behavioral tasks opens up new possibilities to study species-independent principles of cognitive functioning and to address neuronal mechanisms that govern human-specific cognition (e.g. language) on a microcircuit level.

Title: A novel modular behavioral apparatus to standardize experimental context in recognition memory assessment

Authors: *M. TROPEA[1], W. GULISANO[1], D. PUZZO[1,2];
[1]Biomed. and Biotechnological Sci., Univ. of Catania, Catania, Italy; [2]Oasi Res. Institute-IRCCS, Troina, Italy

Abstract: The object recognition test (ORT) exploits the natural curiosity of rodents for novelty to asses recognition memory. Mice are presented with two similar objects during the first session (training), and one of the two objects is replaced by a new object during a second session (testing). The amount of time taken to explore the new object provides an index of memory. The easy technical execution, the lack of aversive stressful stimuli and the possibility to repeat the test on the same mice, make the ORT one of the most commonly used behavioral test to study learning and memory in mouse models. However, mice exploration is strongly influenced by the environment and the high variability of protocols used might critically affect the reliability of the results. To standardize the experimental context, we designed a customized behavioral apparatus by using the SolidWorks software. The apparatus consisted in a frame made by assembling aluminum profiles equipped with 3D-printed components to insert the Acrylic glass panels constituting the arena. Lights and a webcam to record mouse behavior were allocated on the lid of the frame. An anti-glare film was applied on the panels and light sources were located to assure a homogeneous illumination. We first tested different light intensities to assess the optimal environmental conditions. Next, we investigated the preference and/or discrimination capability for objects characterized by different colors, materials, shapes or dimensions. We found that mice tested by our customized behavioral apparatus presented a basal increase of

exploration time and less variability in latency to explore the object for the first time, and exploration time, suggesting a high repeatability of the experimental setting and an improvement of the context. Moreover, the preference/discrimination test provided us with an unbiased set of items to use during the ORT, as ethological characteristics of mice, influencing the natural curiosity and propensity to exploration for a specific object, have been taken into account.Thus, our customized apparatus might be useful when designing a behavioral experiment in order to improve the scientific outcomes and minimize possible biases. Moreover, besides its low cost, the modular design can be easily applied to perform different behavioral tests when the exploration of an arena is required (e.g. open field test, novel object location test).

Title: Using network metrics to characterize network functionality in hippocampal CA1

Authors: ***D. T. GUENTHER**[1], N. DELROCCO[2], C. HERDEGEN[3], N. M. DICOLA[1], D. R. MILLER[1], H. KHOSHBOUEI[1], S. N. BURKE[1], K. DIBA[6], R. VACCA[4], A. P. MAURER[5]; [1]Neurosci., [2]Biostatistics, [3]McKnight Brain Inst., [4]Sociology, [5]Evelyn F. McKnight Brain Inst., Univ. of Florida, Gainesville, FL; [6]Dept of Anesthesiol., Univ. of Michigan, Ann Arbor, MI

Abstract: Structure and function have a dynamic interplay in the brain, organizing the flow of activity in support of behavior. While functional connectivity parameters have been widely studied in human imaging data, less is known regarding the neuronal dynamics of local networks underlying these parameters. Recently, advances in single-cell neurophysiology have enabled the measurement of several neurons simultaneously. Convergent development in graph theory has allowed for the intersection between theory and application of network metrics to the single cell level in freely behaving animals. The current study used hippocampal CA1 recordings from populations of individual CA1 neurons, a subpopulation of which had an additional bilateral hippocampal CA1 implants. Recordings were made immediately before, during, and after rats traversed a linear track to quantify functional CA1 network organization. Neurons were considered connected in the network when the cross-correlogram between two neurons had a significant short-time peak within 5 milliseconds. Across rats, during rest and run epochs,

interneurons showed a higher degree (number of connections) relative to pyramidal cells, indicating their role as hubs. The hub organization of interneurons, however, was largely confined within a hemisphere. The majority of inter-hemispheric connectivity was between pyramidal neurons. This suggests that local network structure is largely governed by the local interneurons while interactions between distal regions is primarily driven through pyramidal neurons. When performing on the task, more neurons were recruited within the network relative to the pre- and post-behavior rest periods. Therefore, the reorganization in network structure may be a result from reorganization during learning.

Title: Translational rat model of cognitive aging using a touchscreen operant platform to test visual discrimination and association

Authors: *S. ZEQUEIRA[1], S. A. JOHNSON[1], A. HAMPTON[2], A. P. MAURER[1], J. L. BIZON[1], S. N. BURKE[1];
[1]Neurosci., [2]Psychology, Univ. of Florida, Gainesville, FL

Abstract: Animal models play an essential role in testing treatments for cognitive dysfunction linked to advanced age and Alzheimer's disease (AD). Within animal models, behavioral paradigms are designed to elucidate neurobiological underpinnings of these cognitive impairments; however, tasks administered to rodents often do not parallel those used in humans. Rodent cognition is frequently assessed in mazes using 3-dimensional object stimuli, while human participants are more often tested with 2-dimensional image stimuli displayed on computer monitors. The Cambridge Neuropsychological Test Automated Battery (CANTAB), a non-verbal cognitive assessment tool administered on interactive touchscreens, has been widely implemented to gauge cognitive dysfunction in humans and non-human primates (Robbins et al. 1994; Roberts 1996) and, more recently, in rats and mice (Bussey et al. 2012). In particular, the CANTAB Paired Associates Learning (PAL) task has been adapted for screening rodent visuospatial learning (Talpos et al. 2009). In the task, three distinct visual stimuli (A, B, and C)

are associated with three touchscreen locations (1,2, and 3, respectively). On each trial, rats choose between a correct stimulus-location conjunction (e.g. A1) and a stimulus presented in one of two incorrect locations (e.g. B3). Impaired PAL performance is observed in humans with AD (Égerházi et al. 2007) and in young adult rats following disruption of neural activity in brain regions associated with AD (Talpos et al. 2009). However, PAL performance has not yet been assessed in rat models of cognitive aging. Another test sensitive to cognitive dysfunction in older adults and AD is the Mnemonic Similarity Task (MST) (Yassa et al., 2010; Stark et al., 2013), which measures participants' abilities to discriminate between image stimuli that share overlapping features. In our rodent adaptation of the MST, two image stimuli are displayed on the touchscreen: a previously learned target image and a lure that ranges in similarity to the target. On each trial, rats choose between the rewarded target and an incorrect lure. The current study assessed performance of adult (10-12 months) and aged (26-30 months) F344 x Brown Norway F1 hybrid rats on touchscreen PAL and MST tasks. Performance was compared across tasks to identify potential differences in visual discrimination and associative memory in aged animals. Future research utilizing these cross-species behavioral paradigms will advance our understanding of neurobiological aging and guide development of effective therapeutic interventions for cognitive decline in advanced age and AD.

Title: A methodology pipeline for CLARITY and Arc imaging following vagus nerve stimulation

Authors: *M. MELTON[1], S. BURKE[1], M. ASH[1], D. LAMB[1], L. BRATTAIN[2], K. OTTO[1], B. SETLOW[1], J. BIZON[1], A. MAURER[1], K. OLCZAK[1], E. DIRR[1];
[1]Univ. of Florida, Gainesville, FL; [2]MIT, Lexington, MA

Abstract: Methods to augment learning rates are of significant interest. Manipulation of neuromodulatory brain systems with pharmaceuticals have been shown to enhance attention, perception, memory, and other cognitive abilities; yet the mechanisms of these systemic treatments can produce non-specific effects that eclipse the cognitive benefits of such interventions. Direct nervous system interfaces offer an intriguing cognitive enhancement

alternative because of the precise spatial and temporal control opportunities, yet they are difficult to realize due to the necessary invasiveness. On the contrary, peripheral nervous system neuromodulation is possible via non-invasive transcutaneous stimulation. Critically, the mechanisms by which peripheral nerve stimulation modulates brain function need to be elucidated to optimize the ability of these types of interventions to enhance cognitive function. We have developed a pipeline for examining the ability of cervical vagus nerve stimulation to modulate the expression of the immediate-early gene *Arc* in cleared brain tissue.
Rats (4-7 months old) were surgically implanted with a stimulating electrode cuff (Qualia) around the cervical branch of the vagus nerve. After a recovery period, rats received high-frequency (50 Hz) vagus nerve stimulation paired with object exploration for 15 min; they were sacrificed 30 min later and perfused via hydrogel solution. After fixation, and subsequent polymerization, the brain tissue was passively cleared for 1-2 months. After sufficient clearing, the sample was incubated with an ARC and tyrosine hydroxylase antibody and nuclei were stained with DAPI. Samples were imaged using a Zeiss lightsheet Z.1 with complimentary ARIVIS Vision 4D modular software. This pipeline will enable the visualization of plasticity networks engaged by vagus-nerve stimulation.

Title: Automated multichannel centroid detection and coincident analysis of cleared brain tissue following vagus nerve stimulation

Authors: D. G. LAMB[1], M. MELTON[2], J. L. BIZON[3], M. ASH[4], *S. N. BURKE[3], K. J. OTTO[4], B. SETLOW[5], A. P. MAURER[6], E. DIRR[4], L. BRATTAIN[7];
[1]Psychiatry, Univ. of Florida, Gainesville, FL; [2]Univ. of Florida, Gainesville, AL; [3]Neurosci., [5]Dept. of Psychiatry, [6]Evelyn F. McKnight Brain Inst., [4]Univ. of Florida, Gainesville, FL; [7]MIT, Lexington, MA

Abstract: Stimulation of peripheral nerves offers an opportunity to non-invasively modulate brain function in order to treat disease as well as to enhance cognitive performance in healthy adults. In particular, Vagus Nerve Stimulation (VNS) has been of interest due to its broad

involvement in autonomic regulation, metabolism, and sensory/motor integration between the brain and viscera. Moreover, as VNS has been shown to induce network modification, efforts are underway to map the induction of plasticity across the brain in response to VNS by labeling the expression of immediate-early genes. Immediate-early genes are transcribed by neurons following patterned neural activity associated with active behavior and can therefore be used to identify cellular populations undergoing plasticity. While large-scale (Terabyte +) 3D fluorescence multichannel z-stack images of cleared rat brain tissue can be used for VNS-induced network plasticity reconstruction and analysis, there is currently no effective tool for automated plasticity analysis at scale. Such an analysis requires the identification of cell bodies and a fluorescently labeled protein of interest, as well as the spatial coincidence of these two signals. Image analysis challenges include the time it takes to extract images from the data acquired by the imager and the lack of robust neuron component detection algorithms that can process TB+ datasets efficiently. To tackle this unmet need, we are developing an automated multichannel centroid detection and coincident analysis pipeline, which consists of three main steps: 1) fast image extraction and compression directly from the microscopy outputs, 2) centroid detection using image processing techniques combined with deep learning 3) coincidence analysis among multiple channels, each corresponding to a particular fluorescent marker. The pipeline is implemented on a high-performance CPU cluster using parallel programming (pMatlab), and is able to process multiple tissue blocks simultaneously. An interactive front-end user interface is also being developed for quick reviews of both the raw data and results, allowing for editing of the centroid detections. Accuracy is currently being assessed by experts and will be reported in the poster. In the future, we plan to leverage deep learning to further improve our algorithm performance.

Abstract: TAR-DNA-binding protein 43 (TD-P43) misfolding and aggregation is a major pathological hallmark of Fronto-Temporal Dementia (FTD) and Amyotrophic Lateral Sclerosis (ALS) but, has also impact in Alzheimer's and Parkinson's. FTD and ALS are characterized by motor and cognitive impairments. However, robust cognitive phenotypes related to TDP-43 proteinopathy have not yet been explored in mouse models of FTD/ALS. In this study, we used the Bussey-Saksida touchscreen technology for assessing executive function in the transgenic FTD/ALS mouse model TDP-43^{Q331K_low}. It has been reported that these mice show motor impairments at 12 months of age. However, cognitive dysfunction has not yet been evaluated in this mouse line. Attention and learning/cognitive flexibility (major constructs affected in FTD/ALS) were assessed in TDP-43^{Q331K_low} male mice using the Five Choice Serial Reaction Time Task (5-CRSTT) and Pairwise Visual Discrimination (PVD) task. In 5-CRSTT, TDP-43^{Q331K_low} mice (5-6-month-old) present greater number of omissions and compulsive-like behaviour. Interestingly, in PVD task TDP-43^{Q331K_low} mice were impaired in the acquisition and reversal phase of the task, suggesting that these mice present learning and potentially cognitive flexibility deficits. These results indicate that the TDP43$^{Q331K\text{-}low}$ mice present attentional, learning and cognitive flexibility deficits, similar to the cognitive impairments observed in humans affected by these diseases. Also, reveal the usefulness of the touchscreen tasks for the development or new therapeutic approaches for FTD/ALS. All the touchscreen results are deposited into an open-access database (www.mousebytes.ca) we have developed that allows for search, upload, storage, and re-analysis of touchscreen data from mouse models of neurodegeneration.

Title: A task that allows analyzing separately the different stages of decision making: An electroencephalographic study

Authors: *P. CORTES ESPARZA, J. GARCÍA-HERNÁNDEZ, M. RAMÍREZ-RENTERÍA, M. HERNÁNDEZ-GONZÁLEZ, M. GUEVARA;
Inst. De Neurociencias, Guadalajara, Mexico

Abstract: Decision making is the ability to process multiple alternatives and choose an optimal course of action to achieve one's goals in a given situation. This definition underlays a temporally structured process that many authors have sought to describe. Ernst and Paulus proposed a theoretical model that divided decision making into 3 temporally different stages based on distinct cognitive process and functionality of several brain structures. These stages were defined as follows: 1) input y process (forming preferences for each stimulus); 2) output (executing an action); and 3) feedback (experiencing the outcome of the action). Although there are cognitive processes specific to each stage, some as motivation, attention and working memory are present during the whole decision making difficult the individual analysis of each stage. Especially, the individual analysis of stage 2 has been challenging since most experimental paradigms can't temporally divide stage 1 from 2 or stage 2 from 3. Because of this, little is understood of how stage 2 integrates cognitive processes into a well-defined motor plan to achieve a set goal. With this in mind, we design an experimental task aimed at temporally separating the 3 stages of decision making proposed by Ernst and Paulus. Against this background, the objective of this study was to characterize the electrical activity of the prefrontal, temporal and parietal cortices during the execution of the proposed task in the different stages of decision-making. In thirty healthy, right-handed men aged 20-35, the electroencephalographic activity (EEG) was recorded from the frontopolar (Fp1-Fp2), dorsolateral (F3-F4), temporal (T3-T4) and parietal (P3-P4) cortices during stages 1, 2 and 3 of the decision-making task. Absolute power (AP) was analyzed in the following EEG bands: theta, alpha1, alpha2, beta1, beta2 and gamma. The stages 1 and 3 showed a similar EEG pattern characterized by a higher AP of alpha and beta bands in dorsolateral and parietal areas, while stage 2 showed a higher AP of theta band in posterior areas (temporal and parietal) and gamma in the left frontopolar area. Alfa and beta bands are related to visual stimuli processing and attentional components, so its higher activation during the stages 1 and 3 could be related to the stimuli-outcome association while theta activation in stage 2 could be related to information processing and motivational components of the task execution. These results show a different cortical activation for each stage (especially stage 2) of decision making thus the proposed task could be a useful tool to study the temporal divisions of the decision-making process.

Title: Nelpy: A powerful toolset for the analysis of electrophysiology data

Authors: *J. CHU, E. ACKERMANN, C. KEMERE;
Rice Univ., Houston, TX

Abstract: Recent advances in neural recording technology have enabled hundreds to thousands of channels. As bottlenecks shift away from data acquisition toward data analysis, it is imperative to have fast, flexible tools for such experiments. Here we introduce the nelpy ecosystem, a collection of Python software packages that enable the neuroscientist to process data with a convenient object-oriented syntax and perform common analyses. The core nelpy package supports a range of data typically encountered by electrophysiologists, including sampled analog signals, spike trains, and binned spike trains, with each of these objects allowing fast time or indexed-based data access. In addition to convenient containerization, nelpy provides a highly customizable plotting library for quick data visualization and exploration.
The nelpy ecosystem provides a comprehensive environment by supplying the user with multiple options for different kinds of analyses. To showcase this power and flexibility, we give examples of neural spike train decoding with a variety of decoders, including the common Bayesian methods, and we demonstrate spectral analyses with our nelpy-compatible package ghost. Ghost augments nelpy's capabilities by being one of the first Python packages to implement the state-of-the-art generalized Morse wavelet transform, and it offers additional features such as multitaper spectrum estimation and cross-frequency coupling analysis.
Nelpy reduces frequently experienced bottlenecks by handling the heavy lifting of data representation and implementing a variety of analyses in a fast, principled manner. We thus believe that nelpy will be an invaluable tool for many neuroscientists and will aid the reliability and reproducibility of results from electrophysiology experiments.

Title: Computational methods for advancing sharp-wave ripple detection and disruption

Authors: *A. K. FELDMAN, S. DUTTA, C. T. KEMERE;
Rice Univ., Houston, TX

Abstract: Hippocampal sharp-wave ripples (SWRs) arise from the synchronous firing of neural populations in CA3 and present as transient 150-250 Hz oscillations in CA1 pyramidal layer accompanied by sharp-waves in CA1 stratum radiatum, lasting approximately 60-150 ms. These events have been shown to be highly correlated with memory consolidation, recall and decision making, as they represent sequential reactivation of cells based on previous experience. Thus, selective interrogation of SWR events provides an attractive opportunity to modulate memory formation, relying on fast, effective algorithms for detection and disruption. While state-of-the-art closed loops systems have enabled perturbation of these events, latency between SWR onset and disruption ranges from 35-60 ms based on more liberal canonical ripple boundaries; essentially, these systems only allow for the interrogation of the latter 40-60% of the SWR event. Here, we look to improve detection accuracy and enable further access to SWR events. Through incorporation of false detection channels, temporal detection requirements and data from multiple hippocampal regions, we show improved detection accuracy. Additionally, we quantify performance of our detection algorithm during active animal behavior with varying canonical SWR frequency definitions in order to isolate SWRs from fast-gamma and ultra fast-gamma bursts. Lastly, we look to incorporate machine learning methods (cascade classifiers, deep neural networks, etc.) in order to enable interaction with a larger portion of SWR events. We combine these features with our current modular real-time ripple detection system, thereby increasing user specificity concerning preferential investigation. Overall, we expect our improved SWR detection algorithm will facilitate a wider range of memory consolidation inquiries, including that of *in vivo* SWR generation.

Title: Neuroimaging decoder of cognitive load under stress

Authors: *A. GREENTAL[1], S. REZNIK[2], N. NUTKEVICH[2], I. SHAPIRO[2], T. HENDLER[3]; [1]Tel Aviv Univ., Tel Aviv, Israel; [2]Sagol Brain Institute, Tel Aviv Sourasky Med. Ctr., Tel Aviv, Israel; [3]Psychology, Neurosci. and Psychiatry, Tel-Aviv Univ., Tel Aviv-Yafo, Israel

Abstract: Introduction - Technological advancements and increased complexity in work-environments have highlighted nowadays the need for objective indication of Cognitive Load (CL) under stress. One of the difficulties in studying CL, known to increase under stress, is that it cannot be directly observed, as task demands and performance are not equivalent for subjective experience of load. However, advancements in decoding otherwise unobservable internal states using neuroimaging, along with accumulated knowledge on executive functions and stress in the brain may help outline these processes. We developed a novel fMRI task that ecologically depicts CL. Using this task, we aim to elucidate the neural substrates of CL experience under stress.

Methods - 50 healthy male participants underwent an fMRI scan in which they performed a flight task, incorporating sub-tasks probing executive functions (e.g. working memory and cognitive inhibition) and stress induced by social and physical threat. A sliding window was applied to the extracted whole brain BOLD time series for each window under parcelled brain regions. Classification and regression algorithms were used to infer which regions were associated with the CL in accordance with individual performance, task demands and induced stress (i.e. CL index). Kernel SVMs, recurrent neural network and Ensemble methods were trained and their prediction performance was evaluated by cross validation.

Results - CL index continuous measure was estimated by a recurrent neural network (R=0.32, MSE=0.056), with classification (Gaussian kernel SVM) resulted in accuracy of 71% (AUC: 0.78). Higher CL index was characterized by higher values of the following regions; Intraparietal Sulcus, vent ant Cingulate Cortex, dorsal posterior Cingulate Cortex, L. Dorsolateral Prefrontal Cortex and R. Amygdala . Lower CL index was associated with higher values of the R. Temporoparietal Junction, R. IFG/ant Insula and the R. Putamen.

Conclusions - Our computational approach depicted a distributed pattern of functional indices in both executive function associated areas, as well as limbic and salience areas related to CL under stress. Our study provides a unique platform for studying the complex relation between cognition and stress with several novel aspects - developing an ecological multi-domain paradigm to probe CL in neuroimaging setting; defining CL index based on task demands and individual performance, as well as induced stress, rather than on task demands alone; and using a machine learning approach for associating mental states with brain activation patterns.

Title: Evaluating translational neurophysiological measures to improve efficacy of preclinical therapeutic target discovery

Authors: *D. J. G. GREGG[1], J. F. CAVANAGH[2], G. LIGHT[3], J. W. YOUNG[3], J. L. BRIGMAN[1];
[1]Dept. of Neurosciences, [2]Dept. of Psychology, Univ. of New Mexico, Albuquerque, NM; [3]Dept. of Psychiatry, UCSD, San Diego, CA

Abstract: Preclinical studies can provide many potential therapeutic targets for neuropsychiatric disorders. However, many such targets prove ineffective during clinical trials. The failure to convert preclinical findings into clinical treatments suggests that behavioral similarity without biomarkers demonstrating similar brain function is not sufficient. Using pharmacology and EEG-like behavioral recordings we assessed the translational validity of several cognitive tasks measuring specific Research Domain Criteria (RDoC) which can be performed by both humans and mice. In phase one of the current study we evaluated three tasks, 5-choice continuous performance task (5C-CPT) which was previously shown to have cross-species similarity as accuracy was increased in both species following amphetamine administration, progressive ratio breakpoint task (PRBT), and probabilistic learning task (PLT). Male and female C57BL/6J mice were trained and assessed in a touch-screen based operant system. Once training criteria was reached, mice were fitted with dura-resting leads targeting mPFC, PPC and M1 with a ground centered over the cerebellum. During each recording session oscillatory activity was captured via a multichannel acquisition processor and assessed. Comparable data were obtained from healthy male and female human participants using non-invasive EEG procedures. Analysis of activity during each rodent task found oscillatory activity which correlated strongly with that seen in EEG of healthy human volunteers tested on a reverse-translated variant of the rodent touch-screen tasks. During 5C-CPT, theta and low-beta frequencies during target and particularly non-target trials correlated between species. For PRBP, an increase of alpha power was observed in both humans and mice as they neared their breakpoint. Lastly in PLT, the reward positivity event related potential (ERP) component scaled with the degree of positive prediction error, varying in strength according to probability ratio in both species. In phase two of the current study we administered varying doses of amphetamine (Mouse: 1.0 mg/kg, 0.3 mg/kg, 0.1 mg/kg, and vehicle), (Human: 20 mg/kg, 10 mg/kg, and vehicle) during recording of PRBP and PLT. The

correlation observed in phase one was seen again across amphetamine doses along with a correlation in dose dependent changes in behavioral performance. Taken together, these data support the use of EEG-like recording to examine neurophysiological biomarkers in rodents and humans to enhance the translatability of potential therapeutic targets.

Title: Neural correlates of uncertainty parameters in temporal prediction

Authors: *M. GRABENHORST[1], G. MICHALAREAS[3], L. T. MALONEY[4], D. POEPPEL[2]; [2]Neurosci., [1]Max-Planck-Institute For Empirical Aesthetics, Frankfurt, Germany; [3]Max Planck Inst. for Empirical Aesthetics, Frankfurt Am Main, Germany; [4]New York Univ., New York, NY

Abstract: The anticipation of events in time, based on sensory input, allows for action preparation before an event has occurred. These well-timed responses to salient cues require estimation of several parameters of temporal uncertainty: i) the probability that an event will happen at all - a parameter likely related to resource allocation, ii) the probability density function (PDF) of events, of which the hazard rate (HR) is a prominent model of behavior and related neural activity, and iii) the uncertainty in time estimation which has been suggested to scale with elapsed time, irrespective of event probability (scalar property, a.k.a. temporal blurring). Here we investigate these three important sources of uncertainty in temporal prediction. We conceptualize event anticipation as an inferential process involving a transfer function that relates the brain's stochastic sensory input to its reaction time output. In a series of visual and auditory MEG and psychophysiological experiments, we find consistent results across the two sensory modalities. We propose new computational models for all three uncertainty parameters: i) the effect of event probability on RT is captured by an exponential function that weights time based on event probability (probabilistic weighting), which - similar to a cost function - describes the effect of the probablilty of event occurrence on anticipation in time; ii) the brain uses the reciprocal PDF of events but *not* the commonly employed HR to model event probability over time; and iii) uncertainty in time estimation scales directly with the inverted event PDF (probabilistic blurring) and is not merely based on elapsed time itself. Analyses of MEG data characterize modality-independent and modality-specific neural activity as correlates of anticipatory processes. We relate these electrophysiological findings to the different

computational models. The results suggest that the neurobiological implementation of temporal prediction involves specific computations based on the reciprocal PDF of events in time.

Title: Fiber photometry of anatomically-defined claustrum populations in awake behaving mice

Authors: *G. ATLAN[1], N. PERETZ-RIVLIN[1], E. SHEINBACH[2], A. CITRI[1,2,3];
[1]Edmond and Lily Safra Ctr. for Brain Sci., [2]Inst. of Life Sci., Hebrew Univ. of Jerusalem, Jerusalem, Israel; [3]Program in Child and Brain Develop., Canadian Inst. for Advanced Res., Toronto, ON, Canada

Abstract: The claustrum is a thin neuronal structure, located deep in the mammalian brain. Enclosed between the insular cortex and the striatum, it is reciprocally interconnected with sensory cortices, frontal regions, and subcortical nuclei. We have recently proposed that by regulating cortical gain, the claustrum may suppress task-irrelevant sensory stimuli in support of attentional processes (Goll et al. 2015, Atlan and Terem et al. 2018). Studies of natural activity of the claustrum *in vivo* have been limited in scope (Remedios et al. 2010). As such, while recent work shows that optogenetic claustral activation can have dramatic effects on the cortex (Jackson et al. 2018), it remains unclear whether such activity occurs naturally, and if so, under which circumstances. To understand the natural dynamics of claustral activity, we utilized retrogradely transported viruses and fiber photometry to record calcium transients from anatomically-defined subpopulations of claustral neurons in awake and behaving mice. During quiet wakefulness, spontaneous claustro-cortical output is characterized by low-frequency large bursts of activity. Sensory stimuli, however, elicited differential responses that depended on the alertness state of the mouse. As the claustrum receives substantial input from sensory cortices (Atlan et al. 2017, Wang et al. 2017), these results indicate that the claustrum is kept under a blanket of inhibition during wakefulness, a finding supported by the extensive inhibitory network of claustral interneurons (Kim et al. 2016). We next trained mice on an auditory figure-background segregation task, requiring mice to identify a target tone within a distracting background. Training was done in automated home-cages, minimizing the number of sessions required to achieve successful performance during recordings. Initial analysis indicates that claustrum

population activity is recruited selectively during the different phases of the task. We are currently analyzing these results to define distinct behavioral epochs during which the claustrum is active, as well as to describe how this activity develops with learning. Determining the particular sensory events that evoke activity in the claustrum during behavior is a necessary step to achieve a better understanding of this central structure, which will help direct future studies that selectively suppress or excite claustrum activity.

Title: The global influence of visual signals in guidance of saccadic eye movements

Authors: *K. HUBBARD[1], B. NOUDOOST[2];
[1]Biomed. Engin., [2]Ophthalmology and Visual Sci., Univ. of Utah, Salt Lake City, UT

Abstract: The transformation of sensory signals into motor outputs is at the heart of our visually-guided behavior. How the information within visual areas, such as V4 and middle temporal, is used by motor areas, such as the Frontal Eye Field, is not known. We studied the characteristics of sensorimotor integration in rhesus monkeys during visually guided eye movements. In our visually guided saccade task, after fixating on a central point, a peripheral random dot motion (RDM) target appears, spanning 3-4 degrees of visual angle. The animal needs to maintain fixation until the fixation point disappears. After this go cue, in 25% of trials the animal makes an eye movement toward the RDM (Toward condition). In 75% of trials, simultaneously with the go cue a stationary circle appears as an alternative target to which the animal must make an eye movement to receive a reward (Away condition). In each trial, the RDM target motion was in one of four directions (45, 135, 225, or 315 degrees). First, we confirmed that the direction of motion biased the endpoint of saccades in the Toward condition. We compared the landing points of saccadic eye movements to the RDM target for different directions of motion. We quantified the visual guidance using the area under the curve (AUC) in the receiver operating characteristics method, for saccades to RDM targets with opposite motion directions. AUC values were significantly different than 0.5, indicating the presence of the classic visual guidance phenomenon. In order to examine the spatial specificity of RDM's

influence on biasing saccade vectors, we assessed the AUC in the Away condition. We found that the presence of an RDM stimulus is sufficient to influence the saccade endpoints, even when that RDM stimulus is not the target of the eye movement. These results suggest that the transformation of sensory information into motor commands involves an integration of sensory signals from sources beyond the current target of the eye movement.

Title: Improve the learning of olfactory working memory tasks by suppressing the delay activity of lateral orbitofrontal cortex

Authors: *Q. CHENG[1,2], H. FAN[3], Z. CHEN[3], R. HOU[3], C. T. LI[1,2];
[1]Inst. of Neuroscience, State Key Lab. of Neuroscience, Chinese Acad. of Sciences, CAS Ctr. for Excellence in Brain Sci. and Intelligence Technology, Shanghai Ctr. for Brain Sci. and Brain-Inspired Technol., Shanghai, China; [2]Sch. of Future Technology, Univ. of Chinese Acad. of Sci., Beijing, China; [3]Inst. of Neurosci., Shanghai, China

Abstract: Learning ability is of great significance for survival in a competitive daily life. How to improve learning ability and its corresponding neural basis were relatively unexplored fields in neuroscience research. In this study, we report that suppressing the delay-period activity of lateral orbitofrontal cortex (lOFC) could improve the learning of olfactory working memory (WM) tasks in mouse, via an inhibition of task irrelevant distractions. Optogenetically suppressing the lateral, but not the ventral or medial parts of OFC, enhanced the learning rate of WM task. This effect was specific to the delay-period, rather than the decision-period activity. Silencing the delay activity of lOFC in a dual task, but not in a value-based WM task, could also improve the learning rate, which was compatible with the cognitive map hypothesis but not the value-coding hypothesis. Consistently, neurons in lOFC could encode both the task relevant and irrelevant stimuli. Furthermore, inhibiting the lOFC-to-dorsomedial striatum and lOFC-to-basolateral amygdala pathways could also improve the behavioral performance during learning and reduce the coding of distractions. Therefore, suppressing lOFC could improve learning

ability of mouse through reducing the coding of task-irrelevant distractions in WM within a distributed neural network.

Title: Virtual reality system for the immersive display of visual and audiovisual objects

Authors: *S. SABHARWAL-SIDDIQI, A. DUBEY, J. CHOI, J. HAGGERTY, S. QIAO, E. VOINAS, B. PESARAN;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: As we navigate this world, we use sensory information to react to behaviorally relevant objects. When an object is itself multimodal, our brains enable us to react with optimal speed and accuracy by integrating the sensory inputs. An important question is to understand how and when this integration occurs in the brain. One approach is to present subjects with unimodal and composite multimodal objects, and then to compare reaction times and target selection biases. In attempting to present audiovisual objects, however, investigators are often limited by their experimental equipment. Indeed, it is easy to present a visual object on a 2D monitor, but difficult to precisely co-localize an auditory stimulus. Some circumvent this problem by using real audiovisual objects (speaker with LED light), but this severely limits the range of target properties that can be manipulated in real time. Therefore, to overcome these constraints, we developed a virtual reality (VR) headset for the immersive presentation of visual and audiovisual targets. We displayed visual objects on a modified Oculus Rift gaming headset. A custom cold-mirror assembly for coaxial stimulus delivery permitted stimulus delivery and IR-illuminated eye-tracking. We furthermore refined procedures and equipment for binocular stimulus calibration and implemented corrections for radial distortion and chromatic aberration produced by custom optics. Sounds were artificially localized to defined points in space using a head related transfer function (HRTF) and delivered through earphones. Using a previously published HRTF for the rhesus macaque, we were able to present audiovisual objects to a monkey. The monkey performed a two-alternative forced choice task in which both targets were visually identical but only one was paired with an auditory stimulus. We found that monkey was able to reliably discriminate the audiovisual target from the visual-only target at a statistically significant rate. This suggests that he was able to integrate auditory and visual information in our

virtual reality system, and that this system can be reliably used for future experiments on multisensory integration.

Title: Cell-type-specific suppression of spontaneous activity by attention in visual cortex

Authors: *E. M. SACHSE[1], A. C. SNYDER[1,2,3];
[1]Brain & Cognitive Sci., [2]Neurosci., [3]Ctr. for Visual Sci., Univ. of Rochester, Rochester, NY

Abstract: Multi-unit recordings have helped identify different features of neuronal populations and how they are modulated by attention. Such cellular and circuitry features are important clues to the mechanisms of spatial attention. Information coding in V4 is influenced by complex organization in cortical columns that contain several cell types. Fast-spiking interneurons make up the majority of inhibitory neurons in the cortex and have dense connections to local regular-spiking excitatory neurons. These cell types are known to exhibit different attention dynamics during spontaneous and stimulus-evoked activity. Local inhibitory activity has been shown to alter correlations among excitatory neurons, indicating these inhibitory circuits likely act to regulate activity of local excitatory populations across space and time through changes in neural synchrony. For example, low synchrony may be beneficial during spontaneous activity, as it indicates reduced dependence on internal signals and greater receptivity to stimulation. On the other hand, higher synchrony may effectively transmit information downstream during stimulus processing. To investigate this, we compared attention dynamics of V4 fast-spiking and regular-spiking neurons by recording population activity while monkeys performed an attention task. We measured dynamics of attention modulation for each neuron during spontaneous activity and stimulus-processing and classified neurons as fast-spiking or regular-spiking based on their action potential waveform. For all neuron pairs with significant attention effects, we calculated average synchrony among different cell types and as a function of location on our Utah array. We found that patterns of attention dynamics co-segregated with cell classes and that average synchrony is influenced by local connectivity and pair type. Together, these suggest that fast-

spiking and regular-spiking cell classes play distinct functional roles in the dynamic allocation of attention across sensory stimulation contexts.

Title: Locus coeruleus stimulation averts stress-induced attentional deficits and anxiety

Authors: *A. BARI[1,2], S. XU[1,2], D. TAKEUCHI[3], J. MARTIN[1,2], S. TONEGAWA[1,4,2];
[1]The Picower Inst. for Learning and Memory, Dept. of Brain and Cognitive Sci., [2]RIKEN-MIT Ctr. for Neural Circuit Genet., [4]Dept. of Biol., [3]MIT, Cambridge, MA

Abstract: The locus coeruleus / noradrenergic (LC/NE) system regulates a wide array of cognitive and emotional processes, including attention and anxiety. Selective attention allows focusing on task-relevant information, and the inhibition of distracting stimuli and intrusive thoughts. On the other hand, anxiety is characterized by distractibility and impulsiveness, both of which increase non-selective responding to internal and external stimuli. Stress is known to induce anxiety, which in turn hinders the efficiency of selective attention. Although the interplay between attention and anxiety is generally accepted, it is currently unclear how the LC/NE system activity regulates both, ultimately promoting the optimization of behavioral output. Attention deficits, impulsivity and anxiety often co-occur in several brain disorders such as depression, attention deficit / hyperactivity disorder (ADHD) and Alzheimer's disease. Moreover, these symptoms are all relieved by increasing norepinephrine (NE) synaptic levels via pharmacological blockade of the NE transporter (NET) in certain patient populations, which is suggestive of common neurochemical underpinnings. Because stress is known to activate the LC/NE system, the clinical efficacy of NET blockers on attention deficits and anxiety symptoms seems paradoxical. To better understand the reciprocal influence between attention and anxiety, and their modulation by the LC/NE system, we used double transgenic mice that allow the selective optogenetic manipulation or recording of NET+ neurons activity. We first confirmed the long-hypothesized causal role of LC neurons activation on ameliorating attention and impulsive behavior. More specifically, our results suggest that stimulation of the LC/NE system is necessary and sufficient for the implementation of selective attention, in that, on the contrary,

its inhibition increases distractibility and impulsivity. We also assessed the effects of LC stimulation on tests of anxiety-like behavior. Contrary to a widespread belief, we found that LC activation decreases both baseline and stress-induced anxiety. Finally, we tested the effects of stress on attentional performance with or without LC stimulation. Stressed animals were anxious and displayed marked attentional deficits and impulsive responding. Activation of the LC/NE system immediately before the attentional task prevented these deficits. In summary, our results show that LC neurons stimulation is anxiolytic and completely abolishes the negative effects of stress-induced anxiety by preventing the distractibility and impulsivity that usually follow a stressful experience.

Title: Aging associated attention decline is prevented by D-serine and correlates with a reduction on functional brain connectivity

Authors: L. NAVA-GOMEZ[1], A. CALERO-VARGAS[2], J. ORTIZ-RETANA[3], S. ALCAUTER[3], *M. LOPEZ-HIDALGO[2];
[1]Facultad de Medicina. Univ. Autonoma de Queretaro, Queretaro, Mexico; [2]Escuela Nacional de Estudios Superiores-Unidad Juriquilla. Univ. Nacional Autonoma de Mexico, Queretaro, Mexico; [3]Dept. de Neurobiologia Conductual y Cognitiva. Inst. de Neurobiologia. Univ. Nacional Autonoma de Mexico, Queretaro, Mexico

Abstract: D-serine is essential for the induction of NMDA-receptor-dependent synaptic plasticity and cognitive processes such as attention. Cerebral D-serine levels are diminished in aged rats which could account for the deterioration of these functions with aging. Results from our lab have shown that chronic administration of D-serine significantly improves the performance of aged rats in attention tasks. However, the cellular mechanisms and neural networks underlying this behavioral effect are not clear. To analyze this, we use resting state functional magnetic resonance imaging to study the effect of D-serine on functional connectivity in the aged rat brain. Using a Bruker 7T MRI scanner, we explored the functional connectivity

between selected anatomical structures, previously related to attention performance, in 18-month-old rats. Specifically, we analyzed the functional connectivity between striatum, hippocampus, insular, cingulate, orbitofrontal, frontal and retrosplenial cortices. Rats treated with D-serine showed decreased functional connectivity when compared to 18-month-old rats that did not receive D-serine. Furthermore, the functional connectivity was negatively correlated with attention performance in the rats treated with D-serine but not in the control group, suggesting that D-serine enhances attention performance through the modification of local and long-range functional networks.

Title: A role for adult-born hippocampal neurons in arousal

Authors: *J. MERCURIO[1,2], H. A. CAMERON[3];
[1]Natl. Inst. of Hlth., Bethesda, MD; [2]Neurosci., Brown Univ., Providence, RI; [3]NIMH, NIH, Bethesda, MD

Abstract: During adulthood, new neurons are born and integrated into the pre-existing hippocampal circuitry of the mammalian dentate gyrus (DG). How these immature neurons contribute to downstream circuit activity in the hippocampus and ultimately to behavior remains unclear. By using a transgenic rat line (GFAP-TK rats) to pharmacologically inhibit adult neurogenesis with temporal and cell-type specificity, our lab is studying the function of these adult-born neurons. Previous literature shows that rats with hippocampal lesions have deficits in their ability to orient toward a distracting stimulus while focused on a task (Hendrickson et al., 1969). Our lab has found that rats lacking adult neurogenesis in the DG orient less frequently toward a novel auditory stimulus that is administered during a simple task (i.e. drinking water). The reason rats lacking adult neurogenesis in the DG have this deficit in shifting attention toward a novel stimulus is unclear, but one possibility could be a difference in internal arousal state of the animal, which can affect the sensory input and thus the behavioral output of an animal within its environment. Pupillometry is a non-invasive technique for measuring an organism's physiological arousal that correlates strongly with the more established measure of hippocampal sharp wave activity (McGinley et al., 2015). The existence of arousal signals in the hippocampus

suggest that newborn granule cells could potentially affect arousal and in turn modulate the ability to selectively attend stimuli. We are using pupillometry to compare the arousal states of rats with and without ongoing adult neurogenesis and to determine whether differences in arousal underlie the role of new neurons in orientating toward a novel stimulus.

Title: Sign-trackers deploy perceptual, but not cholinergic-attentional, mechanisms to respond to salient cues

Authors: *K. B. PHILLIPS, C. AVILA, M. SARTER;
Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Sign-trackers (STs) attribute incentive value to stimuli that predict food and drug rewards and therefore have emerged as a model for studying vulnerability for addiction-like behaviors. Relative to goal-trackers (GTs), who do not imbue discrete predictive stimuli with motivational value, STs also show a reduced capacity for engaging forebrain cholinergic signaling for the processing of behaviorally significant and attention-demanding cues. The greater power of Pavlovian drug cues in STs has been attributed in part to their relatively poor attentional control of such cues. However, when tested in an operant Sustained Attention Task (SAT), STs exhibit only a minor impairment in hit rates but, more robustly, unstable performance over time. These observations raised the question as to the neuro-behavioral or -cognitive mechanisms via which STs perform the SAT. Male and female STs were trained on SAT. The SAT requires the reporting of cues as well as non-cue events via separate levers, yielding four response categories (hits and misses, and correct rejections and false alarms). After reaching criterion, half of STs received bilateral infusions of the cholino-selective neurotoxin 192-IgG saporin while the remaining STs received sham-lesions. Following recovery, performance was assessed on the SAT and a version of SAT incorporating a flashing house light distractor (dSAT). Goal-directed (or top-down) attention is thought to maintain and recover performance during dSAT and mediated via increases in cortical cholinergic activity. In STs, neither SAT nor dSAT performance depended on the integrity of the cholinergic system. We therefore hypothesized that STs perform the SAT using model-free, non-attentional mechanisms, perhaps relying largely on trial-biased perceptual processes to detect salient cues. To test this

hypothesis, separate STs and GTs were trained on SAT. The salience of the cue light relative to the house light was varied across operant chambers. In STs, greater perceptual sensitivity reductions were observed as a function of relatively weaker cue salience. In contrast, GTs' perceptual sensitivity did not relate to cue salience. Associated with their relatively unresponsive cholinergic system, STs rely on perceptual mechanisms, rather than attentional mechanisms, to perform the SAT. The relative absence of (top-down) attentional control of behaviorally significant cues, combined with a propensity to attribute incentive value to such cues, renders STs less likely to reject such cues from guiding their behavior and engaging in alternative action.

Title: Functional dissociation of EEG theta rhythms between prefrontal and visual cortices and their synchronization during sustained attention

Authors: *H.-B. HAN[1,2], K. LEE[1,3], J. CHOI[1,4];
[1]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [2]Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of; [3]Seoul Natl. Univ., Seoul, Korea, Republic of; [4]Korea Univ. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Over a decade, coherent theta rhythms (4-12 Hz) within the cerebral cortex have been believed to facilitate information processing by bridging distal brain regions during a task situation. For example, the theta synchrony between prefrontal cortex (PFC) and visual cortex (VC) has been known to be associated with enhanced task performance and attention. Recently, this conceptual framework has been mitigated by a wayward behavior of theta power in VC during sustained attention task: Spyropoulos *et al.* (2018) observed that the evoked theta in VC decreased as the demands for the visual attention raised in a visual task. Likewise, Stitt *et al.* (2018) observed that the theta power in high-order VC became lessened by arousal but maintained its synchrony with the PFC in a sustained attention task. These inconsistent behaviors of theta rhythms suggest that theta rhythms in PFC and VC might be differently involved during a task situation. In order to enunciate their different roles, we analyzed EEG signals from mouse PFC and VC during visual Go/No-Go task with respect to short-term task performance. The short-term task performance was assessed by the ratio of correct trials obtained through a moving

window over 10 previous trials. We found that PFC and VC theta behaved in an opposite way: PFC (VC) theta was stronger (weaker) in the good-performing epochs compared to the bad-performing epochs. Interestingly, the synchronization between two oscillations increased during the epochs with good performance, despite the suppression of theta in VC. Furthermore, the phase relationship in the fronto-visual phase-locked theta rhythms showed a predominant posterior-to-anterior direction in the order of few milliseconds. Along with the improved synchrony, the delay showed a subtle but systematic decrease, suggesting a boost of information relay from the posterior to the anterior brain region. Our findings not only provide empirical evidence for the distinction between the theta of PFC and VC, but also reveal the overlooked aspect of long-range synchrony between functionally different oscillators in the cerebral cortex.

Title: Cortico-cortical and baso-cortical gamma oscillations represent functionally distinct attentional networks

Authors: *K. LEE[1,2], H.-B. HAN[2,3], J. CHOI[2,4];
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [3]Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of; [4]Korea Univ. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Attentional states contribute to task performance. Yet, the neurological correlates that represent attentional states are poorly defined. Temporal analysis of gamma band oscillations (GBO, 30-80 Hz) in the seconds-to-minutes timescale has shown the cortico-cortical GBO network to be pro-cognitive. On the contrary, a recent study observed prominent GBO in the baso-cortical network during the task-negative state in a longer timescale of few-tens-of-minutes. These two opposing observations raise a possibility that GBO networks are differentially correlated with different cognitive states depending on the brain regions and/or timescale. To elucidate this, we analyzed cortico-cortical and baso-cortical GBO network dynamics in the minutes versus seconds timescales using the Go/No-Go paradigm. EEG and LFP were obtained from prefrontal and posterior-parietal cortices and the basal forebrain in head-fixed mice. We characterized GBO patterns that accompany the long-term shifts in behavioral state in addition to

trial-by-trial fluctuations in task performance. Our results showed that the baso-cortical GBO networks reflect long-term attentional state transitions, manifested by the progressive decline in task engagement. On the other hand, independent of the long-term trends, trial-by-trial performance analysis revealed that stronger cortico-cortical GBO network precedes correct trials. Interestingly, one of the baso-cortical networks exhibited stronger connectivity before error trials. This suggests that on top of being involved in the long-term transition into task-negative states, certain activities of the baso-cortical gamma network can trigger immediate errors in behavior, possibly through causing acute disruptions in attention. Thus, cortico-cortical and baso-cortical GBO networks can be interpreted to be involved in functionally distinct attentional networks that influence brain states and behavior on different timescales.

Title: Timing is everything in the attention network: Specific oscillatory patterns in spike timing predict behavioral performance

Authors: *I. C. FIEBELKORN, S. KASTNER;
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: The deployment of spatial attention is associated with both changes in neural activity across multiple nodes of a large-scale network (i.e., the attention network) and improvements in behavioral performance (e.g., faster response times). Although it is often assumed that attention-related changes in neural activity improve subsequent behavioral performance, the specifics of this relationship have remained largely unknown. Previous studies have frequently observed attention-related changes in neural activity among neurons that represent a behaviorally relevant location. These changes in neural activity occur in the absence of sensory stimulation, in anticipation of a subsequent, temporally unpredictable target (i.e., during a cue-target delay). Such preparatory changes in neural activity are thought to enhance the sensitivity and efficiency of sensory processing. Here, we investigated the relationship between attention-related changes

in neural activity and behavioral performance during a spatial cueing paradigm, while simultaneously recording from frontal and parietal nodes of the attention network in macaques. These higher-order cortical regions direct attention-related neural effects in sensory cortex. We specifically focused on the link between different aspects of spiking activity (e.g., spike rates and spike timing) and behavioral performance. Spiking activity represents the output of neuronal computations and is the primary means through which neurons interact. Despite large increases in spike rates during the deployment of spatial attention, our results show no difference in spike rates between trials that resulted in either faster or slower response times (or between trials that resulted in either hits or misses). Instead, our results demonstrate that differences in behavioral performance are characterized by differences in spike timing, specifically differences in the oscillatory patterns of spike timing. This temporal organization of spiking activity at different oscillatory frequencies reflects specific functions associated with covert spatial attention (e.g., the suppression of eye movements), as well as enhanced functional connectivity among nodes of the attention network. The anticipatory strengthening of between-region connectivity may serve to facilitate visuo-motor integration in response to targets at an attended location, leading to better behavioral performance. While elevated spike rates in the attention network certainly reflect the deployment of spatial attention at a specific location, changes in neuronal spike timing seem to have more relevance for behavioral outcomes.

Title: Flexible feature-based attention and learning in monkeys

Authors: *S. D. KOENIG[1], T. WOMELSDORF[2];
[2]Dept. of Psychology, [1]Vanderbilt Univ., Nashville, TN

Abstract: Visual attention is directed to objects predicting reward as well as to objects that are informative about possible future rewards. In naturalistic environments, both types of attention go hand in hand to ensure an organism’s fitness to harvest maximal rewards, but how attention-to-reward and attention-for-learning are related is poorly understood. For understanding their relation, it is necessary to vary them independently and test how the efficiency of attention-for-learning predicts attention-to-reward and vice versa. Here, we report findings from two novel task paradigms achieving this goal in up to six nonhuman primates using a complex naturalistic environment consisting of 10,800 unique 3D objects composed of four feature dimensions: color, shape, pattern, and arms. With a feature learning task, we quantify how increasing attentional

filtering demands affect the learning of feature values. Monkeys learn feature values of objects through trial-and-error that are defined by one, two or three features, but only one feature value predicts reward. After a certain number of trials, the rewarded feature value suddenly changes. By increasing the dimensionality of the feature space, we increase the demand for attention-for-learning. With a feature search task, we quantify how efficient attention filters out distractors that increase in the number of features and feature similarity to a target object. Using the feature learning task, we find that learning is significantly slowed down with increased dimensionality (bootstrapped learning curves, p's < 0.05). Using the same objects in the feature search task allowed us to quantify the efficiency of attention-for-reward as search slopes. We found significant (z-test, all p's < 0.001) search slopes of 10-33 ms per distractor in a simple feature search but dramatically enhanced search slopes of 88 ms per distractor when feature reward rules were dependent on context. Overall, these results illustrate how to precisely quantify the efficiency of attention-for-learning and attention-for-reward in nonhuman primates in two task paradigms in a naturalistically complex environment. Our findings support the reinforcement learning modeling framework of attention which posits that feature-specific reward prediction errors are continuously updated to ensure fast learning and efficient attentional selection of features in multidimensional environments (Niv, 2015; Leong, 2017; Oemisch, 2019).

Title: Cortex-projecting basal forebrain PV neurons in a sustained attention task

Authors: ***S.-J. LI**[1], B. HANGYA[2], A. KEPECS[1];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Dept. of Cell. and Network Neurobio., Inst. of Exptl. Medicine, Hungarian Acad. of Sci., Budapest, Hungary

Abstract: The basal forebrain plays an important role in modulating cortical activity, potentially influencing attention, learning and memory. Although most studies of basal forebrain have focused on the cholinergic neurons, the functional roles of long-range projecting GABAergic neurons are less well understood. Here we studied the projection patterns of basal forebrain PV neurons and recorded their activity in an auditory sustained attention task.
Using anterograde and retrograde tracing, we first studied the cortical targets of basal forebrain PV neurons. We found that basal forebrain PV neurons are compartmentalized and nucleus-

specific in terms of their targeting cortical regions. We also recorded optogenetically identified basal forebrain PV neurons and imaged the cortical terminal fields of PV neurons using fiber photometry. We tested mice in a sustained attention task in which mice had to detect “tone A” to earn water reward and ignore “tone B” to avoid airpuff punishment embedded in varying noise background. Mice performed the task well and their accuracy and reaction time varied systematically as a function of signal-to-noise ratio. Previously we demonstrated that basal forebrain cholinergic neurons respond phasically to the presentation of outcomes (reward and punishment) and this response is scaled by the unexpectedness of outcomes (Hangya et al., 2015). Here we found that PV neurons have tonic responses to both the tones and the outcomes. Interestingly, tone-induced increases of PV neuron activity were negatively correlated with the reaction time of the animal’s behavioral response towards the tone. These results suggest that basal forebrain PV neurons may be involved in broadcasting signals important for vigilance and outcome expectation and may be relevant to sustained attention.

Title: Corticothalamic networks underlying exogenous and endogenous attention

Authors: *R. CHEN[1], A. B. MARTIN[2,1], S. KASTNER[1];
[1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Physiol., Univ. of Arizona, Tucson, AZ

Abstract: Visual information can be selected actively via endogenous attention, depending on its relevance to the current task. Moreover, salient and sudden events also attract spatial attention through exogenous mechanisms. Neural correlates of these attentional modes have been found in the frontal eye fields (FEF) and the lateral intraparietal area (LIP). These cortical areas have overlapping projection zones in the thalamic nucleus of the pulvinar, which is known to modulate cortical attentional responses. However, the interaction of attentional control in these areas when switching between these modes has not been shown. To explore this question, we recorded simultaneous neural activity (SUA and LFP) from these areas in two monkeys who performed a variant of the Eriksen flanker task. While the monkey maintained central fixation, a

spatial cue was flashed to signal the location of a subsequent target shape. The cue was either a salient disk flashed at the target location to attract exogenous attention, or an arrow at the fixation point to direct endogenous attention to the target location. After a variable cue-target delay window, the target shape was presented at the cued location, embedded in a circular array of distractors. Following a target-response delay, a color change of the target indicated that the monkey should saccade to the target location. While accuracy and reactions times for both cue conditions were remarkably similar, microsaccade patterns, which are thought to signify the direction of covert attention, were different. Corroborating previous studies, we found that attentional modulation of SUA was primarily observed in visual and visual-motor neurons, but was absent in oculomotor neurons. Exogenous attentional modulation was apparent across all three regions during both cue-target and target-response delay periods. Endogenous attentional modulation was restricted to FEF during the cue-target delay period, although it was present in all three areas during the target-response delay. Granger causality and coherence analyses were performed to explore functional interactions across the network. The functional connectivity profiles during the two attention modes also showed different patterns. These findings suggest that although exogenous and endogenous spatial attention share an overlapping neural network, influences on neuronal representations and information communication across the network underlying these two attention modes differ.

Title: Optogenetic excitation of basal forebrain parvalbumin neurons quickens reaction times in the rodent psychomotor vigilance task

Authors: F. L. SCHIFFINO[1], J. M. MCNALLY[1], A. N. HASSLER[2], R. E. BROWN[1], *R. E. STRECKER[1];
[1]VABHS & Harvard Med. Sch., West Roxbury, MA; [2]Stonehill Col., Easton, MA

Abstract: Deficits in attention are a major feature of neuropsychiatric disorders. Thus, understanding the brain circuitry underlying attention is important to develop novel treatments. Dysfunction and degeneration of **basal forebrain (BF)** neurons are early features of many disorders. Previous studies have shown that cholinergic BF neurons are important in attention and their loss contributes to attention deficits. However, the majority of BF neurons are non-cholinergic and little is known about their role in cognition. Here, we use optogenetic techniques and behavioral paradigms in mice to test the role of one non-cholinergic subtype, **basal forebrain parvalbumin neurons (BF PV)**, in attention for the first time. Recent work suggests that BF PV neurons may support levels of alertness underlying sustained attention. First, activity of an unidentified population of non-cholinergic neurons predicted reaction time and accuracy in a manner that was interpreted to reflect momentary fluctuations in sustained attention. It is plausible that these were BF PV neurons, as their fast firing rate patterns were well within the appropriate range. Second, excitation of BF PV neurons enhances wakefulness and overall levels of locomotor activity. **Hypothesis:** We predict that BF PV neurons transiently increase alertness to support short latency, goal-directed responses. **Methods:** We used brief (1s) tonic optogenetic excitation of BF PV neurons during an operant signal detection task that assesses sustained attention, the **rodent psychomotor vigilance task (rPVT)**. The rPVT is a simple reaction time (RT) test that requires monitoring of a central stimulus location (lightbulb) for a brief and unpredictable signal (500ms light flash) and performance of an operant response (lever press) to report detection of the signal. The primary measures in the rPVT are RT and number of lapses in attention (omissions, failure to respond within a specified amount of time: 1500ms). **Results:** In N=3 mice, we found that 1s tonic BF PV excitation beginning 500ms prior to the 500ms signal quickens RT (Stim: 494 ± 33ms vs Baseline: 632 ± 20ms, $p < 0.02$).To control for nonspecific arousal (Ctrl Stim), we delivered 1s tonic BF PV excitation 5s after the outcome of each trial (correct or omission) during the intertrial interval (ITI: ~23s), which did not improve performance (Ctrl Stim: 603 ± 11ms vs Baseline: 632 ± 20ms, $p > 0.09$). **Conclusion:** Brief BF PV excitation prior to signals leads to a transient enhancement of attention. This improved performance is not due to nonspecific arousal. **Significance:** This is the first demonstration of a role for BF PV neurons in attention.

Title: Neuromodulatory- and prefrontal- sensory cortical interactions underlying motivated shifts in attentional effort

Authors: Z. H. MRIDHA, J. DE GEE, Y. SHI, H. RAMSAYWAK, A. BANTA, W. ZHANG, ***M. J. MCGINLEY**;
Baylor Col. of Med., Houston, TX

Abstract: Humans and other animals constantly adapt their allocation of cognitive resources to changes in the environment. In sensory domains, the brain is capable of enhancing the processing of difficult-to-perceive stimuli when they are important (Kahneman, 1973). In the context of perceptual decision-making, this is referred to as attentional effort (Sarter et al., 2006). In contrast to the extensive study of e.g. the *selective* aspect of attention (Desimone and Duncan, 1995), the neural circuit mechanisms of attentional effort are poorly understood. Key candidate mechanisms are direct neuromodulation of sensory cortex (Aston-Jones & Cohen, 2005), and bi-directional interactions of sensory and frontal cortical regions (Miller & Cohen, 2001).
Here, we seek to determine the neural circuit basis of attentional effort. We developed an attentional effort (AE) task for head-fixed mice. In the AE task, mice lick for sugar-water reward to report detection of the unpredictable emergence of temporal coherence in an ongoing tone cloud, analogous to coherent motion in common visual attention tasks. Perceptual difficulty is parametrically and unpredictably varied, trial-by-trail, through partial degradation of the coherence. To manipulate attentional effort, we alternate between a large and small reward volume in blocks of 60 trials. Thus, mice are motivated to expend more attentional effort in blocks with large rewards.
Increased attentional effort in high-reward blocks manifested as increased sensitivity (d' from SDT) to detect coherence in noise (2-way rmANOVA $F_{1,21} = 38.5$; $p < 0.0001$; N=22 mice), particularly for weak-coherence targets (interaction $F_{2,42} = 11.7$; $p < 0.0001$). Mice exhibited >5 effort shifts within each session, tightly time-locked to block changes. In addition, contrary to the trivial prediction that high reward increases global neuromodulator levels (arousal), mice *decreased* their arousal in high reward blocks, apparent in baseline pupil size ($p = 0.002$). Thus global neuromodulation doesn't account for attentional effort. Finally, feedback pupil responses exhibited multiple signals reflecting flexible AE regulation, including: correctness, reward context, and prediction errors. In ongoing 2-photon GCaMP imaging, we are determining the roles of frontal-sensory and neuromodulatory signals in mediating these shifts in overt behavior.

Title: Non-invasive trigeminal nerve stimulation effect on locus coeruleus response and autonomic nervous system changes

Authors: *J. C. TANNER[1], S. I. HELMS TILLERY[2];
[1]SBHSE, [2]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: Neural activity in the midbrain structure locus coeruleus (LC) modulates attention, arousal, working memory, and stress. The structure consists of noradrenergic (NA) cells with widespread projections throughout cortex, cerebellum, and brainstem. Activation of NA modulates synaptic signal transmission for attention and/or sensory stimuli. Using direct (fMRI or PET) and indirect (pupillometry) measures, literature provides evidence that tasks requiring increased exploration/attention correlate with locus coeruleus activity. Being able to affect LC activity could provide access to modulate plasticity, arousal, or working memory. Modulating LC activity is possible through invasive vagus nerve stimulation, and parameters have been characterized for optimal effect. Both the vagus nerve and the trigeminal nerve have common direct projections and respectively project to the LC through the nucleus tractus solitarius and trigeminal nucleus caudalis. In this study, we aim to investigate the tonic and phasic components of LC response to non-invasive trigeminal nerve stimulation, determine optimal stimulation duration and parameters, and observe the effect on the autonomic nervous system via the pupillary light reflex (PLR). The latter model allows an independent and parallel measure of sympathetic and parasympathetic nervous activation and inhibition by measuring pupil constriction and redilation in response to repeated short bursts of light. Through both the LC recordings and the PLR, a parallel observation of the autonomic changes and neural changes can be seen in response to trigeminal nerve stimulation. At present, 10 minute stimulation periods have induced LC responses correlated with activation of the sympathetic nervous system. These responses have a consistent tonic component and a pseudo-phasic increase in activity to stimulation onset and offset, each lasting a few minutes. This leads to an interesting set of experiments where we attempt to harness the separate on-off phasic responses by cycling the stimulation in an attempt to maintain higher LC activity over longer periods of time.

Title: Development of a method for assessing divided attention in a rodent model of ADHD

Authors: *A. TWISSELMANN[1], T. M. AUBELE-FUTCH[2];
[2]Psychological Sci., [1]St. Mary's Col., Notre Dame, IN

Abstract: There are four types of attention that allow individuals to focus and process the information available to them, one of which is divided attention. Also known as multitasking, divided attention describes the ability to maintain mental focus on two or more tasks at the same time. Divided attention is used often in humans' everyday lives; however, the neuropsychological assessment of this type of attention in rodents is currently lacking. In fact, only one method has been published that assesses this specific cognitive task in rodents, (Arnold, Bruno and Sarter 2003), and that paradigm has never been used in the Spontaneously Hypertensive Rat (SHR) model of ADHD. Thus, here, we build off of this previously published method and adapt it for use with this widely accepted rodent model. Briefly, SHR rats and their controls (WKY) were trained on two operant rulesets, learning to discriminate a steady versus pulsing light, and a steady verus pulsing sound by pressing one of two available levers. After each ruleset was learned independently, all four options were presented randomly within a session. The previous method was adapted by changing the rate of light pulsing to accommodate the poor vision of albino rodents, and learning was scaffolded by the addition of corrective trials as animals learned the original rulesets. After these methodological adaptations, two rats (one SHR and one WKY animal) were able to complete the entire paradigm, confirming that the revised method does indeed work. Since such a small number of animals were able to complete the protocol, parametric statistics were difficult to perform; however, assessments within individual rodents showed expected trends in response latency. The development of this paradigm will allow for future research into this attentional realm in the ADHD model animal.

Title: Evaluating “productivity” vs “quality” of performance in rodent assays of goal-directed behavior and cognitive function

Authors: *R. L. NAVARRA[1], C. P. KNAPP[1], D. P. FOX[1], S. B. FLORESCO[2], B. D. WATERHOUSE[1];

Abstract: A wide variety of neuropsychiatric disorders and brain insults impair aspects of cognitive function. Psychostimulant drugs sometimes restore these processes in models of compromised brain function as well as improve baseline performance in otherwise healthy animals. Sophisticated behavioral assays for use in rodents have been developed to characterize and understand experimentally induced manipulations across multiple dimensions of cognitive performance. Standard measures include accuracy and response latency; however, there are dynamic components of sensory processing, decision making, and motor output that contribute behind the scenes to the behavioral outcomes we are able to quantify in these tasks. The present data exemplify improvements or impairments in response latency following either methylphenidate (MPH) administration or repetitive mild traumatic brain injuries (rmTBI), respectively, without concomitant effects on traditional measures of performance accuracy. First, MPH improved reaction times to make correct responses without affecting overall accuracy during performance of a signal detection task. MPH also reduced latency of visually evoked activity recorded in response to visual cues used to guide performance of the task. Improvements in reaction speed were correlated with faster visually evoked responses, suggesting that enhanced sensory processing was a significant component of the observed enhancement of behavioral performance. Second, in a an operant strategy shifting task, MPH selectively improved reaction times on trials where animals made the correct choice without broadly affecting overall accuracy or trials to reach criterion. Lastly, following rmTBI (three closed skull controlled cortical impacts over a period of one week), injured animals demonstrated slower reaction times as compared to sham controls. Impaired reaction times observed following rmTBI were independent of whether animals made correct or incorrect choices, indicating a non-selective

impairment of processing speed and response latency. Numerous factors may impede the ability to detect effects on accuracy of performance, but still reveal important information about productivity vs quality of performance. Together, these data beg further consideration of whether manipulating the speed of information processing and behavioral output are sufficient to contribute meaningful and translationally relevant information towards further understanding alterations in productivity of performance.

Title: Involvement of a locus coeruleus-to-prefrontal (LC-mPFC) circuit in a touchscreen variant of the continuous performance test (CPT) in mice

Authors: *H. L. HALLOCK[1], A. C. DEBROSSE[1], M. NOBACK[2], H. M. QUILLIAN, IV[1], J. C. BARROW[3], G. V. CARR[4], K. MARTINOWICH[5];

Abstract: Sustained attention is disrupted in a variety of neuropsychiatric disorders, including schizophrenia and attention deficit hyperactivity disorder (ADHD). Much research suggests that interregional communication between subcortical brain areas (i.e., basal forebrain, ventral tegmental area, locus coeruleus) and the PFC may contribute to attention-directed behavior. The exact role of these circuits in sustained attention, however, remains unclear. In humans, the continuous performance test (CPT) is a neuropsychological tool that is frequently used for evaluating sustained attention. In the human CPT, subjects attend to a visual cue on a screen, and either respond or inhibit responding depending on the type of cue that is presented. In order to understand how distinct frontal-subcortical circuits participate in sustained attention and improve translatability of results from rodents to humans, we trained mice to perform a touchscreen-mediated variant of the CPT. In this CPT variant, mice are trained to make a nose poke following the presentation of one visual cue (S+), and inhibit responding following the presentation of a second visual cue (S-). Our previous research has shown that systemic administration of the catechol-O-methyl transferase (COMT) inhibitor tolcapone improves performance of the task in

mice, implicating dopaminergic function in successful CPT performance. To investigate how PFC function contributes to the CPT, we imaged calcium dynamics in medial PFC (mPFC) neurons during CPT performance with a miniature head-mounted microscope. To further understand which frontal-subcortical circuits mediate the CPT, we injected a retrograde virus encoding a fluorescent reporter (tdTomato) into the mPFC of wild/type (w/t) mice, and compared expression of the immediate early gene (IEG) c-Fos in tdTomato+ cells between mice that learned to discriminate the S+ and S-, and mice that only learned to respond to a visual cue for a reward (yoked controls). We found that projection neurons from the locus coeruleus to the mPFC (LC-mPFC projectors) were selectively recruited during CPT performance. Current research focuses on identifying a molecular signature of LC-mPFC projectors, and understanding how these neurons contribute to mPFC population activity during the CPT.

Title: Stable cognitive computations in the prefrontal cortex of unrestrained monkeys

Authors: *C. TESTARD[1], S. TREMBLAY[2], M. PETRIDES[3];
[2]Neurosci., [1]Univ. of Pennsylvania, Philadelphia, PA; [3]Montreal Neurolog Inst. Mc Gill Univ., Montreal, QC, Canada

Abstract: Neurophysiologists studying the primate caudal lateral prefrontal cortex (area 8A) using standard visual-saccadic paradigms have mostly described neurons encoding visual-attention and eye movement signals in this area. However, we know from lesion studies that bilateral ablation of area 8A produces no deficits in basic visual attention nor in eye movement control. In fact, bilateral lesions of area 8A result only in a specific impairment in using “if-then” instructional cues to select visual objects from the environment. We believe that this discrepancy between neuropsychological (i.e. lesion) and neurophysiological evidence is the result of the low ecological validity of standard visual- saccadic paradigms ubiquitous in monkey neurophysiology. Although these paradigms are useful to study visual areas of the brain, we posit that they offer a limited portrait of higher-order associative areas such as the prefrontal cortex. In the current study, we introduce a new paradigm that combines multi-electrode neurophysiology in monkeys with ecologically valid cognitive testing. By performing intracranial multi-electrode recordings in monkeys that are unrestrained in their head, eye and arm movements, we show that neural ensemble activity in area 8A encodes the cognitive process predicted by lesion studies

(i.e. conditional visual selection; decoding accuracy >90%). Importantly, we show that this cognitive representation is stable even while the monkey is freely moving and looking around. We expect that this paradigm will provide a more accurate portrait of the neuronal properties of associative areas.

Title: Controlling the balance between goal directed and habitual behaviour: Parsing the contribution of primate medial and orbital prefrontal cortex sub-regions and the caudate nucleus

Authors: *L. Y. DUAN[1,4], N. K. HORST[1,4], S. A. W. JACKSON[1,4], N. HORIGUCHI[1,4], R. N. CARDINAL[2,4], T. W. ROBBINS[1,4], A. C. ROBERTS[3,4];
[1]Dept. of Psychology, [2]Dept. of Psychiatry, [3]Dept. Physiology, Develop. and Neurosci., Univ. of Cambridge, Cambridge, United Kingdom; [4]Behavioural and Clin. Neurosci. Institute, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Normal behaviour can either be goal-directed, when performing an action to obtain a specific goal, or they can become habitual, where a stimulus in the environment can trigger a response regardless of the outcome. An extreme form of this habitual responding may hypothetically be seen in obsessive-compulsive disorder (OCD) patients. Degrading contingencies between responses and their outcomes challenges beliefs about cognitive control and can be used to distinguish between behaviour that are goal-directed or habitual. Given that in OCD patients the prefrontal cortex (PFC) and prefronto-striatal circuits are dysfunctional, it is important to determine the causal role of these regions in controlling the balance between goal-directed and habitual behaviour. Thus, we compared the roles of the primate anterior cingulate cortex, BA32, 24 and 25, anterior orbitofrontal cortex (OFC, BA11), medial OFC (BA14) and the caudate nucleus (CN) in mediating effects of contingency degradation. We developed a touchscreen-based contingency degradation task for the common marmoset, a New World non-human primate that is a key link bridging rodent and human studies as it has a PFC more similar to humans than rodents. Trained marmosets were implanted in two brain regions with chronic, indwelling cannulae. We then examined the effects of reversible pharmacological inactivation (using GABA A/B agonists, muscimol/ baclofen) or activation (using a glutamate transport blocker, dihydrokainic acid (DHK) to enhance extracellular glutamate levels) of each region on

the ability to adapt responding after degradation of action-outcome contingencies. Results showed that inactivation of either BA24 or CN impaired, while BA11 apparently enhanced, animals' sensitivity to contingency degradation. In contrast, manipulations of BA14 or BA32 did not affect sensitivity. In summary, BA24 and CN are critical for the expression of action-outcome associations, while other frontal regions such as BA11, BA14 and BA32 are not required for their expression. The apparent facilitatory effect of BA11 inactivation may be understood in terms of a dysregulation of motivational arousal. Based on a careful analysis of the response patterns across degraded and non-degraded sessions the differential contribution of these distinct regions to goal directed actions will be discussed.

Title: Laminar profile of context-dependent computation in dorsomedial frontal cortex

Authors: *H. SOHN[1], M. JAZAYERI[2];
[1]McGovern Inst. for Brain Res., [2]Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Laminar organization of neocortex is a key feature of cortical microcircuitry, providing a structured scaffold for neural computation. Recent technical developments have opened the possibility of simultaneous recording from multiple cortical layers allowing investigators to dissect the underlying circuitry. For example, laminar recordings in early sensory areas have revealed how bottom-up sensory inputs entering intermediate layers gradually propagate to the deep and superficial layers for further processing. In contrast, little is known about the role of laminar information processing in higher brain areas that are involved in cognitive computations.
We tackled this question by analyzing the laminar profile of neural activity in the dorsomedial

frontal cortex (DMFC) of monkeys during a context-dependent time reproduction task. In the task, animals measured a sample interval demarcated by two visual flashes (“Ready”, “Set”) and had to reproduce that interval immediately after the second flash using a motor response (“Go”). In each trial, the sample interval was randomly drawn from a uniform prior distribution. Animals performed the task in two contexts, a “Short” context where the interval varied between 480 and 800 ms, and a “Long” context where the interval was between 800 and 1200 ms. The context was cued at the beginning of each trial allowing animals to adjust their prior expectations. Animals learned to perform the task and their responses exhibited a characteristic regression to the mean for both contexts, indicating that they relied on their prior belief about the sample interval to perform the task.
In DMFC, the firing rate of a large proportion of neurons (>60%) was modulated by the prior context, and the strength of the modulation increased in anticipation of the Set flash. These dynamic contextual modulations could either reflect modulations of inputs to DMFC or result from recurrent interactions within DMFC. Given the laminar organization of inputs to DMFC, we reasoned that these modulations would exhibit laminar specificity if they were inherited from upstream areas. In contrast, a lack of laminar specificity would suggest that contextual modulations are supported by local recurrent interactions in DMFC. We analyzed how context-dependent modulations in DMFC change as a function of cortical depth. Although the magnitude and dynamics of contextual modulations were highly heterogeneous across the population, they did not seem to exhibit any laminar specificity. These preliminary results suggest that contextual modulation of neural activity are largely dependent on recurrent interactions within the frontal cortex.

Title: Effects of ketamine on prefrontal cortex activity during decision making in macaques

Authors: ***M. OEMISCH**[1], A. F. ARNSTEN[1], D. LEE[1], H. SEO[2];
[1]Neurosci., [2]Psychiatry, Yale Sch. of Med., New Haven, CT

Abstract: In everyday life, we make a plethora of decisions, in which we process multiple options and then choose an optimal course of action. Across many choices, we tend to repeat actions that have previously led to a positive outcome, and tend to refrain from repeating actions

that have previously led to negative outcomes. One psychiatric disorder in which decision-making behavior is often disrupted is depression. Individuals with depression show for instance a diminished tendency to base their decisions on the likelihood of obtaining rewards, and they show hypersensitive behavioral and electrophysiological responses to losing. How current antidepressants may alleviate this type of behavior is not fully understood. Here we set out to elucidate the effects of the rapid-acting antidepressant ketamine on neural activity in prefrontal cortex. We recorded single unit activity in dorsomedial prefrontal cortex (dmPFC) of macaque monkeys performing a biased matching pennies task. In each trial, monkeys chose one of two targets, which led to either the gain of a token, the loss of a token, or no change in token number. Any time the monkey had collected six tokens, these were exchanged for juice reward. We found that a low dose (0.5mg/kg) of ketamine affected the monkeys' choices selectively following loss and neutral outcomes, but not following gain outcomes. Specifically, monkeys were less likely to switch away from a target that had led to a loss or neutral outcome under ketamine compared with control conditions. In line with this change in behavior, we found that many dmPFC neurons changed their spiking activity following ketamine injections. We found that 60% of task-modulated neurons changed their firing rate modulation with ketamine, with most showing a decrease in their modulation strength. These neurons were most prominently those that encoded, at the time of feedback, (a) whether the animal was gaining a token or not, or (b) the number of tokens to be collected until the next reward, suggesting that the disruption of these signals may relate to the change in behavior observed with ketamine. Overall, we found that ketamine may mitigate negative valuations of aversive outcomes, in line with its antidepressant actions and thereby lead to selective changes in choice behavior. We found evidence that neurons in dmPFC may contribute to mediating this change in behavior, allowing further insights into the neural basis of ketamine's actions in the brain.

Title: Exploration of the eligibility trace as a link between choice and temporally-delayed feedback

Authors: *S. K. MURRAY[1], D. LEE[2], H. SEO[3];
[1]Interdepartmental Neurosci. Program, Yale Univ., New Haven, CT; [2]Neurosci., [3]Psychiatry, Yale Sch. of Med., New Haven, CT

Abstract: Theoretical and empirical work has demonstrated that in uncertain environments, humans and other animals learn desirable actions through experience by iteratively updating the estimates of long-term reward from alternative actions (i.e. action values) with unpredicted outcomes; these estimates are used to select the action that maximizes expected reward. In the natural world, outcomes are often separated in time from their causative actions by long and variable delays. Reinforcement learning theory (RL) postulates that an exponentially decaying memory trace of chosen actions, called the eligibility trace (ET), can bridge temporal gaps for delayed outcomes. However, it remains unknown whether and how ET might be implemented in the brain. Previous work has shown that neurons in primate prefrontal cortex (PFC) exhibit mnemonic signals representing past choices and their outcomes. For example, signals related to previous actions and choices encoded by individual neurons tend to decay exponentially, with heterogenous time constants. In some contexts, these signals are dynamically reactivated around the time of choice on the subsequent trial. Although cortical memory traces for past choices may provide a neural ET, whether those mnemonic signals can bridge long and variable temporal delays between choice and its outcome has not been rigorously tested. It is also unclear how the temporal dynamics of mnemonic signals might contribute to the update of the values of actions with delayed outcomes. In order to understand the role of choice memory in reinforcement learning, we trained a rhesus monkey on a variant of the computer-simulated matching pennies task, in which the feedback for each choice was delivered after variable temporal delays. We independently manipulated the interval between each choice and its feedback (choice-feedback interval, CFI) and the interval between feedback and each subsequent choice (inter-trial interval, ITI). Each of these time intervals was either 1 or 5s, with both CFI and ITI randomly and independently drawn on each trial. Using logistic regression, we analyzed how choice and outcome affected the animal's subsequent choice as a function of CFI and ITI. We found that both CFI and ITI independently affected the animal's tendency to adopt a win-stay-lose-switch (WSLS) strategy. Specifically, the probability of WSLS decreased with both CFI and ITI length (*t*-test, $p<.01$ for both), suggesting that decaying ET might be involved during reinforcement learning from delayed outcomes. We will examine the dynamics of neural activity in PFC that mediate this effect of temporal delay in learning, a potential instantiation of ET.

Title: Functional signatures and intrinsic timescales of single unit types in the midcingulate and lateral prefrontal cortex

Authors: *E. PROCYK[1], F. M. STOLL[2], V. FONTANIER[1];
[1]Stem Cell and Brain Res. Inst., Inserm U1208, Lyon, France; [2]Dept. of Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Fluctuation in spiking activity is a characteristic of neurons across cortical areas. The timescales on which such fluctuation operates are likely shaped by multiple factors including membrane properties, local network and synaptic properties as well as large scale network architecture. Prefrontal regions such as the lateral prefrontal cortex (LPFC) and especially the midcingulate cortex (MCC) exhibit the longest timescales across primate cortical areas. Long timescales, indicative of a stable activity state across time, could contribute to integration over long time periods, a fundamental feature of functions like decision making and working memory. We recently showed different properties of activity during exploratory decisions and integration of information across trials in MCC vs LPFC (Stoll, Fontanier and Procyk 2016 Nat. Comm). Here we assess whether those functional differences relate to different single spike dynamic properties.
To describe intrinsic timescales we computed between-trials autocorrelograms of spiking activity as well as classical spike autocorrelograms of individual MCC and LPFC units (251 MCC units and 248 LPFC units) recorded in awake monkeys engaged in a cognitive task. Because area intrinsic timescales might reflect properties of local dynamics and excitation/inhibition balance in local networks, we tested whether single unit types - fast or regular spiking clustered based on spike shape- could reveal differences between MCC and LPFC.
We first replicated findings showing that MCC units have longer timescales than LPFC on average. Moreover we found that the MCC autocorrelogram temporal signatures differ from LPFC in particular for regular spiking units. However, cross-correlograms between single unit types did not reveal any particular functional difference between the two regions. Additionally, we found that populations of units with short or long average intrinsic timescales contribute differently to information processing at short (post-feedback adaptation) or long (across trial information integration) time scales.
In conclusion, different spiking dynamics in MCC and LPFC reveal intrinsic properties that contribute to functional difference between the two frontal regions.

Title: The causal role of midcingulate cortex in the regulation of decisions to check

Authors: *V. FONTANIER[1], F. M. STOLL[2], E. PROCYK[1];
[1]INSERM U1208 - Cell and Brain Res. Inst., Lyon, France; [2]Dept. of Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Recent theories argue that midcingulate cortex (MCC) dynamically tracks the value of options to guide behaviour away from default or routine actions, and explore alternatives. Yet MCC causal contribution to behaviour is still subject of intense debates. Interestingly the anterior part of MCC includes cingulate motor areas with somatomotor maps. The role of these maps to exploratory decisions remains to be uncovered.
We designed a so-called checking-task in which monkeys, while performing a default categorization task, can at will seek information (provided by a visual gauge increasing in relation to categorization performance) on an incoming reward bonus. In this task, monkeys' checks are positively modulated by positive categorization outcome and increasing gauge. We performed single unit and LFP recordings in MCC and dLPFC in two monkeys doing the task (Stoll, Fontanier and Procyk 2016 Nat. Comm), and showed specific MCC neural dynamics for feedback processing, checking decisions, as well as encoding of gauge size. We here test the causal role of MCC in this task.
We performed pharmacological perturbations in the MCC where we observed neural activity related to checking using either a GABA agonist (multiple injections of 2 µL of muscimol at 10,15 or 20 µg/µL) or a GABA antagonist (multiple injections of 2µL of bicuculline methiodide at 15 µg/µL) (1 monkey, 16 muscimol sessions, 8 bicuculline sessions). We assessed effects on checking frequency, checking patterns, RTs, oculomotor patterns and saccade frequency, performance in categorization, etc.
MCC muscimol inactivation altered the frequency of checking but did not change the probability of checking after positive vs negative outcomes. Bicuculline in particular altered the pattern of checking in relation to gauge increase. Oculomotor patterns indicate that part of the deficit might be related to information gathering at the time of gauge observation.
In conclusion, combined electrophysiological and pharmacological data suggest a key role of the MCC in the maintenance and updating of information used to regulate exploratory decisions.

Title: Prospective goal encoding in monkey OFC-RSC circuit in a 3D virtual reality foraging task

Authors: *M. WANG[1], B. Y. HAYDEN[2];
[1]Neurosci., [2]Univ. of Minnesota, Minneapolis, MN

Abstract: During natural foraging, animals exhibit goal-directed behavior to learn the structure of the environment and obtain reward. Prospective goal state representation and navigational planning are essential to this process. Although neural activities for route planning have been shown in hippocampus, the neural underpinnings for the learning and use of goal state encoding, which potentially informs hippocampal route-planning activities, is still unknown. We hypothesized that reward simulation, i.e. reactivation of reward state in neural populations, is the key to prospective goal state representation. We developed a 3D virtual reality foraging task to test this hypothesis. In this task, a jackpot reward is hidden at a random location in the virtual maze (goal location) for each session, while other maze configurations stay the same across all sessions. On each trial, the subject is teleported to another random location (start location) during the inter-trial interval. The subject then navigates through the virtual maze with a joystick to forage for the hidden jackpot reward. Subjects took significantly longer search time (from start to goal location) and less efficient travelled paths during pre-learning than during post-learning trials. We simultaneously recorded around 40 single-units in each of orbitofrontal (OFC) and retrosplenial (RSC) cortices across a minimum of 50 trials for each session. We defined goal state as population activity pattern containing averaged firing rates from each neuron across 1500 ms at goal locations during jackpot reward receipt. Representational similarity and state-space analyses reveal that: (1) goal state representation was prospectively reactivated at start of the navigation; (2) it was reactivated during navigation, after but not before, the learning of hidden jackpot location; (3) goal state representation across trials was stable in OFC but correlated with learning in RSC. We further investigated: (1) the correspondence between decision points during navigation and goal state reactivation; (2) the correlations among the behavioral indications of learning, the population dynamics in OFC, and the population dynamics in RSC.

Title: The role of the OFC-PCC circuit in a multi-attribute gambling task

Authors: *H. LEE[1], M. WANG[2], B. Y. HAYDEN[3];
[1]Univ. of Minnesota, Minneapolis, MN; [2]Neurosci., [3]Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: Reward-based decisions are prevalent in our daily life. To choose optimally, we sometimes need to take into account multiple attributes of the prospective outcome and generate an estimate of the reward value over all attributes. Alternatively, sometimes we need to ignore certain attributes of the prospective outcome and heuristically and strategically use information from a selective set of attributes. This flexibility is crucial to successful decision-making and yet the neurocomputational basis for such flexibility in evaluation and decision-making, and the dynamics of information represented in reward circuits during such process remain largely unknown. To address this problem, we trained two rhesus macaques on a simple gambling task. Each trial started with a 1000ms inter-trial interval, followed by the visual presentation of gamble1 for 500ms and a delay with blank screen for 500ms. Gamble2 then was visually presented for 500ms followed by another delay of 500ms with blank screen. After a brief eye fixation, both gambles were visually presented and monkeys made their choice between gamble1 and gamble2 by directing a saccade toward the chosen gamble and maintaining fixation on the choice for 200ms. Following choice, the outcome of the chosen gamble was visually revealed for 800ms while monkeys experienced the gamble outcome: a winning gamble resulted in water reward delivery and a losing gamble resulted in no reward delivery. Each gamble was presented explicitly with two distinct attributes: reward magnitude and reward probability. Reward magnitude came in three sizes: 125, 165, 250 uL. Reward probability follows a uniform distribution ranging from 0-1 with 0.01 step size. During the gambling task, we recorded simultaneously in both area 13 of orbitofrontal cortex and area 23/31 of posterior cingulate cortex. To examine the neural population dynamics on a trial-by-trial basis, we simultaneously held ~50 single-units in each of OFC13 and PCC across each session with a minimum of 500 trials. We found that monkeys understood the task and showed consistent preference for gambles with larger expected values in over 80% of the trials. We found that OFC13 and PCC neurons dynamically encoded each attribute (reward magnitude and probability) and expected values (= magnitude x probability) simultaneously on both single-unit and population decoding level. With

representational similarity and state-space analyses, we examined the encoding and decoding dynamics for each attribute and the expected value in relation to trial-by-trial task/behavioral parameters. We also investigated the information flow and population dynamics correlations between OFC13 and PCC.

Title: Dorsal anterior cingulate cortex encodes cognitive control signals in a value-based conflict task

Authors: *P. MEHTA, B. Y. HAYDEN;
Univ. of Minnesota, Minneapolis, MN

Abstract: A lot of a good thing, or a little of a great thing: the most difficult decisions often involve comparing two options that have both positive and negative attributes. Weighing the relative pros and cons of one option causes us to experience "conflict": to hold two competing mental representations of the option. Numerous human functional magnetic resonance imaging (fMRI) studies report that the brain's dorsal anterior cingulate cortex (dACC) encodes the presence of conflict during behavioral tasks. However, most electrophysiological studies of macaque dACC neurons report no such signatures of conflict. It remains unclear whether the incompatibility of these results is due to a difference in species (humans versus non-human primates), methodology (fMRI versus electrophysiology), or something different. Explaining this difference is crucial both for legitimizing the widespread application of macaque neurophysiological data to human neurophysiology, and for facilitating comparisons between imaging and electrophysiological data. We hypothesize that the differences between human fMRI and macaque electrophysiology results are at least partially due to a difference in the kinds of tasks used to test conflict encoding between species. To emulate the more abstract nature of human conflict tasks, we have designed a novel "value-conflict" task in which macaque subjects must select between large amounts of a small reward and small amounts of a large reward. Here, we find single neurons in dACC whose firing rates differ contingent upon the presence of conflict within a trial. We also find encoding of error monitoring, task difficulty, and other variables related to decision-making. We conclude that cognitive control signals are present

within macaque dACC. On a broader level, our conclusions will not only inform the conflict literature but also facilitate interpretation of translational research that is performed in macaques but applied to humans.

Title: Suboptimal decision making in macaques during low reward trials

Authors: *K. EDMONSTON[1], P. MEHTA[3], B. R. EISENREICH[4], B. Y. HAYDEN[2]; [1]Neurosci., [2]Univ. of Minnesota Twin Cities, Minneapolis, MN; [4]Neurosci., [3]Univ. of Minnesota, Minneapolis, MN

Abstract: Neuroeconomics seeks to better understand the mechanisms of decision-making processes in the brain, which have commonly been analyzed in contexts like gambling and delay discounting. Foraging theory emphasizes the importance of developing a decision making strategy to fit the environment, and being in a deprived environment may warrant searching for a new environment to forage in. Previous studies have used macaques (Macaca mulatta) as a model to examine decision making behaviors through tasks that involve choosing between two risky choices. In our task, macaques were presented with two possible reward values associated with a dimension of probability and stakes. Gambles were chosen randomly, so by chance some trials had two low values. We call these low reward trials. During low reward trials, macaques exhibit suboptimal behaviors such as time wasting and longer reaction times. Time wasting involved physical frustration and lack of focus. Furthermore, their ability to choose the larger reward drops close to chance. Interestingly, when compared to trials with at least one high reward, the macaques made significantly worse decisions. These behaviors imply that low reward trials significantly impair decision making in the task. According to foraging theory, tasks should reflect naturalistic environments and in naturalistic environments macaques can walk away from a decision. Low reward trials may represent a deprived environment, which is unfavorable for the macaques to be in. Therefore, we next examine macaques' choices during this task with the option of completely skipping trials. Adding this flexibility in the decision-making process for macaques more accurately reflects natural situations. This would result in easier analysis of the brain in decision-making tasks as it was evolved to process these decisions in natural contexts.

Title: Encoding of spatial information in orbitofrontal cortex neurons

Authors: ***H. AZAB**[1], S. M. YOO[1], V. B. MCGINTY[2], B. Y. HAYDEN[1];
[1]Univ. of Minnesota, Minneapolis, MN; [2]Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ. - Newark, Newark, NJ

Abstract: The orbitofrontal cortex (OFC) is a core element of the brain's decision-making system whose contribution to cognition remains to be determined. Recent work supports the idea that OFC representations are not limited to economic parameters, but instead include a detailed representation of the structure of the task environment. Consistent with this idea, a recent study (McGinty, Rangel, and Newsome, Neuron, 2016) indicates that OFC activity is sensitive for the locus of gaze relative to the position of salient (reward-predicting) objects in the visual scene. This result suggests that OFC may have a richer and more complex representation of gaze information, and raises the question of whether this representation is tethered to salient items in the environment. Here we performed a new analysis on that previously collected data set to answer this question. In the task used in that study, visual cues predicting specific reward amounts were displayed on a computer monitor. Macaque subjects were free to direct their gaze anywhere on the monitor during the display period. Rewards were given regardless of the subject's behavior. We used a recently-developed generalized linear modeling (GLM) approach that was designed to characterize spatial maps in rat entorhinal cortex (Hardcastle, Ganguli, Maheswaranathan, and Giocomo, Neuron, 2017). We find that a significant proportion of neurons (23%) show spatially-selective responding depending on gaze position, and a similar proportion of neurons (22%) were selective to reward. Receptive fields for gaze position generally included a single peak, located at different locations of the gaze field for different neurons. Information about these two variables was often encoded in the same neurons. The pattern of modulation for individual neurons was often non-linear, which may be indicative of mixed selectivity. These results indicate that reward and non-reward information are simultaneously encoded in OFC neurons, and may not be encoded independently.

Title: Single trial anterior cingulate population dynamics predict ensuing decision-related premotor cortex activity and behavior

Authors: *T. CASH-PADGETT[1], B. Y. HAYDEN[2];
[1]Univ. of Minnesota, Minneapolis, MN; [2]Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: The neural computations underlying cognition and behavior are carried out through ongoing, dynamic interactions between brain areas. A key challenge in understanding these interactions is determining which components of population activity play a causal role in information processing. To investigate how specific population dynamics contribute to the neural computations underlying value-based decision making, we recorded from dorsal anterior cingulate cortex (dACC) and dorsal premotor cortex (PMd) while subjects performed a risky decision-making task. Using non-linear recurrent neural networks, we trained sequential autoencoders to infer the latent factors underlying single-trial activity in each area. We then examined how these reduced-dimensionality population trajectories related to one another over time, using linear regression.

To examine potential signatures of inter-area communication, we regressed PMd activity against dACC population trajectory over a range of temporal offsets. Activity in dACC was most strongly predictive of PMd activity that followed it by approximately 60 - 100 ms. On trials in which the subject made an inaccurate choice (by choosing the less valuable of the two presented offers), PMd activity was significantly more dependent on dACC activity. DACC population trajectory displayed a transient, bidirectional relationship with PMd activity immediately preceding the choice epoch of inaccurate-choice trials, while there was no modulation on accurate-choice trials. Specifically, choice accuracy was well explained by the extent to which sharper deflections in the dACC trajectory predicted changes in subsequent PMd activity. This effect was only observed at temporal offsets from 60 to 100 ms.

The relationship between dACC and PMd population activity also predicted which offer would be chosen. Early in the offer-2 epoch, dACC trajectory magnitude was associated with an increase in PMd activity on trials in which offer 1 was chosen and a decrease in PMd activity on trials in which offer 2 was chosen. Interestingly, while this modulation was significantly predicted by offer 2 value, it was not significantly predicted by offer 1 value, suggesting an asymmetric decision process. The effect was only observed at temporal offsets of 60 and 80 ms.

These results are consistent with the idea of a hierarchical relationship in which dACC exerts control over PMd.

Title: Investigation of economic decisionmaking in macaques performing delaybased foraging task

Authors: *A. SURI[1], B. R. EISENREICH[2], T. CASH-PADGETT[2], B. Y. HAYDEN[1]; [1]Univ. of Minnesota Twin Cities, Minneapolis, MN; [2]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Within the natural environment, animals face a critical challenge in balancing the costs and benefits of searching for and consuming different food sources, or more generally rewards. Foragers must decide between what is and what could be. Often this involves making sequential decisions to either accept what is currently available or to continue searching for better offers. By contrast, traditional studies of animal choice behavior often use simultaneous presentations and formats that fail to reflect the natural transitions from searching to consuming rewards. We designed a task based on the restaurant row paradigm (Steiner and Redish, 2014) adapted for non-human primates that allowed for the study of choice behavior as it evolves over transitions from searching to consuming. In brief, this task involves encountering sequential offers that involve a delay to reward and offer amount. Taking advantage of this paradigm we examine economic decision-making behavior as rhesus macaques make wait/skip decisions based on pseudo-randomly varied delay times required to receive the reward. In total, the subjects travel through a series of four different reward zones or 'restaurants', each of which contains an 'offer' and 'wait zone'. When a subject approaches the entrance of each restaurant (the 'offer zone') it views a delay. This length of time is signaled on a screen and only made visible when the subjects are in close proximity to the feeder. At this point, the subject could choose whether to stay or go. When a subject chose to stay, it proceeded to enter the 'wait zone' where it must stay the entirety of the delay in order to receive a reward. Rewards were consistent within a session for each restaurant despite the variation in delay times and the total session time was a set duration. We trained macaque subjects (n=2) on the task. Our analysis of subject behavior revealed that subjects are more likely to accept a longer delay when they had previously

skipped a shorter one and traverse faster to the next restaurant based on whether or not they had previously skipped a smaller delay restaurant. Another result found that lingering time was significantly predicted by the delay. Higher lingering times were associated with longer delays. These results provided tentative evidence that monkeys utilize recent past experience when making new choices.

Title: Neurons in the pigeon nidopallium caudolaterale, but not the corticoidea dorsolateralis display value and effort discounting related activity

Authors: *M. DYKES, B. S. PORTER, M. COLOMBO;
Psychology, Univ. of Otago, Dunedin, New Zealand

Abstract: There is a growing body of literature finding that the pigeon nidopallium caudolaterale (NCL) is the anatomical and functional equivalent of the mammalian prefrontal cortex (PFC). We recorded from single neurons in two areas of the pigeon brain while birds were required to peck a stimulus indicating that either a high effort task or a low effort task would follow. Upon completion of the task, the birds received the same reward. We recorded from the NCL in four pigeons, and from the corticoidea dorsolateralis (CDL) in two pigeons. We found that activity in the NCL was modulated by the value of the reward that would be received based on how much effort was required to obtain it. The pattern of firing we saw was similar to that observed in the mammalian anterior cingulate cortex (ACC). Value coding was most prominent during the presentation of the stimulus indicating a high or low effort task, and in the delay period immediately prior to carrying out the effort task. In contrast, activity in the CDL was not modulated by value; however, population firing patterns suggest that it may be involved in associating actions with outcomes. Our findings support the view that activity in NCL reflects value of reward as a function of effort discounting and as such may serve functions similar to the mammalian anterior cingulate cortex.

Title: Intracellular determinants of CA1 pyramidal cells activation or silencing during locomotion

Authors: F.-X. MICHON, G. MARTI, C. FILIPPI, R. BOURBOULOU, J. KOENIG, ***J. EPSZTEIN**;
INSERM U1249/Aix-Marseille University/INMED, Marseille, France

Abstract: Spontaneous locomotion strongly influences the state of the hippocampal network and is critically important for spatial information coding. However, the intracellular determinants of CA1 pyramidal cells activation during locomotion are poorly understood. Here we recorded the membrane potential of CA1 pyramidal cells (PCs) while non-overtrained mice spontaneously alternated between periods of movement and immobility during a virtual spatial navigation task in a familiar environment. We found opposite membrane polarization between regular firing and bursting CA1 PCs during movement. Regular firing CA1 PCs were more depolarized and fired at higher frequency during movement compared to immobility while bursting CA1 PCs were hyperpolarized during movement in a speed dependent manner. We propose that the speed-dependent suppression of a subpopulation of CA1 PCs could enhance signal to noise ratio for efficient spatial coding during locomotion.

Title: The spatial localization of reward-related changes in hippocampal sharp-wave ripple rate requires normal dopamine signaling

Authors: *M. R. KLEINMAN, D. J. FOSTER;
Psychology, Univ. of California, Berkeley, Berkeley, CA

Abstract: The hippocampus is involved in goal-directed spatial navigation. Previous work has demonstrated that hippocampal replay sequences overrepresent remembered high value locations, and that increases in reward at a particular position increase the rate of sharp wave ripples (SWRs) and reverse replays there, providing a potential substrate for associating the location of a reward with the spatial locations, actions, and stimuli that temporally preceded it. We sought to determine whether this structuring of SWRs and replay to reflect reward contingencies in the environment requires normal signaling in the midbrain dopaminergic (DA) system. The inhibitory DREADD hM4Di was expressed in dopaminergic neurons in the ventral tegmental area (VTA) using targeted injection of a cre-dependent viral construct in transgenic TH-cre rats. Each animal was implanted to perform tetrode recordings from the dorsal CA1 field of the hippocampus. Animals then explored familiar and novel linear environments to collect chocolate fluid rewards, with different trial blocks incorporating spatially localized unexpected changes in reward. During control saline-injection sessions, locations in which the relative reward volume increased led to an increased rate of SWRs, in line with previous work. Intriguingly, suppression of DA VTA neurons by i.p. CNO injection led to increased SWR rates at all reward locations when the reward volume at only one was increased, despite the relative value of the unchanged locations actually decreasing from the equal reward block. Across three rats, there was a significant interaction between CNO condition, reward block and track end, suggesting that the suppression of normal dopamine signaling disrupted the spatial localization of reward-related changes to SWR rate, and thus possibly SWR-associated replay. These results provide evidence for a learning circuit in which hippocampal SWRs rely on DA signaling to properly link the spatial locations associated with new, behaviorally-relevant information. This poor localization of SWRs to positions in the environment with increased reward is expected to cause impaired learning in downstream structures relying on hippocampal output to relate positions with value.

Title: Hippocampal replay rapidly and repeatedly adapts to reconfigurations of barrier wall structure in a changing complex maze

Authors: *J. WIDLOSKI[1], D. J. FOSTER[2];
[1]Univ. of California Berkeley, Berkeley, CA; [2]Psychology, Univ. of California, Berkeley, Berkeley, CA

Abstract: Hippocampal replay has been proposed as an important substrate for path planning and learning because it encodes behaviorally relevant trajectories. However, there is little work on how replay responds to environments with barriers. Barriers change the topological structure of the environment and can have profound effects on how the environment is subsequently navigated. To address this, we developed a new task to elicit replay through barriers. We adapted a previous lab task (goal-directed navigation in unobstructed open field) to include transparent jail bar barriers that impeded the rat's path but minimized interruption of visual and olfactory cues. The 6 barriers could be fitted into 12 different positions, giving a total of 231 unique configurations (not including rotations); new configurations were chosen pseudorandomly for each session, and each rat received between 30-70 training sessions before recording. All other features of the environment remained fixed. The task consisted of goal directed trials to a fixed unmarked "home" well (which changed across sessions) alternating with cued trials to random wells backlit by a flashing light. These trials in particular were designed to lure the replay through the barriers. We recorded up to 300 place cells simultaneously in dCA1 using high tetrode-density hyperdrives. Remarkably, across rats and across barrier configurations, awake replays never crossed the barriers, instead exhibiting trajectories that strongly resembled the rat's own obstacle-avoiding paths. We developed a new quantitative method to measure and visualize replay-like representational transitions in all candidate replay events, to avoid being biased toward smooth trajectories that might not have been as readily detected because of sampling issues at the barriers. This method confirms the finding. Since multiple sessions were recorded each day, we were able to assess the relationship between place field remapping and barrier-respecting replay. We found that most place cells do not remap between configurations, suggesting that the same place cells with the same place fields rapidly reconfigure their relationships to one another to support awake replay that obeys the topological constraints of each environment.

Title: Fast triggering of brain stimulation contingent on the trajectory content of online-detected hippocampal replay

Authors: W. D. CROUGHAN, ***D. J. FOSTER**;
Univ. of California, Berkeley, Berkeley, CA

Abstract: Place cells in the hippocampus exhibit during rest or sleep spontaneous activity patterns that depict behavioral trajectories. These patterns, known as replay events, compress long behavioral sequences into rapid bursts of activity on the order of 100ms, making them intriguing candidates for synaptic plasticity's role in memory consolidation, as well as in the possible planning of future behavior. Numerous studies have shown correlations between the content of replay events and an animal's goals during spatial navigation. However, causal testing of replay function requires the ability to disrupt or otherwise interact with replay events in realtime, with selectivity for replay content. For example, testing the hypothesis that the prospective replay of a planned trajectory is necessary for its subsequent execution requires the ability to disrupt replays of the trajectory while leaving other replays intact. However, the fast time scale of replay, and the need to decode information from hundred of cells simultaneously, have made such closed-loop experiments extremely challenging. The difficulties include both the time required to analyze recorded data by hand for accurate replay decoding, and the low latency required to decode the events in real time. Here we describe a computational package that enables fast and accurate decoding of replay for use in closed-loop experiments. First, recorded spiking data is analyzed and single units are isolated automatically. The place field of each unit is then determined and used to decode ongoing activity. Replay events are decoded in real-time, and events with specific content can be isolated to trigger arbitrary interventions. This enables, for instance, feedback to target only forward or reverse replays, or replays of a certain area in an environment. Classification accuracy was compared to offline decoding using hand-clustered units. Multi-core processing and continuous decoding allows content to analyzed with a processing latency on the order of 1ms. Latency was measured on a standard desktop computer with an 8-core processor. This tool sets the stage for a variety of closed loop experiments to uncover the function and mechanisms of hippocampal replay, and how replay events relate to wider brain function and behavior.

Title: Prefrontal neurons are tuned to the spatial trajectory information content of hippocampal neurons during non-local hippocampal representation of future and past places, but not during local hippocampal representation of current place

Authors: *A. BERNERS-LEE[1,2], X. WU[3], D. J. FOSTER[2];
[1]Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Psychology, Univ. of California, Berkeley, Berkeley, CA; [3]Comprehensive Epilepsy Ctr., NYU Langone Med. Ctr., New York, NY

Abstract: The use of experience to guide decision-making is critical for adaptive behavior. The hippocampus (HP) can represent experience locally, by signaling the current position in an environment, or non-locally, by representing future or past experiences, either in the form of short look-ahead sequences during theta or extended replay sequences. Activity in the medial prefrontal cortex (mPFC) is often coincident with hippocampal activity and local field potential events, and is implicated in decision-making. However, unlike HP neurons, mPFC neurons do not exhibit tightly spatially tuned place fields, prompting the questions of whether and how the information content in each area becomes integrated to promote decision-making. We recorded neurons in mPFC and HP simultaneously while rats navigated a novel Y-maze, during early learning. We found that individual mPFC neurons were differentially modulated to replay sequences depicting different arms of the maze. Indeed, the trajectory identity of the HP replay could be decoded from the coincident mPFC firing alone. Despite this trajectory selectivity during HP replay, mPFC neurons did not show spatially selective activity patterns during running on the maze, as has been reported. However, mPFC neurons exhibited trajectory selectivity during the non-local portions of HP theta sequences (also called theta sweeps). Furthermore, the pattern in which mPFC cells were modulated to theta sequences was consistent with how they responded to replay sequences. Thus, across different behavioral and brain states, mPFC neurons reflect the information content of HP specifically during non-local representation. This suggests that mPFC neurons are specifically tuned to the representations generated by the internal model of the world in HP, possibly to support model-based decision-making, and indeed mPFC firing temporally associated with non-local theta sequences was predictive of the rats' future choice, while firing temporally associated with local representations was not. These data

shed light on the dialogue between HP and mPFC as they generate and explore an internal model to guide decision-making.

Abstract: Population neuronal activity in the hippocampus underlies spatial navigation and memory formation processes in mammals, including mice and humans. However spatiotemporal dynamics of neuronal ensembles are not well understood in the context of spatial mapping, learning and memory. In the present study, we address spatiotemporal ensemble representations in hippocampal CA1 during behavior tasks through *in vivo* Ca++ imaging using head-mounted miniature microscopes ("miniscopes"). For imaging experiments, mouse brains express the genetically encoded calcium indicator GCaMP6 (after injection of AAV expressing GCaMP6) such that neural activities of large ensembles of neurons over extended periods of time can be recorded through microscopic imaging of calcium signal events. This approach allows us to simultaneously examine hundreds of the same neurons in hippocampal CA1 across different environments and different days, and correlate single-cell firing patterns with mouse spatial mapping and learning behaviors. We find that during the free exploration of open field arenas and running on a linear track, CA1 neurons form place specific firing fields, which is consistent with previous studies with electrical recordings. Interestingly, the neural ensembles can be divided into specific activation groups as they share similar calcium event patterns in the temporal domain. This "temporal clustering" of longitudinally tracked neurons exhibits dynamic changes and the same set of neurons form distinct clusters as the mouse explores in different environments. The "optimal" grouping was determined by a nonnegative matrix factorization (NMF) based method adapted from Brunet et al. (2004). Given a searching range of 1-50, the optimal number of groups ranges from 10 to 40 for each imaging session. Neurons belonging to

the same cluster tend to share place firing fields, while firing fields of neurons from different clusters are largely non-overlapping but cover different locations of the arena. Such temporally specific clustering and spatial tiling of CA1 neuronal ensembles also exists in the training and testing sessions of a hippocampus-dependent object-location memory task. Together, these new and important results lead to the notion that CA1 populations are organized into distinct groupings that share spatiotemporal patterns of activity.

Title: Dendritic plateau potentials shape hippocampal place cell representations

Authors: *C. GRIENBERGER, J. C. MAGEE;
Baylor Col. of Med., Houston, TX

Abstract: A crucial function of the brain is to produce useful representations of the external world. The hippocampus contains neurons tuned to fire action potentials (APs) in particular spatial locations within an environment. Collectively, populations of these place cells encode abstract and concrete environmental features. Our previous results demonstrate that place cells are driven by a subset of inputs whose elevated synaptic weights provide excitation that exceeds a spatially uniform level of inhibition. A novel form of synaptic plasticity called behavioral timescale synaptic plasticity (BTSP) mediates the increase in synaptic weights. BTSP has several distinct characteristics, including that it depends on dendritic plateau potentials (plateaus) instead of APs. Here we sought to determine how plateaus and BTSP shape CA1 place cell representations. We used two-photon Ca^{2+} imaging in mice exploring a novel linear track for the first time. We observed the formation of an environment-specific representation during the first recording session that correlated with learning of reward position. Notably, the majority of place fields were not initially present but abruptly appeared later during the session, suggesting that completing the representation requires the animal's experience. Finally, several pieces of evidence implicate BTSP: (1) the abrupt appearance itself; (2) the width of the new fields was correlated with the animal's velocity during induction; (3) new fields were shifted back in space with respect to their induction; (4) the development of the representation was severely attenuated by the plasticity and Ca^{2+}-spike blockers, APV and SNX-482. Taken together, our results point

towards a fundamental role of BTSP in creating CA1 representations and, thus, identify plateaus as a key signal that instructs CA1 neurons in how to represent an environment.

Title: Continuous reward-place coding properties of dorsal distal CA1 hippocampus cells

Authors: *Z. XIAO[1], S. NAGL[2], K. LIN[1], J.-M. FELLOUS[2];
[1]Program of Applied Mathematics, The Univ. of Arizona, Tucson, AZ; [2]Psychology, Univ. of Arizona, Tucson, AZ

Abstract: Hippocampal place cells are involved in goal-directed spatial navigation and the consolidation of spatial memories. Recently, using calcium-imaging in mice navigating in a virtual reality environment, Gauthier and Tank found a subpopulation of hippocampal cell selectively activated in relation to rewarded goals. However, the relation between these cells' spiking activity and goal-representation as well as goal-related-memory consolidation remains elusive.
In this study, we analyzed data from experiments in which rats were pre-trained to acquire sugar-water rewards from 8 equidistant feeders at the periphery of an open-field arena. The rats then underwent experiments made up of 5 different tasks and 10 flanking rest epochs. These tasks included separate cue-driven and memory-driven spatial navigation epochs in which the spatial context was manipulated.
Using tetrode recordings, we found CA1 populations with coding properties continuously ranging from place cells to reward cells. Specifically, we found regular place cells insensitive to reward locations, reward cells that only fired at correct rewarded feeders in each task regardless of context, and "hybrid cells" that responded to both fixed locations and change of locations of feeders. In addition, we observed transitions between place cells and reward cells within each session, i.e., a reward cell in previous tasks could encode a fixed location in the next few tasks, and vice versa. In this population, most of the reward sensitivity was due to obtaining the reward rather than expecting it.
With these observations, we hypothesized that some pyramidal cells (if not all) integrate both

spatial and reward inputs with various and plastic weights. Consistent with previous studies, some place cells exhibited excess firing around correct feeders, which was well explained by the hypothesis. To measure the place and reward components of a cell quantitatively, we defined "place" & "reward" scores for each neuron based on its firing rate map. Generally, place cells had larger place scores and smaller reward scores, and vice versa. Hybrid cells lay between the other 2 groups of cells.
We also studied the relationship between reward sensitivity of these cells and their contribution to replay-like rest population bursts. We found that the portion of reward-cell-dominated population bursts was much higher than expected by chance, suggesting an independent reactivation pathway from reward-related areas to CA1.
Overall, this study provides insights into the integrative coding properties of CA1 pyramidal cells, focusing on their abilities to carry spatial and reward information in a mixed and plastic manner.

Title: Value-dependent changes occur dynamically in spatial firing patterns of place cells in the ventral hippocampus, but not in the dorsal hippocampus

Authors: *S.-W. JIN, J. SHIN, I. LEE;
Brain and Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: The dorsal hippocampus (dHP) has been studied extensively for its roles in spatial navigation and memory. However, the major roles of the ventral hippocampus (vHP) are relatively unknown although prior studies indicate that there should be fundamental differences between the dHP and vHP. We hypothesize that encoding the value of an event at a specific location takes priority in the vHP, compared to the dHP whose priority resides in representing the precise location of an animal presumably in the cognitive map. To test this hypothesis, we recorded single units from both the dHP (n = 2158) and vHP (n = 4573) simultaneously using a 24-tetrode recording drive while rats (n=6) alternated between two adjacent arms of a radial

maze. During training, rats obtained the same type of reward (sunflower seeds, or SS) in both arms (SS session) as a baseline. Afterward, in the main task, both arms were unexpectedly baited with less desired reward (Cheerios, or CC) in certain blocks interleaved with the baseline conditions. We analyzed only place cells (mean firing rate > 0.5Hz, spatial information > 0.25 bits/spike) of the dHP and vHP. When the reward was changed from SS to CC, the proportion of units maintaining their location-associated firing rates was higher in the dHP (72%, n = 169/234) than in the vHP (59%, n = 196/332) ($p < 0.01$). On the other hand, place cells in the vHP (28%, n = 94/332) shifted their firing locations more within a session than those in the dHP (16%, n = 38/234) ($p < 0.01$). The spatial rate maps of the place cells recorded from the vHP in the SS session were significantly changed as reward was changed to less desirable one (i.e., CC) ($p < 0.001$), whereas this was not the case in the dHP ($p > 0.05$ between the rate maps of the SS and CC sessions). Approximately 40% (n=15/37) of the vHP place cells that remapped in the CC session formed their place fields immediately after the reward type was changed from SS to CC. Next, we tested whether such differences between the dHP and vHP would also show similarly in a mnemonic task. For this purpose, rats were trained in a spatial food-preference task in which two arms of a T-maze were baited with different types of reward (SS and CC). Rats naturally tried to visit the SS-baited arm more. After the rat chose the SS-baited arm for 12 of the last 15 trials, the reward types associated with the two arms were reversed. Our preliminary results show that the place fields of the vHP cells shifted forward toward the location where the more preferred reward was found, whereas no such reward-related dynamic location encoding occurred in the dHP place cells ($p < 0.05$). Our results suggest that reward value and its associated locations make dynamic changes in the vHP, but not in the dHP.

Title: Extending evidence for REM-associated replay in hippocampal CA1 place cells

Authors: T. HOWE[1], M. A. WILSON[2], D. JI[3], *M. W. JONES[1];
[1]Physiology, Pharmacol. & Neurosci., Univ. of Bristol, Bristol, United Kingdom; [2]Picower Inst. Learn/Memory, MIT, Cambridge, MA; [3]Baylor Col. of Med., Houston, TX

Abstract: During periods of inactivity, hippocampal CA1 neurons with spatial receptive fields (“place cells”) reactivate in patterns that recapitulate previously experienced spatial sequences, a

phenomenon known as replay. CA1 replay is most prominently associated with sharp-wave ripple (SWR) events during non-REM sleep or quiet wake, and has been implicated in the consolidation of episodic memory.
Replay has also been reported during REM sleep [1], however evidence for this phenomenon is substantially less extensive than for replay during non-REM. Non-REM replay occurs on a temporally compressed timescale (approximately 8 times faster than during active behaviour) around brief, discrete SWR events. REM-replay appeared less temporally compressed and occurred during extended periods of elevated theta power, necessitating alternative detection methods to those established for SWR-associated replay.
Using tetrode recordings from adult rat dorsal CA1, we present data that corroborate the existence of REM-replay. The activity of multiple place cells was recorded simultaneously while rats performed simple goal-directed maze tasks, and during subsequent extended rest periods in a sleep box. Replay was detected using a moving-window correlation algorithm (from [1]), and confirmed with complementary approaches including hidden Markov model (HMM) and Bayesian trajectory decoding.
Extending evidence for REM replay paves the way for analyses exploring its experience-dependence, extra-hippocampal correlates and functional contributions.

Title: The dynamics and mechanisms of place field formation in the hippocampal CA3

Authors: *C. DONG, M. SHEFFIELD;
Neurobio., Univ. of Chicago, Chicago, IL

Abstract: Hippocampal place cells are a subset of pyramidal neurons in the hippocampus that fire at specific locations in an environment. They are a critical component of the brain's

cognitive map of space, and are thought to represent the spatial component of episodic memories (memories that occur at a particular time and space). The development of 2-photon calcium imaging techniques enables neuroscientists to measure the activity of large populations of neurons, and also fine dendritic structures, in the hippocampus. This approach has been used to study the dynamics and mechanisms of place field formation in the CA1 region of the hippocampus during novel environment exposure, providing new insights into how place fields form in the CA1 at the population and dendritic level. One of the insights gained from this work is that across the population CA1 pyramidal neurons form many place fields instantaneously (instant place fields) in novel environments, with other place fields forming slowly with experience. The delayed forming place fields form through a dendritic spike induced synaptic plasticity mechanism that takes time/experience to occur. However, the major input source to CA1, the CA3 region, which forms its own place fields and integrates information from dentate gyrus (DG), entorhinal cortex (EC), and its own population in the CA3, has not been systemically investigated to the same level. Here, we studied the dynamics and mechanisms of place field formation in CA3 at both the population and dendritic level. We have found that compared with CA1 place cells, CA3 place cells form place fields slowly during novel environment exposure, and form a very limited number of instant place fields. Our data suggest that cognitive maps in the CA1 and CA3 form differently in response to novel environments, and that the CA1 encodes these new environments quickly, whereas the CA3 requires experience to form new maps. This also suggests that CA1 place fields that form instantly in novel environments are not simply driven by instant place fields in CA3. We are also measuring dendritic activity across CA3 dendrites during place field formation to try to understand the underlying mechanisms of place field formation in individual neurons.

Title: Characterising stability and fluctuation of hippocampal place cell activity using calcium imaging

Authors: *C. P. KOH, A. TASHIRO;
Nanyang Technological Univ. (NTU), Singapore, Singapore

Abstract: Hippocampal place cells exhibit stable location-specific activity in a relatively fixed place. However, fluctuations in their activity were also commonly observed. For example, it has been reported that their firing rate may vary or the cells may turn on/off between multiple sessions of exploring a constant environment. To characterise the stability and fluctuation, male C57/BL6 mice were injected with adeno-associated viral vector expressing GCaMP6s under the control of the CaMKIIα promoter and implanted with a GRIN lens, and calcium imaging was conducted using a head-mounted microendoscope while each animal traversed a one-metre long linear track in two sessions one-week apart. Subsequently, we selected neurons which were active in both sessions, and CNMF-e (Constrained Non-negative Matrix Factorisation for Endoscopic data) was used to detect Ca^{2+} signal and approximate spike information from individual neurons. The event output from CNMF-e for each cell was compared visually against the corresponding calcium imaging movies. We found that there were 57.9% and 6.3% false positive and false negative events respectively. After eliminating the false positive events, the remaining events and the animal's positional information in the track were used to generate rate maps. Of all the active cells analysed from the two sessions one-week apart, three groups of active cells emerged. The first group was only active at the ends of the track in both sessions (46.15%) while the other two groups were active when the animal was in motion and exhibited direction-specific activity (53.85%). The second group (30.77%) is place cells with stable location-specific activity between the two sessions, showing statistically significant, strong, positive spatial correlation between the sessions ($r = 0.729$ to 0.965; $p < 0.01$); shift in place field centre of mass was 4.59 ± 3.73 cm (mean ± S.D). The third group (23.08%) showed location-specific activity with variable locations, and did not display statistically significant spatial correlation ($r = 0.130$ to 0.199; $p > 0.05$); shift in place field centre of mass was 23.06 ± 17.34 cm (mean ± S.D). From a previous study, we expected to find a major population of cells which were active while the animal was in motion in one session but not the other. Although the number of cells examined at present is limited, none of the cells showed this pattern of activity. Our findings from calcium imaging followed by CNMF-e support the idea that there are two distinct groups of active cells when an animal is in motion, one with stable, and the other with variable location-specific activity.

Title: Place cells in head-fixed mice during navigation in a floating real-world environment

Authors: *M. GO[1], J. ROGERS[1], C. DAVEY[2], S. V. PRADO[1], G. GAVA[1], L. KHIROUG[3,4], S. R. SCHULTZ[1];
[1]Imperial Col., London, United Kingdom; [2]The Univ. of Melbourne, Melbourne, Australia; [3]Univ. of Helsinki, Helsinki, Finland; [4]Neurotar Ltd, Helsinki, Finland

Abstract: "Place cells" in the hippocampus encode spatial information, and have been observed in both rodents moving freely, and in head-fixed mice navigating in virtual reality environments. It has been shown that hippocampal patterns of activity in rodents differ between virtual and real environments (Aghajan et al 2015, Nature Neurosci 18:121-8). Recently, a real-world environment system for head-fixed mice which allows for sensory feedback has been developed, consisting of an air-lifted track (Kislin et al 2014, J Vis Exp 88:e51869). Until now, the presence of place cells in such a system has not been shown. Methods: We injected mice with hSyn1-GCaMP6s-mRuby into the hippocampal CA1 region and aspirated the cortex above the injection site until the corpus callosum was exposed. After three weeks, animals were put under water restriction and trained to move on a track, either a circular linear track or an open circular arena, lined with phosphorescent visual cues. The track floats on an air table (Neurotar Ltd) under a two-photon resonant scanning microscope (Scientifica Ltd) and is fitted with a magnet-based position tracking system. Animals were trained in 45 min sessions twice daily with water rewards randomised by location (8 for circular linear track and 3 for open arena). After a training period of 6 days and 13 days, for the circular linear track and open arena, respectively, two-photon calcium imaging was performed during navigation. Calcium imaging videos were corrected for movement artefacts and segmented for cell regions using the ABLE algorithm (Reynolds et al 2017, eNeuro 4:ENEURO.0012-17.2017). Place field analysis was performed to monitor the changes in neural activity across the different locations across several imaging sessions. To identify cells with spatial selectivity, we computed the mutual information between neuronal activity and track position. Place field maps above the mutual information threshold were sorted in order of vector average place preference. To verify that the increase in firing rate in place fields was statistically significant, we performed a bootstrap shuffle test. Results and conclusions: Free exploration behaviour was induced in the mice as a result of cued learning. Consistent place tuning was observed in approximately 60% of the cells in the circular linear track. Moreover, place cells remapped when the animal was in a novel environment, with additional cells recruited. Two-dimensional place cell tuning was also observed in the open arena. To our knowledge, this is the first demonstration of place cells in head-fixed mice navigating an air-lifted track.

Title: Spatial firing patterns of hippocampal CA1 neurons are not sensitive to changes in the social context

Authors: ***W.-Y. WU**, E. YIU, A. G. OPHIR, D. M. SMITH;
Psychology, Cornell Univ., Ithaca, NY

Abstract: The hippocampus is thought to play a key role in social memory, particularly the ventral region which is closely interconnected with the social behavior network. For example, inactivation of ventral CA1 neurons impairs social memory (Okuyama et al, 2016, Science, 353:6307). Hippocampal neurons exhibit spatial firing patterns (place fields) which undergo remapping in response to changes in the environmental context, suggesting that these representations might also be sensitive to changes in the social context. However, recent results indicate that dorsal CA1 neurons do not remap when a conspecific is added to the environment (Alexander et al, 2015, Nat. Comm. 7:10300). Interestingly, dorsal CA2 neurons did show remapping and projections from dorsal CA2 to ventral CA1 have been implicated in social memory (Miera et al, 2018, Nat. Comm. 9:4163). In the present study, we manipulated the social context while rats foraged in an open field and we recorded neurons in dorsal and ventral CA1. In order to maximize the salience of the social manipulation, two conspecifics were present for each recording trial (in small cages) and their cage bedding was scattered around the environment. Recordings were obtained during four 15 min trials in an ABAB pattern with alternating sets of conspecifics, including different sets of familiar and unfamiliar same- or opposite sex rats. We also included a control manipulation of the visual environment for a subset of subjects in which the conspecifics were constant but the wall color was changed from black to white. We found little evidence of remapping in either dorsal or ventral CA1 in response to the social context manipulations. Dorsal CA1 neurons exhibited similar spatial firing patterns across trials, regardless of whether the social context was the same or different (same r=0.57, different r=0.60). Preliminary data indicate that ventral CA1 neurons exhibited lower spatial correlations than dorsal CA1, but they were unaffected by the social context (same r=0.24, different r=0.26). Importantly, the same neurons exhibited significant remapping in response to manipulation of

the visual context, as indicated by reduced spatial correlation scores for black and white trials (dorsal CA1: $t_{(25)}$=4.08, p<.001; ventral CA1: $t_{(72)}$=3.77, p<.001). Interestingly, some neurons exhibited selective firing near the conspecifics and this appeared to be more common in ventral CA1. Overall, these results suggest that hippocampal neurons do not encode social contexts in the same way they encode other kinds of environmental context and social memory may be supported by mechanisms other than hippocampal remapping.

Title: Role of hippocampal CA1 place cells in fear memory encoding and recall

Authors: *S. KRISHNAN, C. CHERIAN, M. SHEFFIELD;
Neurobio., Univ. of Chicago, Chicago, IL

Abstract: Episodic memories—memories of experiences placed in time and space— form through associations made in the hippocampus between distinct stimuli within specific contexts. The spatial components of these memories are thought to be represented in place cells that encode animal position. Consistently, in a contextual fear conditioning (CFC) paradigm, which causes the formation of an episodic-like memory, optogenetic activation of hippocampal neurons "tagged" during induction of contextual fear can sufficiently trigger retrieval of the fear memory. These neurons termed "engram-cells" are thought to contain the physical trace of the fear-memory. However, because direct neurophysiological data collected from engram-cells during memory formation is lacking, it is unclear if the fear-memory engram-cells are also place-cells or are they distinct cells located in distinct layers or regions. What are the firing characteristics of engram cells during memory formation that allows them to be tagged, and how do they fire during natural memory recall? To answer these questions, we designed a device that provides tail shocks to head-fixed mice during navigation of virtual reality (VR) environments. In these mice, we implemented a novel behavioral paradigm for CFC where simultaneous functional two-photon imaging of large populations of hippocampus neurons at cellular resolution can be performed prior to and during fear conditioning as well as during fear memory recall. During

memory recall, mice showed substantial increase in freezing and backward running in the VR environment associated with the tail shock when compared to a control VR environment, allowing our paradigm to be comparable with CFC performed in freely-behaving mice in which engram tagging studies have been performed. Thus, this paradigm provides us with access to the activity of hippocampal neurons during fear memory formation and recall allowing us to identify and quantify the characteristics of fear engram-cells and place cells within the same animal. By precisely probing memory circuits in the hippocampus on a large scale during behavior in this way, we aim to reveal the mechanisms and population dynamics involved in the formation and recall of a specific memories and how distinct memory representations interact at the population level.

Title: Transcriptomic analysis to identify brain region specific enhancers

Authors: *R. A. PHILLIPS, III, N. CARULLO, K. SAVELL, J. J. DAY;
Neurobio., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Genomic enhancers are cis-acting regulatory elements that undergo bidirectional transcription to form long non-coding RNA molecules, termed enhancer RNAs. In the brain, enhancers control the precise gene expression programs needed to regulate cellular function in response to stimuli. Furthermore, SNPs discovered in GWAS studies for brain diseases often map to regulatory regions within the genome that contain enhancers. While evidence for the importance of enhancers in cellular function and brain disease is steadily increasing, enhancer discovery often neglects the presence of transcription at genomic enhancers. Here we show that transcriptomic analysis from total RNA identifies bidirectional transcription from putative enhancers across the genome and can be used to predict potential enhancer-gene pairs based on co-regulated basal and stimulus-dependent activity states. Using this approach in multiple neuronal subtypes, we demonstrate comprehensive mapping of cell-type and stimulus-dependent putative enhancers and show that these enhancers differ based on brain region of origin and

activity-regulated neuronal responses. We are currently using this transcriptome-assisted discovery pipeline to identify candidate enhancers for CRISPR-based functional validation of enhancer-gene pairs. Our results suggest that the presence of enhancer RNAs can assist in enhancer discovery, providing an additional tool for the characterization of regulatory elements within the genome.

Abstract: Epigenetic mechanisms are central regulators of neuronal function, experience-dependent gene expression, and adaptive behavior. Histone acetylation is a well studied epigenetic modification that is commonly used to define enhancer elements in the genome, as these sites are marked by H3K27 acetylation and binding of histone acetyltransferases such as Creb binding protein (CBP). However, although histone acetylation patterns at enhancers are actively modified by neuronal activity and behavioral experience, it is presently unclear how these site-specific changes are induced and maintained over time. Here, we aimed to elucidate the role of CBP on enhancer activity and gene expression with particular focus on the intersection of non-coding enhancer RNAs (eRNAs) and CBP. RNA mobility shift assays (REMSA) revealed that two distinct eRNAs arising from separate enhancers upstream and downstream of the *Fos* gene bind the CBP HAT domain but not the bromodomain, suggestive of direct physical interactions between CBP and eRNAs. HAT domain recruitment to *Fos*

enhancers with a CRISPR-dCas9 approach increases local eRNA transcription and distal mRNA expression from the *Fos* gene, supporting the role of histone acetylation in gene regulation and enhancer dynamics. Finally, we used another CRISPR-dCas9 system (CRISPR-Display) to recruit CBP-interacting eRNAs to specific sites in the genome. This approach revealed that tethering of *Fos* eRNA sequences to their respective enhancer induces similar increases in *Fos* mRNA expression as HAT recruitment, while recruitment of a control RNA (based on a non-regulatory region between the *Fos* enhancers) does not reproduce these effects. Intriguingly, targeting of the eRNAs to other sites (other enhancer or control regions) did not affect *Fos* mRNA levels. Along with our data showing that non-targeting overexpression doesn't affect *Fos* mRNA expression, this suggests location specificity as major regulatory factor in eRNA function. In ongoing work, we investigate the role of eRNAs on HAT activity, and modulate endogenous CBP expression to examine the effects on CBP target enhancers and genes. Overall, our results suggest that CBP interacts with eRNAs to regulate enhancer and gene induction. The location and sequence specificity of eRNA-mediated effects provide a novel mechanism for spatiotemporal control of CBP function.

Title: Combined electrophysiological, behavioural and bioinformatic assessment of the role of MSK1 in the molecular mechanisms of experience-dependent synaptic plasticity

Authors: *D. D. COOPER, P. RICHARDSON, E. CONDON, S. PINDER, B. G. FRENGUELLI;
Sch. of Life Sci., Univ. of Warwick, Coventry, United Kingdom

Abstract: Exposure of experimental animals to an enriched environment (EE) has profound effects on neuronal morphology, synaptic activity and cognitive function. Brain-derived neurotrophic factor (BDNF) has been repeatedly implicated in initiating the molecular cascade and genomic response that leads to enduring changes in the nervous system that underpin the

benefits of EE. However, the identity of these molecular and genomic events have remained elusive. We have previously shown that a nuclear enzyme activated by BDNF, mitogen- and stress-activated protein kinase 1 (MSK1), and which regulates transcription, notably via the phosphorylation of cAMP response element binding protein (CREB), is necessary for the EE-induced enhancement of synaptic transmission. (Corrêa et al., 2012; Lalo, et al., 2018). Using a mutant mouse expressing a kinase-inactive form of MSK1 (MSK1 KD), we have been investigating the role MSK1 plays in modulating the cognitive, synaptic, anatomical and genomic responses to environmental enrichment. 3D neuronal reconstruction, RNA sequencing and single-cell patch-clamp electrophysiological recordings from the hippocampal region of male mice (3-5months of age) reared in standard housing and EE housing were used to characterise the spectrum of changes from the transcriptomic to the cellular after various durations of enrichment. In addition, tests of cognitive function (object location, sociability) were performed to relate these cellular and molecular changes to behavioural performance. Currently these studies indicate that the majority of genomic changes induced by EE require the kinase activity of MSK1. This suggests that MSK1 is responsible for initiating a genomic homeostasis in response to enrichment that may both stabilise EE-induced neuronal changes, and make the brain better able to respond to new challenges. Title: The role of MSK1 in the experience-dependent regulation of AMPA receptors and plasticity-related proteins

Authors: *P. RICHARDSON, D. D. COOPER, B. G. FRENGUELLI;
Sch. of Life Sci., Univ. of Warwick, Coventry, United Kingdom

Abstract: The benefits of environmental enrichment (EE) for experimental animals include increased spine density, enhanced synaptic transmission and plasticity, and improved cognition. A prime molecular candidate underlying these positive effects is the enrichment-induced release of brain-derived neurotrophic factor (BDNF). We have shown that mitogen- and stress-activated protein kinase 1 (MSK1), which is activated by BDNF and which regulates transcription through CREB phosphorylation, is not only necessary for the regulation of the strength of basal synaptic transmission in hippocampal area CA1 (Daumas *et al.*,2017), but also necessary for the enhancement of mEPSCs by EE (Correa *et al.*, 2012; Lalo *et al*., 2018). Since changes in cell-surface expression of glutamate AMPA receptors (AMPARs) is a likely explanation for the MSK1- and EE-dependent effects on synaptic transmission, we have been investigating the influence of MSK1 on AMPAR GluA subunits and key plasticity-related proteins using wild-type (WT) mice and mice harbouring a knock-in mutation of the MSK1 gene that inactivates the kinase activity of MSK1 (MSK1 KD mice).
We have compared AMPAR GluA subunit expression across four groups: WT and MSK1 KD mice raised under either standard or enriched conditions for 1 week, 5 weeks or 3 months. In addition, we have investigated the expression of CREB and arc/Arg3.1 after various durations of enrichment in WT and MSK1 KD mice, and have performed parallel behavioural studies (novel object recognition, spontaneous alternation) to equate any expression changes with cognitive function.
These studies will shed new light on the influence of MSK1 in the experience-dependent regulation of key proteins regulating synaptic activity and will illuminate the molecular pathways linking BDNF to enduring cellular and molecular changes underpinning the enhancement of cognition by enrichment.

Title: Large-scale, *in vivo* functional characterization of molecularly-defined gabaergic interneurons in CA1 by 3D random-access imaging during spatial navigation

Authors: *T. GEILLER[1], B. VANCURA[1], S. TERADA[1], B. RÓZSA[2], A. LOSONCZY[1]; [1]Columbia Univ., New York, NY; [2]Hungary Acad. of Sci., Budapest, Hungary

Abstract: In the hippocampal region CA1, GABAergic interneurons account for nearly 15% of the neuronal population and are comprised of heterogeneous subtypes. This diverse group of inhibitory cells varies with respect to developmental origin, anatomical location, connectivity patterns, gene expression profiles, and electrophysiological properties. Despite their relatively small number, hippocampal interneurons have been shown to play crucial roles in controlling network oscillations, as well as input integration in and selectivity of pyramidal cells. So far, most in-vivo studies aiming at characterizing their functions during behavior were performed using low-throughput electrophysiological techniques that allowed relatively limited sampling from this very heterogeneous population.Here, we combine a novel high-throughput, random-access imaging technique with post-hoc immunochemistry to perform an unbiased sampling of nearly 300 interneurons in CA1 during spatial navigation and goal-directed learning. VGAT-Cre mice are injected with the calcium indicator GCaMP6f and trained to run on a belt for either randomly delivered water rewards (random foraging) or hidden rewards kept at a fix location (goal-directed navigation). Interneurons activity is recorded by 3D random-access two-photon imaging using acousto-optical deflection (AOD) in a nearly cubic-millimeter volume from Stratum Oriens (S.O) to Stratum Lacunosum Moleculare (S.L.M) at a fast rate (~5Hz). Post-hoc immunochemistry is then performed in fixed brain slices and the molecular identity of imaged interneurons is determined by registering confocal images to two-photon stacks. We aim at assessing the spatial tuning of molecularly-defined interneurons, a characterization currently missing from the literature, notably from cells residing in distal dendritic layers. We also examine the extent to which different subclasses of interneurons exert collective inhibition during navigation, as such analysis is not possible with classic, low-throughput recording techniques.Thus, our strategy will allow us to perform an unbiased, functional characterization of hundreds of neurochemically-identified CA1 interneurons in a given animal, ultimately providing a more complete picture of interneuronal networks during behavior.

Title: Correlated physiology and transcription amid learning in the hippocampus

Authors: *S. A. HERRLINGER, J. GOGOS, A. LOSONCZY;
Columbia Univ., New York, NY

Abstract: *Episodic memory* (EM) encoding is dictated in part by place cell activity and tuning in the CA1 region of the hippocampus. However, it remains largely unknown what the biological mechanisms in place cells are that facilitate this learning capacity. Notably, there is a marked heterogeneity of *in vivo* physiological properties (e.g., *in vivo* firing rate, place cell identity, and place cell properties) within pyramidal neurons in the hippocampus, including the CA1PCs (Soltesz and Losonczy, 2018). For example, in any given environment, only a subset (~20-40%) of CA1PCs exhibit place cell activity. While it has been generally assumed that this active coding subset is selected from and allocated randomly onto the CA1PC population, multiple pieces of evidence suggest that differences in intrinsic, genetic profiles among CA1PCs also determine their *in vivo* physiological properties. These properties 1) do not follow a normal distribution (Buzsáki and Mizuseki, 2014; Grosmark and Buzsáki, 2016), 2) are assumed to be organized along major anatomical axes of the hippocampus (Geiller, 2017; Soltesz and Losonczy, 2018), and 3) exhibit a spatial code, suggesting developmental or transcriptional origins (Lee 2019). Gradients of gene expression have been identified across the hippocampus (Cembrowski et al., 2016a, 2016b; Shah et al., 2017) but not with the single cell resolution required to parse out the full heterogeneity of the hippocampus. Despite these intriguing observations, there is no available information on how gene expression patterns correlate with in vivo physiological properties at the level of individual hippocampal cells, nor how these patterns are affected by mutations (such as 22q11.2 deletions) associated with cognitive dysfunction and known to affect episodic memory as well as the pattern of activity and plasticity of place cell ensembles in the hippocampus.
To this end, we have 1) sought out to correlate physiological changes in place cell activity with their transcriptomic changes to better understand the molecular biology underlying place cell tuning in the hippocampus, and 2) compared changes in the transcriptome in wildtype and *Df(16)A*$^{+/-}$ mice *in vivo* to uncover biological processes disrupted in a model for 22q11.2 deletion syndrome during EM encoding. To achieve this, we are utilizing single-cell sequencing in the hippocampus to define transcriptional hippocampal cell type identifiers and adapted an *in vivo* Patch-seq technique to correlate physiology and transcriptomics in behaving mice.

Title: Heterogeneous activity of parvalbumin synaptic boutons surrounding CA1 pyramidal cell bodies during trace fear learning and memory

Authors: *S. TERADA, M. AHMED, E. BALOUGH, J. ZHANG, A. SOLIS CANALES, A. LOSONCZY;
The Mortimer Zuckerman Mind Brain and Behavior Inst., Columbia Univ., New York, NY

Abstract: The hippocampus mediates the association between discontinuous events during episodic memory. While circuit ensemble activity patterns of CA1 pyramidal cells, such as theta sequences or activity motifs during replay, are studied extensively, little is known about how interneuron activity is recruited during memory formation. This is a critical gap in knowledge, especially given that various interneuron types are believed to be essential to control the spike timing of pyramidal cells and shape their ensemble recruitment. Here, we combined two photon Ca^{2+} imaging of synaptic boutons of parvalbumin (PV) basket cells in stratum pyrimadale with LFP recording in hippocampal CA1 to chronically track the activity from the same boutons during several days of a head-fixed auditory trace fear learning paradigm. We found subpopulations of PV boutons showing activity responses to task related events and stimuli, such as the tone (CS), trace period, and airpuff (US). Notably, the activity patterns of these subpopulation ensembles of boutons became gradually structured, paralleling the animals' fear learning behavior. We observed that the occurrence of sharp wave ripples (SWRs) increased during the behavioral course of fear leaning and that SWR events evoked rapid and strong activation of PV boutons. These results suggest that PV basket cells input task-related information to CA1 pyramidal cells during the learning of associated events across time delays. We hypothesize these inputs could contribute to structure the circuit ensembles of CA1 pyramidal cells mediating learning and supporting episodic memory.

Title: Role of ER-mitochondria contacts in Ca^{2+}-dependent processes in dendrites

Authors: *J. O'HARE[1,2], A. VILLEGAS[1,2], S. ROLOTTI[1,2], A. LOSONCZY[1,2,3], F. POLLEUX[1,2,3];

Abstract: In dendrites, Ca^{2+} is critical in determining how neurons respond to incoming excitation. In non-neuronal cells, mitochondria can act as sinks for Ca^{2+} released from the endoplasmic reticulum (ER) by forming direct contacts with these concentrated intracellular Ca^{2+} stores. Recently we identified a tethering protein, PDZD8, that is required for these contacts and, consequently, for mitochondrial buffering of synaptically-evoked Ca^{2+} release from ER in dendrites. Using a variety of *in vivo* and *ex vivo* approaches in hippocampal area CA1, we are currently investigating how ER-mitochondria tethering (ERMT) contributes to dendritic morphology during development as well as ongoing dendritic function in adult mice. In addition to understanding the biological role of ERMT in neurons, we are interested in leveraging these interorganellar contacts as a means to specifically manipulate dendritic Ca^{2+} dynamics *in vivo*.

Title: A role for the locus coeruleus in hippocampal CA1 place cell reorganization during spatial reward learning

Authors: *A. KAUFMAN[1], T. GEILLER[1], A. LOSONCZY[2];
[2]Neurosci., [1]Columbia Univ., New York, NY

Abstract: During goal-directed navigation, place cells in the hippocampal area CA1 exhibit strong overrepresentation of rewarded locations, which is correlated with behavioral performance. Although previous studies have implicated canonical cellular mechanisms underlying the maintenance of this enrichment, the circuit mechanisms at its origin are still largely unknown. Neuromodulation via locus coeruleus (LC)-hippocampal projections regulates hippocampal circuit functions, notably spatial memory and learning. The co-release of both dopamine and norepinephrine in CA1 from LC-fibers makes this structure a strong candidate to promote the encoding and retention of reward locations through reconfiguration of hippocampal place cells. Here, we combine two-photon calcium imaging, together with a head-fixed goal-directed paradigm, to record the activity of LC axons and pyramidal neurons in CA1 of the hippocampus. We report that the LC-hippocampal projection signals the translocation of a reward in a familiar environment, predicting behavioral performance. Optogenetic stimulation mimicking this change in LC activity, performed simultaneously with CA1 pyramidal cell imaging, is sufficient to induce goal-directed remapping, primarily through a shift and stabilization of place cells near the reward. Stimulation in a task outside the reward zone, or that did not require the animal to learn the location of a reward, did not cause place field reorganization. Our results implicate the LC in a conjunctive system underlying spatially-guided reward learning.

Title: Network mechanisms of long-term spatial memory consolidation

Authors: *A. D. GROSMARK[1], F. T. SPARKS[2], M. J. DAVIS[4], A. LOSONCZY[3]; [2]Dept. of Neurosci., [3]Neurosci., [1]Columbia Univ., New York, NY; [4]Inst. for Neurosci., The Univ. of Texas at Austin, Austin, TX

Abstract: The mechanisms by which SWR-related activity leads to stable or unstable spatial-coding outcomes remains little understood. Moreover, limits on the sensitivity and speed of Ca^{2+}-imaging techniques, as well as the absence of well-defined Ca^{2+}-analogues of established biomarkers of 'offline' activity such the LFP-detected SWRs, have restricted the accessibility of 'offline' activity to Ca^{2+}-imaging. Here we employ combined chronic CA1 LFP recordings with simultaneous fast (60 Hz) two-photon Ca^{2+} imaging to stably track the activity of genetically identified mouse CA1 principal neurons over weeks of 'online' spatial behavior and 'offline' resting. This project aims to predict the diverging cross-day spatial-coding stability outcomes of place cells by their recruitment to and replay in SWR events - to link long-term spatial memory to the 'offline' SWR-related replay activity thought to underlie memory consolidation. On each recording/imaging day head-fixed animals ran on one of two cued-rich treadmill belts for a stably placed but 'hidden' water reward (RUN-epoch), thus facilitating the assessment of long-term spatial coding and its specificity to a given treadmill belt. On each day immediately 'PRE' and 'POST' the RUN epoch two additional recording/imaging sessions were carried out on an un-cued, unrewarded treadmill belt facilitating the analysis of 'offline' content. Our preliminary results recorded under this paradigm demonstrate: 1) that joint LFP recording and Ca^{2+}-imaging is an effective tool for studying fast neural dynamics, such as 'offline' SWR-related responses and 'online' theta-phase preferences, 2) the presence of both stable and unstable long-term (cross-day) spatial coding in CA1 place cells, 3) the first reported Ca^{2+}-imaging of SWR-associated place cell reactivation of a recent but non-local spatial experiences, 4) that POST epoch SWR-recruitment, but not overall firing rate, predicts long-term spatial stability outcomes, and 5) that individual cells' increases in PRE to POST contributions to SWR-associated reactivation are predictive of their long-term, multi-day spatial coding stability. These results, for the first time, directly implicate 'offline' SWR-related mnemonic activity as serving as a privileged window for the long-term consolidation of specific spatial memory traces in the

hippocampus. Ongoing work will test this hypothesis mechanistically through interventions triggered through the online detection of individual SWR events.

Title: The relationship of CA1 place cell dendritic activity during SWRs to online spatial tuning

Authors: *S. V. ROLOTTI, H. BLOCKUS, F. T. SPARKS, A. LOSONCZY;
Neurosci., Columbia Univ., New York, NY

Abstract: Recent findings have connected active dendritic integration mechanisms to CA1 place cells' (PCs) apparent role in spatial memory, suggesting that the generation of dendritic spikes might be important for the long-term maintenance of spatial tuning in single neurons. While previous work has focused on the role of dendritic activity during online navigation, far less is known about dendritic activity during 'offline' immobility states. In particular, sharp-wave ripples (SWRs) - network events that predominate during immobility - are thought to drive synaptic potentiation that may strengthen CA1 PC ensembles previously co-active during navigation and, by extension, stabilize the place map.
It remains unknown, however, how SWRs alter dendritic activity *in vivo*, or how dendritic activity during offline states affects online PC spatial tuning dynamics. We therefore conducted experiments in which we pair multi-plane, two-photon calcium imaging of sparsely labeled CA1 PCs with extracellular electrophysiological recordings in a head-fixed, behaving mouse over the course of many days. Using these methods, we longitudinally observed dendritic, somatic, and network activity of CA1 PCs as mice passively explore a novel environment or actively learn the location of a hidden reward.
We have found clear evidence for behavior- and network-state differences in somatic-dendritic coupling. The amplitude and frequency of somatic-related activity across the basal dendritic arbor is significantly increased during awake immobility, and in particular during SWRs, suggesting that SWRs may indeed modulate dendritic excitability and spiking. Further analysis of the specific subsets of basal dendrites active during exploration suggests that reactivation of

these patterns during SWRs may be indicative of a SWR-dependent dendritic stabilization process. We will share results on the impact of these changes on the stability of spatial tuning of CA1 PCs during exploration and learning behaviors.
Using this unique intersection of approaches, we directly examine the impact of network-level events on CA1 PC dendritic activity *in vivo* and in turn explore how these changes in dendritic activity might persistently modify PC spatial tuning.

Title: Characterizing direct cortical influences on hippocampal region CA1 in behaving mice

Authors: *J. BOWLER, A. LOSONCZY;
Neurosci., Columbia Univ., New York, NY

Abstract: The hippocampus plays critical roles in navigation and episodic memory, with the most prominent neural correlate of these behaviors being “place cell” activity. It is widely assumed that afferent excitatory inputs to the hippocampus carry critical information required for these navigational and memory-related changes in hippocampal network dynamics. Two subregions of the Entorhinal Cortex (EC) have been particularly implicated in this process by providing distinct input streams to the hippocampus. Specifically, the medial EC (MEC) is thought to be involved in primarily processing spatial information related to global contextual reference frame, while the lateral EC (LEC) is thought to primarily process information related to individual items and locations based on a local reference frame. Despite these activity patterns having been well studied in the EC, a detailed understanding of the circuit level mechanisms of entorhinal cortical influences on hippocampal population dynamics is still lacking. The direct projections from MEC and LEC to CA1 pyramidal cells (CA1PCs) offer a tractable circuit to bridge this knowledge gap. Chronic, subcellular-resolution two-photon functional imaging of identified EC afferents and CA1PCs during head-fixed virtual reality navigation and learning provides an opportunity for direct observation and characterization of the it information transferred between the EC and CA1. These experiments test the hypothesis that CA1PCs

receive spatial and sensory information from identified EC inputs which instruct CA1PCs population dynamics. Results indicate that it is possible to decode navigational variables from activity observed in the direct EC projections to CA1 such as position, cue identity and speed which could be critical to spatial representations in the hippocampus.

Title: Eph-Ephrin signaling is essential for formation of the cell clusters in layer II of medial entorhinal cortex

Authors: *N. YAMAMOTO[1], H. OSANAI[1], W. D. MARKS[1], S. K. OGAWA[1], M. HENKEMEYER[2], T. KITAMURA[1];
[1]Psychiatry, [2]Neurosci., Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: The medial entorhinal cortex (MEC) has characteristic hexagonally arranged cell clusters in the layer II (MECII). These cell clusters are composed of Wolfram syndrome1 (Wfs1)+ pyramidal cells and surrounded by Reelin+ stellate cells in the MECII. The MEC integrates multimodal sensory inputs for memory formation, spatial navigation and time perception. Accumulating evidence from neural recording and imaging suggest that cells coding similar spatial/temporal information tend to be clustered in MEC, implicating that the cell clusters in the MECII may generate the functional modules. However, it remains unknown the molecular basis for the formation of anatomical cell clusters in MEC and how the anatomical modules affect functional modules in the MEC. Here, we hypothesized that the cell clusters may be generated by cell-cell-mediated interaction/repulsion. As the Eph receptors B1-3 and their ligands, the Ephrin-Bs, are well known as initiators of cell-contact-mediated neuromigratory signals, we first comprehensively examined their expression patterns in the MEC of adult mouse by fluorescent *in situ* hybridization (FISH). Among EphB/Ephrin-B family genes, we found EphB1 and EphrinB2 were selectively expressed in MECII. Double-FISH analysis revealed that EphB1 was expressed in Reelin+ cells, while Ephrin-B2 was expressed in Wfs1+ cells. Next, we

examined their expression pattern in the MEC during developmental stage. At postnatal day 0 (P0), EphB1 was already expressed in Reelin+ cells in MECII. At that time, no cell clusters were identified in MECII by nuclear staining. Rather, Ephrin-B2+ cells were located in the layer V of MEC at P0. At P2, Ephrin-B2+ cells have migrated to layer II and formed cell clusters in the MECII. At P4, the Ephrin-B2+ cells have expressed Wfs1. Finally, we examined the effect of EphB/Ephrin-Bs knockout (KO) on the formation of cell clusters. We found that cell clusters in the MECII of Ephrin-B2 mutant mice were severely impaired. We also found that the cell clusters were smaller in EphB1/EphB2 double knockout mice. These results suggest that Eph/Ephrin signaling between Reelin+ and Wfs1+ cells is critical for formation of cell clusters in the MECII during early postnatal development.

Title: Disrupting medial prefrontal cortex with DREADDs alters hippocampal place cell firing in sharp wave ripples in rats

Authors: *B. SCHMIDT, A. D. REDISH;
Dept. Neurosci, Univ. of Minnesota, Minneapolis, MN

Abstract: Current theories suggest that place cell firing sequences during hippocampal (HC) sharp wave ripple complexes (SWR, 180-220 Hz) play multiple roles in learning, memory, and decision-making. These functional differences can vary contingent upon the animal's behavioral state. The medial prefrontal cortex (mPFC) may interact differently with HC in these different behavioral states.
To examine the role of the mPFC in HC SWRs, rats were transfected with inhibitory DREADDs (h4MDi) targeting the prelimbic cortex. Behavior was compared under CNO or vehicle (VEH) control from 7 rats while recording neural ensembles from HC and mPFC. Rats ran the Restaurant Row task for 1 hr each day. On this task, rats encounter a series of stay or skip

decisions for flavored food pellets. Upon restaurant entry, the pitch of a tone signals the wait needed to receive the food reward (random delay 1-30s). At each choice, the rat could wait out the delay to receive the reward or skip and leave for the next “restaurant”. On this task, rats show thresholds for each flavor, below which they accept the offer and above which they reject the offer. The Restaurant Row is a neuroeconomic task because of the limited time on this task (time was a scarce resource).
To measure the effects of mPFC disruption on consolidation, we compared SWR events during pre- and post-maze rest. Disrupting mPFC with CNO reduced the number of SWRs expressed during post-maze rest. Under VEH, SWRs increased from pre- to post-maze rest, consistent with previous studies, a phenomenon believed to support consolidation. However, we did not observe this increase under CNO. However, we also found that sequence scores (Gupta et al 2010 Neuron) were greater under CNO than VEH. These data suggest that while mPFC disruption reduced the number of SWRs in post-maze rest, the SWR sequences that were expressed remained coherent. On the maze, during the time waiting for the reward, SWRs were expressed at a higher rate in the most-preferred restaurants (highest threshold). In contrast, during time lingering after receiving reward, SWRs were expressed at a higher rate in the least preferred restaurants (lowest threshold). During both waiting and lingering, CNO reduced the number of SWRs expressed in the most-preferred restaurants more than in the less-preferred restaurants. The different relationships on and off the maze suggest that on-maze and post-maze SWRs likely play different roles. Consistent with this, we also found that the relationship between mPFC cell firing and HC SWRs changed on and off the maze, and that on-maze mPFC cell firing relationships to SWRs were changed more than off-maze relationships.

Title: Representation of choice and value in the ventral striatum during the restaurant row task

Authors: *G. W. DIEHL, B. SCHMIDT, Y. A. BRETON, A. D. REDISH;
Dept. Neurosci, Univ. of Minnesota, Minneapolis, MN

Abstract: A central component of decision making is the ability to weigh the subjective value of a choice and determine if it is worthwhile. The Restaurant Row task (RRow) provides an effective means of investigating such subjective decisions. On this task, rats circle an octagonal track earning different flavored food rewards at each of four "restaurants". Upon entering each restaurant, rats are "offered" a random 1-30 sec delay, cued via an auditory tone, that they must wait out before earning the reward. Rats must decide to either stay and wait out the delay to earn the reward, or skip the offer and advance to the next restaurant where a new offer will be presented. Because rats are limited to 1hr on RRow, waiting out long delays has inherent cost and reduces the number of subsequent rewards that can be earned.
We sought to evaluate how the ventral striatum (predominantly Nucleus Accumbens Core; NAcC), a structure strongly implicated in the assessment of value, may represent the value of offers presented during RRow. We recorded 384 phasically spiking neurons (putative MSNs) from NAcC of 10 rats while they performed RRow and examined their firing properties when offers were presented and rats made stay/skip decisions. As rats approached each restaurant, aware of which flavor they were approaching but not yet informed of the delay they must wait to earn a reward, 23% of vStr cells exhibited significant firing rate changes with about half increasing and half decreasing firing rate. Following offer presentation, 31% of vStr cells exhibited additional changes in firing rate, again with about even proportions of cells increasing and decreasing firing rates. Interestingly, we found 13% of NAcC cells that exhibited rhythmic increases in firing rate every second, likely corresponding to the auditory tones that were played each second counting down the delay period. Collectively about 50% of NAcC cells exhibited significant firing rate changes around the initial offer period in the RRow task during which rats must make a stay/skip decision.
To determine how these firing rate changes may encode information necessary for a rat to make its decision we used Bayesian decoding to decode stay/skip decisions or offer value at each restaurant visit. NAcC ensembles did not represent offer value along a continuum but rather as a binary designation of "Good Offers" and "Bad Offers". Furthermore, stay/skip encoding was initially consistent with skip decisions on most trials, but on trials with good offers encoding shifted to stay decisions after 0.5 - 1 sec. Thus, on this version of RRow, skip decisions appear to be the default cognitive state, with stay decisions emerging over time and only for high value offers.

Title: Goal encoding in prelimbic cortex and CA1 on a contingency-switching task for rats

Authors: *B. HASZ[1], A. D. REDISH[2];
[1]Grad. Program in Neurosci., [2]Dept. Neurosci, Univ. of Minnesota, Minneapolis, MN

Abstract: Hippocampus (HC) and prelimbic cortex (PL) are thought to play roles in a deliberative neural system which uses information about reward, state, and context to make goal-directed decisions. Previous work has shown that during vicarious trial and error (VTE, a behavioral marker of deliberation), HC ensembles sometimes represent paths to the goal. While PL is known to represent contextual information, it remains unclear if PL participates more actively in deliberative processes, and what relationship exists between the information encoded in PL and HC during deliberation.

To investigate this relationship, we designed a contingency-switching task for rats, in which rats alternated between procedural modes (as they repeatedly made choices under a single contingency) and deliberative modes (after intermittent contingency changes). The task consisted of a spatial maze with a single choice point between left or right. The contingency on each lap was either “left” (go left at the choice point to receive reward), “right”, or “alternate” (make the opposite choice as the previous lap to receive reward), and this contingency changed every 30 +/- 5 laps. Consistent with previous results, VTE increased after contingency changes and decreased as paths became regularized with repeated laps under a given contingency.

6 rats (4M, 2F) were run on this switch task while recording simultaneously from HC dorsal CA1 (using 24-tetrode drives) and PL (using 32-site silicon probes). Position was decoded from HC and PL ensemble firing rates using Bayesian decoding. Replicating previous results, we found that HC ensembles encoded positions further ahead of the rat during passes through the choice point where VTE occurred. We also found that PL ensembles encoded positions further ahead of the rat during VTE than during non-VTE choice point passes, though the effect was smaller than in HC. Additionally, the distance ahead of the animal encoded by HC ensembles was correlated with the distance ahead of the animal encoded by ensembles in PL. This correlation may have been driven by nonlocal representation of the goal: we also observed a correlation between the encoding of the reward zone in PL and forward representations in HC at the choice point. Our results suggest that in addition to HC, PL also represents future goals during deliberation, and that these goals are often encoded in both structures simultaneously. Future work will need to determine whether the goal encoding in one structure is driven by the other, or whether this representation is due to some common input from a separate source.

Title: Human cocaine users, like cocaine-treated mice, display unique disruptions on a neuroeconomic task

Authors: *B. M. SWEIS[1], J. CAMCHONG[2], S. V. ABRAM[5], S. SPECKER[2], A. W. MACDONALD, III[3], M. J. THOMAS[4], A. D. REDISH[4], K. O. LIM[2];

Abstract: Individuals who desire to recover from addiction often make poor decisions and relapse despite this desire. Impairments in decision conflicts that result in relapse could arise from dysfunctions in distinct neural systems. Recently, we used a novel neuroeconomic task translated across species to dissociate separable conflict algorithms through complex behavioral analyses equally applicable to both rodents and humans. We previously found that conflict when deliberating about the future was uniquely disrupted in cocaine-treated mice distinct from conflict when re-evaluating past actions, the latter of which was uniquely disrupted in morphine-treated mice and sensitive to infralimbic-accumbens shell circuit manipulations in mice. To date, only healthy humans have been tested in this novel paradigm. How human cocaine dependent users perform within this neuroeconomic framework is unknown.
We recruited 12 cocaine users (mean age: 39.7 [sem 3.0], 16.6% female, 58.3% white) and 9 healthy matched controls (mean age: 35.9 [sem 2.9], 22.2% female, 55.6% white) from online advertisements. Participants were tested on the computer-based Web-Surf task. Participants spent time from a limited budget (20 min) to earn natural rewards, i.e., entertaining video clips (4s in playback length) of different genres (cued by an icon), available after varying costs (delays ranging 1-30s, cued by a download bar and text). Participants were tasked to accept or reject serial offers and then rate consumed videos on a scale of 1-4 stars. Participants filled out drug use history questionnaires and were compensated $40.

All participants performed the Web-Surf task, reliably responding to randomly presented cued offers differently in each video gallery as a stable function of cost and subjective preferences. Only when encountering unique conflict scenarios (offers with a delay above one's willingness to wait), cocaine users were less likely to appropriately reject economically disadvantageous offers compared to healthy controls. Furthermore, cocaine users did so despite spending more time deliberating. These data match cocaine-treated mice tested on the translated Restaurant Row task. Interestingly, for post-consumption hedonic valuation responses, human cocaine users and cocaine-treated mice each differ in a dissimilar way from their respective controls.
These data help elucidate the pathophysiological mechanisms of substance use disorder underlying impairments in distinct aspects of decision making that are both shared and different between humans and non-human animals, particularly in the context of the conflict between wanting versus knowing better.

Title: Neuroeconomic decision-making in J20 mice

Authors: *R. M. ANDERSON[1], B. M. SWEIS[2], D. HART[1], M. SHERMAN[1], S. E. LESNE[1], M. J. THOMAS[1], A. D. REDISH[1];
[1]Dept. Neurosci, [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Current theories suggest that decisions arise from interacting systems accessing distinct neural networks. Disruptions (such as in Alzheimer's Disease) can change the integrity of these networks and thus change neuroeconomic behavior. 15 6-month old mice were run behaviorally on the Restaurant Row task, in which mice forage for food under a time constraint. The task consists of four restaurants, each providing a different flavor of food. On encountering a

restaurant, the mouse is informed of the delay before food arrives (1-30s) by pitch of a tone. The mouse can then accept the deal, waiting out the delay, or reject it, proceeding on to the next restaurant. Each restaurant consisted of two zones: an OFFER zone in which the mouse was informed of the delay, but the delay did not count down, and a WAIT zone in which the delay counted down until reward was delivered. On this task, mice reveal unique delay thresholds for each flavor below which they tend to accept and above which they tend to reject offers. Deliberation can be observed in the OFFER zone as vicarious trial and error behavior, while quitting out of the WAIT zone engenders regret.
Mice (8 wild type, 7 J20 transgenic) were run for 70 consecutive days. The environment began reward-rich and transitioned to reward-scarce as the range of delays increased (1s for 1 wk, 1-5s for 5d, 1-15s for 5d, 1-30s for the rest of the experiment). At this age, J20 mice display spatial reference memory retention deficits in the Barnes maze. All mice altered their strategy after reaching the reward-scarce scenario, increasing deliberation and planning behaviors over time. However, J20 mice altered their behavior much more quickly compared to their control counterparts. As a result of this quick change in their behavior, J20 mice became more efficient more quickly as evident by their ability to earn significantly more rewards in the same time span when compared to control animals.
J20 mice deliberated significantly more than controls in the OFFER zone. Upon further examination, J20 mice were found to deliberate for both bad deals (delays above threshold) and good deals (delays below threshold) unlike control mice who only deliberated for bad deals. J20 mice showed fewer enters into restaurants and fewer quits for bad deals. These results suggest that rather than showing a problem with deliberation, J20 mice deliberate more, potentially due to disruptions in other neural circuits.
This study highlights the importance of behavioral tasks that allow for dissection of multiple decision-making systems that may be at play and independently change in neurodegenerative diseases that might otherwise manifest as gross “memory deficits” using simpler paradigms.

Title: A spoonful of sugar helps theta-gamma coupling go down

Authors: *L. A. CREW[1], A. M. MCNEELA[1], R. A. WIRT[1], A. A. ORTIZ[1], H. PEREDO[2], S. HERNANDEZ[1], J. W. KINNEY[1], J. M. HYMAN[1];
[1]Psychology, [2]Psychiatry, Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: Working memory impairments are among the many debilitating symptoms of Alzheimer's disease (AD) and other neurodegenerative disorders. Working memory is supported by synchronization of theta and gamma frequencies in the anterior cingulate cortex (ACC) and hippocampus (HC). In fact, decreased theta-gamma coupling is the most significant predictor of WM performance in human AD patients, and alterations in this cross-frequency relationship precedes histological hallmarks in a rodent model of AD. Although the etiology of sporadic AD is unknown, several risk factors have been identified and prominent among these is diabetes mellitus (DM). Patients with DM are 4 times more likely to develop AD and also exhibit similar working memory impairments as those found in AD. Chronic neuroinflammation is a pathological symptom of both DM and AD, and it is possible that neuroinflammation itself impacts cognitive performance. Given the links between DM and AD, an examination of ACC and HC cross-frequency synchronization in a diabetic rodent model could potentially help elucidate the neural processes underlying AD-related working memory impairments. In this study, we hypothesize that neuroinflammation disrupts network oscillatory activity within the ACC and HC, as well as the interactions between these areas, these combined effects lead to impaired cognitive function. To test this, we trained rats to perform a delayed alternation task, which is dependent upon both the ACC and HC, as well as interactions between these areas. Following training, we induced chronic hyperglycemia by injecting experimental animals with multiple low doses of streptozotocin. We found delay dependent spatial working memory impairments in hyperglycemic animals compared to healthy controls. Electrophysiological data revealed decoupling between the theta (5-12 Hz) and gamma (30-50 Hz) bands within both areas. We also found significant disruptions in theta coherence between brain regions in the hyperglycemic group. These animals also exhibited increased theta band oscillations and decreased delta (1-3 Hz) band oscillations in the ACC and HC. Together, these results suggest that the hyperglycemia-driven neuroinflammatory state that is associated with the physiological and cognitive pathologies of AD, also induces alterations in ACC and HC oscillatory activity and interactions.

Title: Isolating orthogonal learning signals from ACC ensembles

Authors: *R. M. FRANCIS[1], R. A. WIRT[1], J. M. HYMAN[2];
[2]Psychology, [1]Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: Basic principles of learning suggest that associations are preserved until new, contradictory information is encountered. When expectations are not met, one must quickly adapt to the newly encountered information. This can be observed in both behavioral and physiological responses, but the mechanisms involved have yet to be fully characterized. When outcomes change, neurons in multiple brain areas adjust their responses to the new information which is thought to lead to behavioral shifts. How neurons track these outcomes, or more generally, how they track the entire learning experience, is still a matter of intense study. In recent years, neuronal discharge patterns have been successfully fit to Q-learning algorithms, suggesting that neuronal activity states follow simple learning rules. To investigate such responses further, we evaluated the role of the rodent anterior cingulate cortex (ACC) during a reversal learning task with three reward ports, each with a different reward probability. We performed a principal component analysis on ACC ensemble signals during this task to create base parent signals for further examination. We then isolated various signals within the top 3 principal components using support vector machines tuned to decode categorical state homologues to specific learning strategies. This method revealed nine clearly orthogonal signals derived from specific learning assumptions nested within the same parent signal. These included a signal that was sensitive to the mid-session probability reversal, a signal that was reversal-agnostic and sensitive to the outcome of only the previous trial, and another that updated based on the entire sample of trials akin to Q-learning models. Thus, we demonstrate how the ACC can simultaneously process multiple changing reward probabilities while tracking time-sensitive representations of the most recent outcomes and time-invariant signals such as reversal occurrence. The ability to maintain real-time parallel computations potentially explains why the ACC is so strongly involved in this type of learning. These types of embedded multiplexed representations are likely integral to cognitive flexibility by offering alternative streams of information to exploit based upon specific contextual criteria.

Title: Interactions in the local field potentials of the perirhinal and postrhinal cortices during memory and attention tasks

Authors: *S. G. TRETTEL, R. D. BURWELL;
Dept. of Cognitive, Linguistic, and Psychological Sci., Brown Univ., Providence, RI

Abstract: The perirhinal and postrhinal cortices each are involved in both memory and attention. The perirhinal cortex is primarily involved in object recognition memory whereas the postrhinal cortex is primarily involved in visual-spatial memory and attention. Though these two regions appear to have differing roles, there are reciprocal connections between the two regions. How these two regions interact, and the roles these interactions play in supporting the functions of the other region during memory and attention tasks are not well understood. In this study, our objective was to use field potential recordings during tasks that engage attention and memory to investigate how these two regions interact. We recorded simultaneously from both regions while rats performed either a visual-spatial attention task or a novel-object-recognition task. Oscillations in the local field potential are thought to coordinate the activity of neuronal ensembles across brain regions. Previous studies have shown that in the hippocampus and its connected cortical regions, theta (6-10 Hz), slow gamma (25-55 Hz), and fast gamma (65-100Hz) oscillations all appear to play a role in temporarily synchronizing cell ensembles to perform different computations. In previous work from the Burwell lab, 10-15 Hz stimulation of the perirhinal cortex caused rats to explore novel objects as if they were familiar during a novel-object recognition task. We used local field potential data recorded simultaneously from the perirhinal and postrhinal cortices of Long-Evans rats as they performed a visual-spatial attention task in addition to a novel-object-recognition task. We compared the oscillations between these two regions, and we investigated how these oscillations changed across cortical layers. Preliminary analyses from animals exploring an open field suggest that the strongest oscillatory coupling happens in the fast gamma band, but there is some evidence that theta and beta (11-20 Hz) oscillations in the postrhinal cortex synchronize with weak theta and beta-band activity, respectively, in the perirhinal cortex.

Title: Local field potential and single cell encoding of the retrosplenial cortex during performance of a visuospatial attention task

Authors: *E. HWANG[1], F.-C. YANG[3], R. D. BURWELL[2];
[2]Dept. of Cognitive, Linguistic, and Psychological Sci., [1]Brown Univ., Providence, RI; [3]Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: The retrosplenial cortex (RSC) is defined in primates and non-primate mammals. The anatomical location and neuronal connections of the RSC make this brain area an important putative intermediary region for a variety of cognitive and behavioral functions. Recently, the RSC has become an important focus of human cognition research, but there is considerable disagreement about the precise role of the RSC in cognition. Current studies implicate the RSC in navigation, spatial memory, processing of contextual information, sensory integration, cross-modal information processing, and the representation of stability or reliability. Although the preponderance of the literature addresses hypotheses about the spatial functions of the RSC, there is evidence to suggest that the core function of the region is not limited to the processing of spatial information. We hypothesize that the core function of the RSC contributes to non-spatial domains. Here we report a study where we examine single cell recordings and local field potential (LFP) of the RSC in a visuospatial attention task. The VSA task is a purely visual task that was adapted from the five choice serial reaction time task (Bari, Dalley, Robbins, 2008) for a double-sided, bowtie shaped enclosure atop the Floor Projection Maze (Jacobson et al., 2014). The VSA task involves top-down and bottom-up visuospatial attention, multiple spatial reference frames, and the processing of multiple task epochs and reward. In this study, we specifically investigate if the single cell recordings and LFP power changes show correlates to stimulus onset and prediction error. Detailed analyses of neuronal correlates and LFP for RSC will be presented.

Title: Hippocampal projections target excitatory and distinct inhibitory neurons in anterior cingulate cortex in primates

Authors: *J. WANG, M. D. FEINBERG, I. N. ONOCHIE, H. BARBAS;
Boston Univ., Boston, MA

Abstract: Direct pathways from hippocampus to medial prefrontal areas in the anterior cingulate cortex (ACC) carry information about current context and past experiences and play key roles in decision making and emotional regulation. However, our knowledge about the features of these pathways in primates is limited. We thus investigated hippocampal terminations in ACC, including A25, A32 and A24a, with anterograde tracers in rhesus monkeys. We found that hippocampal pathways innervate both upper (I-III) and deep (V-VI) layers of ACC. Stereologic analysis showed that subgenual A25 contained the highest proportion and density of hippocampal boutons among the three areas, suggesting that it is a major target of the hippocampus. Using brightfield microscopy, we found that the major bouton diameters were similar in A25, A32 and A24a, and between the upper and deep layers, a pattern confirmed for hippocampal terminations in A25 using electron microscopy (EM). We then studied the postsynaptic targets of the hippocampal terminations in the upper and deep layers of A25 using EM. Interestingly, most (~90%) hippocampal terminations formed synapses on spines of presumed excitatory neurons in all layers of A25, while a small proportion (~7%) formed synapses on dendritic shafts of presumed inhibitory neurons. To further investigate the type of inhibitory neurons innervated by hippocampal afferents in A25, we used calcium binding proteins calbindin (CB), calretinin (CR) and parvalbumin (PV), which label non-overlapping populations of functionally distinct cortical inhibitory neurons in primates. Using fluorescent confocal microscopy, we investigated appositions between hippocampal terminals and labeled inhibitory neurons. More hippocampal axon boutons were apposed with CR+ neurons than CB+ or PV+ neurons, consistent with EM analyses. These findings suggest that the hippocampus has a stronger effect on CR+ neurons, which are thought to inhibit other inhibitory neurons, and thus disinhibit nearby pyramidal neurons. This evidence suggests that primate hippocampal pathways can enhance activity in A25 via innervation of mostly excitatory neurons and CR+ (disinhibitory) neurons, facilitating mnemonic and cognitive processes.

Title: Context and motivation: A computational model of interactions between hippocampus and medial prefrontal cortex, and their roles in depression

Authors: *Y. J. JOHN[1], D. H. BULLOCK[2], H. BARBAS[1];
[1]Neural Systems Lab., [2]Psychological & Brain Sci., Boston Univ., Boston, MA

Abstract: Depression is a multifaceted disorder that affects emotion, cognition, and motivation for goal-oriented behavior. Despite the existence of several types of treatment, treatment-resistant forms of depression are still widespread, as are post-treatment relapses. Understanding the neural bases of depression subtypes will enable insight into the origins of depression as well as the diversity of patient responses to treatments. Several lines of evidence implicate limbic circuitry in depression, particularly limbic prefrontal area A25, ventral striatum, and the hippocampus. Here we focus on possible neural substrates of the loss of motivation in depression. Evidence suggests this aspect of depression may involve abnormal signaling from medial prefrontal cortices to the ventral striatum, which has long been linked with motivational vigor. Specifically, abnormal firing in medial prefrontal cortices appears to preferentially suppress reward-seeking behaviors mediated by ventral striatal activity. Normally, contextual representations activated in the anterior hippocampus inform processes in key limbic areas that enable an organism to flexibly switch among behaviors, by invigorating those with net-positive prospects and disengaging from those with net-negative prospects, which vary by context. In depression, disordered processing in hippocampus and A25 may lead to dis-invigoration of behaviors with net-positive prospects. In our analysis, projections from the primate anterior hippocampus to medial prefrontal cortices, and particularly A25, allow abnormal processing of context to contribute to the emergence of low motivational states. Our simulations show how perturbations to the circuit linking hippocampus and A25 can disrupt context processing, cause abnormal signaling to ventral striatum, and disrupt its ability to generate invigoration signals. The proposed mechanisms suggest experimental tests to probe the origins of depression-related symptoms, and may lead to novel strategies for treatment.

Title: Behaviour matters learning influences hippocampal ripple occurrence and cross brain responses during sleep

Authors: A. ALEMAN[1], F. P. BATTAGLIA[2], ***L. GENZEL**[1];
[1]Donders Inst., Nijmegen, Netherlands; [2]Donders Inst. for Brain, Cognition and Behavior, Radboud Univ., Nijmegen, Netherlands

Abstract: Many studies have shown that sleep benefits memory. We are starting to understand the mechanisms occurring during sleep, with sleep-related memory replay leading to systems consolidation and strengthening cortical memory networks. Memory replay in the hippocampus and prefrontal cortex occurs during sharp-wave-ripples, a very fast oscillation measurable in the hippocampus. However, most replay studies focus use over-trained tasks such as track-running or non-informative behaviors such as random foraging. Under such circumstance one would not expect memory consolidation mechanisms to be as present as after a significant learning event. Here we record from electrodes in the hippocampus, prefrontal and parietal cortex during sleep after different behaviors: a novelty event, a track-running foraging task and learning a new goal location in a Plusmaze task. Surprisingly, learning led to a decrease in hippocampal ripple power, however the ripples that did occur showed stronger responses in both the prefrontal and parietal cortex within the ripple frequency range. The opposite was seen after track-running. Further, granger causality indicated stronger connectivity between the three brain areas selectively after learning. We went on to show that learning the new goal location in the Plusmaze is dependent on sleep after learning and using a closed-loop, electrical ripple disruption paradigm we could mimic the sleep-deprivation effect on memory. In sum, we could show that only after significant learning experiences increased hippocampal-cortical connectivity could be seen during NonREM sleep ripples, which was necessary for the beneficial effect of sleep on memory.

Title: Allocentric vs egocentric memory in rats and humans: Effects of sleep

Authors: *A. SAMANTA[1], J. JACOBSE[2], J. ROSSATO[2], R. G. MORRIS[3], L. GENZEL[4];
[1]Radboud Univ., NIjmegen, Netherlands; [2]Univ. of Edinburgh, Edinburgh, United Kingdom; [3]Ctr. for Cognitive and Neural Systems, The Univ. of Edinburgh, Edinburgh, United Kingdom; [4]Donders Inst., Nijmegen, Netherlands

Abstract: AIM: To study the effect of sleep on egocentric vs allocentric spatial memory training and the underlying neural mechanisms in rats and humans
It has been shown that hippocampal-led replay during sleep leads to subsequent improvements in memory and is thus interesting to see its differential effects on allocentric (hippocampal) vs egocentric (striatal) memory conditions.
Rats were first trained on the water maze under either allocentric or egocentric condition. In the allocentric condition, they had a different starting location to find the platform, whereas in the egocentric condition, the starting location remained the same throughout. Post training they either had 6h sleep or sleep deprivation (SD) followed by a probe trial after 24 hours. After probe trial, retrieval induced immediate early gene expression were measured in the hippocampus, PFC and striatum. Analogously a virtual water maze was developed to train humans under both conditions. They were initially trained on the task in the MRI scanner under either allocentric or egocentric condition, followed by a short nap or movie and later tested with a probe trial in the scanner.
In rats, the improvement in memory was observed for those who slept only in the allocentric condition. Performance in the egocentric condition was independent of sleep effects. Following sleep they showed increased levels of c-fos, ARC and zif in all three brain areas for both training conditions. SD rats, however, showed increased expression only in the hippocampus and striatum under allocentric and egocentric conditions respectively. In humans, however, the improved memory effect was observed for those who took a nap independent of training condition. Analogously, MRI findings in humans show an activation of regions in the Default Mode Network during training and a shift to activation of cortical regions during test session, only in the sleep condition.
Overall, we show sleep to have an improved memory effect across both models. IEG expression analyses and MRI findings indicate that sleep leads to a whole brain systems consolidation, which potentially is the underlying reason behind the improved memory effects.

Title: Increasing plasticity in the cortex with RGS14$_{414}$ leads to semantic interference effects

Authors: *I. NAVARRO-LOBATO[1,2], F. P. BATTAGLIA[3], L. GENZEL[4];
[1]Neuroinformatics, Radboud Unviversity, Nijmegen, Netherlands; [2]Neuroinformatics, Donders Inst. for Brain, Cognition and Behaviour / Radboud Unviversity, Nijmegen, Netherlands; [3]Donders Inst. for Brain, Cognition and Behavior, Radboud Univ., Nijmegen, Netherlands; [4]Donders Inst., Nijmegen, Netherlands

Abstract: RGS14 is an endogenous multidomain protein implicated in the control of several intracellular signalling pathways which facilitate memory consolidation. Insertion of this protein leads to an increased structural plasticity and memory consolidation of simple tasks. Here we want to test the effect of increased plasticity in the cortex on semantic memory updating. How are semantic memories created and stored? These questions have been under theoretical inquiry for decades. Marr proposed the need for a two-step storage system: 1) a fast learner rapidly recording for intermediate storage - represented by the hippocampus - and 2) a slow learner with compressed, long-term storage - the cortex. These two storage systems are thought to differ in the amount of plasticity and how easily memory traces are updated, however concrete evidence is missing due to the lack of appropriate methods. The Object Space Task is a newly developed multi-trial behavior task to test for memory abstraction in rodents. The rats are exposed to multiple sample trials where they are exposed to novel objects in specific spatial arrangements in a box. In the key condition of the task (overlapping), one location is stable across all trials while the other keeps changing. In the test trial, rats show a preference for the object in the changing location, indicating that they are capable of abstracting memory across several episodes. Interestingly, by rendering the prefrontal cortex more plastic via the overexpression of RGS14 made the usually robust abstracted memory become vulnerable to an interference trial at 24 h, which spatial configuration was incongruent to the previous trained pattern. In contrast, simple episodic memory was strengthened. Interestingly, in control animals the interference event led the original abstracted memory to be more long lasting (72 h instead of only 24 h).

Title: A hippocampus prefrontal cortex network for reward prediction

Authors: *J. L. KLEE, F. P. BATTAGLIA;
Donders Inst. for Brain, Cognition and Behavior, Radboud Univ., Nijmegen, Netherlands

Abstract: Learning to predict future rewards constitutes a central element of intelligent behavior but also poses a complex problem for neural networks. While a multitude of studies have implicated both the hippocampus and the prefrontal cortex in learning as well as in responses to reward predicting cues, relatively little is known about the underlying interactions between the two structures. In this context, we combined an auditory trace conditioning paradigm in head-fixed mice with simultaneous silicon probe recordings from the hippocampus CA1 region and the medial prefrontal cortex. We find that CS+ presentations result in a learning dependent increase in HPC PFC Gamma phase coherence (80-120 Hz) and simultaneously elevated CA1 and mPFC Gamma power. Furthermore, on the single cell level, subpopulations of both CA1 as well as mPFC neurons exhibit learning dependent sustained activity during the trace period following CS+ presentations. Interestingly, by introducing a second CS+ sound to the conditioning task, we show that CA1 as well as mPFC population activity maintains a working memory representation of stimulus identity rather than of response type. Finally, we find that patterns of evoked responses after CS presentations are replayed during Sharp-Wave Ripples in CA1 and PFC and that this replay is stronger for patterns derived from CS+ stimuli. In combination, these results suggest that the hippocampus and medial prefrontal cortex interact in multiple ways to support learning of and correct responses to reward predicting cues.

Title: Neural substrates of memory impairment and rescue in a mouse model of schizophrenia

Authors: *C. DELGADO-SALLENT[1], T. GENER[1], A. B. FATH[1], P. NEBOT[1], M. BRY[2], M. V. PUIG[1];

Abstract: Cognitive deficits are a core feature of schizophrenia (SCZ) but respond poorly to the available medication. Better understanding of the neural basis of these deficits is essential for the development of new treatments. Higher-order cognitive processes depend on a precise synchronization between the prefrontal cortex (PFC) and the hippocampus (HPC) that is

disrupted in SCZ. The subchronic phencyclidine (sPCP) mouse model induces SCZ-like symptoms including cognitive impairment. We recorded neural activity in the PFC and HPC of C57BL/6J mice before and after administration of sPCP during quiet wakefulness, open field exploration and the novel object recognition test that assesses working memory and long-term memory abilities. During rest, sPCP mice showed increased delta (2-5 Hz) power in PFC, increased prefronto-hippocampal phase synchronization (wPLI) at theta (8-12 Hz), beta (15-25 Hz) and low gamma (30-50 Hz) and desynchronization at high gamma (50-100 Hz). During active exploration, sPCP mice showed increased PFC theta, beta and high gamma and reduced HPC low and high gamma oscillations. Prefronto-hippocampal synchronization was also disrupted during active exploration in sPCP-treated mice. Theta and beta wPLI increased, as it also did in resting states, while low gamma wPLI decreased. Importantly, working memory and long term memory were profoundly impaired in sPCP-treated mice and partially rescued by a 14-day treatment with the atypical antipsychotic drug risperidone. Risperidone is a broadly used drug that targets the dopaminergic and serotonergic systems. Our findings suggest that the alterations on prefronto-hippocampal networks may underlie the neural mechanisms of memory impairment in sPCP-treated mice that can be corrected by risperidone.

Title: Serotonin 5-HT1a, 5-HT2a and dopamine D2 receptors strongly influence prefronto-hippocampal neural networks in alert mice: Contribution to the actions of risperidone

Authors: *T. A. GENER[1], A. TAUSTE CAMPO[2], M. ALEMANY[1], P. NEBOT[1], C. DELGADO-SALLENT[1], J. CHANOVAS[3,1], M. V. PUIG[1];

Abstract: Atypical antipsychotic drugs (APDs) useful to treat positive and negative symptoms in schizophrenia block serotonin receptors 5-HT2AR and dopamine receptors D2R and stimulate 5-HT1AR directly or indirectly. However, the cellular mechanisms mediating their therapeutic actions remain unresolved. We recorded neural activity in the prefrontal cortex (PFC) and hippocampus (HPC) of freely-moving mice before and after acute administration of 5-HT1AR, 5-HT2AR and D2R selective agonists and antagonists and atypical APD risperidone. We investigated the contribution of the three receptors to the actions of risperidone on brain activity via statistical modeling and pharmacological reversals (risperidone + 5-HT1AR antagonist WAY-100635, risperidone + 5- HT2A/2CR agonist DOI, risperidone + D2R agonist quinpirole). Risperidone, 5-HT1AR agonism with 8-OH-DPAT, 5-HT2AR antagonism with M100907, and D2R antagonism with haloperidol caused varying degrees of sedation in mice that correlated with a suppression of neural spiking, power of theta and gamma oscillations in PFC and HPC, and a reduction of PFC-HPC theta phase synchronization. By contrast, activation of 5-HT2AR with DOI enhanced high-gamma oscillations in PFC and PFC-HPC high gamma connectivity likely mediating its hallucinogenic effects. Together, power changes, regression modeling and pharmacological reversals suggest an important role of 5-HT1AR and 5-HT2AR in risperidone-induced effects on delta, beta and gamma oscillations, while D2R may contribute to risperidone-mediated changes in delta oscillations. This study provides novel insight into the neural mechanisms of risperidone and may help elucidate the neural substrates of widely prescribed psychiatric medication targeting the serotonin and dopamine systems in two brain regions involved in the pathophysiology of schizophrenia.

Title: Neurophysiological effects of the selective 5-HT7 antagonist, SB-269970, in a mouse model of schizophrenia

Authors: *A. B. FATH[1], T. GENER[1], C. DELGADO-SALLENT[1], P. NEBOT[1], M. BRY[2], M. PUIG[1];
[1]Integrative Pharmacol. and Systems Neurosci., IMIM -Hospital Del Mar Med. Res. Inst., Barcelona, Spain; [2]Univ. of Bordeaux, Bordeaux, France

Abstract: A wide body of evidence has extensively demonstrated that normal executive function depends on a specific pattern of spatio-temporal communication between the prefrontal cortex (PFC) and the hippocampus (HPC). It has been found that this type of PFC-HPC communication is abnormal in schizophrenia (SCZ). 5-HT7 receptors have been implicated in learning and memory processes and the blockade of these receptors may be a potential target for cognitive amelioration in SCZ. In order to elucidate the cellular mechanisms of the 5-HT7R we administered the 5-HT7R agonist, AS19 (10 mg/kg), and subsequently the 5-HT7R antagonist, SB-269970 (8.0 mg/kg) while recording neural activity in the PFC and HPC of freely-moving C57BL/6J mice. After injection of AS19 we find a decrease in low gamma (30-50 Hz) and high gamma (50-100 Hz) power in the PFC and HPC that is recovered by SB-269970. In order to elucidate the pro-cognitive actions of 5-HT7R antagonism, we assessed the behavioral and neurophysiological effects of the 5-HT7R antagonist before and after subchronic phencyclidine (sPCP)-treated mice while assessing memory performance in the Novel Object Recognition task (NOR). The NOR was performed one hour after acute injection of the 5HT7R antagonist (4.0 mg/kg). The 5HT7R antagonist increases memory performance in healthy mice and ameliorates sPCP-induced memory impairment in the NOR task. In normal and sPCP-treated mice, the 5HT7R antagonist induces a robust decrease in the PFC low gamma and high gamma power and increases delta (2-5 Hz) power. In the HPC it decreases beta and high gamma power, while increasing delta. Following sPCP, there is also a hypersynchronization of prefronto-hippocampal connectivity at high gamma which is rescued by the 5HT7R antagonist. Our findings provide new insights into neural mechanisms of the 5HT7R actions and potential new treatments for cognitive impairment in SCZ.

Title: Neural substrates of memory impairment and rescue in a mouse model of Down syndrome

Authors: M. ALEMANY-GONZÁLEZ[1], T. GENER[1], P. NEBOT[1], M. VILADEMUNT[1], M. DIERSSEN[2], ***M. V. PUIG**[1];
[1]IMIM -Hospital del Mar Med. Res. Inst., Barcelona, Spain; [2]CRG - Ctr. For Genomic Regulation, Barcelona, Spain

Abstract: Down syndrome (DS) is the most common form of intellectual disability. The cognitive alterations in DS are thought to depend on abnormal neuro-architecture, deficient synaptic plasticity, and excitation-inhibition imbalance in brain regions critical for learning and memory such as the prefrontal cortex (PFC) and the hippocampus (HPC). Previous studies have proposed that immature development of connectivity in DS would lead to impaired ability to integrate information from distant brain regions. Here we recorded neural activity simultaneously in the PFC and HPC of trisomic Ts65Dn mouse model of DS and their non-trisomic littermates during quiet wakefulness, natural sleep and memory acquisition and retrieval. During rest, trisomic mice consistently showed pathological theta oscillations, increased slow-to-fast phase-amplitude coupling in both PFC and HPC and hypersynchronous prefrontal-hippocampal phase synchronization. During sleep, slow waves were reduced and gamma oscillations amplified in Ts65Dn, likely reflecting sustained superficial sleep states. In addition, hippocampal sharp-wave ripples were disrupted, probably contributing to deficient memory consolidation. In WT mice, memory acquisition was encoded by PFC-to-HPC theta connectivity, whereas memory retrieval was encoded by HPC-to-PFC low gamma connectivity. These measures correlated strongly with memory performance and were disrupted in trisomic mice. Importantly, both behavioral and neurophysiological alterations were rescued by chronic oral administration of a green tea extract containing epigallocatequin-3-gallate (EGCG), previously shown to improve executive function in young adults with DS. Our findings suggest hyper-synchronization of prefrontal-hippocampal circuits as a major neural mechanism underlying intellectual disability in DS and could explain EGCG´s cognitive improvement.

Title: Hippocampal theta sequences and associated prefrontal activity during memory guided behavior

Authors: *M. C. ZIELINSKI[1], J. D. SHIN[1], S. P. JADHAV[2];
[1]Grad. Program in Neurosci., [2]Neuroscience, Psychology & Volen Ctr. for Complex Systems, Brandeis Univ., Waltham, MA

Abstract: Rhythmic coordination of network activity between the rodent hippocampus (CA1) and medial prefrontal cortex (PFC) supports working memory guided decision-making. Continuous theta (6-12 Hz) oscillations are a prominent mode of rhythmic hippocampal activity in the local field potential (LFP), seen during goal driven behavior, active sensory sampling of the environment, and rapid eye movement (REM) sleep. Theta oscillations pattern the firing of hippocampal place cells and mediate temporal organization of PFC activity. A majority of PFC cells exhibit phase-locked spiking to hippocampal theta during spatial behavior (Siapas et al., 2005; Jones & Wilson, 2005; Jadhav et al., 2016), and we have shown that theta phase sharpens coherent spatial representations in CA1 and PFC (Zielinski, Shin, and Jadhav, 2019). Within theta cycles, short and fast sequences of hippocampal spikes continuously recapitulate the slower behavioral timescale and place field order. These "theta sequences" are thought to underlie cognitive chunks of information, with their timing implying a possible means of continuous synaptic strengthening between units (Lisman and Redish, 2009; Mizuseki et al., 2009; Foster and Wilson, 2007). Theta sequences are hypothesized to support cognitive processes such as planning and evaluation of paths in space and time (Wikenheiser and Redish 2015; Colgin, 2013), with theta-paced PFC responses likely facilitating these processes (Zielinski, Tang, and Jadhav, 2017), although the nature of PFC activity during theta sequences remains unexplored. To address these unresolved questions, we simultaneously recorded neural ensembles in PFC and CA1 throughout learning and performance during a W-track spatial alternation task, known to require spatial working memory and dependent on interactions between these two areas (Maharjan et al., 2018). We then used a simultaneous Bayesian decoding approach to determine spatial representations of ensemble activity during periods of high theta power. We then identified putative hippocampal theta sequences and concomitant prefrontal activity within theta cycles in different states. We show the evolution of theta sequences over behavior and their corresponding prefrontal representations throughout learning. These findings establish and expand a role for theta sequences and associated prefrontal activity in memory guided decision-making behavior.

Title: CA1 neurons encode non-spatial cues as a conjunction of location and cue identity

Authors: *W. HOCKEIMER[1,2], J. J. KNIERIM[1,2];
[1]Solomon Snyder Dept. of Neurosci., [2]Zanvyl Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: The hippocampus is believed to subserve episodic memory by integrating spatial and non-spatial information into a cognitive map (O'Keefe and Nadel, 1979). This integration is believed to occur through a form of multiplexing wherein a population of hippocampal neurons with stable spatial firing fields encodes the animal's current position and the distribution of their firing rates encodes the constellation of non-spatial cues present (Leutgeb et al., 2005). To provide a direct test of this hypothesis, populations of hippocampal CA1 neurons were recorded via tetrodes as rats randomly foraged through an arena consisting of a series of interlocking passageways arranged in a city-block format. Removable textured plates were placed on the floor of each segment and were interchanged during the course of a recording session such that each location harbored each stimulus multiple times. Pilot data from this design revealed a subset of cells (15/74) that exhibited texture-dependent firing rate modulations within a mostly stable place field, according to a permutation test. However, given the complicated nature of the design, a number of possible confounding variables were present. Thus, the design was simplified such that a second animal was restricted to traversing unidirectional laps around the outer perimeter of the arena. New data were collected from 107 isolated units across four days of recording. To determine what information this population encoded, a series of random forest classifiers was trained to decode different types of information using linearized rate maps of each stimulus site visit. These classifiers revealed a conjunctive coding of texture identity and spatial location. On an example day of recording, a random-forests decoder was able to decode what segment of the track the rat occupied at 30% accuracy, a level approximately three times above chance levels (11%). In contrast, the ability to decode the textured stimulus identity by itself was around chance levels. However, the decoder was able to extract information about texture identity when information about the location of that texture was incorporated. The random forest classifier was trained on categorical labels corresponding to every combination of texture identity and stimulus location and achieved a classification performance of 15%, or four times above chance (3.7%). The fact that the conjunction of spatial and non-spatial information can be accurately decoded, but not the stimulus identity by itself, supports the cognitive map theory's assertion that information about the items and events of experience is encoded in terms of a conjunction of spatial and non-spatial information.

Title: Age-related hyperactivity in the hippocampal CA3 region

Authors: *H. LEE[1], A. TILLEKERATNE[1], K. NNAH[1], M. GALLAGHER[2], J. J. KNIERIM[1,3]; [1]Mind/Brain Inst., [2]Dept Psych & Brain Sci., [3]Solomon H Snyder Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Elevated hippocampal CA3/dentate activation is observed in individuals with amnestic mild cognitive impairment (Yassa et al., 2010; Bakker et al., 2012). Studies in an animal model of age-related memory loss have demonstrated subregion-specific hyperactivity in the CA3 region of the hippocampus (Wilson et al., 2005, Robitsek et al., 2015, Haberman et al., 2017). To address how the age-related hyperactivity in CA3 contributes to memory impairment, we recorded neurons from the CA3 region in 5 young (Y), 5 aged-impaired (AI), and 5 aged-unimpaired (AU) male, Long-Evans rats. Aged rats were pretested in the Morris water maze and categorized as learning impaired or learning unimpaired. Young rats were 5-7 months old and aged rats were 25-26 months old at the time of recording. All rats were trained to run around a circular track containing salient local texture cues in a curtained room containing salient global landmark cues. Three standard sessions were interleaved with two mismatch sessions, in which the local cues were rotated counterclockwise and the global cues were rotated clockwise to result in 45°, 90°, 135°, or 180° separations. We first examined the proportion of active cells with place fields. Active cells were classified as cells with cluster quality fair or better, total running spikes > 20, and mean firing rate < 10 Hz. An active cell was considered to have a place field if it passed the spatial criteria: spatial information > 0.5 with $p < 0.01$, and on track spikes > 20. Each session was counted independently so the same cell may have been repeated over sessions. Approximately 69% of active CA3 neurons (889/1292) in Y rats and 63% of active CA3 neurons (662/1048) in AU rats had place fields, while only 53% of active CA3 neurons (503/951) in AI rats had place fields (X^2=59.53, $p < 0.0001$). The on track (i.e. spikes that fired when the rat's head position was on the track) mean firing rates of the place cells among the three groups were not different (Y: 1.09 Hz, AU: 1.17 Hz, AI: 1.16 Hz; One-way ANOVA, $F = 1.1$, $p = 0.333$). However, the off track (i.e. spikes that fired when the rat's head position was off the track) mean firing rates of the place cells were significantly higher in the AI group (Y: 0.42 Hz, AU: 0.74 Hz, AI: 0.96 Hz; One-way ANOVA, $F=92.91$, $p < 0.0001$). The spatial information content of the place cells was significantly lower in the AI group (Y: 2.29 bits/spike, AU: 2.18 bits/spike, AI:

1.84 bits/spike; One-way ANOVA, $F = 59.17$, $p < 0.0001$). These results suggest that the memory impairment associated with age-related hyperactivity in CA3 may be due to spikes that fire outside the place field, reducing the spatial information in the AI rats.

Title: Head scanning behavior and CA3 place field potentiation in aging rats

Authors: *G. RAO[1], H. LEE[1], A. TILLEKERATNE[1], K. NNAH[1], C.-H. WANG[1], M. GALLAGHER[2], J. J. KNIERIM[1];
[1]Mind Brain Inst., [2]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Scanning occurs in rats when the animal pauses to investigate the environment with head movements (Whishaw et al., 1994). The significance of this behavior to hippocampal function has been previously demonstrated (Monaco et al., 2014). In that study a small but significant number of place fields appeared or potentiated at the site where the animal had engaged in a head-scan on the previous lap. We ask here whether this phenomenon is present in aged animals. Scan-induced place cell potentiation was analyzed in hippocampal cells from 14 rats: young (YG, n=5), aged-unimpaired (AU, n=4), and aged-impaired (AI, n=5) as behaviorally assessed in the Morris water maze. The animals were trained to run on a textured circular track, located in a curtained room containing peripheral objects. They were subsequently implanted with hyperdrives targeting CA3. Recordings consisted of 3 sessions with a standard cue configuration identical to training, interleaved with 2 mismatch sessions in which global cues were rotated CW and local cues CCW. The exposure to unique mismatch angles (45, 90, 135, 180 degrees) in this protocol evokes scanning behavior in all age groups. A total of 168 place fields demonstrated significant potentiation of their firing rates from one lap to the next. Forty-eight of these place fields were designated scan-activated, as the firing during a scan on the lap prior to potentiation was higher than expected. Scan-potentiated fields were detected at approximately equal proportions in all age groups: YG, 25/93; AU, 10/41; AI, 13/34 (chi-square $=2.0372$, $p =0.36$). Firing rates (spikes/sec) for the scan-activated place cells were not significantly different across the three age groups (mean± se, YG, 1.47 ± .23; AU, 1.98 ± .56; AI, 1.04 ± .18; $F (2,45) =1.68$, $p =.20$). Information scores (bits/spike) for these place fields were

also not significantly altered with age (mean± se, YG, 2.98 ± .14; AU, 2.81 ± .26; AI, 3.36 ± .19; F (2,45) =1.82, p =.17). Whether there are age-related differences in other characteristics of these scan-activated fields, such as persistence and proximity to local and global cues, will be investigated further. These initial analyses suggest no major differences among the age groups in the overall prevalence of scan-related place field potentiation.

Title: An open-source 3D pose tracking system for neuroscience research

Authors: B. P. VAGVOLGYI[1], R. P. JAYAKUMAR[2], M. S. MADHAV[3], M. K. FERREYROS[4], F. SAVELLI[3], J. J. KNIERIM[3,5], *N. J. COWAN[2,1];
[1]Lab. for Computat. Sensing & Robotics, [2]Dept. of Mechanical Engin., [3]Zanvyl Krieger Mind/Brain Inst., [5]The Solomon H Snyder Dept. of Neurosci., [4]Johns Hopkins Univ., Baltimore, MD

Abstract: We present a robust high-precision single-camera system for tracking the pose - position (x,y,z) and orientation (roll, pitch, yaw) - of a custom visual target attached to a test subject. Our system builds upon existing monocular tracking algorithms, referred to as Perspective from n Points (PnP), that use a visual target comprising point-like fiducials (passive retroreflective markers in our implementation) arranged in known configuration (Faessler et al. ICRA 2014, Savkin et al. VRST 2017). Such methods are constrained by the tradeoff between fiducial count and range of detectable orientations. A low fiducial count limits the range of angles from which enough fiducials are visible due to self-occlusion, leading to loss of tracking. However, time needed for video processing and recapture of target pose upon loss of tracking scales poorly with the number of fiducials due the combinatorial complexity of possible point

correspondences. We introduce geometric constraints and multiple fiducial sizes, drastically reducing the number of possible correspondences facilitating a higher fiducial count. Our improvements enable real time operation (15-30 ms per frame at 4MP resolution using 11 fiducials) in a host of new applications where a wide range of orientations need to be tracked. The system consists of custom software, a Near-IR camera, an IR LED light source mounted near the camera, and the custom visual target described above. The software can process a video file input, but is also capable of real time operation on live camera images with a supported camera model. The 3D printable design of the visual target, target assembly instructions, calibration and tracking software will be open source. Cost of implementation is a fraction of commercially available solutions.
The tracker's real time mode is being used to manipulate the visual scene in the augmented reality dome described in Jayakumar*, Madhav* et al., Nature 2019. Previously, the dome system relied on the animal being tethered to a boom arm instrumented with an angular optical encoder that measured the position of the animal as it ran on a circular track. The new real time tracking system allows for a freely behaving, untethered animal. We also present results from an experiment where the system, post-processing a video file, was used to track the head of a rat. In the experiment, the surrounding visual scene of virtual landmarks was either static or rotated coherently as a function of the rat's running speed. Simultaneous neural recordings were taken from CA1 place cells and ADN head direction cells. We find that that the place cell and head direction cell map respond coherently to the visual cue manipulation.

Title: Odor-place associative memory in the hippocampal-prefrontal network

Authors: *C. A. SYMANSKI, E. KULLBERG, S. P. JADHAV;
Brandeis Univ., Waltham, MA

Abstract: Rodents use olfactory cues to learn and remember information about their environment. This requires forming associations between odors and locations, and then recalling these associations to guide behavior. The physiological mechanisms by which these odor-place

associations are formed and retrieved are thought to involve a brain-wide network that includes the hippocampus and the prefrontal cortex (PFC) (Tse 2007; Fujisawa 2011; Igarashi 2016). Recent evidence suggests that coordinated activity between the hippocampus and PFC is important for formation and for recall of associative memories and memory-guided decision making (Maharjan 2018; Zielinski 2017; Shin & Jadhav 2016). We therefore investigated how coordination between these two regions, along with the olfactory bulb, supports the retrieval of learned odor associations to guide spatial decision making in an odor cue-guided T-maze task. In this task, rats (n = 7) recalled familiar associations between odors and reward locations on the maze arms (75-90% performance accuracy). Multi-site tetrode recordings were used to simultaneously monitor neural activity in the olfactory bulb, medial PFC, and dorsal hippocampal CA1 in freely-behaving rats as they performed this task. We measured local field potential in all regions, as well as spiking activity in CA1 (n = 678 neurons) and PFC (n = 286) to investigate the physiological basis of the recall of odor-place associations. During the period of acute olfactory sampling and recall, respiratory rhythms and beta oscillations (15-35 Hz) were prominent in olfactory bulb, CA1, and PFC; further, beta coherence was enhanced between the three regions. Inter-regional phase locking of hippocampal and PFC neurons to beta oscillations was also observed, suggesting beta-driven coordination of these regions as part of a functional network. Individual neurons in both CA1 and PFC exhibited choice-selective responses that were reversed on incorrect trials, implicating their involvement in memory-guided behavior; furthermore, ensemble responses in CA1 and PFC evolved during the recall period to indicate correct choice with CA1 leading PFC. These results point to an olfactory-hippocampal-prefrontal network underlying the recall of olfactory-place associations. Future analyses will investigate dynamic phase relationships between the beta rhythm and choice-related ensemble activity during the recall period, as well as predictive coding properties of ensembles during recall and maintenance of odor-place associations.

Title: Awake hippocampal-prefrontal replay mediates spatial learning and decision making

Authors: *W. TANG[1], J. D. SHIN[1], S. P. JADHAV[2,3,1];
[1]Neurosci. Program, [2]Psychology, [3]Volen Natl. Ctr. for Complex Systems, Brandeis Univ., Waltham, MA

Abstract: Goal-directed spatial learning requires remembering and choosing critical paths to desired goals, a process that requires hippocampal-prefrontal circuits (*Jadhav et al., 2012; Maharjan et al., 2018; Tang and Jadhav, 2019*). Hippocampal place cells replay spatial paths in reverse and forward order during sharp-wave ripples (SWRs) in immobility periods, and we have shown that this awake hippocampal replay is coordinated with prefrontal cortical (PFC) activity for memory reactivation (*Jadhav et al., 2016; Tang et al., 2017*). Although it is known that awake replay is necessary for spatial learning (*Jadhav et al., 2012*), how replay activity mediates both goal-directed learning and memory-guided decision making is unclear. We therefore continuously tracked replay in the same hippocampal-prefrontal ensembles in rats ($n = 6$) throughout learning of a W-track spatial alternation task across multiple behavioral sessions in a single day. We found that during pauses between behavioral trajectories, awake reverse and forward hippocampal replay consistently mediated an internal cognitive search of all available past and future possibilities throughout learning and performance of the task. Further, reverse and forward replay exhibited opposing learning gradients for prediction of behaviorally actualized past and future paths, respectively. Coordinated hippocampal-prefrontal replay distinguished correct past and future paths leading to reward from alternative choices based on the hippocampal cognitive search, thus supporting recall of past path to guide selection of future choice for execution of spatial working memory rules. Our findings reveal a learning shift from hippocampal reverse-replay-based retrospective evaluation to forward-replay-based prospective planning, with prefrontal filtering of memory-guided paths for learning and decision-making.

Title: Ontogeny of coordinated representations in the hippocampal-prefrontal network during spatial learning

Authors: *J. D. SHIN[1], W. TANG[1], S. P. JADHAV[2,3];
[1]Neurosci. Program, [2]Psychology, Brandeis Univ., Waltham, MA; [3]Volen Natl. Ctr. for Complex Systems, Waltham, MA

Abstract: Spatial learning and memory-guided behavior involves interaction of hippocampal spatial maps with prefrontal cortical (PFC) representations for evaluation and selection of task-relevant information (Shin and Jadhav, 2016; Maharjan et al., 2018; Zielinski et al., 2019). However, the specific nature of these task-relevant representations, the relative timescales at which they emerge in the hippocampus and PFC in novel environments, and how they support learning and subsequent memory performance is still unclear. To address these questions, we continuously and simultaneously recorded the same neuronal ensembles in PFC and hippocampal CA1 area in rats (n = 8) throughout learning of a novel W-track spatial alternation task across multiple behavioral sessions in a single day. We found that behavioral learning was correlated with the co-stabilization and refinement of spatial representations, which emerged in parallel in both CA1 and PFC. Additionally, we observed the co-development on similar timescales for two key task-dependent representations in CA1 and PFC during learning. First, activity patterns became more distinctive in different running directions occurring in the same spatial location, i.e., directional selectivity. Second, neurons developed retrospective and prospective trajectory-dependent activity, representing not only instantaneous position but also past and future choices, i.e. choice selectivity, which is thought to mediate memory-guided trajectories (Wood et al., 2000; Baeg et al., 2003, Fujisawa et al., 2008). Our results suggest that spatial learning elicits coordinated changes in context-selective representations in both the hippocampus and PFC. The emergence of these stable representations from a naïve state underlies the establishment of hippocampal-prefrontal associations that are important for learning rules in novel environments, and can therefore provide the neural basis to support memory guided behavior.

Title: Development of a computational theory of gain recalibration in the brain's path integration system

Authors: *K. R. HEDRICK, B. GEIGER;
Mathematics, Southern Methodist Univ., Dallas, TX

Abstract: Path integration is a navigational strategy that, in combination with landmark navigation, supports the creation of "cognitive maps" and allows an organism to remain oriented even in the transient absence of stable landmarks (Savelli & Knierim, J Exp Biol, 2019). With the use of a novel, augmented reality system and recordings from hippocampal place cells, the Knierim and Cowan Labs recently reported that the gain of the path integration system—i.e., the relationship between the distance traveled by an organism in the world and the corresponding updating of the organism's location on its cognitive map—is a plastic variable that can be recalibrated by a continual mismatch between path integration and landmarks (Jayakumar et al., Nature, 2019). We are working to develop computational theories to understand the network dynamics underlying the interaction between path integration and landmarks in this recalibration phenomenon. In particular, we are incorporating a plastic gain into existing models of path integration using various hypotheses for the source of error correction. Through numerical simulations and mathematical analysis, we then use the models to predict the response of grid cell modules in the upstream MEC, which provide the primary spatial inputs to hippocampal place cells.

Title: Quantifying the influence of grid-cell input scale relative to environment size in a Hebbian model of hippocampal place field formation

Authors: *F. SAVELLI[1], J. J. KNIERIM[2];
[1]Zanvyl Krieger Mind/Brain Inst., [2]Zanvyl Krieger Mind/Brain Inst. and Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Entorhinal grid cells provide a prominent spatial input to hippocampal place cells. When this input is compromised, place cells can fail to develop place fields in novel and large environments, but not in familiar ones, or their stable fields tend to concentrate in the periphery of the environment, where other types of spatial inputs are available. Moreover, most existing

studies target CA1/3 place cells, which receive both direct and processed grid inputs. What exactly do grid cells contribute to hippocampal place fields? In a model based on a fast, postsynaptically-gated, Hebbian rule, place fields can be generated by spiking models of grid-cell inputs (Savelli & Knierim, J Neurophys, 2010). This model is compatible with the modular organization of grid scale and orientation, and it is robust against grid distortions when tested with real behavioral recordings in typical apparati of various shapes and sizes (cylinder/square box/platforms, 0.36-1.87m^2; Savelli & Knierim, SfN, 2018). In this model, however, 'conventional' place cells are prevalently found among cells that receive inputs from grids at scales that are commensurate with the environment. For example, rate maps of cells receiving inputs from a subset of grid modules at the lower end of the scale range show many place fields in the larger environments, similar to some experimental observations. Do these fields coexist throughout the session or are they expressed at different times? We quantified their intra-session stability in two ways: (1, cell-based) by the similarity of two partial rate maps from the first and second halves of the session; and (2, field-based) by the similarity of the temporal profiles of the cell's activity and of the animal's visits to the field over the course of the entire session. Spatial stability by both measures was observed across the whole population of simulated place cells in all environments. In contrast, instability was far more prevalent in place cells receiving grid inputs that had a low scale-to-environment-size ratio and in place fields that had a low area-to-environment-size ratio. These results suggest the possibility that experimental properties of place cells such as the spontaneous relocation of place fields and the 'overdispersion' of in-field firing may in part reflect continuing plasticity of grid inputs. It remains experimentally under-investigated, however, if actual place cells involved in the initial and/or most septal stage of hippocampal processing conform to our results, and if other inputs or a regulation of grid input plasticity in these cells promote greater field stability than observed in our current model.

Title: Object-related firing of cells in the dentate gyrus

Authors: *D. GOODSMITH[1,3], S. KIM[3], K. M. CHRISTIAN[3], H. SONG[3], J. J. KNIERIM[1,2]; [1]Krieger Mind/Brain Inst., [2]The Solomon H Snyder Dept. of Neurosci., Johns Hopkins Univ.,

Baltimore, MD; [3]Dept. of Neurosci. and Mahoney Inst. for Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Granule cells in the dentate gyrus (DG) receive egocentric sensory and object-related information from the lateral entorhinal cortex (LEC) as well as an allocentric spatial signal from the medial entorhinal cortex (MEC). One function of the DG may be the conjunctive encoding of spatial and non-spatial information into a single representation of both the context and content of an experience. While there is behavioral evidence for conjunctive encoding in the DG (Kesner, 2013), how the firing of DG cells contributes to this function is unclear. We recorded from DG cells as mice foraged for food in an environment that contained two discrete objects. We alternated sessions in which the objects were in a standard location (STD) with sessions in which an object was moved (MOVE), to examine how manipulation of the objects affected the spatial firing of DG cells.
We recorded 381 DG cells (191 active during behavior) from 13 mice. In a subset of DG cells with place fields that were affected by object movement, we observed six main response categories: 1) move: distance to object is maintained when the object is moved, 2) trace: field appears at previous object location, 3) appear: new field appears near object, 4) disappear: loss of firing near object, 5) rotate: change in direction of firing relative to object, 6) Capture: field shifts to moved object location. Many cells (likely mossy cells) had multiple place fields, and individual fields of these cells appeared to respond to object manipulations, while other fields of the same cell remained stable. We did not find any significant clustering of place fields at the object locations, or any population differences in the number of place fields, place field size, or firing rates between STD and MOVE sessions. Rate map correlations between the STD sessions before and after a MOVE session were significantly higher than the correlation between a STD and MOVE session for 12% of DG cells. We next restricted our analysis to a portion of the environment centered at the location of the object or centered at a stable spatial location. 26% of DG cells had a significantly higher correlation between a STD and MOVE session at the object location than at the spatial location. Our results indicate that cells in the DG respond to the manipulation of objects in space, and support the proposed role for DG in conjunctive encoding.

Title: Effect of medial septal selective and non selective lesions on exploratory behavior and recognition memory

Authors: *L. KRUASHVILI, G. BESELIA, N. CHKHIKVISHVILI;
Lab. of Behaviora nd Cognitive Function, I.Beritashvili center of Exptl. Biomedicine, Tbilisi, Georgia

Abstract: Investigation of cholinergic system and memory interaction has especially become the object of scientific attention due to the clinical and experimental data, in which the severity of dementia in Alzheimer's disease (AD) was found to have a positive correlation with the extent of the cholinergic loss. The septum is connected to the hippocampus via the fimbria-fomix, which carries projections from the medial septum (MS), and the vertical limb of the diagonal band of Broca. These projections are predominantly cholinergic and GABAergic. Lesions of the fimbria-fomix, or electrolytic lesions of the MS, impair hippocampal-dependent learning and memory. The purpose of this study was to investigate ability to acquire and use spatial (or non-spatial) information as well as to habituate exploratory activity over time in sham-operated, electrolytic, neuro or immunotoxic MS lesioned rats. Methods: A total of 39 male rats were used. For electrolytic lesions a stainless steel was inserted in the MS. All injections were performed stereotaxically. Rats were individually given five 3-min sessions in the open field. All experiments were approved by the Animal Care and Use Committee of the Center and were in accordance with the principles of laboratory animal care. Results: Examination of the AChE stained sections showed that after injections of 192 IgG saporin into the MS, animals exhibited significantly less AChE staining in MS and hippocampus as compared to sections obtained from control animals. The MS electrolytic and ibotenic acid lesioned rats showed an increase in their exploratory activity to the objects and were impaired in habituating to the objects in the repeated spatial environment, rats with immunolesions of the MS did not differ from control rats. Electrolytic lesions of the MS disrupt spatial recognition memory, rats with immuno- or neurotoxic lesions of the MS were normal in detecting spatial novelty. The MS lesioned and control rats clearly reacted to the object novelty by exploring the new object more than familiar ones Conclusions: MS is sufficient for spatial recognition, but is not sufficient for object recognition memory, the selective loss of septohippocampal cholinergic or noncholinergic projections does not disrupt the function of the hippocampus to a sufficient extent to impair spatial recognition memory. Therefore, the present study demonstrates dissociation between the two major components (cholinergic and noncholinergic) of the septohippocampal pathway in exploratory behavior assessed in the open field.

Title: Sleep deprivation impairs learning and memory through downregulation of *O*-GlcNAcylation in the brain of adult zebrafish

Authors: *S. KIM, Y. LEE, J. PARK, J.-W. LEE, I.-O. HAN;
Dept. of Physiol. and Biophysics, Inha Univ., Incheon, Korea, Republic of

Abstract: Sleep is an evolutionarily conserved physiological process implicated in the consolidation of learning and memory (L/M). Here, we hypothesize that sleep deprivation (SD)-induced cognitive deficits in zebrafish are mediated through reduction in *O*-GlcNAcylation in the brain. At the molecular level, SD downregulated mRNA of key enzymes of HBP metabolism and *O*-GlcNAc transferase (OGT) along with increased *O*-GlcNAcase (OGA) expression. Fear conditioning (FC) induced an increase in the expression or activities of proteins associated with long term memory (LTM), and at the same time, OGT protein and *O*-GlcNAcylation were significantly increased in the normal- but not in the SD-group of zebrafish. Suppression of HBP by the GFAT inhibitor, diazo-oxo-norleucine (DON), impaired L/M function and FC-mediated activation of PKA/CREB signaling. Conversely, enhancement of HBP by glucosamine significantly restored cognitive deficits and increased PKA/CREB signaling in the SD group of zebrafish. To our knowledge, the current study has provided valuable insights into the molecular and biochemical changes associated with L/M at the whole-brain level using the zebrafish system for the first time. Our findings highlight the role of the HBP during the L/M process and provide potential therapeutic targets for cognitive defects.

Title: Mental navigation of mnemonic space in primates

Authors: *S. NEUPANE, M. JAZAYERI;
Dept. of Brain and Cognitive Sci., McGovern Inst. for Brain Research, Massachusetts Inst. of Technol., Cambridge, MA

Abstract: A 'cognitive map' (Tolman,1948) is thought to organize the underlying structure of a contingent task in a unitary space (O'keefe and Nadal, 1978). During spatial foraging, neural correlates of allocentric place code have been discovered in the hippocampal formation of rodents pointing towards a spatial map that utilizes Euclidean geometry (O'Keefe and Dostrovsky, 1971; Hafting et al 2005). More recently, signatures of such place code were found in rodents and humans along non-spatial dimensions of sound and arbitrary abstract concepts (Aronov et al 2017; Constantinescu et al 2016) supporting the possibility that the hippocampal formation functions as a generalized cognitive map. However, how the nervous system interrogates such a map to make cognitive inferences in the absence of sensory input is not understood.

To address this question, we designed a novel mental navigation task for humans and monkeys in which subjects had to make inferences about the relative direction and distance of arbitrary points on a cognitive map, without sensory feedback. On each trial, subjects were presented with two images chosen randomly from a previously learned ordered sequence of images. One image represented the subjects' current position along the sequence and the other, the target position. Subjects could use two buttons to drag the sequence of images rightward or leftward at a fixed speed. To complete the trial, subjects had to use their memory of the image sequence to infer the position of the target relative to the current image, and press the appropriate button for the appropriate length of time. Importantly, button presses advanced the image sequence covertly forcing subjects to navigate the sequence mentally. Upon button release, the new position along the sequence was revealed.

Preliminary behavioural results exhibited three features consistent with the use of a cognitive map. (1) After training on a subset of image pairs from a given sequence, humans and monkeys were able to learn the remaining unseen pairs faster. The overall learning curve for a new sequence was also faster suggesting that the structure of the cognitive map was learned. (2) Probability of direction error decreased when either the current or target image were at the extrema of the sequence suggesting an inference mechanism that relies on the representation of borders as an integral part of the cognitive map (3) Reaction time distribution varied with image distance suggesting an inference strategy based on mental simulations of the sequence. Electrophysiology experiments are currently underway to examine the neural basis of learning and use of cognitive maps in the hippocampal formation of monkeys.

Title: A short term relief learning paradigm to discriminate safety in *Drosophila*

Authors: ***J. HE**[1], K. WANG[2], Y. ZHONG[1];
[1]Tsinghua Univ., Beijing City, China; [2]China Agr. Univ., Beijing City, China

Abstract: Posttraumatic Stress Disorder, PTSD, as a neurological disease afflicting thousands of people who experienced psychological trauma has been drawing widespread concern. Extensive efforts have been devoted to identifying causal paths leading to danger learning and memory. Alternatively, the low discrimination ability upon safety signal in PTSD remains neglected. Relief learning is an ideal paradigm to study safety signal discrimination. However, current relief learning paradigm needs long training cycles and has low behavior performance index. In this study, we introduce a new relief learning paradigm with one cycle training and high behavior performance index to study quick safety signal discrimination ability. Further studies about the mechanisms of how PTSD patients discriminate safety using this new paradigm may help to discover new treatments.

Sch. of Med., New Haven, CT

Abstract: Studies in rats, monkeys and humans have found multiple types of value-related neural signals in the striatum, suggesting that the striatum might play an important role in reinforcement learning and decision making. For example, action-value signals in the striatum might contribute to biasing actions toward more valuable options. Recently, concerns were raised regarding the statistical methods used to identify action-value signals (Elber-Dorozko and Loewenstein, 2018). First, the statistical significance of temporal correlation between neural activity and action value might be inflated by the serial correlation in both variables. Second, striatal activity seemingly related to action values might code other decision variables correlated with action value, such as a policy or relative action values. To address these concerns, we reanalyzed the neural data previously recorded from the striatum of rats performing a dynamic foraging task and monkeys performing an intertemporal choice task. We found that our previous analysis procedures, such as a within-block permutation test or the inclusion of autoregressive terms, effectively dealt with the problems related to serial correlation in neural and behavioral signals. Moreover, we also found significant action-value signals using a more stringent cross-session permutation test proposed recently. These results show that striatal action-value signals cannot be accounted for by serial correlation in neural activity and action value. Next, we analyzed neural activity in the rodent and primate striatum related to multiple types of decision-related variables, such as action value, policy, and state value. We found that in both species, action-value signals cannot be fully accounted for by activity related to policy or state-values. Together, these results indicate a robust coding of action values in the rodent and primate striatum.

Title: Calorie restriction induces memory enhancement

Authors: *C.-H. CHIEN, C.-C. HUANG, P.-Y. WANG, S.-K. CHEN;
Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Since the light/dark cycle in the world is about 24 hours, in order to act normally throughout every single day, almost all organisms have developed the circadian clock system to sensor outside environment and collaborate the physiological function of different organs. Except for light, daily fed calorie is one of the external cues, which affecting body weight, immune system as well as gut microbiota, of an organism. Here, using wild-type mice as model animals and combining next generation sequencing and several behavior tests, we found that calorie restriction, i.e. only 60% energy intake compared to control groups, would modulate the composition and oscillation of gut microbiota and improve memory ability of mice.

Title: Diversity of molecularly defined GABAergic interneurons in the mouse perirhinal cortex

Authors: *M. J. NIGRO, R. NAIR RAVEENDRAN, C. KENTROS, M. P. WITTER;
Kavli Inst. for Systems Neuroscience, Ctr. for Neural Computation, Egil and Pauline Braathen and Fred Kavli Ctr. for Cortical Microcircuits, NTNU Norwegian Univ. of Sci. and Technol., Trondheim, Norway

Abstract: Cortical inhibitory interneurons powerfully shape information processing in cortical networks. Their wide diversity is believed to endow cortical microcircuits with a variety of computational capabilities. Recently the distribution of GABAergic interneurons has been shown to vary among cortical areas, particularly in the rhinal cortices (Kim et al., 2017). This is of particular relevance given that neocortical information traveling to the entorhinal-hippocampal system is subject to an inhibitory control in perirhinal cortex (PER). Here we used a combination of mouse genetics, immunofluorescence and intersectional genetics to describe the diversity of GABAergic classes in the mouse PER. We used immunofluorescence for parvalbumin (PV), somatostatin (SST) and vasoactive intestinal peptide (VIP) in the GAD67-GFP transgenic mouse

line to quantify these non-overlapping populations as well as the total GABAergic population in PER and barrel cortex. Our data show that PV cells represent a minority of interneurons in PER as compared to barrel cortex and their numbers decrease along the rostro-caudal axis. On the other hand, a population negative for all three markers represents ~50% of GABAergic interneurons across the layers of perirhinal cortex, but less than 30% in barrel cortex. By injecting interneuron specific viruses (Dimidschstein et al., 2016) in the CCK-cre mouse line we identified a population of GABAergic interneurons that do not express SST and partially overlaps with VIP (~6%) and PV (30-50%). These results suggest that in deep layers of PER 50-70% of intersectionally labelled cells are negative for PV, SST, and VIP. Current clamp recordings show that intersectionally labelled cells express an irregular type of firing pattern. This peculiar ratio of different molecularly defined GABAergic interneurons might endow PER circuits with specialized computational properties.

Abstract: The cholinergic efferent network from the medial septal nucleus to the hippocampus has an important role in learning and memory processes. This cholinergic projection can generate theta oscillations in the hippocampus to efficiently encode novel information. Hippocampal cholinergic neurostimulating peptide (HCNP) induces acetylcholine synthesis in medial septal nuclei. HCNP is processed from the N-terminal region of a 186 amino acid, 21 kD HCNP precursor protein (HCNP-pp), also known as Raf kinase inhibitory protein (RKIP) and phosphatidylethanolamine-binding protein 1 (PEBP1). In this study, we generated HCNP-pp knockout (KO) mice and assessed their cholinergic septo-hippocampal projection, local field

potentials in CA1, and their behavioural phenotype. No significant behavioural phenotype was observed; however, theta power in the CA1 of HCNP-pp KO mice was significantly reduced because of fewer ChAT-positive axons in the CA1 striatum oriens, indicating disrupted cholinergic activity in the septo-hippocampal network. These results indicate that HCNP may be a cholinergic regulator in the septo-hippocampal network.

Title: Mechanisms of inhibitory interneuronal network synchrony for type 1 versus type 2 excitability

Authors: *R. A. TIKIDJI-HAMBURYAN, C. C. CANAVIER;
Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA

Abstract: PV+ fast spiking (FS) basket interneurons are often implicated in gamma rhythms, which in the hippocampus are thought to organize information for memory encoding and retrieval. Here we focus on mechanisms present in purely inhibitory networks. Neurons with type 1 excitability are able to spike arbitrarily slowly, whereas those with type 2 excitability have an abrupt onset of re-petitive firing that cannot be maintained below a threshold frequency. FS neurons likely exhibit type 2 excitability in the entorhinal cortex, striatum and cortex. We systematically examine how excitability type affects synchronization of individual spikes to a population rhythm in the pres-ence of heterogeneity and noise. Model neurons of each type were calibrated to have very simi-lar F/I curve, input resistance, time constant and action potential shape.
In a coupled oscillator models with no noise or heterogeneity, all neurons fire on every cycle. During pharmacologically induced gamma in vitro putative fast spiking basket cells fire on aver-age every other cycle, with a narrow variance in the spikes emitted per gamma cycle but with no

particular pattern with regard to which cycles are skipped. Recently, we showed that networks of type 2 neurons coupled by hyperpolarizing inhibition support cycle skipping due to their intrinsic dynamic properties. However, inhibitory networks comprised of type 1 neurons and networks with shunting inhibition also exhibit cycle skipping; we show the cycle skipping mechanism for type 1 neurons or type 2 neurons with shunting inhibition is synaptic and not intrinsic.
Type 2 networks with hyperpolarizing inhibition homogenize the firing rate across noisy, heterogenous networks due to a strongly repelling quasithreshold that separates neurons that fire from those that skip. In contrast, in a type 1 network, the neurons that escape first though a bottleneck near the SNIC close the bottleneck for the remaining neurons. Since the rate of change of membrane potential is very slow in the bottleneck, the resultant firing times are easily scattered by noise and heterogeneity. Moreover, shunting inhibition is more robust than hyperpolarizing for type 1 because it moves the population closer to spike threshold, so that neurons spend less time in the bottleneck. Low amplitude theta modulation synchronizes type 2 networks with hyperpolazing inhibition more quickly and tightly than type 1 because of the intrinsic mechanism for cycle skipping that is not as dependent on accumulation of inhibition. A more mechanistic under-standing of oscillatory mechanisms may help elucidate the functional roles of oscillations.

Title: Circadian rhythm modulate the frequency of carbachol-induced beta oscillations in rat hippocampal slices

Authors: *K. NATSUME, M. SHIGEMOTO;
Kyushu Inst. Technol., Kitakyushu city, Japan

Abstract: Diurnal rhythm is 1-day biological rhythm of almost animals. The rhythm is affected by light stimulation and memory is also regulated by the rhythm. In behavioral experiments, rodents show different memory performance depending on the times of a day. The brain waves such as theta (4-8 Hz) and beta (13-30 Hz) waves relate to memory process, and the relationship between the occurrence of brain wave and the diurnal rhythm has not yet been clarified. A cholinergic agent carbachol can induce oscillations in the frequency similar to that of theta and beta waves with the application to hippocampal slices. Here we analyzed the effect of the diurnal rhythm on the carbachol-induced oscillations. Thirty two rats were kept on 12:12 Light / Dark

(LD) cycle for one week or more before the preparation of hippocampal slices. The activity of rats was measured using an infrared sensor to confirm that they were adapted to the LD cycle. The oscillation in the beta frequency band (called beta oscillation) was induced with the application 30μM carbachol to hippocampal slices. We classified and compared the mean of frequency of beta oscillation based on zeitgeber time (ZT; from ZT0 to 11 indicates light phase and from ZT12 to 23 indicates dark phase). The frequencies were grouped every 4 ZT hours. In results, the frequency at ZT16-19 was 15.5 $\pm$ 0.7 (mean $\pm$ standard error of the mean) Hz and significantly lower than the others (17-20 Hz). The frequency of beta oscillations induced in the slices at other than ZT16-19 was significantly decreased with the application of 10μM bicuculline, a $GABA_A$ receptor antagonist. The decreased frequency was close to that at ZT16-19. The results suggest that the $GABA_A$ receptor transmission will cause to decrease the frequency of beta oscillations. Nakatsuka and Natsume (2014) have proposed that the long-term potentiation (LTP) increased in slices at night, that is, ZT 15-21 and the increase was also induced with application a $GABA_A$ receptor antagonist at the day ZT5-11. The result also suggests that disinhibition occurs in hippocampus at night in the nocturnal rat. Therefore, inhibition will be modulated in the diurnal rhythm and the modulation will lead to the modulation of LTP and frequency change in beta rhythm of a rat.

Title: *In vivo* imaging of membrane potential dynamics in populations of hippocampal interneurons during network oscillation

Authors: *Y.-C. HUANG[1], L. D. LAVIS[2], E. R. SCHREITER[2], B.-J. LIN[1], T.-W. CHEN[1]; [1]Inst. of Neurosci., Natl. Yang-Ming Univ., Taipei City, Taiwan; [2]Howard Hughes Med. Institute, Janelia Farm Res. Campus, Ashburn, VA

Abstract: Interneurons play a critical role in coordinating network oscillation in many brain regions. In hippocampal CA1 area, distinct subtypes of interneurons participate in network oscillations in highly specific ways. For example, the firing of parvalbumin positive (PV+)

interneurons are strongly related to the timing of theta oscillation and sharp wave ripple (SWR) events. Manipulating the activity of PV+ interneurons disrupts these oscillations, suggesting their important roles. However, little is known about how subtypes of interneurons coordinate among themselves to control the dynamics of hippocampal network. Here we simultaneously imaged the membrane potential dynamics of multiple hippocampal PV+ neurons in awake, head-fixed mice. A novel protein voltage indicator 'Voltron' was expressed in CA1 PV+ neurons through virus injection. A tungsten electrode was implanted at the edge of the imaging window for field potential recording. JF525-Halotag was delivered by retro-orbital injection before imaging. Labeled neurons were focally illuminated by a pattern of excitation light tailored to optimize image contrast. Voltage dependent fluorescence signals were imaged at ~1-8 kHz using high speed camera. Pupil diameter and whisker movement were monitored using a video camera. Fluorescence signals related to supra- and subthreshold membrane potential dynamics were readily observable at single cell level. Action potentials of individual PV+ interneurons were modulated by both SWR events and arousal states. Simultaneously imaged PV+ interneurons display highly coordinated membrane potential dynamics. We are in the process of investigating other CA1 neuron subtypes. These data provide insights into the membrane potential mechanisms underlying the coordination among specific interneurons important for hippocampal circuit dynamics.

Title: Optical measurement of dendritic membrane potential in the behaving mouse hippocampus

Authors: *A. NEGREAN[1], C. D. KIM[1], D. LI[1], J. S. JEONG[1], D. HOLDER[1], J. ZHANG[1], M. CHAVARHA[2], S. W. EVANS[2], M. Z. LIN[2], A. LOSONCZY[1];
[1]Neurosci., Columbia Univ., New York, NY; [2]Neurobio., Stanford Univ., Stanford, CA

Abstract: In the hippocampus, excitation, inhibition and a variety of ion channels interact at the level of dendrites of principal cells to give rise to a rich repertoire of electrical signaling that drives somatic action-potential generation and place-cell formation. Studying this input-output transformation is a formidable technical challenge. Sharp electrode and patch-clamp based

dendritic recordings amenable to in-vitro and anesthetized preparations have so far proven unsuitable to withstand movement artifacts encountered in awake running mice, even when head-fixed on a treadmill. Optical means of measurement are clearly needed. Imaging of calcium activity has sufficient signal-to-noise ratio to be useful in studying dendritic integration in the behaving animal, however, relying on depolarization it offers only a limited view. Membrane potential imaging, on the other hand, can resolve both excitation and inhibition, but sensors and their use have proven to be challenging. Here, using latest improvements in ASAP-family of genetically encoded voltage sensors we report on two-photon imaging of dendritic membrane potential in hippocampal CA1-area pyramidal cells of mice running on a treadmill.

Title: Modulation of cortical population activity in resolving proactive interference

Authors: *C. CAMMARATA, E. D. DE ROSA;
Cornell Univ., Ithaca, NY

Abstract: Proactive interference (PI), when previously learned information intrudes on encoding of similar items, can hinder learning and adaptive behavior. PI is exacerbated during normal aging, contributing to cognitive decline. Little is known about the neural population activity associated with overcoming PI. Here we recorded local field potentials (LFP) from the prelimbic (PrL) and posterior parietal (PPC) cortices of young (9 months, n=3) and aged (22 months, n=2) adult male Long Evans rats performing an odor discrimination task that contrasted learning a novel odor pair (Novel trials) with learning a pair that elicited PI (PI trials). Young rats displayed PI by initially having lower accuracy in PI trials than Novel trials ($p<0.05$) but resolved this interference so that the difference was no longer significant by the end of training ($p=0.75$). In Novel trials beta (10-30 Hz, $p<0.01$) activity in the PrL was significantly higher when rats responded correctly than when they responded incorrectly. Conversely PI trials with a correct response had lower beta activity in the PrL ($p<0.01$), and lower theta (10-30 Hz, $p<0.01$) and beta ($p<0.01$) activity in the PPC than those with an incorrect response. Aged rats were unable to

resolve PI, as indicated by significantly lower accuracy in PI trials compared to Novel odor trials even at the end of training (p= 0.046), and rats lacked the LFP modulation seen in young rats. This suggests that overcoming PI involves a disruption of the LFP activity associated with learning novel stimuli, and that the mechanisms for this disruption are lacking in aged rats. The neuromodulator acetylcholine (ACh) is necessary for PI resolution in young rats and declines with age, and ACh-dependent beta activity in the PrL and PPC supports flexible attention, so ACh is a strong candidate to regulate the LFP activity observed. We are currently replicating to above experiment in young (9-12 month, n=10) and aged (18-22 month, n=10) rats with I.P. injection of 0.25 m.g./k.g. scopolamine, a muscarinic antagonist that hinders PI resolution but not new learning at this dose, or methyscoplamine which cannot enter the brain. We predict that inhibiting ACh activity will prevent the suppression of low frequency activity seen in young rats, causing them to resemble aged rats neurally (a lack of LFP modulation) and behaviorally (inefficiency in resolving PI).

Title: Cholinergic modulation of hippocampal theta and hippocampus-dependent trace and contextual fear conditioning

Authors: *K. D. STEVANOVIC, Z. GU, J. M. DEFILIPP, J. L. YAKEL, J. D. CUSHMAN; Neurobio. Lab., Natl. Inst. of Envrn. Hlth. Sci., Durham, NC

Abstract: Hippocampal theta rhythm has been studied extensively, however, relatively little is known about the lower frequency or Type II theta. It was classically characterized by its presence during immobility and sensitivity to cholinergic antagonism. It is thought to play an important role in fear and anxiety responses, though exactly what function it serves in this regard and the underlying cellular and molecular mechanisms are still largely unknown. In order to study the generation and subsequent contribution of Type II theta in fear behaviors we conducted wireless local field potential recordings in stratum lacunosum-moleculare of dorsal CA1 in multiple lines of mice with cell type-specific knock-outs of cholinergic receptor sub-types (floxed M1 and alpha7 crossed with CamKII-cre, GAD2-cre, Chrna2-cre, SST-cre and PV-cre). The mice were subjected to a standard trace fear conditioning paradigm in order to assess the role of theta rhythms in the acquisition and retrieval of this hippocampus-dependent form of auditory fear conditioning. This high-throughput wireless approach allows for the simultaneous assessment of the functional behavioral impact of these genetic manipulations combined with

local field potential recordings. Freezing behavior and power in the lower frequency Type II band (4-7 Hz), the higher frequency (7-10 Hz) band, total theta power as well as the ratio of Type II to Type I were assessed prior to and during acquisition, during the context test and during the tone test. The behavioral results indicated that loss of the M1 muscarinic cholinergic receptor in both CamkII-Cre and GAD2-Cre mice impairs contextual fear conditioning whereas loss of the alpha7 nicotinic receptor subunit in SST-Cre and CamkII-Cre enhanced contextual fear conditioning. No differences were observed in trace auditory fear conditioning in these lines. Local field potential recordings showed a relative increase in type II theta with successful acquisition correlated with expression of freezing consistent with prior findings that type II theta is associated fear behaviors. This general approach provides a rich data set from which to determine the functional relationships between multiple cholinergic receptor subtypes in specific cell populations with the simultaneous readout of hippocampus-dependent learning and memory, and may also provide a peek into the potential interactions between type I and type II theta.

Title: Direct assessment of effective connectivity and plasticity in the human hippocampal-cortical network

Authors: *K. N. WARREN, S. SCHUELE, S. VANHAERENTS, J. L. VOSS;
Northwestern Univ., Chicago, IL

Abstract: Episodic memory is supported by the hippocampus and a distributed network of interacting cortical regions. We have previously shown that noninvasive brain stimulation targeting this hippocampal-cortical network (HCN) increases resting-state fMRI correlations among network regions and influences episodic memory. However, direct electrophysiological measurements in humans of connectivity and plasticity in this network have not been well examined. Using human neurosurgical patients undergoing invasive monitoring for medically intractable epilepsy (n=5), we evaluated the effective connectivity and plasticity of regions in this network based on evoked potentials (EPs). EPs were measured in the hippocampus evoked by direct stimulation of an in-network site in lateral temporal cortex and an out-of-network

control site. Hippocampal EPs were measured before and after plasticity induction via 40 seconds of theta stimulation (5Hz) of the lateral temporal cortex, as noninvasive stimulation at this frequency induces changes in hippocampal-cortical network connectivity. We found increased amplitude of hippocampal EPs from temporal cortex, but not control regions, following plasticity induction. These findings provide direct electrophysiological evidence supporting the conclusion that stimulation regimens associated with plasticity induction cause changes in effective connectivity within the hippocampal-cortical network.

Title: Aging alters frequency specificity of noninvasive brain stimulation effects on hippocampal network involvement in recollection precision

Authors: *S. DAVE[1], M. S. HERMILLER[1], A. NILAKANTAN[1], S. VANHAERANTS[1], J. L. VOSS[2];
[2]Med. Social Sci., [1]Northwestern Univ., Chicago, IL

Abstract: Memory precision can vary even when items are successful recalled, ranging from detailed and highly precise to generalized and less exact. Highly precise memories depend on the hippocampal-cortical network, and memory precision declines with normative aging. The hippocampal-cortical network exhibits neural synchrony at theta-band frequencies, and therefore noninvasive stimulation might have frequency-dependent effects on memory precision. In a recent study, we found that theta-burst stimulation (TBS; 5-Hz bursts) had a greater influence on item memory and hippocampal fMRI connectivity than did beta-frequency (20-Hz stimulation). In the current study, we sought to compare the effects of TBS versus beta-frequency stimulation on memory precision and to determine whether frequency-specific influences vary by age. In a within-subjects study (15 young adults (range: 21-28 years old), 15 older adults (range: 60-73 years old), participants received TBS, beta-frequency, or sham control stimulation prior to an episodic memory task that measured object-location recall precision. Stimulation was delivered to a left parietal cortical hub of the hippocampal-cortical network, based on individualized MRI-guided connectivity between the stimulation target and the left hippocampus. In young adults, both stimulation types increased spatial recollection precision relative to sham, but with fMRI

evidence suggesting that this occurred via distinct mechanisms. TBS increased precision-related fMRI connectivity between the hippocampus and visual cortex, whereas beta-frequency stimulation increased precision-related fMRI connectivity between the parietal cortex stimulation location and the visual cortex. Thus, TBS impacted hippocampal-cortical function whereas beta-frequency stimulation impacted cortical function, with either effect yielding enhanced recollection precision. In older adults, spatial memory precision improved following beta-frequency stimulation but not TBS, suggesting that aging impairs the ability for TBS to affect the hippocampus. These findings suggest that frequency as well as aging modulate the influence of stimulation on memory processing and that alternate stimulation regimens might be needed to influence hippocampal function in older adults, such as multiple-day stimulation. fMRI findings in the older adult sample will be discussed.

Title: Pre-encoding activity in the hippocampus is related to subsequent memory

Authors: Z. J. URGOLITES[1], ***J. T. WIXTED**[2], L. R. SQUIRE[3], S. GOLDINGER[4], M. PAPESH[5], P. N. STEINMETZ[6];
[1]Dept. of Psychiatry, UCSD, La Jolla, CA; [2]UC San Diego, La Jolla, CA; [3]Veterans Affairs San Diego Healthcare Syst., San Diego, CA; [4]Arizona State Univ., Tempe, AZ; [5]Louisiana State Univ., Baton Rouge, LA; [6]NeurTex Brain Res. Inst., Dallas, TX

Abstract: Studies using fMRI have found that activity in the hippocampal region during encoding is higher for subsequently remembered stimuli compared to subsequently forgotten stimuli. It is generally supposed that memory-related activity during encoding is driven by the presentation of the to-be-remembered stimulus. However, another possibility is that activity immediately preceding stimulus onset substantially pre-determines the memory-related activity that occurs during stimulus presentation. If so, then *pre-stimulus* encoding activity might differ for subsequently remembered vs. forgotten items. To test this possibility, single neuron activity was recorded from intracranial microwires implanted in 30 epileptic patients while they performed a continuous recognition memory task. The task consisted of the auditory presentation of 300 words that were each repeated once at lags ranging from 0 to 32 intervening words (600

word presentations in all), and the patients had to decide whether each word was novel or repeated by pressing a key. Activity in left hippocampus was measured 1000 to 200 ms before word onset (i.e., before encoding) and 200 to 1000 ms after word onset (i.e., during encoding). Pre-stimulus activity for words later correctly judged as repeated (hits) was higher than pre-stimulus activity for words later incorrectly judged as novel (misses). In addition, across participants, the magnitude of this difference in pre-stimulus activity correlated with the overall ability to discriminate between repeated and novel words (i.e., *d'*). Activity measured 200 to 1000 ms after the onset of novel words yielded a similar pattern. The results suggest that activity in the hippocampus prior to stimulus presentation partially determines how well it will be encoded and subsequently remembered.

Title: Single-neuron phase coding of novelty in the human hippocampus

Authors: *J. MILLER[1], P. N. STEINMETZ[2], J. JACOBS[1];
[1]Dept. of Biomed. Engin., Columbia Univ., New York, NY; [2]NeurTex Brain Res. Inst., Dallas, TX

Abstract: From studies of patients with lesions, we have obtained strong evidence that the hippocampus is important for episodic memory. However, we do not have a detailed understanding of the specific patterns of neuronal activity in this structure that are used by humans and animals to differentiate and represent individual memories. To examine the electrophysiology of memory encoding in the human hippocampus, we recorded single-neuron activity from neurosurgical patients as they performed a verbal episodic memory task. We compared the rate and timing of individual neuronal activations between timepoints when subjects viewed old vs. new items to characterize the neural code for memory novelty in the hippocampus. As in previous work, we found some individual neurons increased their overall firing rates when subjects viewed novel stimuli. In addition, by examining the temporal relation between individual action potentials and network field potential oscillations, we found a new form of temporal coding for memory novelty. The spiking of individual neurons was phase locked to hippocampal oscillations in the 1-4-Hz “slow theta” band, and the precision of this

phase locking significantly increased when subjects viewed novel stimuli. This suggests that the hippocampus exhibits a temporal code for memory novelty based on phase coupling of individual neurons to network oscillations. By demonstrating that the hippocampal code for memory involves changes in spike timing in addition to changes in mean spike rate, it suggests that separate phases of network oscillations have distinct functional roles with regard to memory novelty.

Title: Behavioural discrimination for gist of everyday scenes

Authors: *N. V. HOANG, F. N. AHMAD, M. MOSCOVITCH;
Rotman Res. Inst., Toronto, ON, Canada

Abstract: Behavioural discrimination between repeated and similar items is assumed to rely on a neural mechanism known as pattern separation. Pattern separation has been assessed in humans by the Mnemonic Similarity Task (MST), which measures recognition memory at test for previously presented items (targets), lures that are similar to targets, and novel items (foils) (Bakker et al., 2008). This study adapted the MST to measure if difficulty in lure discrimination at retrieval, as observed in the MST, is maintained when multiple exemplars of the same category are presented at both encoding and retrieval. The goal was to investigate if behavioural discrimination is mediated by prior knowledge of exemplars per scene category more so than by 'pattern separation' of overlapping items. Moreover, it is relevant to understand if the behavioural discrimination process is mediated by an individual's recollection (remembering distinct representations) or familiarity (knowing gist-like representations) of the items. Thirty-two undergraduate students studied three exemplars per scene category, and were tested on 24 targets, 24 lures, and 24 foils. Contrary to findings reported by Stark and Stark (2017), there was no significant difference in recognition accuracy between lure and target discrimination. Participants showed higher false recognition to targets than lures. Similarly, target accuracy corresponded to greater recollection of details than familiarity; meanwhile, lure accuracy was more supported by familiarity of gist-like features than recollection. Our findings suggest that in the context of multiple exemplars, behavioural discrimination of exemplars per scene category may rely more on prior knowledge and less on pattern separation.

Title: Organising knowledge for value generalisation

Authors: *M. M. GARVERT[1], N. SCHUCK[2], C. F. DOELLER[1];
[1]MPI for Human Cognitive and Brain Sci., Leipzig, Germany; [2]Max Planck Inst. For Human Develop., Berlin, Germany

Abstract: It has been suggested that the brain organises spatial and non-spatial information in a cognitive map. Such a representation of events and knowledge may facilitate goal-directed behaviour by enabling the generalisation of information across related states. Here, we combine a novel virtual reality task with computational modeling to investigate whether humans infer stimulus-reward associations that were never directly experienced based on learned knowledge about the relationships between stimuli in space. In this task, the spatial position of stimuli learned on day 1 predict rewards in a decision making task on day 2. We find that updates of stimulus-reward associations in the decision making task go beyond directly experienced associations and instead spread across stimuli located nearby in the cognitive map, enabling correct decisions even between stimuli whose values have never been directly experienced. Relational knowledge organised in cognitive maps can thus be used to extrapolate across related states and thereby facilitate novel inference. In most subjects, this behaviour can be captured well by a Bayesian model, where beliefs about the reward distribution are updated on a trial-by-trial basis. Participants whose choice behaviour can be particularly well captured by the model are also better at inferring values of stimuli they never chose. By including stimuli in the decision making task whose spatial locations are unknown, we further demonstrate that novel stimuli can be integrated into existing cognitive maps if their statistical structure is consistent with previously experienced regularities. Using fMRI, we investigate the neural dynamics underlying the spread of values across cognitive maps in hippocampal-medial prefrontal networks. Together, our novel approach opens up the possibility to connect seemingly disparate fields of spatial coding, learning and decision behaviour.

Title: Integrating knowledge from physical and conceptual spaces

Authors: *D. KUHRT[1], J. L. S. BELLMUND[2,3], R. KAPLAN[1], C. F. DOELLER[2,1];
[1]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway; [2]MPI for Human Cognitive and Brain Sci., Leipzig, Germany; [3]Donders Institute, Radboud Univ., Nijmegen, Netherlands

Abstract: How do we represent knowledge? One intriguing idea is that our knowledge is stored using a spatial representational format: the cognitive map. Studying spatial navigation has shed light on underlying neural mechanisms with recent work suggesting that cognitive map-like coding of physical space might also map conceptual knowledge. Examining how spatial and conceptual information is integrated, we created a two-dimensional conceptual space and a corresponding virtual model of a physical space, where space-defining features such as dimensionality, size, shape and informational content were carefully matched. Testing object-location memory, participants learned to navigate both spaces using identical egocentric controls and successfully created object-location associations. Further, participants were able to transfer knowledge about object positions from one space to the other. We probed object representations in a passive-viewing fMRI task both before and after learning, allowing us to assess the change in representation. We used multivariate pattern analysis to test if neural similarity after training scales with distances between objects and whether this scaling holds for the integrated map of both spaces. Preliminary fMRI analyses have uncovered pattern similarity changes in the hippocampal formation and prefrontal regions following knowledge acquisition in both spaces. Our findings demonstrate a transfer of knowledge between cognitive maps that differ in content, as well as domain. Taken together with findings from a parallel behavioural study using immersive virtual reality, our data highlight potential domain-invariant codes in navigation that transcend physical space and help us navigate our knowledge.

Title: Cognitive map formation through tactile and visual exploration

Authors: *L. OTTINK[1], M. HOOGENDONK[1], T. M. VAN DER GEEST[2], R. J. A. VAN WEZEL[1], C. F. DOELLER[3];
[1]Donders Institute, Radboud Univ., Nijmegen, Netherlands; [2]Hogeschool van Arnhem en Nijmegen, Arnhem, Netherlands; [3]MPI for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: The human brain can form a cognitive map of an environment, which represents spatial information and can support navigation. Most research on this has focused on visual information. In this study, we investigated cognitive mapping of environments presented in a non-visual modality, thereby focusing on tactile information. This may have implications for visually impaired persons, to whom visual information is less available. Blinded and non-blinded sighted participants learned three different tactile maps of a city-like environment in three successive tasks. The maps differed in complexity, and each had five marked locations associated with an item. To assess cognitive map formation after map exploration, participants estimated Euclidean and path distances between item pairs, rebuilt the map, recalled the locations of the items, and navigated two routes. Both blinded and non-blinded participants overall performed well, indicating the formation of accurate cognitive maps. Interestingly, there were smaller differences between the groups than hypothesised. Blinded participants performed worse than non-blinded participants, but only on the more complex maps, suggesting no distinct advantage of the use of vision on the least complex map. Furthermore, there were no significant differences between maps or between the blinded and non-blinded participants for estimations of distances between item pairs. These results suggest that with and without visual information, metrics of a tactilely presented environment are stored in a cognitive map. Interestingly, it furthermore suggests not just memory of explicit information of the map, but storage of, or the ability to infer, implicit spatial information. This is evidence supporting ideas of a modality-independent representation of space. This line of research will be extended to include visually impaired participants, and to additionally focus on the auditory modality. We will assess how spatial information presented in the tactile and auditory modality is integrated into a cognitive map in visually impaired persons, and how this compares to sighted participants. Furthermore, we will use functional magnetic resonance imaging to investigate the influence of presenting environments through these modalities on neural representations of space.

Title: Spatial learning of abstract multimodal concepts

Authors: *L. B. SANDØY[1], J. B. JULIAN[1], L. SOMMER[1], C. F. DOELLER[1,2];
[1]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway; [2]MPI for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: Spatial coding in the hippocampal formation has traditionally been studied in the context of navigation. However, recent studies suggest that the hippocampal formation may mediate a diverse range of cognitive functions beyond navigation, including conceptual learning. The hippocampal formation may be involved in concept learning since concepts often are defined based on a set of continuous feature dimensions, akin to the latitude and longitude of navigational space. Importantly, most real-world concepts are defined based on multimodal features. For example, different citrus fruits can be defined by their color and amount of sweetness, which are derived from visual and gustatory sensory modalities, respectively. Yet, whether the hippocampal formation is involved in learning multimodal concepts is unknown. Our main objective was to develop a multimodal conceptual learning task to investigate hippocampal representations of non-navigational domains. More specifically, are multimodal conceptual spaces represented similarly as navigational cognitive maps?
To address this question, we developed a computer-based multimodal concept learning task using pitch and color to create a two-dimensional continuous concept space. In this task, participants were trained to associate specific pitch/color combinations with distinct symbols. Participants then conducted memory tests for these stimulus-symbol associations using a behavioral task modeled after standard assays of spatial memory during navigation. Preliminary results show that participants were able to successfully maneuver around in this multimodal concept space. The results indicate that participants formed an integrated representation of the multimodal space, beyond simply learning the correct stimulus-symbol associations. Follow-up studies are currently exploring if representations of multimodal space obey the same principles as map-like representations of navigational space, as well as using fMRI to interrogate the role of the hippocampal formation in supporting such representations. Together, this research will reveal

how new concepts are learned, and whether similar processes guide conceptual learning and spatial navigation.

Title: Conceptual relevance in cognitive space

Authors: *S. THEVES[1,2], G. FERNANDEZ[3], C. F. DOELLER[1,4];
[1]MPI for Human Cognitive and Brain Sci., Leipzig, Germany; [2]Donders Institute, Radboud Univ., Nijmegen, Netherlands; [3]Donders Inst., Radboud Univ. Med. Ctr., Nijmegen, Netherlands; [4]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway

Abstract: The hippocampal formation encodes maps of the physical environment and a key question in neuroscience is whether its spatial coding principles also provide a universal metric for the organization of non-spatial, conceptual information. In support of this view, we recently demonstrated that the hippocampus encodes distances between points in an abstract space spanned by continuous stimulus-feature dimensions that were relevant to the acquisition of a novel concept. Here, we further probe whether this distance code reflects a mapping of just any task-relevant, or specifically conceptually-relevant dimensions. During fMRI scanning, we presented every-day objects, which had beforehand been associated with specific values on three abstract dimensions, of which only two were relevant to concept learning. We find that the hippocampal signal is significantly better explained by inter-object distances in a space defined along the conceptually-relevant dimensions as compared to distances in a space defined along all task-relevant dimensions. We further rule out that this result is explained by a difference in complexity between mapping two-dimensional versus three-dimensional information. These findings suggest that the hippocampus supports knowledge acquisition by encoding a combined space along conceptually-relevant dimensions.

Title: Integrating episodic and spatial context signals in the hippocampus

Authors: *A. NITSCH[1,2], N. DE HAAS[2], L. DEUKER[3], C. F. DOELLER[1,4];
[1]MPI for Human Cognitive and Brain Sci., Leipzig, Germany; [2]Donders Institute, Radboud Univ., Nijmegen, Netherlands; [3]Dept. of Neuropsychology, Ruhr-University Bochum, Bochum, Germany; [4]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway

Abstract: Episodic and spatial memory are two major forms of memory. Episodic memory allows remembering events from the past whereas spatial memory allows forming a map-like representation of the environment. Interestingly, these two memory forms are supported by the same brain structure: the hippocampus. However, the exact relationship between episodic and spatial memory processes in the hippocampus still remains unclear. In this study, we test two different models assuming that the hippocampus supports both memory forms either via a parallel processing or a common coding mechanism, respectively. For this purpose, we conducted an fMRI experiment with a life-simulation task and a virtual reality game to manipulate episodic and spatial relations between objects. In the life-simulation task, subjects watched two different stories whereby regular objects were associated with one of the two stories (episodic contexts). In the virtual reality game, subjects delivered objects to stores in two different neighborhoods of a virtual city whereby regular objects were associated with one of the two neighborhoods (spatial contexts). Ultimately, this resulted in a 2 × 2 design with pairs of objects sharing both an episodic and a spatial context, pairs of objects sharing only one (either episodic or spatial) context and pairs of objects sharing no context. We presented all objects in picture viewing tasks to assess overlapping neural representations of objects caused by shared episodic and / or spatial contexts in cross-stimulus adaptation analyses. Preliminary results show differences between adaptation effects for pairs of objects sharing only an episodic or a spatial context as well as a trend of an interaction between episodic and spatial context processing in the hippocampus, characterized by a stronger adaptation effect for pairs of objects sharing both contexts. This indicates that our experimental approach is powerful enough to induce neural similarity between objects sharing episodic and / or spatial contexts in the hippocampus. Furthermore, our preliminary results provide evidence for both models of a parallel processing and a common coding mechanism for episodic and spatial memory in the hippocampus.

London, London, United Kingdom; [5]Open Climate Fix, London, United Kingdom; [6]Deepmind, London, United Kingdom; [7]Max Planck Inst., Leipzig, Germany

Abstract: Decoding provides a way of placing a limit on the information present in a neural population. We used multichannel recordings from hippocampal and additional structures to assess the accuracy with which behaviour can be decoded from the underlying neural activity. Typical decoding algorithms use spike sorted action potentials detected from ongoing neural activity, which potentially introduce selection biases, and methods limited to action potentials inevitably discard the information contained in the local field potential. Here we decode behaviour directly from the wavelet-transformed electrophysiological signals. For this purpose, we developed a novel deep neural network architecture which takes as input the wavelet transformed signal and predicts continuous behaviour. The model consists of stacked two-dimensional convolutional layers with weights shared between channels and time, followed by a fully connected layer. This architecture captures both spatial and temporal information in the signal and is able to successfully decode complex behaviours, outperforming established location-decoding methods, such as a Bayesian decoder, trained on manually sorted spikes. We show that our model generalises across different brain regions and recording techniques, successfully decoding information about position, speed, head direction, and sound frequency from electrode and two-photon calcium imaging data.

Title: Predictive spatiotemporal integration in the human medial temporal lobe

Authors: *I. POLTI[1], M. NAU[1], R. KAPLAN[1], V. VAN WASSENHOVE[2], C. F. DOELLER[3,1];
[1]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway; [2]CEA, DRF/Joliot, NeuroSpin; INSERM, U992, Cognitive Neuroimaging Unit, Univ. Paris-Sud; Univ. Paris-Saclay, Gif Sur Yvette, France; [3]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: Converging evidence from single-unit recordings in non-human primates and human functional MRI (fMRI) suggests that the medial temporal lobe maintains a cognitive map of visual space. Entorhinal grid cells are one critical component of the cognitive map, and are thought to support vector computations. On the population level, grid cells putatively give rise to a six-fold rotationally symmetric (hexadirectional) fMRI signal. In parallel, the hippocampal-entorhinal circuit and the striatum have been implicated in temporal processing, feedback learning, and the representation of future states. Here, we combined fMRI with a tightly-controlled time-to-contact (TTC) estimation task. We examined activity in the hippocampal formation as a function of behavioral performance and feedback. Participants fixated on a dot that moved on linear trajectories at different speeds within a circular boundary. Whenever the dot stopped moving, participants extrapolated its trajectory and speed, ultimately pressing a button when the dot would have hit the boundary if it continued moving. This design allowed us to examine TTC estimates as a function of gaze direction for a variety of motion speeds. We found that behavioral precision and accuracy were modulated by temporal context and that activity in the hippocampal-entorhinal circuit and the striatum reflected feedback valence. We further examine how hippocampal-entorhinal and neocortical trial-by-trial activity and hexadirectional signals relate to behavioral performance in this task. Our approach provides new insights into how space and time are processed dynamically across the visual field and sheds new light on how the hippocampal formation guides human behavior.

Title: Does hippocampal volume and/or tissue microstructure explain performance differences on hippocampal-dependent tasks?

Authors: *I. A. CLARK[1], A. M. MONK[1], V. HOTCHIN[1], G. PIZZAMIGLIO[1], A. LIEFGREEN[1], N. WEISKOPF[2], M. F. CALLAGHAN[1], E. A. MAGUIRE[1];
[1]Wellcome Ctr. for Human Neuroimaging, Univ. Col. London, London, United Kingdom; [2]Dept. of Neurophysics, Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: The imagination of scenes, autobiographical memory, future thinking and spatial navigation are four cognitive functions known to be hippocampal-dependent. Marked differences exist across healthy individuals in their performance on tasks assessing these functions, but clear reasons for this variability are lacking. Task performance may be related to hippocampal structure. For example, damage to the hippocampi impairs these four cognitive functions, and healthy individuals with extreme navigation expertise (London taxi drivers) have increased posterior hippocampal grey matter volume. However, only a few studies have interrogated the relationship between hippocampal volume and these four cognitive functions in the general population, mostly focusing on autobiographical memory and navigation. Results have been mixed, and may have been influenced by relatively small sample sizes. Extant studies have also predominantly concentrated on hippocampal volume, but advances in neuroimaging techniques now permit examination of tissue microstructure in the form of myelination and iron biomarkers. Here, we investigated whether performance on scene imagination, autobiographical memory, future thinking and spatial navigation tasks was related to hippocampal volume and/or tissue microstructure. Behavioural and whole brain structural MRI data (0.8mm isotropic quantitative multi-parameter maps) were collected from 217 healthy male and female human participants aged between 20-41 years. Grey matter volume was assessed using voxel-based morphometry, and tissue microstructure using voxel-based quantification. Neither hippocampal grey matter volume nor tissue microstructure was related to overall scene imagination, autobiographical memory or future thinking performance, even at liberal statistical thresholds. There was also no significant correlation with a composite navigation measure. However, performance on a navigation subtask specifically assessing route knowledge was positively associated with anterior hippocampal grey matter volume. Overall, therefore, in this relatively large sample of young,

healthy participants, with a wide variance of performance on the hippocampal-dependent tasks of interest, neither hippocampal volume nor tissue microstructure could explain individual differences. We conclude that a healthy adult hippocampus likely has sufficient capacity for even the best performance on scene construction, autobiographical memory, future thinking and most spatial navigation tasks. It may be only in extreme situations, such as London taxi drivers, that the hippocampus exhibits measurable structural changes.

Neurosciences, Univ. of Oxford, Oxford, United Kingdom

Abstract: Sleep and dreaming have each been posited to play a role in memory processing and consolidation. Intact hippocampi are essential for the proper functioning of memory, and yet little is known about how hippocampal lesions affect sleep and dreaming.
Here, we examined male human patients with focal bilateral hippocampal damage and matched healthy control participants in order to investigate the specific contributions of the hippocampus to sleep physiology and the frequency and content of dreams.
We characterised sleep phenotype by performing in-home polysomnography on three nights. Despite similar sleep efficiency, total sleep time, sleep onset, and sleep fragmentation, the patients spent significantly less time in slow wave sleep (SWS, also known as N3 sleep) compared to the control participants. By contrast, N1, N2, and REM sleep were comparable between the groups. The lack of SWS in the patients was further confirmed by a data-driven

approach, independent of sleep staging, which showed a similar significant decrease of delta band power in the EEG (1.8–4.0 Hz), the hallmark of SWS. We also scrutinized N2 sleep for features that might presage the decrease in SWS sleep, including slow oscillations (0.5–1 Hz), slow (9–12 Hz) and fast (12–15 Hz) spindles, and the coupling of slow oscillations and fast spindles. We found no differences between the patients and their controls on any of these measures.
We assessed dreaming during a separate night of sleep using a provoked awakening protocol. This involved participants being woken up at various times, including in non-REM and REM sleep. Despite being roused a similar number of times, patients had significantly fewer dreams compared to the controls. Moreover, when patients reported dreams, they were significantly less vivid, detailed, and episodic-like compared to those of the control participants.
SWS sleep in particular has been linked with the offline consolidation of recently-formed memories. The near-absence of SWS in the patients, coupled with their less frequent and impoverished dreams, leaves them bereft of two key features that are known to be important for memory processing. Overall, these results serve to highlight that vital sleep functions depend on hippocampal integrity.

Title: Are scenes the smallest units of events? Evidence from hippocampal and vmPFC oscillatory dynamics

Authors: *A. M. MONK, D. N. BARRY, V. LITVAK, G. R. BARNES, E. A. MAGUIRE; Wellcome Ctr. For Human Neuroimaging, UCL, London, United Kingdom

Abstract: Our lived experience comprises a series of ongoing contiguous events. This allows us to construct a coherent autobiography, imbuing our lives with a sense of continuity, and a capacity to recall experiences even when the original events occurred many decades ago. How the brain achieves this monumental feat is a central question in neuroscience. In this experiment, we sought to understand how such events are built by the human brain, and in particular the roles

played by the hippocampus and ventromedial prefrontal cortex (vmPFC). We also tested the hypothesis that scene imagery is central to the representation of events, given the extant literature showing that the anterior hippocampus and vmPFC are involved in constructing such imagery. We leveraged the high temporal resolution of magnetoencephalography to examine oscillatory dynamics in twenty one healthy female and male participants while they watched simple movie clips built from individual frames that either depicted the evolution of events comprised of scenes, or events composed of non-scenes (abstract patterns). In both cases, the movie clips created a sense of an unfolding event over time, as small changes in the stimuli image-to-image showed the progression of an activity. We performed analyses of power in source space, inter-regional coherence and effective connectivity.

Unfolding scene and non-scene events resulted in low frequency power changes in the hippocampus and vmPFC relative to non-event stimuli. However, there was higher coherence between activity in the anterior hippocampus and vmPFC during events built from scenes and, by contrast, higher coherence between the posterior hippocampus and vmPFC during events built from patterns. Dynamic causal modelling of scene-based events revealed the vmPFC drove oscillatory activity in the anterior hippocampus, whereas during non-scene events the posterior hippocampus drove activity in the vmPFC.

These results extend previous findings by showing that not only do the anterior hippocampus and vmPFC support the construction of single scenes, but that unfolding events built from scenes are also supported by these regions, where the vmPFC exerts a driving influence. This aligns with perspectives that propose the vmPFC guides the construction of scene and event representations in the hippocampus.

Title: Imaging the human hippocampus in real-world contexts using wearable MEG

Authors: *D. N. BARRY[1], T. M. TIERNEY[1], S. MELLOR[1], R. BOWTELL[2], M. J. BROOKES[2], G. R. BARNES[1], E. A. MAGUIRE[1];

Abstract: During conventional human neuroimaging, such as magnetoencephalography (MEG), participants must remain still with their heads immobilised in order to avoid compromising the localisation of brain activity. This imposes substantial limitations on the types of cognitive paradigms that can be deployed. However, the development of optically-pumped (OP) magnetometers represents a significant evolution of MEG technology.
OP-MEG does not require cryogenic cooling, and so the sensors can be placed directly on the scalp. The resulting proximity to the brain increases the magnitude of the measured signal. However, the most significant advance associated with OP-MEG is the capacity for participant movement. OPM sensors can be mounted on a scanner-cast moulded specifically to a participant's head, allowing the person to move freely when combined with an innovative approach to nulling the magnetic field surrounding a participant. The potential, therefore, exists to study more complex behaviours in which movement plays an integral part. For example, spatial navigation in a naturalistic setting involves changes in head direction and coordinated body movements.
To fully leverage the wearability of OP-MEG in such a real-world domain, one must be able to detect signals from deeply-located brain structures upon which behaviours like navigation depend, such as the hippocampus. Consequently, as a proof of principle, we first had healthy male and female participants perform a hippocampal-dependent task - the imagination of novel scene imagery - while being scanned using OP-MEG. We found that task-related modulation of theta power in the medial temporal lobe was observable, with a peak in the anterior hippocampus. We then proceeded to show that it is possible to examine head direction signals while participants move their heads naturalistically, including the concomitant vestibular inputs that are typically absent from standard MEG and fMRI studies.
We conclude that OP-MEG heralds exciting new opportunities for investigating the neural correlates of a range of crucial cognitive functions in real-world contexts that have hitherto eluded conventional neuroimaging methods.

Title: Neural correlates of recognition memory in the human visual ventral stream

Authors: *N. M. DE LA ROSA-RIVERA[1], K. LEGER[2], N. BLAUCH[3], R. A. COWELL[4]; [1]Univ. of Massachusetts Amherst, Amherst, MA; [2]Brandeis Univ., Waltham, NH; [3]Ctr. for the Neural Basis of Cognition, Carnegie Mellon Univ., Pittsburgh, PA; [4]Psychological and Brain Sci., Univ. of Massachusetts, Amherst, MA

Abstract: Long-term declarative memory has traditionally been tied to the medial temporal lobe (MTL). An important question is whether such memory can be supported by regions outside MTL under certain circumstances? Representational accounts of cognition hold that memory for an item is supported by whichever brain region best represents that item. One theory, the Representational-Hierarchical Account, claims that representations are organized in a hierarchy extending from simple features in visual cortex, through conjunctions of features in temporal cortex, to high-dimensional associative representations of events in hippocampus. This theory makes two predictions. First, memory for simple stimuli should be computed outside of MTL, in visual cortex. Second, cortical sites supporting memory discrimination should map onto the sites containing the representations most useful for the memory task. If to-be-remembered items are objects comprising conjunctions of visual features (color, shape), then cortical regions supporting memory for the particular conjunctions should be those containing a conjunction code, whereas regions supporting memory for the features should be those containing a feature code.

We conducted an fMRI study to measure 1) the neural code elicited by visual stimuli and 2) the neural correlates of remembering those stimuli. Stimuli were abstract objects defined by conjunctions of color, shape and spatial frequency. In the study phase, participants viewed 24 stimuli 20 times each. In the test phase, subjects saw 3 item types: studied, novel (entirely novel features) and recombined (novel conjunctions of familiar features, created by recombining features of studied objects). At test, subjects responded “familiar”, “novel” or “recombined”. We measured the neural code elicited in the study phase using a multi-variate technique that first assesses feature information and conjunction information, then pits these against each other to ask whether a region is biased toward a feature code or a conjunction code. We predict that regions containing a feature code (in the study phase) should provide the best signal for remembering novel features (in the test phase), which we assess by contrasting “recombined” with “novel” items. Conversely, regions containing a conjunction code should provide the best signal for remembering novel conjunctions, assessed by contrasting “familiar” with “recombined”. Results in 3 subjects suggest a transition from feature-coding in V1 to conjunction-coding in V3, and neural correlates of mnemonic discrimination in visual cortex. Thus the paradigm is suitable for addressing the key questions in a larger sample size.

Title: Induced plasticity caused by regular and targeted mnemonic discrimination training: An fMRI approach

Authors: *J. GÜSTEN[1,2], D. BERRON[1,2,3], E. DÜZEL[1,2,4];
[1]Inst. Cognitive Neurol. and Dementia Res., Magdeburg, Germany; [2]German Ctr. for Neurodegenerative Dis., Magdeburg, Germany; [3]Clin. Memory Res. Unit, Dept. of Clin. Sci. Malmö, Lund Univ., Lund, Sweden; [4]Inst. of Cognitive Neuroscience, Univ. Col. London, London, United Kingdom

Abstract: With an increasingly ageing population, the possibility to improve or preserve cognitive function throughout life via training interventions has become a popular focus of research. When looking at transfer effects of cognitive training, the complexity of earlier training regimes makes it difficult to pin down those features underlying the training-related gains (Karbach, 2014). While using highly targeted paradigms may restrict the probability of transfer to other domains, understanding the precise pattern and mechanisms of transfer might be more important for theoretical advances than generality of transfer (Lövden et al., 2010). In the present training study, we were interested in studying patterns of transfer caused by highly specific mnemonic discrimination training, an ability that typically decreases with age (Stark, Yassa, Lacy, & Stark, 2013). Fourty young participants (age range 18-30 years) performed a web-based object-scene mnemonic discrimination task (Berron et al., 2018), three times a week, for two weeks in a row. Each training session lasted around 60 minutes. During the task, participants saw blocks of object and scene images and had to indicate whether a stimulus was repeated identically (repeat) or presented in a similar version (lure) via button presses. In contrast to the original task, object and scene blocks were presented in a 6-back instead of 2-back task design. In a control task focused on processing speed and change detection, half of the participants had to identify moving targets on the screen by clicking them. Before and after training, whole-brain functional and structural MRI data was acquired using a 3T MAGNETOM Skyra fit scanner. This included a task-based fMRI session using the original object-scene mnemonic discrimination task. As expected, the training group showed significantly increased task performance compared to the control group. Given that the task is thought to rely on pattern separation (PS), we hypothesized to find group by timepoint interactions of PS-related activity along the two processing streams involved in object and scene memory, including the MTL subregions. First, we expected a change in the univariate measure of repetition suppression. Second, we performed an encoding-retrieval similarity analysis (ERS), hypothesizing that

multivariate activation patterns become more distinct in those regions involved in the task. The present study provides important insights on adaptation patterns emerging from highly targeted mnemonic discrimination training. These could yield a more mechanistic understanding of potential transfer effects of memory training interventions in the future.

Title: Behavior-dependent directional tuning in the human navigation network

Authors: *M. NAU[1], T. NAVARRO SCHRÖDER[1], M. FREY[1], C. F. DOELLER[2];
[1]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway; [2]MPI for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: Human scene-processing and navigation regions have been extensively studied, yet the relationship between their neural tuning and active spatial behavior remains poorly understood. We leveraged 7T-fMRI to monitor human brain activity at sub-millimeter resolution while participants navigated a virtual reality environment and performed an object location memory task. We used voxel-wise encoding modeling of the navigation behavior to predict each voxel's time course to map position-invariant directional tuning across the cortex. By iterating through multiple basis sets of directional kernels, we also estimated the corresponding tuning width of each voxel. Our approach revealed a narrow-to-broad topography of directional tuning from posterior to anterior parahippocampal cortex as well as distinct tuning curves in visual, retrosplenial and entorhinal (EC) cortices. Next, we asked whether and how the estimated tuning curves reflect different mnemonic and behavioral states. While tuning strength, but not tuning width, of the posteromedial EC reflected how well participant performed in the spatial memory task, the opposite pattern could be observed in the retrosplenial cortex. A whole-brain analysis confirmed these results and demonstrated behavior-dependent directional tuning in a brain network including occipital, medioparietal and mediotemporal regions. Directional representations were stronger in visual and retrosplenial cortex during locomotion and stronger in parahippocampus and hippocampus when standing still. Our approach demonstrates the feasibility of using encoding models to study neural tuning during naturalistic behavior and sheds new light on the relationship between mnemonic performance, behavioral states and directional tuning in the human brain.

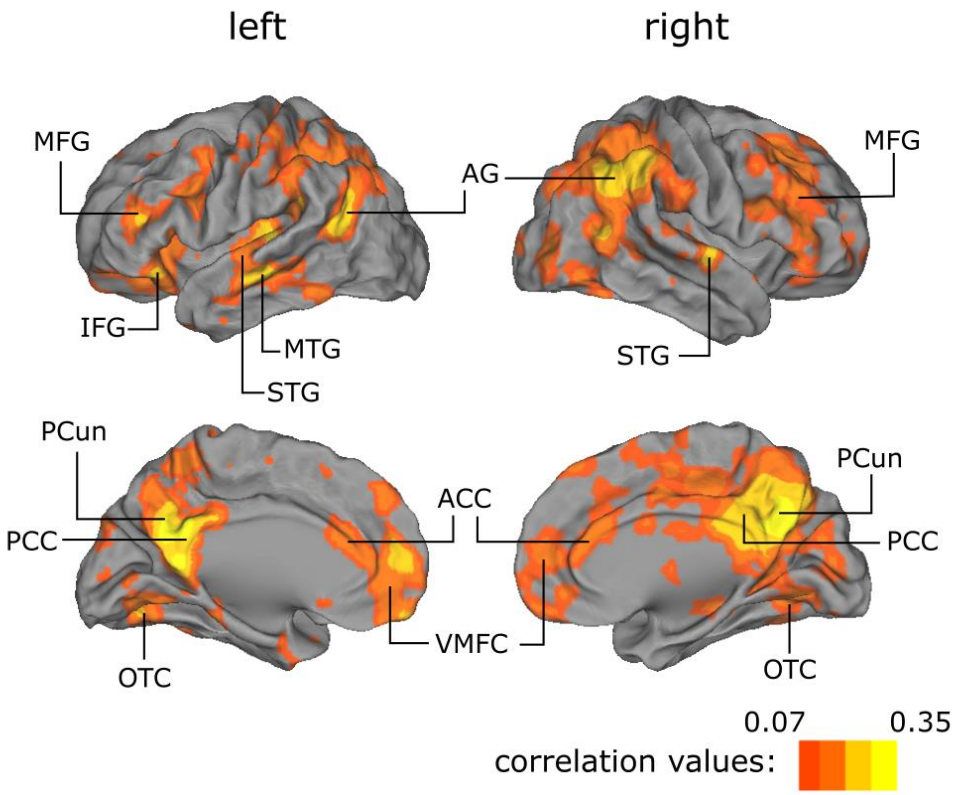
Abstract: The interpretation of an identical narrative varies between listeners, because of differences in their life histories. We studied whether we can also find differences in listeners' brain activity. We recruited 48 healthy volunteers, fluent in Finnish. Half of the subjects had both parents with Finnish cultural background. For the other half, either one or both parents had Russian cultural background. The subjects listened to a 71-min narrative during ultra-fast fMRI. The narrative told a story of two protagonists, one with a Finnish and the other with a Russian background. Afterward, the narrative was replayed in 101 segments, and the subjects were asked to produce associations related to each segment to describe what had been on their minds while they had heard the story in the scanner. Between-subject similarities of brain hemodynamic activity were estimated using inter-subject correlation analysis. The similarity in how the narrative was interpreted was estimated by comparing the semantic relatedness of the associated words between each pair of subjects in a semantic space (Word2Vec) generated from a large internet text corpus. An intersubject representational similarity analysis (RSA) between the BOLD-similarities and the semantic similarities of the associated words across the subjects revealed that the more semantically similar words two subject associated the more similar also were their BOLD responses in the temporal (superior temporal gyrus, middle temporal gyrus) and frontal cortices (medial frontal gyrus, left inferior frontal gyrus) as well as in regions associated with the default mode network. Our results suggest that multiple brain areas of the narrative processing hierarchy support the elicitation of individual narrative interpretations.



Brain areas where the similarity in the narrative interpretation between subjects correlated with BOLD-similarity between subjects (q<0.05, FDR corrected at the cluster level with 5000 permutations).

Abstract: The ability to encode the complex spectrotemporal features of speech sounds from birth is capital to acquire the phonetic repertoire during the first months of life. Previous studies with infants suggest the encoding of voice pitch variations and vowel formants structure to take place at different stages of infant development. However, no previous study has investigated the ability to encode simultaneously both elements of speech in newborns. We use the frequency-following response (FFR) to reveal the neural tracking accuracy of F0 and formant structure in a sample of healthy newborns (N=17; gestational age 37-42 wk; 6 males) compared to adults (N=14; mean age 26 yr; 4 males). FFRs were recorded to 4000 presentations (alternating polarities) of a single two-vowels (/oa/) 250 ms-long stimulus with a rising pitch ending (F0=113 Hz from 0 to 160 ms, then rising up to 152 Hz; /o/ from 10-80 ms, F1=452 Hz, F2=791 Hz; /a/ from 90-250 ms, F1=678 Hz, F2=1017 Hz). FFR to alternating polarities were averaged together to emphasize F0 encoding, and analyzed separately for steady (10-160 ms) and rising (160-250 ms) segments. They were also subtracted to isolate the encoding of fine structure for the /o/ (10-80 ms) and /a/ (90-160 ms) steady pitch segments. F0 encoding was similar in newborns and adults as revealed by similar SNR of the F0 spectral amplitude ($t[29]=-0.43$, $p=0.67$) and pitch strength retrieved from the autocorrelogram ($F[1,58]=2.245$, $p=0.139$). Pitch tracking was less robust during the rising segment ($F[1,58]=24.362$, $p<1e-4$), but similar across groups. In contrast, the encoding of the format structure yielded significant differences across groups, as revealed by ANOVA with the factors group ($F[1,58]=7.482$, $p=0.008$) and vowel ($F[1,58]=21.517$, $p<0.0001$), as well as their interaction ($f[1,58]=4.279$, $p=0.043$). Post-hoc analyses revealed that the encoding of the first formant differed across vowels only in adults, and that the spectral amplitude of F1 for the /a/ (at 678 Hz) was larger in adults than in newborns, with no differences for the /o/ (at 452 Hz) across groups. Together, these results indicate that the encoding of voice pitch is fully functional already at birth but that some aspects of fine structure encoding develop later.

Title: Cortical tracking of words during natural story comprehension

Authors: C. LUO[1], ***J. ZOU**[2], N. DING[3];
[2]Col. of Biomed. Engin. and Instrument Sci., [1]Zhejiang Univ., Zhejiang, China; [3]Zhejiang Univ., Hangzhou, China

Abstract: During speech comprehension, the brain decodes meaning based on the acoustic features of speech. Words are primary units of meaning and a crucial step of speech comprehension is to segment a continuous speech stream into discrete words. Finding the boundaries between words is not a trivial task, which relies on not only auditory analysis but also linguistic knowledge. Previous studies have found that, when listening to speech, low-frequency cortical activity can track multi-syllabic words even when the word boundaries are not conveyed by acoustic cues. These results suggest that the brain can apply linguistic knowledge to group syllables into multi-syllabic words. Nevertheless, these results are obtained when listening to either word lists or lists of unrelated sentences. Whether low-frequency cortical activity can track multi-syllabic words during more natural speech comprehension remains unclear. Here we constructed short stories in which all words are bisyllabic words and recorded neural responses to these stories using electroencephalography (EEG). The only task of the listeners is to answer comprehension questions after each story. We found that EEG responses of the listeners concurrently tracked both syllables and bisyllabic words. These results demonstrated that the brain groups syllables into words during natural story perception and this process is reflected by word-rate neural entrainment.

Title: What happens in the cerebral cortex when one says 'uh' or 'um'?

Authors: *Z. ALQATAN[1], A. SUGIURA[2], Y. NAKAI[4], T. KAMBARA[5], B. H. SILVERSTEIN[3], E. ASANO[6];
[1]Wayne State Univ. Sch. of Med., Detroit, MI; [2]Dept. of Pediatrics, Children's Hosp. of Michigan, [3]Translational Neurosci. Program, Wayne State Univ., Detroit, MI; [4]Dept. of Neurolog. Surgery, Rochester Hills, MI; [5]Dept. of Psychology, Grad. Sch. of Education,

Hiroshima Univ., Higashihiroshima-Shi, Japan; [6]Pediatric Neurol., Children's Hosp. Michigan, Wayne State Univ., Detroit, MI

Abstract: Previous studies have illuminated the neural basis of formation and overt production of sentences during conversation. There are common utterances, however, called “filler words” that interrupt the flow of a sentence. Filler words are typically words or sounds like ‘uh’ or ‘hm’ that signify the speaker’s hesitation and intention of finishing the sentence. We determined how the spatiotemporal dynamics of neural modulations differ between overt utterance of filler and normal phrases, by measuring event-related high-gamma activity at 70-110 Hz during extraoperative electrocorticography recordings. Three patients were presented with images of scenes and instructed to describe who was depicted in the image, what they were doing, at what time, and where. Naturally occurring filler words and normal phrases were tagged at the beginning and end of vocalization. Time-frequency spectral analysis, using a complex demodulation method, was conducted time-locked to the onsets and offsets of phrases. The data showed that filler phrases were specifically associated with high-gamma augmentation in dorsolateral prefrontal regions including the middle-frontal and inferior-frontal gyri on either hemisphere. The right lingual cortex showed high-gamma attenuation specifically during utterance of filler phrases. The precentral and superior-temporal gyri showed high-gamma augmentation commonly during utterance of filler and normal phrases. During spontaneous filler word utterances, the human brain may activate dorsolateral prefrontal regions which support the search for an optimal phrase to be verbalized next, while suppressing lower-order visual processing.

Title: Brain networks for speech understanding and mathematics computation - Evidence from task-evoked and tak-free BOLD activity

Authors: *S. GENG[1], M. ZHU[2], Y. LIU[1];
[1]Beijing Normal Univ., Beijing, China; [2]State Key Lab. of Cognitive Neurosci. and, Beijing, China

Abstract: Previous studies have suggested that brain activities for language comprehension and mathematical computation are some overlapped but also different. The present study aims to

directly compare these two key characteristics achieved early in life and happens very often in our brains. Distinct from most of previous studies, the data from three modalities - task-induced BOLD response, resting-state brain functional connectivity (RSFC) and behavioral performance of 78 participants from the Human Connectome Project (HCP) database, were jointly analyzed in present study. As expected, the differences between language and mathematics network are consistently observed in both task-evoked BOLD response and RSFC, which means that the language network including bilateral superior temporal gyrus, sulcus temporal gyrus, middle temporal cortex, and left angular gyrus, and inferior frontal gyrus, whereas math network covering bilateral inferior parietal lobule, intraparietal sulcus, precuneus, supplementary motor area, and middle and superior frontal gyrus. Further, the ROI-based hierarchical networks from RSFC showed differentiated correlations with the task-induced networks, which means the lower level networks are more similar, and the higher ones are different on story and math. In addition, we also observed that the correlation between the RSFC and the task-induced BOLD activity varied with their behavioral performance. To sum up, the brain networks for speech understanding and arithmetic computation are distinct on both task-induced and task-free brain activity, and some inherent coherences are observable on task-based, task-free resting state BOLD activity and human's behaviors.

Title: Characterization of cortical correlates of syntax structures

Authors: ***S. MICERA**[1], F. ARTONI[2], I. SARTORI[3], G. LO RUSSO[3], S. F. CAPPA[4], A. MORO[4], E. CATRICALA'[4], F. BOTTONI[5];

Abstract: Syntax is the universal set principles and combinatorial operations that pairs sound and meaning generating the potentially infinite set of sentences in any human language. Despite the success in defining its formal structure, little is known of the computational mechanisms underlying syntax at the neuronal level. Crucially, in order to provide an electrophysiological characterization of the basic syntactic structures, such as "noun phrases" (NPs) and "verb

phrases" (VPs), syntactic information must be disentangled from the acoustic support. Italian syntax provides a particularly felicitous set of data which could be used to approach this goal. Here, we investigated the electrophysiological correlates of these basic syntactic structures by using stereo-electroencephalography (SEEG), an invasive technique which allows a precise localization of cortical activation. Seventeen subjects undergoing SEEG implantation for the treatment of refractory epilepsy were enrolled in the study. We used a purposely designed protocol able to factor out acoustic information by construing pairs of phrases that have exactly the same acoustic content but that are interpreted as NPs, or "verb phrases" VPs depending on their syntactic context (homophonous phrases).Several contacts exhibited significant high gamma (150Hz - 300Hz) event related spectral perturbation (ERSP) increase during the hearing of the homophonous phrases with respect to both the baseline and the other strings of words. Moreover, responsive contacts that also exhibited a significantly different response according to whether the phrase were VPs or NPs were present in several cortical areas and no localization of the specific activity was identifiable. This suggests that syntax, at least when explored from an electrophysiological point of view, appears to be a much more integrated brain activity than expected, although language impairment may clearly be caused by focalised lesions in crucial hubs of the overall network as traditionally identified by clinical studies. Our findings pave the way for a deeper understanding of the electrophysiological mechanisms of syntax.

Title: The neural basis of program comprehension

Authors: *A. A. IVANOVA[1], S. SRIKANT[1], Y. SUEOKA[1], U.-M. O'REILLY[1], E. FEDORENKO[1,2];
[1]MIT, Cambridge, MA; [2]MGH, Charlestown, MA

Abstract: Computer programming is a novel cognitive tool that is gaining prominence in modern society. However, little is known about the neural systems that support this skill. Here, we test the involvement of two candidate brain networks in program comprehension: the language system and the multiple demand system. Participants (N=25) underwent an fMRI experiment during which they read snippets of Python code and had to predict their output upon

execution. The control condition involved reading short paragraphs of text describing similar problems and predicting the result. We find that the language system responds to both code problems and text-based problems; however, its response to code is primarily driven by frontal regions (lying within inferior frontal and middle frontal gyri) and not by temporal regions. The multiple demand system also responds to both code and text, with stronger responses observed for code. These results indicate that program comprehension and language comprehension share partially overlapping neural substrates and that program comprehension additionally recruits the multiple demand system. In sum, our work establishes programming as a novel domain for studying cognitive processing within the human brain and suggests that this cognitive skill might make use of both language-specific and domain-general neural systems.

Title: Politeness in the oral complaints: Pauses and neural indicators during speech in English (L1/L2), Spanish (L1/L2) and heritage Spanish

Authors: *N. ENRIQUEZ[1], J. L. CONTRERAS-VIDAL[2], L. DIAZ[3];
[2]Electrical and Computer Engin., [1]Univ. of Houston, Houston, TX; [3]Univ. Pompeu Fabra, Barcelona, Spain

Abstract: We present a study on processing problem indicators in oral production in both Spanish and English in a simulated complaint task. Subjects are native English, native Spanish and heritage Spanish speakers. The aim was to describe the role of speech pauses as problem

processing indicators in oral production as a communication strategy and their differences between groups of speakers and the language used in the simulation.
Hypotheses: i) pauses are different quantitative and qualitatively depending on the speaker's competence; ii) results for heritage speakers will be closer to L1 group than to L2; iii) cognitive load will be higher using a second language and iv) pragmatic and cultural aspects do play a role in the amount and type of pauses in each language.
In order to test these hypotheses, we gathered two different corpora. Recla/SP (10050 tokens) which consists of a sample of 30 dialogues in Spanish (10 native, 10 heritage and 10 non-native) and Recla/EN (9270 tokens) which contains 30 dialogues in English (10 native, 10 heritage and 10 non-native).
We report preliminary findings on EEG data (32 channels, 500 Hz) during oral production. The bandpower in EEG data during 36 speech pauses was compared to baseline, where the subjects relaxed and looked at a blank paper in front of them for 1 min. The data was preprocessed by using the H-inf filter to remove eye-related artifacts, band-pass filtering the signal between 0.3 and 50 Hz, using the PREP pipeline for robust re-referencing, and ASR for removal of artefactual power bursts. At the onset of the speech pauses we found statistically significant ($p<0.01$) modulation in the left frontal areas for the delta band (1-4Hz), and activation of central-left regions in the alpha (8-12 Hz) and gamma (30-50 Hz) bands. The pattern was found both in English and Spanish speech production, with pre-frontal bandpower deactivation in the English task.
Linguistic data confirms the role of pauses as indicators of the difficulty of the task itself and the linguistic difficulty in carrying it out in L2, as stated in hypothesis (i), (ii) and (iii) above. The study also reveals significant differences between native, heritage and non-native speakers, related to hypotheses (i), (ii) and (iv). Specifically, in native speakers, pauses are indicators of difficulty in management decisions, while in non-native speakers pauses indicate difficulties with syntax and verb inflection. Also, as was stated in (ii) results for heritage are closer to L2.

Title: The canonical frequency bands reflect sleep-based memory consolidation of a modified miniature language

Authors: *Z. R. CROSS[1], L. ZOU-WILLIAMS[2], M. KOHLER[4], M. SCHLESEWSKY[2], R. F. HELFRICH[5], G. GASKELL[7], R. T. KNIGHT[6], I. BORNKESSEL-SCHLESEWSKY[3];

Inst., [6]Univ. of California Berkeley, Berkeley, CA; [7]Dept. of Psychology, Univ. of York, York, United Kingdom

Abstract: Language is a prime example of a domain where information is extracted according to statistical dependencies, and which has been shown to be preferentially consolidated during sleep. However, there is limited evidence supporting a link between oscillatory-based models of hippocampal memory consolidation and the learning of sentence-level combinatorics. Here, we report results from an EEG study employing an 8-hour nocturnal sleep period and sentence judgement tasks of a modified miniature language.
36 monolingual English speakers (16 male, mean age=25.4) participated in one of two conditions (Sleep, Wake). Both conditions involved an implicit learning phase, baseline sentence judgement task, followed by either an 8hr sleep opportunity (Sleep, n=18) or an equivalent period of wake (Wake, n=18) and a delayed judgement task. We used non-linear directional cross-frequency coupling analyses to quantify the temporal relationship between NREM slow oscillations (SO) and spindles. We also quantified spectral activity in the θ, α and β bands during sentence judgement tasks. Individual differences in statistical learning ability (SLA) were controlled for. Linear mixed-effects modelling revealed that θ power increased from Baseline to Delayed testing, with this effect more pronounced in the Sleep versus the Wake group, and which predicted greater accuracy on the judgement task ($\chi^2(1)=14.61$, $p<.001$). By contrast, while an increase in α power at Delayed testing predicted better behavioural performance for the Sleep group, the reverse was observed for the Wake group ($\chi^2(1)=10.67$, $p<.001$). An increase in β power predicted higher accuracy ratings, with this effect being more pronounced for the Sleep group at Delayed testing ($\chi^2(1)=25.20$, $p<.001$). Additional models revealed that as the number of SO and spindle coupling events increased with an increase in task-evoked θ power, so did percent of correct responses ($\chi2(1)=33.07$, $p<.001$).
The relationship between task-evoked θ power and improved behavioural performance after sleep may reflect sleep-induced connectivity between the hippocampal complex and neocortex, which is supported by the finding that SO-spindle coupling and increases in task-evoked θ power predicted increased accuracy. Further, while the difference in α power between groups may reflect time-of-day effects, the difference in β power may reflect the propagation of predictions via a hierarchically organized predictive coding architecture that is instantiated by sleep-dependent synaptic downscaling. This predictive coding architecture, strengthened during sleep, likely facilitates the processing of a newly learned language.

Title: Different sources of predictions during natural reading: A co-registration study

Authors: *B. BIANCHI[1], R. LOREDO[2], J. R. CARDEN[2], V. JAICHENCO[2], T. VON DER MALSBURG[4], D. E. SHALOM[3], J. E. KAMIENKOWSKI[1];

Abstract: During reading our brain predicts upcoming words. This predictions, if correct, could speed up the processing of the word when it is finally read. It have been amply shown that Predictability (the variable that estimates the probability of guessing the next word) have an impact on how we move our eyes across the text: more predictable words are fixated for shorter periods of time than less predictable words. Additionally, EEG experiments showed that the amplitude of the N400 potential is modulated by this variable: more predictable words correspond to less N400 amplitude. Classically, EEG experiments were performed avoiding eye-movements, because the muscular contraction interfere with the brain electrical signal. During the last years, helped by the advances in computational power, co-registration experiments, in which eye movements are allow, generated more natural contexts to study such a complex process.
In the present work we analyzed brain potentials during natural reading to address for the sources of predictions. Previously, in independent studies, it was shown that mnemonic predictions (i.e. predictions performed purely on long term memory, like when reading a proverb or a son lyric) and predictions done purely on the linguistic context have different impact, both on gaze duration and on the N400.
Categorical analyses of fixated-word-Predictability showed a N400 effect. A late effect on fixated word is also seen in correlation with the next word Predictability (parafoveal-on-foveal effect). The categorical analysis of the interaction between Predictability and Sentences Type also showed slight differences. Finally, analyses performed using nonparametric cluster based statistics and Linear Mixed Models replicate effects seen in the previous study on fixed gaze.

Title: Electroencephalogram for context retrieval and temporal processing in understanding the implicit intention of a speaker in discourses

Authors: *S. TOKIMOTO[1], N. TOKIMOTO[2];
[1]Mejiro Univ., Tokyo, Japan; [2]Shobi Univ., Saitama, Japan

Abstract: In a daily conversation, a speaker often expresses his/her intention indirectly, and the comprehender understands the speaker's implicit intention by pragmatic inference. For example, we often use an interrogative for asking others to do something ('Can you reach the salt?'). This study examines the relationship between the retrieval of context and the event time in pragmatic inference to understand a speaker's implicit intention in discourses by an experiment recording the 64-channel electroencephalogram (EEG) elicited by Japanese discourses. Twenty native speakers of Japanese participated in the study. We auditorily presented the experimental discourses by three speakers, in which the first speaker introduced a topic, the second asked a yes-no question concerning the topic, and the third answered the question indirectly. The discourses were manipulated in the 2-by-2 manner for context explicitness and event time. That is, (1) Context Explicit or Implicit: We changed one word of the first utterance so that the contexts to derive the spekar's implicit intentions from were given explicitly or implicitly. The second and the third utterances were the same between the two conditions. (2) Past or Future: Whether the third speaker's utterance referred to his/her Past or Future behaviors.
The EEG data were analyzed time-locked to the words in the third utterances at which the implicit answers were drawn out. We observed a significant positive event-related potential (ERP) in the central-parietal region and a significant negative ERP in the occipital region in the time-window of 200-400 ms for Past in Context Implicit condition. We found no significant contrast between Past and Future in Context Explicit and between Context Explicit and Context Implicit in Future. We localized the generators of the ERPs by the dipole fitting of the EEG data and the clustering of the dipoles. Both of the generators of the occipital negativities observed for Past against Future in Context Implicit and for Context Implicit against Context Explicit in Past were localized in precuneus. These localizations in precuneus coincide well with the experimental findings for temporal processing by fMRI and our localization suggests a close

relationship between the retrieval of the context relevant to the implicit intention of a speaker and the taking the subjective time of the speaker.

Title: VWFA resting connectivity in the skilled reading project

Authors: *B. T. CARTER[1], S. G. LUKE[2];
[2]Psychology, [1]Brigham Young Univ., Provo, UT

Abstract: Introduction - The Skilled Reading Project is a study of the neural networks and structure supporting reading behavior in a group of undergraduates at Brigham Young University. Previously this dataset has been used to examine the functional networks associated with linguistic predictability in paragraphs of text. The visual word form area (VWFA) has been shown to associated with reading and functionally coupled with other regions specific to language. This exploratory analysis was conducted to determine which regions were coupled with the VWFA in a group of skilled readers. Methods - Participants underwent T1-weighted structural and $T2^*$-weighted resting MRI. A group structural model was constructed first in the following manner: participant DICOMs were converted into NIFTI files, ACPC aligned, N4 bias field corrections were applied, affine registered and registered to MNI space via the MNI ICBM 2009 Nonlinear Symmetric atlas, then a group template was constructed via ANTs. The following preprocessing steps were taken: the first three TRs were removed, followed by despiking, slice timing alignment, registration to participant anatomy, 4 mm FWHM blur was applied, non-brain intensities were then masked, followed by scaling, and regressing out motion and bandpass filtering. 34 participant datasets survived motion censoring. Seed coordinates were selected based on an automated meta-analysis of 117 studies conducted via Neurosynth (Yarkoni, Poldrack, Nichols, Van Essen, & Wager, 2011). A 5 mm mask was constructed, individual time courses were extracted, correlation maps constructed and converted to Z-maps. A Student's T-test was then applied to determine group level associations. Results - The peak associations were found in the left inferior frontal gyrus, right inferior parietal lobule, right inferior frontal gyrus, right insular cortex, and two peaks in the right orbital frontal gyrus. Conclusion - The functional connection the left inferior frontal gyrus demonstrates that the VWFA is primarily associated with language function in skilled readers. Connectivity with right sided regions may be evidence of increased ability to integrate language processing with higher level cognition. Further investigation is needed to determine the significance of this connectivity.

Title: Modulation of communicative intention through facial expression and its neural correlate

Authors: *J. RASGADO-TOLEDO, M. GIORDANO;
Univ. Nacional Autónoma de México, Queretaro, Mexico

Abstract: Speakers use a variety of contextual media, such as facial emotional expressions for successful transmission of their message. Listeners must decipher the meaning of the verbal message by understanding the intention behind it (Recanati, 1986). A traditional approach to the study of communicative intention has been through speech acts (Escandell, 2006). The objective of the present study is to contribute to the understanding of the influence of facial emotional expression to the recognition of communicative intention in Spanish-speaking, well-educated young adults. The study was divided in several experimental phases. For all phases the CFEE face database was used (Du et al., 2014), and utterances were constructed with neutral emotional valence using NRC Emotion lexicons (Mohammad & Turney, 2010) and LEXMEX corpus to calculate the frequency of use. Phase one evaluated the relationship between begging, demanding, ordering and requesting with basic emotional facial expressions in a sample of 40 participants. Phase two, assessed the compatibility of anger, joy and sadness with sentences that had the linguistic characteristics of a demand, a request and an assertion in 30 participants. In phase three, 40 participants had to categorize a series of affrmative statements as demands, begging or assertions after viewing expressions of anger, joy and sadness. In phase four, the participants solved the behavioral task inside a scanner. We used the same set of stimuli, adding a blur face as a control, and random jittering. In this phase 22 right handed, neurotypical Mexican participants performed the task. A 3 Tesla GE MR750 scanner with a 32-channel head coil was used. 36 slices acquired using a T2* weighted EPI sequence, TR of 2000 and TE of 40 ms, FOV 25.6, with a matrix of 64 x 64 and a 4-mm slice thickness. BOLD signal was examined during the presentation of the sentences, including a regressor for each emotional expression. Analysis was made using Feat in FSL (Smith, et al., 2004). The results of phase one suggested a link between demanding with anger face, and a sad face with the act of begging. Phase two indicated an association between demands with anger, begging with sadness, and happiness with

assertions. Phase three showed that the sentences were categorized differently according to the facial emotional expressions that were presented. The neuroimaging data showed activation of regions involved in language, intentionality and face recognition during presentation of the statements. The results suggest that these areas could contribute to the contextual processing and different speech act categorization according to the emotional face presented.

Title: Modulation of EEG partial directed coherence in creative writing

Authors: *J. G. CRUZ-GARZA[1], A. SUJATHA RAVINDRAN[1], C. RIVERA GARZA[2], J. L. CONTRERAS-VIDAL[1];
[1]Electrical and Computer Engin., [2]Hispanic Studies, Univ. of Houston, Houston, TX

Abstract: With mobile EEG technology, it is now possible to study human neuroscience in context-aware settings where movement and social interaction can occur freely. We used portable dry EEG headsets (four channels: TP09, AF07, AF08, TP10, with reference around Fpz), video cameras, and journal entries, to record the brain activity of bilingual students (English and Spanish) as they participated in an undergraduate creative writing workshop in Spanish over four months. The workshop aimed to develop their creative writing skills by having the students physically experience different locations around the city of Houston and producing creative texts from their bodies' experience. The students (N = 8) recorded their brain activity as they experienced areas in the city (Preparation phase), and as they created the first draft of their creative texts (Generation phase). We used Partial Directed Coherence (PDC) and compared it between the Preparation and Generation phases in their writing process. Higher PDC was found in the Preparation Phase at a significance level of $p < 0.05$, from right temporo-parietal to left anterior frontal areas of the scalp across all frequency bands analyzed: 1-50 Hz. In the Generation phase, we found the opposite directionality PDC in high frequency bands: 13-50 Hz. Information transfer from temporal-parietal to anterior-frontal areas of the scalp during the Preparation phase may be indicative of sensory processing and evaluation. High frequency from the anterior-frontal areas to temporo-parietal areas during the Generation phase may indicate the

consolidation of evaluation and decision making processes, translating them into a creative textual representation of those memories and sensory experiences.

Title: Does it matter how it's written? The effect of misspelled words in sentence reading

Authors: *J. F. QUIÑONEZ-BELTRAN[1], F. R. GÓMEZ VELÁZQUEZ[2], V. D. RUIZ-STOVEL[2];
[1]Lab. de Neurodesarrollo Cognitivo, Univ. De Guadalajara, Guadalajara, Mexico; [2]Lab. de Neurodesarrollo Cognitivo, Univ. de Guadalajara, Guadalajara, Mexico

Abstract: Reading comprehension depends on the integration of words in a sentence. The analysis of each word and the access to the meaning will be determined by the recognition of the word. If we know the word, this will trigger the word identity very rapidly. The process of matching the visual features of the word with the representations stored in our lexicon is automatic. This recognition primarily relies on two characteristics: the orthographic representation and the phonological representation associated to the word. In recent years in Mexico, the importance of spelling has been undermined, originating a popular belief that “it doesn’t matter how a word is written”. But what happens when we find words whose orthographic representations have been altered?
In this study, we aim to determine if misspellings affect the semantic processing of sentences. We designed a semantic decision task with 172 high cloze probability sentences. The sentences consisted of 6 words in which the last word was completed by a) a congruent word, b) a congruent word with a pseudohomophone error, c) a congruent word with a transposed letter error, d) an incongruent word, or e) an incongruent word with a pseudohomophone error. The participants were asked to read the sentences and decide if the sentence was semantically congruent or incongruent regardless of spelling errors. We recorded EEG activity while participants performed the task. As expected, we observed in the ERP results that the semantically incongruent sentences elicited an N400. On the other hand, sentences with spelling errors (pseuohomophone and transposed letter) elicited a P600. These results support the monitoring hypothesis, showing that there is a process of evaluation during language perception when the brain has to decide either to accept or reject a word, and that this could bring the system into a state of indecision that is reflected in electrophysiological activity.

Title: Inhibitory transcranial magnetic stimulation to the left inferior frontal gyrus modulates verbal selection in controlled language tasks in a context dependent manner

Authors: ***J. P. ZIMMERMAN**[1], A. KELKAR[1], D. Y. HARVEY[1], J. D. MEDAGLIA[2], R. H. HAMILTON[1];
[1]Dept. of Neurol., Univ. of Pennsylvania, Philadelphia, PA; [2]Psychology, Drexel Univ., Philadelphia, PA

Abstract: Background: In language production, it is often necessary to select from multiple appropriate competing words to convey intended meaning to listeners. Verbal selection has been strongly linked to processing in the left inferior frontal gyrus (LIFG), however it is unclear how processing in the LIFG differs in cases differing language task demands. Here were apply transcranial magnetic stimulation (TMS) to the LIFG of subjects to modulate performance on two controlled language tasks that differ in their degree of semantic context: verb generation (low semantic context) and sentence completion (high semantic context).
Methods: Thirty healthy right-handed subjects participated in the study. Subjects were randomized to receive either active TMS neuromodulation or sham TMS. TMS neuromodulation was applied using a continuous theta burst stimulation (cTBS) protocol known to produce LTD-like cortical inhibition. Subjects performed sentence completion and verb generation tasks before receiving TMS to the LIFG and then repeated the tasks after cTBS. Task order was counter-balanced across subjects. Selection cost was calculated as the difference between median reaction time on trials with high selection demands and trials with low selection demands. Effects of cTBS on verbal selection were assessed using a 2x2 ANOVA with factors of session (pre/post) and treatment (active/sham). Additionally, trial level reaction times were analyzed using a linear-mixed effects model to assess the effects of session, treatment and selection demands on reaction time in controlled language tasks.
Results: In the sentence completion task (high semantic context) there was a significant session*treatment interaction in the trial level reaction time analysis such that reaction times were faster compared to baseline following active cTBS and slower compared to baseline following sham cTBS. There was no significant session*treatment interaction on selection cost

in sentence completion. In the verb generation task (low semantic context), there is a significant session*treatment interaction in the selection cost analysis such that selection cost is increased following active cTBS neuromodulation compared to sham.
Conclusion: TMS neuromodulation to the LIFG modulates performance on controlled language tasks in a context dependent manner. In tasks with high semantic context there is a general effect on reaction times indicating that cTBS may speed up semantic processing. In low semantic context tasks there is no general effect on reaction times, but an increase in the cost of high selection demands indicating cTBS may be slowing down the verbal selection process.

Title: Word analogy relations predicted from addition and subtraction of fMRI activation patterns

Authors: *M.-H. WU, A. J. ANDERSON, R. A. JACOBS, R. RAIZADA;
Univ. of Rochester, Rochester, NY

Abstract: Consider a word analogy, such as “teacher is to chalk, as mechanic is to wrench”. Computational semantic models such as Word2Vec have found that simple addition and subtraction of word embeddings can solve such analogies; that is, the word embedding of teacher vec(“teacher”) is closest to the predicted embedding vec(“chalk”) + vec(“mechanic”) - vec(“wrench”). We used pattern-based fMRI analyses to ask whether answers to analogies can be inferred in a similar manner by adding and subtracting fMRI activation patterns elicited by the words. Participants viewed common English words, presented one at time, in the MRI scanner and were asked to form mental images of the displayed word. The stimulus set consisted of triplets made up of a person, building and tool related to one of 15 semantic categories (e.g., teacher / school / chalk in the teaching category). Analogical pairs were formed by first selecting two semantic categories and then picking two words of the same type from each semantic category. This underlying structure was unbeknownst to participants, and the study did not involve explicit analogical reasoning. For each participant, we identified voxels across the whole brain that had the highest inter-trial correlation. The fMRI pattern for each word was the averaged BOLD pattern across all its repetitions. Similar to Word2Vec, for each analogical pair,

we calculated the predicted pattern of the target word based on the patterns of the other words in the analogical pair. For example, the predicted pattern of "teacher" was pattern("chalk") + pattern("mechanic") - pattern("wrench"). We ranked the correlations between the predicted pattern and the actual fMRI patterns of all words other than the three used in the calculation. This procedure was repeated for all four words in each possible analogical pair, and the scaled rank of the true word pattern was averaged and compared against chance across participants with a one-sided t-test. We observed a small but significant effect ($p < 0.02$), which suggests that fMRI patterns of a word can be predicted from that of other words in an analogical pair. Significant rank ($p=0.03$) was still observed when a more rigorous ranking procedure was applied, where we only compared the predicted pattern to the patterns of words sharing the same type as the true word (i.e. only ranking other person words against "teacher"); this eliminated the possibility that successful ranking was driven purely by voxel selectivity to word types instead of identity. Our work demonstrated that geometric regularities found in word embeddings can also be observed in word-induced fMRI activation patterns.

Title: Associations between resting-state and reading task lateralization of language-related cognitive networks

Authors: T. K. DAY[1,3], T. M. MADHYASTHA[2];
[1]Dept. of Radiology, [2]Radiology, Univ. of Washington, Seattle, WA; [3]Inst. of Child Develop., Univ. of Minnesota, Minneapolis, MN

Abstract: Lateralization of language is perhaps one of the most well-known features of the human brain. This has been studied with many methods involving active language tasks, including functional magnetic resonance imaging (fMRI). However, resting-state (RS) fMRI provides a way to interrogate the resting configuration of the brain and areas related to language. Broca's area (BA) and Wernicke's area (WA), located in the left hemisphere (LH) and linked to production and understanding, are the primary language areas in the brain. Zhu et al. [1] identified regions of the cortex ("asymmetry seeds") where RS functional connectivity (FC) to BA and WA vs. their right-hemisphere (RH) analogues was asymmetric, describing six asymmetry seeds where (1) FC to the left BA > right BA; (2) left WA > right WA; and (3) right

WA > left WA. However, they didn't link RS asymmetry to task asymmetry. In this study, we directly test whether RS asymmetry is related to the asymmetry during a language task. The Reading Brain Project [2] contains RS scans and five repetitions of a passive reading task (n = 50). We calculated FC from BA and WA in the passive reading task and at rest and, using regions of interest centered on the asymmetry seeds, calculated three measures (as above) of LH-RH FC asymmetry. We found that FC asymmetry during the passive reading task predicts FC asymmetry in RS in two out of the three measurements. FC in BA regions (described as primarily LH asymmetric) varied roughly equally across subjects between LH and RH in both RS and task. FC asymmetry in BA regions was correlated between the RS and task (r^2 = 0.235, p = .002). FC asymmetry in WA regions described as LH-asymmetric was not correlated between RS and task (r^2 = 0.154, p = 1.64), but was positively correlated with age (β = 0.006, p = 0.029). FC in WA regions described as primarily RH were primarily RH-asymmetric in both RS and task, and were correlated (r^2 = 0.356, p < .001). (All p values corrected for three multiple comparisons). There was no effect of age on BA or WA RH or gender in any analysis. Our findings suggest BA networks are the most robust in comparing RS and task FC asymmetry. The inconsistent WA measurements suggest more work is needed to understand the LH/RH components of the WA networks. Although other work has shown linkages between RS and task network configurations, this study links resting measurements of language networks to their task configuration, possibly allowing estimation of language network configuration in participants - such as young children - who are unable to respond to an active language task. Title: N400 in lexical decision of words and pseudowords on a Yuto-Nahua language: The case of Wixarika

Authors: D. L. CANELA, A. E. CARRILLO, W. F. LARA GALINDO, *F. A. ROBLES; Univ. of Guadalajara, Guadalajara, Mexico

Abstract: Several studies have shown that similar lexical processing effects in distinct languages are due to the grounding of language into neurobiology (Friederici, 2002; Willems, Özyürek &

Hagoort, 2008). However, except from some Asian languages, studies have replicated these findings only with European tongues. Wixarika is an agglutinative Yuto-Nahua language spoken in the northeast of Mexico. In this experiment, we compared the N400 for 10 Wixarika and 20 Spanish speakers (ages 18-27) in a lexical decision task using their mother tongue. Task consisted of hearing 50 nominal phrases for each condition: words (*nuestra agua*/*tame haá*/our water), and pseudowords type I (*mi cuchillo-chicullo*/my knife, *xeme hikuri-hukiriti*/your *cactaceae*) and type II (*tu abeja-abeje*/your bee, *tame haá-hué*/our water). N400 peak was found in central channels at 423 ms (-1.4 μV) for Spanish and at 331 ms (-1.7 μV) for Wixaritari speakers. When comparing N400 between conditions (words vs. pseudowords) we found no differences neither in Spanish amplitudes (F=1.01, p=0.32) nor latencies (F=2.30, p=0.14), neither in Wixarika amplitudes (F=0.376, p=0.55) nor latencies (F=2.60, p=0.15) speakers. When comparing groups, there were no differences in response latencies neither in words (t= 0.574; p=0.571), pseudowords I (t= 1.420; p=0.167) or pseudowords II (t= 0.428; p=0.672). Also, there were not differences between groups in N400 amplitudes (t=1.410, p=0.170) or latencies (t=0.46, p=0.69). These findings line up with the proposal that states that N400 is produced by the temporal synchrony of a stimulus-driven activity (represented or non-represented in lexicon) with a broad neural network set by recent linguistic input (Federmeier & Laszlo, 2009).

Title: Metaphors comprehension throughout development and its neural correlate

Authors: *E. NAVARRETE, E. VALLES-CAPETILLO, M. GIORDANO;
Lab. D-12, Inst. de Neurobiología, Querétaro, Mexico

Abstract: Introduction:
The objective of this research is to identify those brain areas associated with an aspect of pragmatic language, specifically, metaphor comprehension through development from childhood to adolescence. The design is descriptive and correlational. The technique used is task-related functional Magnetic Resonance Imaging (fMRI).
Methods:
In a sample of 898 participants (9-16 years old, mean age = 12.08 ± 1.92, 468 female), a qualitative instrument was used to evaluate metaphor comprehension. Significant differences were identified for the comprehension level between genders (female > male) and developmental stage (adolescents > children). Differences between stimulus conditions were also identified: literal and absurd > metaphors. From this instrument 63 stimuli were selected (21 metaphors, 21 literal and 21 absurd) and were presented in audio format (male and female voices) to a sample of 63 children (9 -13 years old, mean age = 11.07 ± 1.83, 35 female). Comprehension scores and reaction times were obtained. Using this information a fMRI task was designed, it included 3 runs (5.5 min each) with 21 events (7 literal, 7 metaphors, 7 absurd). Each event included one auditory stimulus (2 s) + fixation cross (4-8 s) + question (does it make sense?: "yes" or "no") (6 s) + fixation cross (2-6 s). Presentation of stimuli was optimized with optseq2. Activation averages were calculated for each condition and contrasts were made between conditions and between each condition against each pair of the remaining conditions, using the FSL FEAT tool.
Results:
Initial results for the contrast between metaphor> literal and absurd conditions showed one cluster of relevant activation with a maximum z-value of 3.8, which was located on the right precuneus (Harvard Oxford Cortical Structures atlas). Other areas with z activation values greater than 3 were the right lingual and left fusiform gyrus.

Conclusions:
It is currently known that the precuneus participates in four general functions: consciousness, spatial movement, self-consciousness, and recovery of episodic memory and visuospatial images. The lingual gyrus appears to be activated when people try to attribute meanings to symbols, while the fusiform gyrus participates in semantic association and specifically in metaphor interpretation.
These initial findings suggest that brain areas involved in visual imagery and possibly in Theory of Mind, may be involved in metaphor comprehension in children.

Title: Combining fMRI activation patterns and semantic vector representations to predict activation patterns for new concepts

Authors: *R. J. VARGAS, M. A. JUST;
Carnegie Mellon Univ., Pittsburgh, PA

Abstract: In the past two decades, fMRI has been used to study the semantic organization of concepts in the human brain. The activation patterns of concepts are used to discover underlying neurally-defined semantic dimensions and their spatial organization in the brain. Scanner cost and participant fatigue constrain each study to investigate small samples of a narrow set of concepts (typically 30-60 items) limiting the semantic coverage. Natural language processing of large text corpora (e.g. Wikipedia) has led to the development of semantic characterizations of concepts [e.g. GloVe (Global Vector)] based on their co-occurrence with other words. This project relates the neural representation of a concept to its GloVe representation, to create a mapping that can be used to generate predicted activation patterns for as-yet unassessed concepts. The goal is to investigate the semantic organization of human thought on a large scale using a comprehensive brain image library of concept representations that has been generated using this mapping. A kernelized ridge regression model is used to predict the neural representations (defined as the vector of activation levels of the 1800 most consistently activating voxels across the stimulus set) for all but one concept in a set, using each of the concepts' 300-dimensional GloVe semantic vector representations. The resulting learned mapping is then applied to the GloVe representation of the left-out concept to generate a

predicted image. The predicted image is then compared to the actual fMRI activation pattern. The rank distance (among the distances of all the other concepts) of the predicted image to the actual image is used to determine a predicted image's accuracy. This approach was applied to three existing fMRI studies of a set of concepts: 60 concrete nouns (e.g. apple, hammer; N = 11); 18 emotions (e.g. sadness, pride; N = 10); and 28 abstract concepts (e.g. truth, ethics; N = 9). The mean rank accuracies across concepts and participants are as follows: 0.76 for the 60 concrete nouns; 0.61 for the 18 emotion concepts; and 0.68 for the 28 abstract concepts, where chance is approximately 0.5. The learned mapping generated by the model was then applied to the library of 400,000 GloVe representations to generate predicted images for virtually every word in English. The similarity between the actual activation patterns for concepts and the library of predicted patterns revealed which semantically similar concepts the individual participant or group were thinking about. Factor analysis of the predicted fMRI space was used to discover neurally-generated semantic dimensions for concepts that have no corresponding fMRI data.

Title: Dynamics of effective connectivity between the human cortex and subthalamic nucleus during speech production

Authors: *A. R. WEISS[1], A. KORZENIEWSKA[1], W. J. LIPSKI[2], A. BUSH[2], A. CHRABASZCZ[2], N. E. CRONE[1], M. RICHARDSON[2];
[1]JHU Cognitive Neurophysiol. and BMI Lab, Dept. of Neurol., Johns Hopkins Med. Inst., Baltimore, MD; [2]Brain Modulation Lab, Dept. of Neurolog. Surgery, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Speech production requires interactions across large-scale cortical networks, and human intracranial electrocorticographic (ECoG) studies have shown that increases in spectral power in the high gamma (70-220 Hz) frequencies are associated with causal interactions at the same frequencies (Korzeniewska, 2011). While recent work by Chrabaszcz et al (2019) has revealed that articulatory features are encoded by different locations within the subthalamic nucleus (STN), questions remain regarding the contribution of subcortical nodes to speech production. Further, the role of cortico-basal ganglia interactions in encoding linguistic and/or

speech motor processes remains poorly understood. Here, we probe event-related causality (ERC) at high gamma frequencies between the STN and cortex to investigate how speech motor encoders are transferred across the cortical-subthalamic network.
ERC is a multichannel method based on the concept of Granger causality that estimates the time-course, directionality, magnitude, and spectral content of neural interactions. We simultaneously recorded ECoG and local field potentials (LFP) from subjects undergoing deep brain stimulation electrode implantation surgery for Parkinson's Disease as they read aloud single consonant-vowel-consonant words and pseudowords. During surgery, patients were implanted with depth electrodes in the STN (the locations of which were altered over the course of surgery) and with ECoG strips over premotor cortex, primary motor cortex (M1), primary somatosensory cortex (S1), middle temporal gyrus (MTG), supramarginal gyrus (SMG), and superior temporal gyrus (STG). We aligned trials to either stimulus presentation or spoken response onset prior to analyzing high gamma event-related activity and ERC.
As expected, the word reading task elicited significant increases in high gamma activity in several cortical regions: in MTG, S1, STG, and SMG following the presentation of stimuli; in S1 immediately preceding speech production; and in S1 and STG immediately following speech production. ERC analysis revealed interactions between STN and these cortical regions, as well as between different STN locations. Interestingly, interactions between STN and S1, M1, STG, and SMG were reciprocal, and varied depending on STN recording location.
These results indicate that a complex network between cortex and STN is activated during speech processing, reflected by high gamma modulation. Moreover, causal interactions in the high gamma frequency range occurring between these cortical regions and the STN vary depending on the recording location within the STN.

Title: Investigating the role of first language flexibility in bilingual language development: An ERP study

Authors: *A. LUQUE, K. MORGAN-SHORT;
Dept. of Hispanic and Italian Studies, Univ. of Illinois at Chicago, Chicago, IL

Abstract: In today's world, many adults find themselves in a situation in which it is beneficial or even necessary to learn a second language (L2). Yet, learning an L2 during adulthood is a complex and challenging endeavor that results in a great deal of variability in learning outcomes. Researchers who examine L2 learning are interested in identifying the characteristics shared among proficient bilinguals in order to shed light on the mechanisms that may contribute to successful L2 learning. One relevant characteristic of proficient bilingualism, as posited by a recent hypothesis (Bice & Kroll, 2015) may be that learners with more "flexible" first language (L1) systems may be better at acquiring an L2. In this study, we assessed first language (L1) flexibility among intermediate learners of Spanish (N= 21) using event-related potentials (ERPs). Participants completed an ERP picture-sentence matching task following Sanoudaki & Thierry (2015) and Luque et al., (2018), two studies that provided neurocognitive evidence of L1 flexibility among highly proficient bilinguals. Preliminary data analyses reveal evidence of L1 flexibility among some but not all L2 learners, suggesting that that the role that L1 flexibility plays for adult L2 development seems to differ along the continuum of bilingualism, with other factors, such as linguistic and cognitive, modulating this phenomenon. The implications of these preliminary results will be considered in the context of both theoretical and applied questions related to bilingual language development during adulthood. Future research directions will also be discussed, including research that examines the intersection of L1 flexibility with cognitive, socio-affective factors, and different contexts of L2 learning.

Title: Two times four = Dos por cuatro: Bilinguals engage similar neurocognitive processes in both languages when verifying multiplication facts

Authors: *V. R. CERDA, N. Y. Y. WICHA;
Biol., Univ. of Texas At San Antonio, San Antonio, TX

Abstract: Bilinguals typically learn multiplication tables through verbal rehearsal in one language. In turn, they are faster and more accurate at retrieving memorized multiplication facts in the language of learning (LA+) than the other language (LA-). These findings are explained by

math cognition models in two ways. The math facts may be uniquely represented and retrieved in LA+, requiring a less efficient neurocognitive process in LA-, such as translation or calculation. Alternatively, independent verbal memory networks for each language have differing strength of access when retrieving multiplication facts from memory. Evidence from bilingual language research suggests that a bilingual's two languages are interconnected and engage similar neurocognitive processes for language tasks. This is especially true for bilinguals who learn both languages early in life. Here, we tested whether early Spanish-English bilingual children (n = 28) and adults (n = 29) use qualitatively or quantitatively different processes for math fact verification across their languages. We recorded event-related potentials (ERPs) as participants verified the correctness of spoken multiplication problems ("two" "four"), followed by a visually presented digit solution that was either correct or not (8 vs 9). The operands were presented in LA+ or LA- in separate blocks. Given that digit solutions were used across languages, any differences in the ERPs at the solution would be driven by the language used to access the math facts. For children, incorrect solutions elicited a larger negative-going ERP component, or N400, compared to correct solutions, reflecting access to semantic memory. This N400 effect was the same in both languages, implying that bilingual children process the problems for meaning when verifying solutions in both LA+ and LA-. Consistent with monolinguals, bilingual adults showed a larger positive-going ERP component for correct solutions, a P300, compared to incorrect solutions, reflecting detection of a highly memorized target. Critically, this effect was again the same across languages. Overall, even though bilinguals show a preference for performing math in one language, both adults and children engage similar processes in both LA+ and LA-, at least when verifying multiplication facts. These findings are consistent with the bilingual literature that shows comparable neurocognitive processes for language tasks in both languages. Moreover, our findings suggest that the bias toward monolingual math education may be unfounded from a neurocognitive perspective.

Title: Bilingual impact on left frontal lobe functionality for children's sentence processing

Authors: *I. KOVELMAN[1], **N. WAGLEY**[1], X. HU[2], A. BARON[4], L. BEDORE[5], T. SATTERFIELD[1], J. BOOTH[6], J. BRENNAN[3];

[1]Psychology, [2]Dent., [3]Linguistics, Univ. of Michigan, Ann Arbor, MI; [4]Univ. of Rhode Island, Kingston, RI; [5]Temple Univ., Philadelphia, PA; [6]Psychology, Vanderbilt, Nashville, TN

Abstract: How does bilingualism influence children's emerging neural architecture for language? We examine this question through the Neuroemergentism framework (Hernandez, 2019) positing that bilingual experiences can alter brain development for higher cognitive function. It is generally established that developmental increase in language proficiency is associated with increased automaticity of language processing. At the neural level, greater proficiency is typically associated with increased left temporal and decreased left frontal activation. Yet, bilinguals often show heightened attention and sensitivity to linguistic input, which is associated with left IFG functionality. Within this theoretical framework, we predicted that bilingual children with greater dual language proficiency will show stronger left IFG activation during language tasks, relative to bilinguals with less balanced bilingual proficiency. We used fNIRS to test 82 Spanish-English bilinguals (7-11 yo) using a grammaticality judgment task. The ungrammatical sentences included early acquired -ing (He is dance), and later acquired -ed/s omissions (He dance). Bilinguals were exposed to Spanish at birth, English before age 5, and were educated in English-only schools in the US; they were English-dominant, had age-appropriate English proficiency, and lower/varied Spanish proficiency. The findings revealed that greater English proficiency was indeed associated with increased left STG/MTG activation and decreased left IFG activation. New findings revealed that consistent with our predictions, children with more balanced bilingual proficiency, or stronger Spanish proficiency in addition to age-appropriate English proficiency, showed greater left IFG activation. Importantly, more balanced bilinguals did not show greater difficulty with the task, as revealed by reaction time analyses. The findings suggest that balanced and systematic use of the two languages yields greater engagement of left IFG regions associated with heightened sensitivity to linguistic input. The findings thus inform theories of bilingualism as well as broader theoretical perspectives on child brain development by illuminating the impact of early-life language experiences on cortical organization for higher cognitive functions.

Title: Monolinguals catch up to bilinguals on executive control, but not neural processing of sound, over the course of adolescence

Authors: *J. KRIZMAN, V. MARIAN, N. KRAUS;
Northwestern Univ., Evanston, IL

Abstract: While the presence of a bilingual enhancement for executive control is considered by some controversial, bilingualism's impact on sound processing is not. With respect to executive control, a major source of contention is that enhancements found in children can be absent in young adults. In contrast, auditory processing enhancements have been observed across ages. During development, either differences in maturation rate of a skill or overall attainment level for that skill can lead to a perceived enhancement. Therefore we hypothesized that the executive control enhancement is due to differences in maturation rate of that skill, while auditory processing enhancements are due to differences in overall attainment level. We predicted that if we assessed bilinguals and monolinguals early in adolescence (~14 yrs), when these abilities are still developing, and again late in adolescence (~18 yrs), when these abilities are more mature, we should see both executive control and auditory processing enhancements at the first time point, but only auditory processing enhancements at the second time point. Spanish-English bilinguals and English monolinguals' executive control abilities were tested using the IVA+, an integrated test of auditory and visual attention and executive control, and subcortical auditory processing was tested using the frequency-following response, an obligatory response to sound originating in the auditory midbrain. In line with our predictions, bilinguals showed an executive control advantage at age 14, but the monolinguals caught up to them by age 18, while bilingual sound processing enhancements were present at both time points and were specific to speech sound features important for real-world language perception. These results suggest that diversity of language experience can accelerate development of executive control and strengthen subcortical auditory processing. While continued language experience may enable monolinguals to reach similar levels of executive control performance, the ongoing needs of bilingual communication maintains the heightened subcortical encoding of speech features. These results may help to explain the incongruent executive control findings in the literature and highlight auditory system plasticity in bilinguals.

Title: Effects of language experience differ according to neuroanatomical metric

Authors: *H. CLAUSSENIUS-KALMAN[1], K. A. VAUGHN[1], P. ARCHILA-SUERTE[2], A. E. HERNANDEZ[1];
[1]Univ. of Houston, Houston, TX; [2]Johnson Space Center, NASA, Houston, TX

Abstract: Although researchers generally agree that a certain set of brain areas underlie bilingual language processing, there is discrepancy regarding what effect timing of language acquisition has on these regions. We aimed to investigate the neuroanatomical correlates of age of acquisition (AoA), an issue that twelve previous studies have examined, but no two of which yield the same conclusion (likely influenced by methodological differences across studies). We analyzed gray matter density, volume, and thickness by using whole-brain analyses in 334 bilinguals and monolinguals. Neuroanatomical correlates of AoA differed depending on gray matter metric. In the present sample, analyses of GM density revealed AoA-related differences in regions associated with language planning, analyses of thickness revealed changes to areas involved in both language planning and articulation, and volume analyses revealed differences in one language area but were overall the least sensitive measure of AoA. Additionally, multiple regions not classically implicated in bilingualism were found, which emphasizes the important role of whole-brain analysis in neuroscience. This is the first study to investigate AoA and gray matter thickness, volume, and density all in the same sample. We argue that cognitive models of bilingualism should consider development and the role of neuroanatomical metric in driving results.

Title: Rapid statistical learning in word segmentation

Authors: *J. ZHANG[1], Y. SHAO[1], M. XU[2], N. DING[1];
[1]Zhejiang Univ., Hangzhou, China; [2]Ctr. for Brain Disorders and Cognitive Sci., Shenzhen, China

Abstract: Learning to segment a continuous speech stream into discrete words is a critical aspect of language acquisition. Word boundaries can be learned by statistical learning but several key questions remain elusive. For example, how many repetitions are required to learn a word? Do all the repetitions need to occur within a time window to enable learning? We here investigate how quickly statistical learning can occur and what are the neurophysiological underpinnings. In typical statistical learning paradigms, how often a word repeats covaries with the number of words to learn. To dissociate these two factors, we control the number of words to learn to one and manipulate the number of word repetitions and the interval between repetitions. Using this paradigm, we observed that the learners could discriminate words from others within 4 repetitions of the word. By adjusting the syllable rate, we find that the learning speed depends on how many syllables are played between two repetitions of a word, rather than the time duration between repetitions. We next investigated the neural basis of statistical learning using MEG. We find that the amplitude of the M100 response is reduced for the 2nd and 3rd syllable in the trisyllabic word and this effect quickly emerges after 3-4 repetitions of the word. Altogether, both behavioral and neural findings reveal that statistical learning of word boundaries only requires a few repetitions of a word and is neurophysiologically implemented by adaptation of auditory responses at ~100 ms latency.

Title: Is the bilingual brain different? An fNIRS comparison of bilingual and monolingual children

Authors: *X. SUN[1], K. ZHANG[1], J. KIM[1], N. NICKERSON[1], Y. LI[1], R. MARKS[1], F. HU[1], T.-L. CHOU[2], T. TARDIF[1], I. KOVELMAN[1];
[1]Univ. of Michigan, Ann Arbor, MI; [2]Natl. Taiwan Univ., Taipei, Taiwan

Abstract: How does bilingual experience influence the developing brain? All words are comprised of morphemes, or the smallest units of meaning. While morphological awareness is one of the foundational skills for successful language and reading acquisition across languages, there are significant differences in morphological structure between English and Chinese. Here we ask, how does bilingual Chinese-English exposure influence children's morphological awareness for learning to read in English? To answer this question, we tested young Chinese-

English bilinguals and English monolinguals (N = 24, ages 5 - 10) during fNIRS neuroimaging. The bilingual participants were exposed to Chinese at birth, and to English before age 5, attended English-only schools and afterschool programs in Chinese. The children completed morphological awareness tasks of compound (e.g., snow-man) and derivational (e.g., re-count, kind-ly) morphology during neuroimaging. The children also completed standard behavioral measures of language and literacy in English. Neuroimaging findings revealed that English morphological awareness task engaged left frontal and temporoparietal regions across participants. A direct comparison between bilinguals and monolinguals revealed that the bilinguals showed stronger left IFG and left Parietal as well as stronger overall right hemisphere activation. A more detailed investigation revealed that the compound condition elicited greater left Parietal activation whereas the derivational condition elicited greater left IFG activation in the bilinguals relative to monolinguals ($q < 0.05$, FDR corrected). Importantly, there were no significant differences between bilinguals' and monolinguals' neuroimaging task performance or English language and reading proficiency ($p > 0.05$). The findings suggest that early bilingual exposure to typologically different language such as Chinese can exert a significant impact on bilingual children's neural organization for word structure processing in English in children with age-appropriate English language proficiency. The findings shed light on neurodevelopmental theories aiming to explain how early language experiences influence children's cortical organization for language function.

Title: Mapping the neural correlates of covert and overt verb generation using high-density diffuse optical tomography

Authors: *M. L. SCHROEDER[1], R. L. ULBRICH[2], A. K. FISHELL[3], A. SHERAFATI[4], A. M. SVOBODA[1], J. P. CULVER[4], **A. T. EGGEBRECHT**[1];

Abstract: Mapping the neural correlates of naturalistic speech has potential clinical applications, such as characterizing and monitoring language function in aphasic patients post-stroke or in patients with cochlear implants post-surgery. Traditional methods, such as functional magnetic resonance imaging (fMRI), pose limitations to studying naturalistic language processing due to a loud and constraining ambient environment, the requirement that participants lie supine and still, and contraindications in populations with implanted devices. Due to its silent and open imaging environment, high-density diffuse optical tomography (HD-DOT) provides a compelling surrogate for fMRI. As HD-DOT been extensively validated in adults, the purpose of the present study is to build upon previous studies to localize differential cortical activation to covert vs. overt verb generation.

14 adult subjects ages 20-42 (7 females, 5 right-handed; 7 males, 7 right-handed) participated in 1 or more HD-DOT scans consisting of 3 tasks: covert word reading (RW), covert verb generation (CV), and overt verb generation (OV). Stimuli for all runs were concrete nouns (n=765) with Zipf frequencies of at least 3.86 selected from the SUBTLEXus corpus.

Nouns were presented visually using an event design paradigm with pseudorandomized inter-stimulus intervals (2-13 seconds), with each event block consisting of 5 nouns each displayed for 200 ms and presented 1 second apart. No noun was presented more than once per scan session and the order of nouns presented for each run was counterbalanced across participants. Additionally, audio responses from the OV runs were recorded.

We found brain responses of increasing magnitude for RW, CV, and OV, respectively, in expected areas of the brain. Results demonstrate additional cortical recruitment with increasing task complexity (RW to CV to OV), with RW primarily evoking responses in primary visual cortex, CV additionally recruiting Broca's area and the visual word form area, and OV additionally activating right-lateralized primary motor cortex. Together, these results demonstrate that 1) HD-DOT localizes activations underlying language processing consistent with those acquired by fMRI and 2) covert language tasks cannot be used as a surrogate for more naturalistic tasks such as speech production. Compared to fMRI, HD-DOT's naturalistic ambient environment and ability to image clinical populations precluded by fMRI motivates continued investigation of language processing. Future directions include analyzing audio responses to investigate performance differences and to isolate the effects of performance from the effects of handedness and sex.

Title: Reading acquisition through bilingual lens: fNIRS study of bilingual children

Authors: *K. ZHANG[1], X. SUN[1], J. KIM[1], N. NICKERSON[1], Y. LI[1], R. MARKS[1], F. HU[2], T.-L. CHOU[3], T. TARDIF[1], I. KOVELMAN[1];

[3]Psychology, Natl. Taiwan Univ., Taipei, Taiwan

Abstract: How does the bilingual brain support reading acquisition? There are significant cross-linguistic differences between English and Chinese orthographies. In English, units of sounds map onto letters. In Chinese, units of meanings map onto characters. How do these differences influence children's emerging neural architecture for learning to read? To answer this question, we compared emerging literacy skills in English and in Chinese of young English-Chinese bilinguals using fNIRS. The investigation focused on morphological awareness, children's active sensitivity to smallest units of meaning, and a critical component of learning to read across languages. We asked young Chinese-English bilinguals (N = 15, ages 5 - 10) to complete tasks of compound (e.g., birth-day) and derivational (e.g., un-do, friend-ly) morphology in both of their languages during neuroimaging. The children also completed standard language and literacy measures in English and Chinese. The children were raised in Chinese-speaking families living in the US and were dominant in their English language proficiency. Neuroimaging findings revealed that in both languages, the morphological awareness task engaged left frontal and temporal regions ($q < 0.05$, FDR corrected). Yet, there were no significant differences in the brain activation between the bilinguals' two languages, in either of the condition ($q > 0.05$). The findings pose two complementary interpretations. First, morphological processing across languages might be fundamentally similar. Second, young bilinguals might be developing similar neurocognitive mechanisms for processing word structure in each of their languages. Taken together, the findings shed light on the how language experiences with typologically-distinct languages influence neural organization for language processing in bilinguals.

Title: Does transcranial direct current stimulation of the dorsolateral prefrontal cortex effect language learning in young adults?

Authors: *A. J. BOLLING, T. ENAM, V. KING, L. SCHROBILGEN, I. M. MCDONOUGH; The Univ. of Alabama, Tuscaloosa, AL

Abstract: Memory is the ability to encode, store, and retrieve information, which is critical for learning a foreign language. While children acquire new languages relatively easily, learning a new language as an adult can be quite difficult. One critical aspect of learning a new language is the ability to learn the pairing between words in the native and foreign language. fMRI research has suggested that the dorsolateral prefrontal cortex (dlPFC) is critical to learn new pairs of words. However, because fMRI is correlational, additional research is needed to further investigate the implicated brain region and how it is involved in language learning. Transcranial Direct Current Stimulation (tDCS) is a non-invasive procedure that uses electrodes to send small electrical currents through the scalp, modulating brain activity. The present confirmatory study aims to use tDCS to determine the degree that the dlPFC is causally involved in foreign-language learning and, in the process, learn how to improve language acquisition in adults. This study includes 3 sessions that each take place 24 hours apart. In the first two sessions, participants were stimulated for 20 minutes, and then learned 72 English-Swahili word pairs. The list of word-pairs was repeated once during each session to increase exposure. On the third day, participants were tested using cued-recall, where the Swahili word was shown, and participants typed the English equivalent. One week later, the test was retaken. The tDCS was administered at the F3 placement site using the International 10-20 system for EEG electrode placement at three stimulation levels (1.5mA, 1mA, and sham- a control) with n=13 per stimulation level (23 women). Participants were young adults in an introductory psychology course at the University of Alabama. We hypothesized that participants who received tDCS would have higher memory retention for the word pairs than those in the sham condition. We found that there were no significant effects of tDCS on the level of retention. This could be due to the small sample size, or it could mean tDCS does not have an effect on language learning. If the findings remain consistent with further research, it could suggest that the dlPFC is not causally involved in language learning as an adult.

Title: The effects of different learning mechanisms on speech segmentation

Authors: *Y. CHEN, P. JIN, N. DING;
Zhejiang Univ., Hangzhou, China

Abstract: Natural speech consists of continuous streams of sound with no reliable pauses between words. Therefore, one major challenge for learners in language acquisition is to discover word boundaries, a process known as speech segmentation. Explicit learning the phonology, semantic and orthography of the words is a critical learning mechanism underlying word segmentation. Meanwhile, statistical learning, an implicit process of becoming sensitive to statistical structure of the language, is also considered to facilitate speech segmentation even before knowing the words of the language. However, it is currently unknown whether these learning mechanisms have different effects on speech segmentation. Here, we used EEG frequency-tagged responses analyses to examine the neural entrainment of the statistically and explicitly learned nonsense words and real words. In our statistical learning experiment, we recorded EEG data while participants listened to a structured stream of trisyllabic nonsense words and then a trisyllabic real word stream. Statistical learning was supposed to occur during exposure of the nonsense word stream. In the explicit learning experiment, another group of participants were exposed to three streams of trisyllabic nonsense words each after learning either the phonology, the semantic or the symbol of the words. They also listened to the real word stream as in the statistical learning group. Learning performance was indexed by an EEG-based measure that quantified neural entrainment at the frequency of repeating words relative to that of individual syllables. The results showed the neural entrainment of real words was higher than nonsense words in statistical learning. However, the entrainment of real word was comparable to nonsense words whose phonology, semantic or symbol has been learned. Moreover, we found an interaction of group (statistical learning group and explicit learning group) and word type (real word and learned nonsense word), indicating poorer effect of statistically learned words than explicitly learned words. These results demonstrate that the effect of statistical learning is poorer than explicit learning, while the effect of explicit learning of nonsense word was comparable to real word. Our study illustrated the effects and mental representations of different learning mechanisms, providing insight into strategies of language learning.

Title: Bilingual Spanish-English literacy development: An fNIRS study of morphological awareness

Authors: *N. NICKERSON, X. SUN, K. ZHANG, R. A. MARKS, J. KIM, I. HERNANDEZ, V. CARUSO, X. XU, T. TARDIF, T. SATTERFIELD, I. KOVELMAN;
Univ. of Michigan, Ann Arbor, MI

Abstract: How does bilingual language experience influence how morphological awareness develops in the brain? Learning to read requires children to extract and decode meaning from sequences of morphological units, the smallest units of meaning with a word. This morphological structure varies across languages. In particular, while Spanish is more flexible in its morphological structure and complexity, English word order and structure is more fixed. During fNIRS neuroimaging, Spanish-English bilinguals and English monolinguals (N = 28, ages 5 - 10) completed English tasks of morphological awareness. Standard measures of language and literacy in both English and Spanish were also collected. English morphological processing elicited activation in left frontal and temporo-parietal regions across participants ($q < 0.05$, FDR corrected). Differences emerged between bilingual and monolingual participants, revealing stronger left parietal activation in bilinguals as well as stronger right frontal and temporal activation ($p < 0.05$). This difference in the brain basis of morphological processing is striking, as there were no significant differences between bilingual and monolingual children in either the neuroimaging task performance or their English language or reading proficiency. Our findings suggest that developing dual language proficiency in Spanish and English does indeed seem to influence young learners' brain development for morphology. Such findings continue to inform our understanding of Spanish- English bilingual language and brain development through optical imaging.

Title: A systematic review and meta-analysis of brain differences in bilingual and multilingual adults

Authors: A. DANYLKIV, *A. J. KRAFNICK;
Psychology, Dominican Univ., River Forest, IL

Abstract: Introduction While differences between bilingual and monolingual children have received much interest, there is growing evidence that speaking multiple languages may also be beneficial for aging adults in slowing brain decay (Gold et al., 2013). Compared to monolingual peers, individuals who speak more than one language perform better on executive function tasks (Grady et al., 2015), show greater activation in brain regions while performing the same task (Luk et al., 2010), and may have greater cognitive reserve and neural efficacy (Gold et al., 2013). Structural and functional neuroimaging studies of bilingual and multilingual subjects have shown considerable heterogeneity. Here we attempt to synthesize the neuroimaging literature through systematic review and meta-analysis. **Methods** PubMed (www.ncbi.nlm.nih.gov/pubmed/) and Google Scholar (google.com/scholar) were used to identify neuroimaging studies of bilingual adults. Search terms included (Bilingual AND neuroimaging), (Bilingual AND adult), (Bilingual AND brain). From these search results, manuscripts not using MRI or those primarily in children were filtered out. The patterns across studies were investigated for both functional and structural MRI (gray matter VBM), and studies with whole brain group comparisons and available Talairach or MNI coordinates were submitted to meta-analysis using GingerALE 2.3 (Eickhoff et al. 2009, 2012; Turkeltaub et al., 2012). **Results** Preliminary results of the structural MRI meta-analysis contained seven individual studies (three of which had no whole brain result foci to include). At an uncorrected voxel wise threshold of $p<0.001$ and a cluster threshold of $200mm^3$, four clusters were identified in bilateral anterior cingulate cortex, right cerebellum, and bilateral inferior frontal gyrus (see Figure). **Discussion** While some consistency is observed across VBM studies of bilingual and multilingual adults, this was only true at uncorrected thresholds. More work is needed fully understand neural plasticity related to speaking more than one language.

Title: Cortical activation during sentence processing among Chinese-English bilinguals and English monolinguals: An fNIRS study

Authors: *G. DING, K. A. J. MOHR, R. GILLAM, C. ORELLANA, A. HANCOCK;
Utah State Univ., Logan, UT

Abstract: Research has shown that both monolinguals and bilinguals process language across specialized brain areas working collaboratively, but with greater variability among bilinguals. Age of acquisition (AoA) is typically considered to be one of the main factors influencing differences in brain activation patterns between first language (L1) and second language (L2). Essentially, the earlier a bilingual acquires the second language, the more like monolinguals the bilingual's neural networking develops. This study examined behavioral and neurophysiological data of 10 monolingual children,10 early-bilingual children and 10 late-bilingual adults to compare mechanisms underlying syntactic processing. They completed the Woodcock-Johnson III auditory working memory test (AWM) and then an English listening comprehension task during fNIRS scans. Bilingual children and adults received a similar task in Chinese. Auditory stimuli in both languages included three sentence types: Control (e.g., click the book), Subject-Verb-Object (SVO) and Passive (PAS). The semantic plausibility of the sentences was controlled, so that word order was the only relevant linguistic cue. Participants were asked to select the agent of each sentence. We expect that bilingual children would evidence similar activation patterns as monolinguals compared to adults, and that processing the more complex sentence type (i.e. PAS) would be more cognitively challenging. One-way and repeated-measure ANOVAs compared results, which showed that adults performed significantly better than children on AWM. Both children groups performed better on SVO than PAS in English and Chinese, but no significant differences on sentence type were found in bilingual adults. For fNIRS data, no main effects were found among three groups in English tasks. However, in comparing the two bilingual groups in both language tasks, a significant interaction (language* region of interest*sentence type*group) was found. For English tasks, adults showed reduced activation in left inferior frontal gyrus [LIFG] and left superior temporal gyrus [LSTG] for PAS compared to controls. Moreover, compared to Chinese (L1), more activation of middle pre-frontal cortex [MPFC], LIFG, LSTG was found for SVO among adults in English (L2). In the

Chinese tasks, both bilingual adults and children showed increased activation in LIFG for PAS than SVO sentences. Findings of different activation patterns among adults in L1 and L2 suggests that AoA is an influential factor in sentence comprehension. Patterns for PAS sentences in both language tasks indicates that sentence complexity also influences sentence comprehension.

Title: An integrated neural decoder of linguistic and experiential meaning

Authors: *A. J. ANDERSON[1], J. R. BINDER[3], L. FERNANDINO[4], C. J. HUMPHRIES[5], L. CONANT[6], R. D. RAIZADA[2], F. LIN[7], E. LALOR[1];

[4]Neurol., [5]Dept Neurol., Med. Col. of Wisconsin, Milwaukee, WI; [6]Univ. of Wisconsin, Milwaukee, WI; [7]Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: The brain is thought to combine linguistic knowledge of words and non-linguistic knowledge of their referents to encode sentence meaning. Despite technological advances that now enable words' meaning to be decoded from brain activity, there remains minimal direct neural evidence for this. Indeed, the dominant neural decoding method maps brain activation to a text-based semantic model that approximates meaning using patterns of word co-occurrences. We present direct evidence that both linguistic and non-linguistic experiences contribute to and can be decoded from neural representations of sentence meaning. We model attributes of peoples' sensory, motor, social, emotional and cognitive experiences with words using behavioral ratings. We demonstrate that functional Magnetic Resonance Imaging (fMRI) activation elicited in sentence reading is more accurately decoded when this experiential attribute model is integrated with a text-based model than when either model is applied in isolation (participants were 5 males and 9 females). In decoding we exploit a representation-similarity-based framework which benefits from being parameter free, whilst performing competitively with parameter fitting approaches such as ridge-regression. We find that the text-based model contributes particularly to the decoding of sentences containing linguistically oriented "abstract" words and reveal tentative evidence that the experiential model improves decoding of more concrete sentences. Finally, we introduce a cross-participant decoding method to estimate an upper-bound on model-based decoding accuracy. We demonstrate that a substantial fraction of neural signal remains unexplained, and leverage this gap to pinpoint characteristics of weakly decoded sentences and hence identify model weaknesses to guide future model development.

Title: Sparse experimental design for encoding models

Authors: *L. XU, A. LEBEL, A. G. HUTH;
UT Austin, Austin, TX

Abstract: Encoding models predict neural or fMRI responses from natural stimuli but have high requirements on both data quality and quantity. This makes it difficult to scale such experiments to very large numbers of subjects or stimuli. Here we aim to solve this issue by using a sparse

experimental design, in which each subject is exposed to a different small fraction of the total stimulus set. This sparse dataset is used to fit a spatio-temporal shared response model (SRM) for the whole brain, which assumes that the same stimuli evoke synchronic and localized responses across subjects. The SRM learns brain response patterns from responses of same subject to different stimuli, and learns stimulus features from the responses of different subjects to the same stimuli. These response patterns and stimulus features are then used to reconstruct data for all the stimuli that were not played for each subject. The original and reconstructed data are then concatenated and used to fit separate encoding models for each subject with standard regression techniques. In a test experiment, 3 subjects listened to all 60 auditory stimuli (12 hours in total) and 6 other subjects listened to a small fraction (around 20/60) of the same auditory stimuli, while undergoing fMRI scanning. With SRM, the concatenated datasets improve encoding model performance by 47.3% (± 18.6) for 3 good subjects, and by 268.8% (± 120.8) for the other 3 poor subjects. In simulations, we tested our model on 40 subjects and 10 to 100 stimuli with the same total data collection budget (each subject sees 10 random stimuli), and found that the concatenated dataset with SRM performs much better than the baseline. Finally, we show how to optimize the design of these sparse experiments by treating the connections between stimuli and subjects as a bipartite graph, and then showing that certain graph properties (such as the eigenvalue gap and mean path length) are closely linked to model performance. In conclusion, our SRM model suggests the sparse experimental design for encoding models with lower cost of time and money on data collection, and also shows the potential to denoise noisy datasets. Further, the response patterns and stimulus features learned by SRM could also be interpreted to gain insight into stimulus features that are represented similarly across subjects.

Title: Voxelwise encoding models of the cerebellum during natural speech processing

Authors: *A. LEBEL[1], S. JAIN[2], A. G. HUTH[1,2];
[1]Neurosci., [2]Computer Sci., The Univ. of Texas At Austin, Austin, TX

Abstract: There is a growing body of research demonstrating that the cerebellum is involved not only in motor responses but in a wide variety of cognitive processes such as language. However, it remains unclear which aspects of language processing the cerebellum contributes to. In this

study, we performed an fMRI experiment where two women and three men passively listened to five hours of natural language stimuli. We then used voxelwise modeling to predict BOLD responses on a held out test data set using five different feature spaces that capture different aspects of language processing. These feature spaces included a word embedding space that captures word-level semantics, a neural network-based semantic space that captures elements of contextual semantics, an articulatory space that captures lower-level language processing, a neural network-based timing space that captures a combination of semantics and prosody, and a word indicator space which served as a baseline for comparison to the other models. We then used variance partitioning to compare the predictive performance of each model in both cerebellum and cortex. The neural network semantic model with the longest context had the highest prediction performance in the cerebellum followed by the word-level semantic space. The articulatory space and the timing space had significantly lower performance than the semantic spaces and were not significantly different from each other. These results demonstrate that the cerebellum is not simply performing timing or motor predictions of language, but is involved in semantic processing. However, this pattern of predictive performance is mirrored in the cortex, suggesting that the cerebellum may merely be replicating cortical representations. To test for this possibility at a finer level of detail we compared representations of eleven different semantic categories across cortex and cerebellum. This analysis showed significant over-representation of the social semantic category in the cerebellum as compared to cortex, and under-representation of categories such as numbers and places. Collectively, this demonstrates that the cerebellum is highly involved in semantic processing of language and that it uniquely responds preferentially to social semantic categories.

Title: Visually grounded language encoding models for fMRI highlight the influence of sensory experience on semantic representations

Authors: *J. TANG[1], A. LEBEL[2], A. G. HUTH[1,2];
[1]Computer Sci., [2]Neurosci., The Univ. of Texas at Austin, Austin, TX

Abstract: To process natural speech, the brain relies on semantic representations which generalize acquired knowledge of the world. Currently accepted theories of grounded cognition

suggest that the brain's semantic representations must be grounded in the sensory systems from which knowledge is initially acquired. However, little is known about how elementary representations from multiple modalities are integrated into semantic representations or how sensory information propagates to the semantic representations of abstract words.
To address these issues we fit voxelwise encoding models to predict BOLD fMRI responses to a natural language experiment, where subjects listen to 6 hours of natural speech from *The Moth Radio Hour*. In contrast to existing encoding models, which represent stimulus words using distributional word embeddings extracted from textual co-occurrence, we use word embeddings explicitly grounded in visual and tactile properties. To create grounded embedding spaces, we represent concrete words by the visual and tactile properties of their referents, extracted respectively through convolutional neural networks and property norms. A novel interpolation method is used to ground abstract words in the sensory properties of their distributional neighbors. As visual and tactile properties may capture overlapping information, we employ a variance partitioning scheme; encoding models are fit for each combination of the distributional, visually grounded, and tactile grounded features spaces, and set theory is used to find the unique response variance explained in each voxel by each subset of the features.
We show that in normally sighted (NS) subjects, visual information uniquely influences semantic representations in language areas around the visual cortex, while tactile information uniquely influences semantic representations near the somatosensory cortex. Repeating the experiment for early blind (EB) subjects, we find that the influence of tactile information on semantic representations extends beyond somatosensory-adjacent language regions into areas which are uniquely influenced by visual information in NS subjects. While the NS results suggest that sensory grounding is constrained by connectivity, the EB results show that in the absence of visual experience, semantic representations may be more heavily grounded in alternative sensory modalities.

Title: Processing syntactic and morphological violations in Spanish and Wixarika

Authors: A. GONZÁLEZ[1], *D. L. CANELA[1], F. A. ROBLES[2], W. F. LARA GALINDO[3];
[1]Univ. De Guadalajara, Guadalajara, Mexico; [2]Univ. de Guadalajara, Colotlán, Jalisco, Mexico;
[3]Univ. de Guadalajara, Guadalajara, Mexico

Abstract: Differences in comprehension processing have been evaluated introducing task, stimuli or language acquistion variations leading to restricted discrepancies in brain physiological measures (Friederici & Alter, 2004). However, only recently gramatical distinctions started to be considered as a source of variance in ERP amplitudes or latencies (Tune *et al*., 2014). Present study was designed to constrast ELAN and LAN components between Wixarika, a Yuto-Nahua agglutinative language spoken in the northeasth of Mexico, and Spanish speakers. In this study, we compared ERPs of 10 Wixarika and 20 Spanish speakers (ages 18-27) during an auditory lexical decision task with nominal phrases using: words (*agua*/*haá*/water), pseudowords type I (cuchillo-chicullo/knife, *hikuri-hukiriti*/cactaceae) and type II (*abeja-abeje*/bee, *haá-hué*/water). Nominal phrases were divided into three conditions: i) agreement (*ne hukâ*/mi panza/my belly), ii) violation of plural (*ta kakaitsi**/sus huarache(**-es**)*/his sho(-e)s*), iii) syntactic violation (*xeme we** *papate/*nuestras (alta*) *tortillas*/our high *tortillas).* There were no differences between conditions neither for LAN amplitudes (Wixarika, F=0.864, p=0.377; Spanish, F=0.005, p=0.94) or latencies (Wixarika, F=0.001, p=0.992; Spanish, F=0.43, p=0.52) nor for ELAN amplitudes (Wixarika, F=1.72, p=0.23; Spanish, F=0.53, p=0.47) or latencies (Wixarika, F=2.09, p=0.19; Spanish, F=0.76, p=0.417). Groups comparisons showed differences only in ELAN latencies before syntactic violation (t=28, p=0.008) and in LAN amplitudes before morphological violation (t=28, p=0.040) only for pseudowords type II. Findings allow us to assert that both ERPs are sensitive to the distinct morphology and syntactic treatment they gave to phrases.

Title: Computations underlying human speech processing from phoneme to semantic meaning

Authors: *X. GONG, J. L. GALLANT, F. E. THEUNISSEN;
Univ. of California Berkeley, Berkeley, CA

Abstract: The transformation from sound to meaning in the brain is carried out by a hierarchy of processing modules that represent progressively more abstract features of sound. However, the computations underlying this transformation are still unknown. We hypothesized that, if cortical representations of semantic meaning are derived from a non-linear transformation of phonemic representations, then it should be possible to model cortical regions that represent semantic meaning in terms of nonlinear combinations of phonemes.
To test this hypothesis, we reanalyzed data collected in an earlier experiment which brain activity was recorded by functional MRI from seven human subjects while they listened to natural narrative speech (Huth et al., 2016; de Heer et al., 2017). We used voxelwise modeling to model every voxel in each individual subject in terms of several distinct feature spaces: single phonemes, combination of two and three phonemes, words and semantic meaning. We used a separate data set to evaluate voxelwise prediction accuracy, and we used variance partitioning to partial out the separate and joint contributions of each feature space. This allowed us to estimate the fraction of response variance accounted by each feature space separately in each voxel and each subject.
We find that regions in superior temporal sulcus (STS), inferior frontal gyrus (IFG), inferior posterior gyrus (IPG) and prefrontal cortex are predicted equally well by bi-phoneme combinations and semantic meaning. This result suggests that these voxels perform a logical AND operations on phonemic representations of speech sound in order to extract meaning. Furthermore, by examining the weights of voxelwise model, we found that these voxels are tuned to combinations of phonemes that occur most frequently in English. Finally, principal component analysis of the voxelwise model weights reveals that voxels located in STS and IFG are best predicted by meaningful, short phoneme combinations (e.g. “sh.iy” and “y.uw”), while

voxels in IPG are best predicted by phonemic combinations that do not convey semantic meaning (e.g. “l.ih” and “t.ao”).

Title: Functional connectivity of the right pars opercularis in American sign language

Authors: *T. IKUTA[1], E. MALAIA[2], R. WILBUR[3];
[1]Univ. of Mississippi, Oxford, MS; [2]Univ. of Alabama, Tuscaloosa, AL; [3]Purdue Univ., West Lafayette, IN

Abstract: Signed languages differ dramatically from spoken languages in that the linguistic signal is encoded spatially. Right hemisphere involvement appears to be critical for sign language processing (Emmorey et al., 2013); however, the specific role and mechanism of this involvement is not well understood. Prior work has identified important roles of right IFG and right STG in both resting state activity (Malaia et al., 2014) and language processing in Deaf signers (Malaia et al., 2013). To better understand the roles of these regions in sign language processing and comprehension, we conducted voxelwise connectivity analysis on fMRI data of 12 Deaf signers and 11 hearing non-signers (Malaia et al., 2013), during presentation of signs and gestures. During four functional series of 5 minutes and 40 seconds, video clips of signs and gestures were presented. Data preprocessing and statistical analyses were conducted using FMRIB Software Library (FSL), as well as Analysis of Functional NeuroImages (AFNI). To conduct voxelwise functional connectivity, each of the regions of interest (left and right pars triangularis (BA 45), pars opercularis (BA 44), and pars orbitalis (BA 47)) was segmented by Freesurfer (Sischl, 2012) on the MNI 1mm space. Using threshold-free cluster enhancement, contrast images were estimated by the threshold of $p<0.001$. The right pars opercularis in Deaf participants demonstrated significantly higher connectivity to right Superior Temporal Gyrus (STG; MNI [64-324 2]) (FWE corrected $p=0.044$) (Figure 1). The five other ROIs (right pars opercularis, and BA 45 and BA 47, left and right) did not show significant differences in connectivity between two groups. The present results suggest that information flow between phonotactic (syllable-segmenting) and semantic system in sign language is right-lateralized. Our finding provides evidence for integration of right-lateralized spatial processing brain networks into linguistic processing algorithms for sign language.

Title: Low-frequency neural activity reflects rule-based chunking during speech listening

Authors: ***P. JIN**, T. ZHOU, N. DING;
Zhejiang Univ., Hangzhou, China

Abstract: During language comprehension, it has been debated whether the brain groups words into higher level chunks such as phrases and sentences. It has been shown that cortical activity tracks phrases and sentences during speech listening, which has been taken as strong evidence for mental construction of multi-word chunks. Nevertheless, it is recently argued that neural tracking of phrases and sentences can be potentially driven by the syntactic or semantic properties of individual words. Here, we test whether cortical activity merely tracks properties of words or also mentally constructed multi-word chunks. When processing a sequence of nouns, two tasks separately require the listeners to group either semantically similar words into chunks or semantically dissimilar word into chunks. It is demonstrated that neural activity actively tracks task-required chunks rather than passively reflecting properties of words. The results indicate that cortical activity mainly tracks multi-word chunks constructed by rules, instead of properties of individual words.

Sch. of Informatics, Kyoto, Japan

Abstract: We recently proposed an analytical method for evaluating subpopulation network structure based on a theoretical coupling of subpopulation network structure and electrocorticogram (ECoG) coherence. The theoretical coupling was first demonstrated by our computational simulation of local field potentials (LFPs) using a biologically plausible network

and further applied to an ECoG signal analysis using distributed semantic representation. In this method, the subpopulation network structure was characterized by individual weights of distributed features at each electrode and these were calculated by multiple regression analysis with a constraint on the theoretical coupling. In the present study, we evaluated the stability of the analytical method based on the theoretical coupling using ECoG signals measured from ten participants during a picture naming task. A set of semantic vectors of picture names was defined by principal components of 100-dimensional word vectors that were calculated using the Word2Vec algorithm and a large text database. The plausibility of the semantic vectors was validated by their behavioral correlation where speech delay was significantly shorter for pictures of which semantic vectors were similar to those of a previously presented picture. The predictability of ECoG coherence using a given picture name was tested for each time period, frequency band, and electrode pair by a 20-fold cross-validation procedure. The individual weights of distributed features were estimated from a training dataset and the predicted coherence to test the set pictures was calculated by using the estimated weights, which was subsequently compared with the true coherence. Cross-subject analysis showed significant predictability of long-range coherence between temporal and frontolateral regions in a wide frequency range of 2-32 Hz and a time period of 0-0.8s after the onset of picture presentation ($p<0.05$, false discovery rate (FDR) corrected). Importantly, the predictability of coherence was higher for higher-dimensional semantic features, where more than one feature (cumulative contribution was 0.17 from the original 100-dimensional word vector) are required for the analysis. This suggests that high-dimensional semantic features contributed to the prediction of the coherence and that the analysis based on the theoretical structure-coherence coupling using distributed semantic representation suitable for ECoG signal analysis. In a future study, it is important to assess various types of networks associated with distributed representation that are compatible with recent machine learning techniques for visual and auditory signals.

Abstract: Visual word recognition (VWR) is the process of mapping the written form of a word to its underlying linguistic item. Characterization of healthy VWR neural mechanisms holds promise for improving treatment of reading deficits and deepening our understanding of literacy. While noninvasive neuroimaging studies have identified putative brain regions and event-related potentials involved in VWR, the spatiotemporal flow of information through the brain remains unclear. In this study, we analyzed high gamma neural activity of more than 13000 electrodes from more than 140 intracranial neurophysiology patients as they read visually-presented words. We find that over 3000 electrodes show a task-sensitive response. Latency analyses reveal that on average, occipital lobe electrodes respond fastest, followed by temporal lobe, with the slowest responses from frontal and parietal lobes. Middle occipital gyrus and fusiform gyrus are among the fastest regions on average. By clustering the responses of all task-sensitive electrodes, we identified a variety of response types including excitatory and inhibitory responses, onset and offset responses, and responses sustained for the duration of the word presentation. We observe that occipital lobe has the highest proportion of excitatory responses while frontal lobe has an almost even excitatory/suppressive balance. Furthermore, we investigated the neural representation of the stimuli's visual, phonemic, lexical, and semantic features. From each feature set, we predicted each electrode's response and investigated the properties of the best-predicted electrodes. Visually-predicted and phoneme-predicted electrode groups had mostly low latencies and excitatory peaks. Visually-predicted electrodes were spread between occipital and frontal lobes. Lexically- and semantically-predicted electrode groups included more suppressive responses, with linguistically-predicted electrodes distributed across frontal, temporal, and occipital lobes, and a plurality of semantically-predicted electrodes in frontal lobe. We further investigated the encoding of these electrode groups of the feature sets over time, showing that visual features peak quickly after word onset, followed by phonemic, linguistic, then semantic features. Together, these results provide a high-resolution look at the spatiotemporal pattern and representation of neural activity during visual word recognition in the human brain.

Title: Evolution of cognitive state during a conversation

Authors: *A. E. HADJINICOLAOU[1], G. BELOK[1], A. C. PAULK[1], C. V. IRWIN[3], J. W. LEE[4], Z. WILLIAMS[2], S. S. CASH[1];
[1]Neurol., [2]Neurosurg., Mass. Gen. Hosp., Cambridge, MA; [3]Neurosci., Brown Univ., Providence, RI; [4]Neurol., Brigham & Women's Hosp., Boston, MA

Abstract: The simple act of conversation involves a rapid sequence of complex behaviors that must be modulated in response to a rapidly changing context. An understanding of how different networks are recruited when the brain shifts between the necessary cognitive states would provide crucial insight into the systems that govern communication, how they are disrupted by neuropsychiatric disease, and how such disruptions might be restored by therapeutic intervention. To examine such processes under natural conditions, we analyzed intracranial brain activity from epileptic patients (implanted with cortical and subcortical electrode arrays for clinical purposes), recorded during loosely structured conversations (45-120 min) with the investigator. Spoken dialog was captured by an audio recorder (H4n, Zoom) and transcribed (in-house software; CoreNLP, Stanford) to yield word lexical categories and their timing within the intracranial recordings. Here we present data from N=4 participants, whose brain activity was collected using a 128-256 channel neural signal processor recording system (Blackrock Microsystems). Recordings were indexed by time windows centered on the verbal onset of either (1) speaking events (participant speech), or (2) listening events (non-participant speech). Intracranial data were analyzed in MATLAB (MathWorks) with the NPMK (Blackrock Microsystems) and FieldTrip (Donders Institute) toolboxes. We used the Similarity Networks (SIMNETS) framework to identify candidates for functionally related recording channel groups, based on the difference in coherence (70-115 Hz) patterns between pairs of time windows (0.5 s duration, before and after speaking and listening events). We observed a widespread increase in alpha-beta band (8-20 Hz) power (relative to baseline), together with a simultaneous decrease in

gamma band (30-120 Hz) power, prior to verbal onset of participant speech. Conversely, alpha-beta power fell when the participant was listening to speech, while gamma power increased after the onset of investigator speech. For certain channel clusters identified by SIMNETS, we were able to characterize neural trajectories associated with shifts in state from receptive speech processing to the articulation of internally generated responses. We speculate that other intermediate states may be invoked during the act of conversation. Our results indicate the involvement of distributed cortical networks in the volitional shift from a receptive, listening state to a productive state.

Title: Statistical testing for event related causality (ERC) among human brain networks using multivariate autoregressive modeling at short time scales

Authors: *A. KORZENIEWSKA[1], P. J. FRANASZCZUK[2], N. E. CRONE[3];
[1]Dept. of Neurol., Johns Hopkins Univ., Baltimore, MD; [2]Human Res. and Engin. Directorate, US CCDC Army Res. Lab., Aberdeen Proving Ground, MD; [3]Neurol., Johns Hopkins Hosp., Baltimore, MD

Abstract: Causal interactions among brain networks in normal or pathological brain states typically occur on very brief time scales. To analyze event-related causality (ERC) in such transient systems, we have used a short-window algorithm for estimating the coefficients of a multivariate autoregressive model (MVAR, Ding et al., 2000) of non-stationary ECoG signals. This method requires multiple repetitions of a given brain process (e.g. testing trials or seizures) to obtain one estimate of an MVAR model, followed by one estimate of the short-time direct directed transfer function (SdDTF, Korzeniewska et al., 2008), representing the directions, intensities, and spectral contents of the direct causal interactions among brain networks, within the time-frequency plane. To test the significance of changes in these interactions in the post-stimulus epochs relative to interactions during baseline epochs (across trials of a stimulus-response-structured cognitive task), we previously fitted the SdDTF time-frequency plane with 2D penalized thin-plate splines constrained by a mesh of knots (Ruppert et al., 2003). This

statistical approach was computationally inefficient, and the required spline interpolation sometimes failed to converge, making it impractical for use in time-sensitive clinical and research applications. Moreover, the mesh of knots introduced artifactual “waves” in the results. Here we report a new approach to statistical testing that overcomes these limitations. In this approach, we construct a joint 95% confidence interval using bivariate smoothing with a rectangular kernel (BSRK). Thus, the variance of the smoothing reflects the variability of SdDTF values, rather than reinforced perfect fits at knots, with poorer goodness of fitting between them. Besides, BSRK is free of the problem of convergence of spline interpolation, and can be applied to other methods of time-frequency analyses. Furthermore, BSRK allows for analyzing much longer time series (e.g. epileptic seizures), because it does not need to hold multiple thin-plate splines in computer memory. The method is also many times faster than the previous method. Comparisons between the results of BSRK and spline-based statistics show that they produce very similar patterns of task-related effective connectivity. However, event-related causality estimates based on bivariate smoothing with rectangular kernels do not suffer from the same artifacts as the old method. Moreover, due to its time and memory efficiency, bivariate smoothing with rectangular kernel is uniquely suitable to both research and clinical applications, e.g. planning epilepsy surgery.

Title: EEG correlates of the verbal transformation effect

Authors: ***M. K. BRUCKER**[1], N. CASTRO[2], J. S. BRUMBERG[3], D. E. THOMPSON[1]; [1]Electrical and Computer Engin., Kansas State Univ., Manhattan, KS; [2]Univ. of Washington, Seattle, WA; [3]Speech-Language-Hearing, Univ. of Kansas, Lawrence, KS

Abstract: The verbal transformation effect (VTE) is experienced when an audio recording of a word or phrase is played repeatedly for a listener. A VTE is when the listener perceives the original word as a word or non-word that may be either similar sounding or phonetically different. This study reports the initial investigation of the detection of VTEs with electroencephalography (EEG) by first considering actual changes in the auditory stimulus to help uncover the neural processing of this complex auditory verbal illusion.
EEG data were acquired from 21 subjects listening to six different audio stimuli, who were instructed to press a button any time they heard a change in the presented stimulus. The task was split evenly between trials that included an actual, objective change in the auditory stimuli, and

those that never objectively changed. Here, we consider transformations where the audio objectively changed between one of the three pairs of stimuli at a rate likely similar to that of illusory verbal transformations. The three pairs (numbered 4/7, 5/8, and 6/9) were presented in switching blocks and were analyzed separately. Stepwise linear discriminant analysis (SWLDA) with 10-fold cross validation was used to classify target and non-target transformation events based on the known transformation times. The 95% confidence bounds for balanced accuracy were then compared to chance to determine statistical significance. The data files of subject 4 and subject 16 were excluded due to recording errors.
Of the 19 tested blocks, the majority were detected significantly above chance level. For pairs 4/7, 5/8, and 6/9, the number of significant results was 14, 13, and 14, respectively. Thus, 41 out of 57 stimulus blocks (71.9%) across 19 subjects presented statistically significant classification accuracies of actual switches between stimuli.
The results of our study support a detectable event-related potential (ERP) associated with switching auditory stimuli in which the switch is presented at a rate similar to expected illusory perceptions due to the VTE. However, the classification accuracies are not ideal and may not be sensitive enough for detection of illusory changes during the VTE. Future work will investigate which ERP components and electrode montages contribute to the correct classification of the VTEs and whether other classification techniques can be used to improve the accuracies. The methods used will then be extended to the detection of the endogenous, illusory VTE changes.

Title: The effect of lexical status on acoustic encoding in human auditory and perisylvian language cortices: Preliminary results from intracranial recordings

Authors: *M. E. SARRETT[1], K. SCHREIBER[1], H. KAWASAKI[2], M. A. HOWARD, III[2], B. MCMURRAY[1];
[1]Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA; [2]Neurosurg., Univ. of Iowa Hosp. and Clinics, Iowa City, IA

Abstract: Speech perception is challenging. Fine-grained acoustic cues must be distinguished quickly to categorize the signal into phonemes. Psycholinguistics suggests listeners maintain fine-grained acoustic detail for longer than the fleeting moment it appears in the auditory signal (Connine, Blasko, & Hall, 1991; McMurray, Tanenhaus, & Aslin, 2008)—subsequent information can bias how listeners categorize ambiguous speech sounds. Further, listeners can use later top-down information about whether a stimulus makes a word to alter categorization (Ganong, 1980). For example, an ambiguous sound between /d/ and /t/ is perceived as a /d/ in the context of "dash" but a /t/ in the context of "task". This requires listeners to maintain fine-grained detail throughout the word or later, and reinterpret this information using lexical status. Studies using fast optical imaging, MEG, and EEG suggest listeners maintain such detail for at least 200 msec (Toscano et al, 2018; Gwilliams et al, 2018; Sarrett et al, in prep). However, it is unclear exactly what brain regions are involved, and whether feedback from higher level areas alters extended auditory representations. We used electrocorticography (ECoG) to address these questions using a variant of Ganong (1980). Participants heard 15 minimal pairs manipulated along a continuum from /b/ to /p/ that differed by which endpoint formed a word. For example, "beach" and "peach" are equi-biased; "boke" and "poke" are p-biased ("boke" is not a word); and "bake" and "pake" are b-biased. Participants were 4 neurosurgical patients with medically intractable epilepsy undergoing chronic monitoring. Participants heard each token and categorized its initial sound. We used multivariate pattern analysis (support vector regression) to recover the cue continuum from local field potentials and high gamma activity (Nourski et al, 2015) in auditory and perisylvian language cortices. Preliminary analyses indicate that fine-grained acoustic cues can be recovered even from high level language processing hubs as late as 300 msec, and that there is an early time window when acoustic cues are processed independent of top-down factors. Analyses in later time windows suggest that lexical status feeds back even to the earliest levels of cortical processing.

Title: Using multivariate pattern analysis on ECoG to characterize neural language pathways

Authors: *A. CURTIS[1,2], O. WOOLNOUGH[2], K. FORSETH[2], P. ROLLO[2], N. TANDON[2,3]; [1]Rice Univ., Houston, TX; [2]Univ. of Texas Hlth. Sci. Ctr., Houston, TX; [3]Mem. Hermann Hospital, Texas Med. Ctr., Houston, TX

Abstract: The dual route model theory of reading originates from data on patients who, due to brain lesions, rely exclusively on one of two routes - a phonological route for grapheme-to-phoneme conversion or a lexico-semantic route for direct lexical access. However, in healthy subjects both routes are engaged simultaneously - implying that a network level representation rather than focal neural activation is more representative of overall processing. To evaluate the validity of the dual route model, we analyzed high spatiotemporal resolution of intracranial recordings with a logistic regression model to evaluate the phonological and lexical streams of reading and to qualify their dynamics. 35 intractable epilepsy patients implanted with depth or subdural grid electrodes were asked to read aloud written stimuli comprising of (i) regular words, (ii) exception words (orthographically irregular), (iii) pseudo-homophones (orthographically novel but phonologically familiar) and (iv) pseudowords (orthographically and phonologically novel). A neural decoding model using logistic regression tracked the spatial distribution of task-relevant information over time. Features including filtered time courses and pairwise connectivity were used as inputs into the model, to maximize stimulus classification accuracy. We found high classification accuracy between words and pseudowords in the first 250 ms following stimulus onset. This decoding accuracy was primarily driven by recordings in the anterior superior temporal gyrus and mid-fusiform cortex. Additionally, around the time of articulation, we saw higher word vs. pseudoword accuracy (both pre- and post-articulation). Decoding performance at these time windows was mainly influenced by the inferior frontal gyrus and partly indexed by a large differential in gamma power between words and pseudowords in this region. This contrasting neural response for words vs. pseudowords lends credence to the dual route theory, which proposes that these two stimulus classes utilize separate mechanisms for word identification and verbalization. Temporal neural decoding enables the tracking of task-relevant information without imposing prior anatomical or functional assumptions, yielding insight into which cortical regions and nonlinear dynamical features are useful for categorical distinctions.

Title: Improving language encoding for fMRI with transformers

Authors: *S. JAIN[1], A. LEBEL[2], A. G. HUTH[2];
[1]Computer Sci., [2]The Univ. of Texas at Austin, Austin, TX

Abstract: Compositionality is the effect of combining information across a sequence of words to extract meaning. It is crucial for language understanding as it goes beyond individual words and examines their meaning in context. Recent work has shown that language models (LM) capture this effect by combining semantic information across words in a sequence to learn contextual representations that can effectively predict the next word. Representations extracted from a Long Short-term Memory (LSTM) LM may then be used to understand how the brain handles compositionality. This is done by building encoding models that use these contextual representations as features for language stimuli to predict the brain responses they elicit. The transformer has recently emerged as a highly successful alternative to LSTMs for language modeling. The crux of this model lies in its multi-head attention mechanism that selectively attends to and combines different information across words without recurrence. This allows transformers to model global dependencies across much longer sequences, possibly learning richer contextual representations. In this work, we extended previous approaches to further understand compositionality in the brain by using a 12-layer transformer LM for language encoding. Different representational spaces were extracted by conditioning on the layer, stage of processing within each layer, and amount of context used. To test this model, we used data from an fMRI experiment wherein 3 subjects (1 female) listened to 13 hours of natural language stimuli. Each feature space was used to build a separate encoding model through ridge regression. Model performance was assessed by testing how well each encoding model could predict responses in a held-out dataset. Our findings indicate that the transformer significantly outperforms earlier models for all subjects by a very large margin. Unlike LSTMs, performance steadily improves with the amount of context, corroborating the claim that transformers can capture compositionality over much longer sequences. Across the 12 layers, middle layers best capture high-level semantic areas in the brain while earlier and later layers best predict lower-level areas. We find that attention heads in each layer behave very differently and seem to encode diverse information, predicting distinct parts of the cortex. These results suggest that the transformer can effectively capture diverse semantics and varying levels of compositionality, allowing it to successfully predict responses across much of the cortex and providing deeper insight into how the brain uses compositionality for language understanding.

Title: Decoding of semantic meaning at single cell resolution during human language perception

Authors: *J. CAI[1], B. L. GRANNAN[1], M. JAMALI[1], E. FEDORENKO[1,2], Z. WILLIAMS[1,3]; [1]Massachusetts Gen. Hosp. - Harvard Med. Sch., Boston, MA; [2]McGovern Inst. for Brain Res., MIT, Cambridge, MA; [3]Harvard-MIT Div. of Hlth. Sci. and Technol., Boston, MA

Abstract: How many neurons do we need to decode the semantic meaning of a word in human language? Current work demonstrates that individual neurons in the left dominant prefrontal cortex of humans respond to the semantic meanings of words. Here, we perform predictive decoding analysis on experimental data to study how prefrontal cortical neurons represent the semantic meaning of individual words when provided in the context of sentences. Using micro-electrodes, we recorded 220 neurons from 11 participants when they listened to audio recordings containing both 8-word sentences and 8-word lists. All words were clustered into 9 main semantic domains using a dimensionality reduction approach. Population decoding was performed with a multinomial logistic regression of the population firing rate in order to predict the semantic domain of each word. The control analysis involved shuffling the labels of the word categories and repeating the decoding analysis. Our results show that decoding accuracy reached 30% when predicting the semantic domains in sentences, compared to 11% accuracy in the control. Interestingly, decoding performance dropped to chance when listening to the same words but in the context of random word-lists. Finally, Bayesian information criterion (BIC) analysis showed that a random selection of 28 neurons from the population resulted in the optimized decoding models. In sum, our work demonstrates that prefrontal neurons encode semantic content within the human language network and that these neuronal responses can be used to decode the semantic meaning of words over the course of individual sentences.

Title: High-density intracranial recordings reveal evidence of speech tracking in dorsal premotor cortex

Authors: *J. BEREZUTSKAYA, C. BARATIN, Z. V. FREUDENBURG, N. F. RAMSEY; Brain Ctr. Rudolf Magnus, Univ. of Utrecht, Utrecht, Netherlands

Abstract: A lot remains unknown about how the human brain processes continuous perceived speech. Previous reports have shown that apart from the core network of regions (transverse, superior temporal and inferior frontal gyri), a number of other brain areas support speech perception. In particular, the role of premotor cortex (PMC) remains debated. Recent work has focused on the ventral portion of PMC and its role in encoding various properties of speech. At the same time, the dorsal portion of PMC is becoming more and more of interest as its involvement appears inconsistent across studies and recording modalities. Thus its specific role in speech processing remains to be further clarified. In this study we investigated the involvement of PMC in continuous speech perception using high-density (HD) intracranial electrode recordings. Two participants implanted with HD grids watched a full-length feature film. We then analyzed their brain responses (high frequency band) in PMC in relation to the speech fragments of the film. First, in each subject we observed that a set of electrodes in dorsal PMC exhibited significantly higher responses to speech compared to non-speech fragments, such as music, noises, animal cries (*t*-stat.>4, p<.001, cor.). Then we correlated the responses of these electrodes to the speech envelope and found significant amount of speech tracking (Spearman's *rho*>=.3). Dorsal PMC electrodes also showed significantly higher correlation to electrodes in the auditory cortex during speech compared to non-speech fragments (*t*-stat.>3, p<.01, cor.). Finally, dorsal PMC electrodes seemed to filter out the noise from the speech envelope (as they exhibited a better correlation to isolated speech track than same fragments of speech in mixed track: *t*-stat.>3, p<.01, cor.) and focused on tracking of the phrasal structure of speech (following of the ON/OFF speech pattern: max. F_{S1}=1492, p<.001, max. F_{S2}=733, p<.001). Interestingly, these effects were strong in participants with HD grids, but lessened substantially in participants with standard density electrode grids, suggesting that HD electrode recordings can provide a finer detail of information about the underlying brain function. Overall, our results suggest that dorsal PMC is largely involved in tracking of perceived speech by filtering out the noise from the

speech stream and following the phrasal grouping patterns in speech. In addition, we report that HD intracranial recordings may uncover a finer level of detail in the acquired brain signal which can be crucial for elucidating the role of cortical regions supporting complex cognitive function, such as continuous speech perception.

Title: Studying perceived language and semantic meaning in the prefrontal cortex at a single-cell resolution

Authors: *B. L. GRANNAN[1], M. JAMALI[3], J. CAI[2], E. FEDORENKO[4], Z. WILLIAMS[5]; [2]Dept. of Neurosurg., [1]Massachusetts Gen. Hosp., Boston, MA; [3]Neurosurg., Massachusetts Gen. Hospital/Harvard Med. Sch., Boston, MA; [4]MGH, Charlestown, MA; [5]Harvard Med. Sch., Boston, MA

Abstract: Humans can extract the meaning of language over remarkably fine temporal scales and myriad contexts. Functional imaging studies suggest that this human ability is subserved by a widely distributed frontotemporal and subcortical network of brain areas. The degree to which semantic meaning is represented by single neurons, however, remains unknown. Here we test the hypothesis that neurons in the dominant, associative prefrontal areas, which are surgically accessible during intraoperative neuronal recordings, are involved in the rapid computation of semantic- and sentence-level content during language perception. We performed acute recordings of left dorsal prefrontal neurons in 10 right-handed participants as they listened to naturalistic sentences that varied in content and theme. Using a dimensionality reduction approach, we tested for single-neuron responses that were selective for certain semantic domains by comparing firing rates in response to words from one domain with responses to all other words. In total we recorded from 220 prefrontal neurons, of which 47 (21.3%) were selective for at least one semantic domain ($p<0.025$ after false-discovery rate correction for multiple domains tested). The majority of these neurons (N=31, 66.0%) were selective for only one domain, and no neurons were selective for more than three. These neuronal response patterns, however, were not

static but rather reflected variations in the intended meaning of words based on the sentence context in which they were heard. When participants listed to non-ordered random word lists, only 5.5% of neurons demonstrated selective activity. Moreover, most neurons reflected the intended meaning of word homophones that were phonetically identical but belonged to different semantic domains. In conclusion, dominant prefrontal neurons demonstrate firing rate activity that is selective for and representative of the semantic content within speech. This is the first study to assess the role of prefrontal neurons during language comprehension and supports the conclusion that dominant frontal neurons are involved in the rapid, context-dependent extraction of intended meaning during language perception.

Title: Unsupervised spike clustering via ensemble of autoencoders

Authors: *J. EOM[1], S. KIM[1], H. JANG[1], H. SHIN[1], Y. HUH[2], D. HWANG[1];
[1]Yonsei Univ., Seoul, Korea, Republic of; [2]Catholic Kwandong Univ., Incheon, Korea, Republic of

Abstract: Spike sorting refers to the technique of detecting the signals (spikes) generated by neuronal activities and assigning the spikes to the neurons they belong to. Although many spike sorting algorithms have been developed to help analyze the recorded signals, manual spike sorting has been preferred by researchers since it provided the most precise performance. Therefore, in order to process a large amount of cellular recording data, spike sorting took an enormous amount of time. The number of neurons (i.e., clusters) has to be set because this is the most critical step required to accurately sort the spikes. Previous attempts tried to estimate the number of neurons by extracting principal features from dimensionality reduction such as diffusion map and combining these features with clustering algorithms. In this study, we propose a deep learning method to find the number of neurons based on unsupervised feature extraction using an ensemble of autoencoders (AE), which is being widely reported to produce superior performance in terms of dimensionality reduction and feature extraction compared to conventional methods. After denoising the acquired signals, additional pre-processing such as sampling the signal at various intervals or calculating the gradient between sampled points have been tested to extract the optimal form of input data. As a result, using the gradients between every 3-point interval has shown the best performance in deciding the optimal number of

neurons when used as AE input. It also reduced the memory used for training and testing the network compared to using entire signal. The proposed network architecture is an ensemble model of 3 different AE. Each AE consists of 1 to 3 hidden layers. The deeper the AE, the compressed feature contains higher-level information. The proposed ensemble network utilizes the combination of the compressed features from 3 different models to have a more expanded hidden representation of the input signal. After that, these vectors are clustered using K-means clustering algorithm. The results of clustering are evaluated by Silhouette method to decide the optimal number of neurons. K with the highest Silhouette score becomes the optimal number of neurons. Because the Silhouette score exhibits a slight fluctuation, we executed 20 times of clustering and averaged the Silhouette scores. The performance of the proposed method to find the optimal number of neurons with the gradients at every 3-point interval shows over 90% accuracy. It is comparable or slightly higher than the conventional methods, with fewer features required (Proposed: 9, Diffusion map: 10, Wavelet transformation: 15).

Title: PsychRNN: An open-source Python package for training artificial recurrent neural networks on cognitive tasks

Authors: ***J. T. STONE**[1], D. B. EHRLICH[2], D. BRANDFONBRENER[4], A. ATANASOV[5], J. D. MURRAY[3];
[1]Computer Sci., [2]Neurosci., [3]Psychiatry, Yale Univ., New Haven, CT; [4]Computer Sci., New York Univ., New York, NY; [5]Theoretical Physics, Harvard Univ., Cambridge, MA

Abstract: Modeling using recurrent neural networks (RNNs) is quickly becoming a popular strategy to probe the mechanisms behind cognitive tasks. RNNs are able to accomplish many popular cognitive tasks but are vastly more manipulable and observable than classic model organisms such as monkeys and humans. Modeling is a fast, inexpensive way to investigate the abilities and limitations of proposed mechanisms behind cognitive tasks, and can lead to deeper understanding of current proposed mechanisms and new mechanistic hypotheses. These insights can in turn guide experimental focus to better distinguish between current proposals.
Here we introduce an accessible and extensible Python package for training RNNs on a variety

of cognitive tasks. Our package provides an accessible framework, requiring only knowledge of Python and NumPy, for easily defining new cognitive tasks and customizing tasks included with PsychRNN. The deep learning details are abstracted away so that researchers do not need machine learning or TensorFlow (TF) knowledge to get started modeling RNNs. PsychRNN includes multiple initializations, loss functions and regularizations as well as a framework to easily add more. For projects that require additional customization and researchers who have TF knowledge, the TF-based backend is easily extensible.
Our package focuses on facilitating specification of neurobiological constraints on synaptic architecture and on learning. We include optional implementations of Dale's principle, neurobiologically plausible sparse connectivity, regional connectivity differences and individual unit time-constants. PsychRNN additionally can return intermediate network solutions so researchers can investigate how network solutions develop over the course of training.
The design of PsychRNN further enables novel investigations. Task modularity makes it easy to investigate how parametric variations in task demands determine network solutions. This modularity means that with only one task definition, it is easy to vary many different task parameters iteratively. This ease of use enables more investigation and experimentation for less researcher time.
PsychRNN also allows researchers to implement task shaping, where training is adjusted in closed loop based on performance. Experimentalists regularly train animals to perform tasks by shaping tasks—PsychRNN allows investigation of how shaping trajectory choice could affect the observed results. This could lead to discovering faster ways of training animals or possible confounds that may result from task shaping in animal training.
PsychRNN is available at https://github.com/dbehrlich/PsychRNN.

Title: The topology of time: Characterizing transitions in simulated neural dynamics using topological data analysis

Authors: *M. ZHANG, M. SAGGAR;
Psychiatry and Behavioral Sci., Stanford Univ., Stanford, CA

Abstract: A key challenge in understanding orders and disorders of brain dynamics is finding mechanistic representations of observed dynamical patterns for systematic comparisons. Such representations should not only detect phase transitions in the underlying dynamical system but also detect changes in the dynamical landscape. Here, we aim to develop a topological representation of dynamics that recovers a priori known transitions in simulated neural dynamics. More specifically, neural dynamics and corresponding fMRI blood-oxygen-level dependent (BOLD) signals were simulated using a dynamic mean field model (Deco et al, 2013) constrained by biologically realistic parameters. Phase transitions were induced by varying the level of global coupling between brain areas over time. Subsequently, we constructed topological representations of simulated BOLD dynamics, building on an existing method of topological data analysis (Mapper; Saggar et al. 2018). We found that recurrence plots defined on the topological representation recovered phase transitions and shifts in the underlying dynamical landscape induced by varying global coupling. Furthermore, this topological method was compared to its relatively traditional counterparts - recurrence plots generated directly from BOLD signals and that generated from dynamic functional connectivity. Recurrence of BOLD signals identified phase transitions but was insensitive to the change in the global coupling leading to such transitions. Recurrence of dynamic functional connectivity reflected whether, but not how, the global coupling was changing. In contrast, recurrence in the topological representation provided rich information on both the transitions and the underlying parameter changes. This work takes important steps toward a theoretically validated topological representation of neural dynamics, which not only detects sudden changes in the dynamic organization of the brain but also anticipates such changes in the gradual shifting of the dynamic landscape. It bears potential as a dynamic-based tool for diagnostics and early prevention of neural disorders.

Abstract: Wide-field optical mapping (WFOM) methods can resolve neurodynamics on fast time-scales over the entire surface of a rodent cortex. The Allen Mouse Brain Connectivity Atlas (AMBCA) gives detailed axonal projections across cortex. We investigate whether connections inferred from dynamic network models applied to WFOM data resemble the axonal projections reported in the AMBCA. We model the cortex as a dynamic network whose nodes correspond to excitation averaged over a pixel. Local excitation-inhibition dynamics are modeled as an auto-regressive AR(p) process, and long-range excitatory axonal connections are modeled as feed-forward connections between pixels with lags estimated from distance and axon conduction speed. Using simulated data, we show that connectivity can be inferred accurately via Least-squares parameter estimation, and with significantly increased efficiency when Tikhonov regularization and other optimization methods are applied. Furthermore, we find that inferring connections based on correlation can fail when inputs are coherent across many pixels, e.g. inputs from thalamus, leading to false-positives. We show that simultaneous estimation of connectivity and coherent inputs can resolve this issue. We also show that such models can exhibit long-range synchronization even when the nodes are driven by noise, and that the output in the synchronized regime is dominated by a low-rank signal with a consistent spatial structure, and a temporal component given by a convolution of the coherent input, when such inputs are present. We compare simulations based on the AMBCA connections to observed dynamics, and attempt to estimate connections in existing WFOM data.

Title: Context-aware *in-silico* synthesis of protoplasmic astrocyte morphology

Authors: *E. ZISIS, L. KANARI, S. DAGAR, D. KELLER, H. MARKRAM;
EPFL, Blue Brain Project, Geneva, Switzerland

Abstract: The astrocytic morphology gives rise to functional properties that are important for the brain circuitry. Thus, neurons are no longer considered as separate functional units, but rather as a puzzle piece in the greater functional ensemble of the neuronal-glial-vascular circuitry. Astrocytic cells in the brain form anatomically exclusive territories that minimally overlap with their neighbors. In these microdomains each cell establishes the connectivity with the vasculature and the neuronal synapses. The astrocytic morphology is dominated by contextual elements of its environment: the proximity to its neighbors, the vasculature and the distribution of the neuronal synapses within its domain. Thus, in order to build a generative model of protoplasmic astrocytes we need both the topological information of their structure and the geometrical constraints that govern their environment and bias their morphological characteristics.
We present a novel method that combines the topology synthesis of branching structures using as input topological barcodes (Kanari et al., 2018) with contextual cues, such as the bounding geometry and the attraction to the synaptic point cloud. Starting with a vasculature dataset, we first distribute astrocytic somata positions satisfying both their spatial densities and their nearest neighbor distributions. We then generate a Laguerre tessellation from the somata positions and radii, which reflects the bounding microdomain of the astrocytes. The microdomain hull is consequently used to establish the connectivity with the vasculature and the neuronal synapses in the neuronal circuit. The interplay of topology and spatially embedded information fuels the synthesis algorithm for protoplasmic astrocytes. We synthesized realistic astrocytic morphologies embedded in space and validated both single cell's morphology and collective circuit wide properties against biologically reconstructed astrocytic morphologies and literature data. The synthesis pipeline lays the groundwork for functional models of energy provision to the neuronal microcircuit in which endfeet reconstruction and surface area can be used for compartmental reaction-diffusion simulations. Furthermore, the indirect communication of neuronal synapses through the astrocytic syncytium could provide us with insights on the plasticity dynamics in the NGV ensemble. Finally, calcium induced intra-cellular and inter-cellular wave simulations require specification of the geometry of domains, morphologies and the degree of astrocytic overlap. Our workflow ensures the reconstruction of the anatomical architecture that renders possible all the above.

Title: Computational synthesis of dendritic morphologies within the rodent neocortex

Authors: *L. KANARI[1], W. VAN GEIT[1], B. COSTE[1], Y. SHI[1], K. HESS[2], H. MARKRAM[1]; [1]EPFL, Blue Brain Project, Geneva, Switzerland; [2]EPFL, Lab. for Topology and Neurosci., Lausanne, Switzerland

Abstract: A neuron's morphology determines its functional properties and its connectivity, both of which influence the dynamical properties of neuronal networks. It is therefore essential for the accurate digital reconstruction of detailed brain networks to replicate the anatomical properties of neuronal morphologies. In particular, the digital reconstruction of a large-scale, physiologically realistic network, such as the Blue Brain Project's cortical microcircuit published in (Markram et al. 2015), requires large numbers of detailed neuronal morphologies, which are difficult to acquire experimentally, due to limitations of the reconstruction techniques. To populate such large-scale networks with unique neuronal morphologies, the computational generation (i.e., synthesis) of detailed morphologies that respect the branching properties of the biological cells is therefore required.

The principles that determine how dendritic and axonal arbors take shape are still largely unknown. For this reason, there is a plethora of synthesis methods for the artificial generation of neuronal morphologies (Ascoli et al. 2001, Koene et al. 2009, Cuntz et al. 2010), each of which contributed to the comprehension of neuronal growth, though no single algorithm has managed to reproduce a wide variety of neuronal shapes without appropriate fine tuning of the input parameters. Here, we apply the topological descriptor of branching morphologies that was introduced in Kanari et al. 2018 to the computational synthesis of dendritic morphologies from all layers and morphological types of the rodent cortex. Each generated morphology was validated against biological dendrites, based on a set of morphological features not directly used as input.

The synthesis algorithm driven by the topological architecture of dendrites generated realistic morphologies for a large number of distinct cortical neuronal cell types. Our results demonstrate that the topology-based synthesis algorithm implicitly captures correlations of features within the dendritic shapes, without the need for manual identification of these dependencies. In addition, electrical simulation of the synthesized cells in Neuron generates traces that reproduce the electrical properties of biological reconstructions. The topology-driven synthesis thus reproduces the morpho-electrical properties of a broad range of different branching shapes. Since the topology-based synthesis is generalizable to a large number of different dendritic shapes, it is suitable for the generation of unique neuronal morphologies to populate the digital reconstruction of large-scale, physiologically realistic networks.

Title: Impact of higher-order network structure on emergent cortical activity

Authors: *M. NOLTE[1], E. GAL[2], E. B. MULLER[1], H. MARKRAM[1], M. W. REIMANN[1]; [1]Blue Brain Project, EPFL, Geneva, Switzerland; [2]Edmond and Lily Safra Ctr. for Brain Sci., The Hebrew Univ., Jerusalem, Israel

Abstract: Synaptic connectivity between neocortical neurons is highly structured, including first-order structure, such as strengths of connections between different neuron types and distance-dependent connectivity, and higher-order structure, such as an abundance of cliques of all-to-all connected neurons and small-world topology. The relative impact of first- and higher-order structure on emergent cortical network activity is unknown. Here, we compared network topology and emergent activity in two neocortical microcircuit models with different null-models of synaptic connectivity, both with similar first-order structure, but with higher-order structure - arising from morphological diversity within neuronal types - removed in one model. We found that morphological diversity within neuronal types creates heterogeneous degree distributions with hub neurons, raises in-degrees at the bottom of layer six, contributes to the abundance of cliques, and increases small-world topology. The increase in complexity of the higher-order network structure was accompanied by more nuanced changes in neuronal firing patterns, including increased activity and response reliability at the bottom of layer six. Without this structure, the dependence of pairwise correlations on the positions of neurons in directed cliques was strongly reduced. Our study shows that circuit models with very similar first-order structure of synaptic connectivity can have a drastically different higher-order network topology, and that the higher-order topology imposed by morphological diversity within neuronal types has a clear impact on emergent activity.

Abstract: The thalamocortical system consists of different thalamic nuclei and their reciprocal interactions with the neocortex. It is involved in numerous functions, for instance transmission of sensory information and transition between brains states, such as sleep and wakefulness. Computer simulations facilitate the integration and standardization of different sources of experimental data and help us understand the structural and functional complexity of neural circuits. This approach has been recently published in the context of the Blue Brain Project as a detailed reconstruction and simulation of a cortical microcircuit [1].
In this work, we followed and extended the pipeline developed in [1] to develop a digital reconstruction of a thalamic microcircuit, including the somatosensory thalamus and the corresponding region of the thalamic reticular nucleus, which provides the main source of inhibition to the thalamus. We performed targeted experiments to capture electrophysiological and morphological cellular data from the adult mouse. We used this data, combined with data from the literature and open access datasets [2], to automatically constrain the firing properties of single neuron models [3]. We defined the microcircuit geometry as in [1] and populated it with neuron densities derived from the Blue Brain Cell Atlas [4] and compared them with stereology studies. The 3D morphological reconstructions constituted the basis to derive the detailed micro-connectome between neurons in somatosensory thalamus and in the reticular nucleus. We then validated the micro-connectome with sparse experimental and literature data, which characterized the number of afferent and efferent synaptic boutons and the synaptic physiology. We included afferent sensory projections from the medial lemniscus and corticothalamic feedback, in order to model extra-thalamic inputs to the microcircuit.
We identified *in vitro* experiments that could be used to simulate and validate network phenomena, such as thalamic oscillations known as sleep spindles. The experimental data, model artifacts and associated metadata are continuously integrated in Blue Brain Nexus [5], in order to make them easily re-usable and track their provenance. The thalamic microcircuit model

provides foundations and principles that can be extended to model the whole thalamus, and ultimately the thalamocortical system.

Abstract: The Blue Brain Project (BBP) seeks to build biologically detailed models of neuronal tissue and perform simulated experiments to help advance the understanding of the brain. Recent work has seen the realization of a tissue reconstruction consisting of 9 million neocortical neurons with 80 billion synapses. Such volume of data is a challenge to simulate and to aid in this endeavor, we participate to advance software capabilities for scalability and performance. From its inception, BBP has used NEURON since it has a rich feature set developed over the last thirty years. In recent years, CoreNEURON has been under development as a new compute

engine for NEURON. CoreNEURON uses a better optimized memory layout which allows for simulations up to 7 times larger to run on the same compute infrastructure. The internal data structures are more easily adaptable to take advantage of modern computing architecture capabilities. During this work to advance CoreNEURON, we also investigated better methods for translation of the domain-specific languages (DSLs) as used to describe biological models simulated in NEURON such as ion channels and synapses. This new NMODL translation allows for qualitative analysis of the user source code and restructures the final organization for better optimization of the final generated code, yielding more efficient execution in the built application. NMODL is capable to implement multiple SIMD and SPMD targets applicable to modern hardware. Benchmarks were executed on Intel Skylake, Intel KNL, and AMD Naples platforms, with individual compute kernels showing a speedup of up to 20x. In production simulations, overall performance gains of ~10x were measured. Further NMODL yields a 2x speed up when compared to a previously published SIMD optimized version that heavily relied on auto-vectorization by the compiler.

Title: Data-driven integration of hippocampal CA1 synapse physiology *in silico*

Authors: *A. ECKER[1], A. ROMANI[1], S. SÁRAY[2], S. KÁLI[2], M. MIGLIORE[3], A. MERCER[4], H. MARKRAM[1], E. B. MULLER[1], S. RAMASWAMY[1];

Abstract: The physiology of synaptic connections in rodent hippocampal CA1 has been the subject of intense experimental study in recent decades. Yet, the resulting knowledge remains disparate and difficult to reconcile. Here, we present a data-driven approach to integrate the current state-of-the-art knowledge on the synaptic anatomy and physiology of rodent

hippocampal CA1, including axo-dendritic innervation patterns, number of synapses per connection, peak conductances and short-term plasticity into a single coherent resource. First, we undertook an extensive literature review of paired-recordings of hippocampal neurons, and compiled experimental data on their synaptic anatomy and physiology. The data collected in this manner is sparse and inhomogeneous, due to the diversity of experimental techniques used by different labs, which necessitates the need for an integrative framework to unify these data. To this end, we extended a previously developed workflow for the neocortex to constrain a unifying *in silico* reconstruction of the synaptic physiology of CA1 connections. Our work identifies gaps in the existing knowledge and provides a complementary resource towards a more complete quantification of synaptic anatomy and physiology in the rodent hippocampal CA1 region.

Title: An automated tool for detecting dynamical chaos in the brain

Authors: *D. TOKER[1], F. T. SOMMER[2], M. DESPOSITO[3];
[1]Univ. of California, Berkeley, Berkeley, CA; [2]Univ. California, Helen Wills Neurosci Inst., Helen Wills Neurosci. Inst., Berkeley, CA; [3]Helen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA

Abstract: Dynamical chaos - i.e., exponential sensitivity to small perturbations - is thought to play a key functional role in the brain. A method for detecting chaos from neural recordings should therefore be a key feature of the neuroscientist's toolkit. But, classic chaos-detection tools are highly sensitive to measurement noise, which has made it difficult to distinguish between stochastic, periodic, and chaotic neurobiological processes. To aid in the experimental study of chaotic neural dynamics, we integrate several new mathematical tools into a fully automated processing pipeline, which can accurately assess the presence and degree of chaos in a diverse range of measurements, biological or otherwise, even when those measurements are noisy, and even for difficult edge cases. Our tool is freely available online.

Title: A low-cost, open-source control and timing system for training animals on behavioral tasks

Authors: H. B. SMITH, O. K. BOTONIS, *I. OZDEN;
Biomedical, Biol. and Chem. Engin., Univ. of Missouri, Columbia, MO

Abstract: We report a low-cost, open-source control system for training lab animals on behavioral tasks. Our system is based on custom electronic circuits integrated with an Arduino Due board. The system can be programmed with a Python-based graphical user interface to design a custom training paradigm with the capability of acquiring behavioral data from many (>10) sensors and delivering TTL control/timing pulses from many output ports (>10) simultaneously. The system also incorporates several timing circuits, two programmable function generators and two audio channels, which can be used during training or behavioral tasks. We demonstrate the utility of our system by presenting the design of a system for training mice to perform an odor-discrimination-based Go/No-Go task, which requires controlling a 4-odor olfactometer with 6 solenoid valves, obtaining behavioral timing data from 2 sensors, triggering a laser for optogenetic stimulation, providing water reward and delivering auditory cues as feedback. The design files and the software of our system are user-friendly, modular and open-source.

Campus, Ashburn, VA

Abstract: Movement is a critical aspect of behavior and can explain a substantial fraction of neural variability. It is therefore important to monitor movements in great detail, especially for behavioral data collected at diverse sites. The International Brain Laboratory (IBL) built 21 standardized behavioral training boxes in six institutions around the world in which mice are filmed using a single Point Grey Chameleon3 camera. Using standardized camera placement and parameters, highly similar videos of head-fixed mice performing a visual detection task are acquired. At full capacity, behavioral training in the IBL produces around 100 hours of video per day. To robustly track body parts in this large dataset of videos, we evaluated DeepLabCut; a toolbox for markerless tracking based on deep learning. We trained networks on a general dataset composed of videos of different mice in different training rigs. The networks generalize well and can be used to track body parts in any IBL behavioral video with average error between 1.2 mm (for paws) and 0.1 mm (for the pupil). We show that DeepLabCut can replace traditional methods used for eye tracking, lick and sniff detection and paw tracking with a single side view video. First, a coarse network is used to detect Regions of Interest (ROIs). Subsequently, an automated crop is made around these ROIs. Finally, specialized DeepLabCut networks are applied to the cropped videos. We trained specialized networks to track pupil movements, sniffing and licking, and paw movements. This pipeline is fully automatized, starting from video acquisition to saving time series of body parts of interest. Combining detailed tracking of body movements with physiological recordings will be a powerful tool for investigating the neural underpinnings of behavior.

Title: Pathfinder: Open source software for analyzing spatial navigation search strategies

Authors: *M. B. COOKE, T. P. O'LEARY, P. K. HARRIS, J. S. SNYDER;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The Morris Water Maze is a widely used task developed to test spatial navigation in rodents. Rodents are trained to learn the location of a platform that offers escape from the pool. Classically, measures such as latency to the escape platform and total distance traversed have been used in order to score spatial learning on this task. However, these measures offer little insight into the underlying navigational strategies that the animals employ. Recently, a number of studies have begun to classify water maze search strategies in order to clarify the precise spatial and mnemonic functions of different brain regions, and to identify which aspects of spatial memory are disrupted in disease models. While search strategies can be intuitively defined relative to escape locations and maze geometry, they have not been widely adopted, presumably due to the lack of available software. In order to address this issue, we developed Pathfinder, an open source application for analyzing spatial navigation behaviour. Here we show that Pathfinder effectively identifies a variety of search strategies, that vary in their spatial specificity, as rodents learn the location of the escape platform. Our software supports inputs from commonly-used, commercially-available software packages (Ethovision, Anymaze, and Watermaze, with more compatibility to be added soon), is optimized for classifying search strategies (Direct Swim, Focal Search, Directed Search, Spatial Indirect, Chaining, Scanning, Random Search, Thigmotaxis), and can also be expanded easily to work with other species and spatial navigation tasks. Pathfinder has the ability to automatically determine the platform location as well as the size of the pool and related pool parameters. It can generate heatmaps of trials, analyze navigation with respect to multiple goal locations and, due to the open source nature of the project, can be easily updated to accommodate future developments in the study of spatial navigation.

Title: Behavioural analysis toolbox for mice engaged in string-pulling task

Authors: *M. H. MOHAJERANI[1], S. INAYAT[1], S. SINGH[1], Q. QANDEEL[1], I. Q. WHISHAW[2];
[1]Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [2]Neurosci., Univ. Lethbridge, Lethbridge, AB, Canada

Abstract: String pulling is a bimanual task in which rats and mice use hand-over-hand movements to pull a string to obtain food rewards. The task requires little training as the animals have a natural tendency to pull strings. Making videos of mice engaged in the string-pulling task and their offline analysis for identification and tagging of body parts in individual frames allows quantification of the topographical and kinematic parameters for the movements of head, body, and forehands which can then be used to assess fine motor functions. Currently, manual analysis of video data acts as a bottle neck limiting data collection. Here we present a Matlab® based toolbox with an easy to use graphical user interface to aid researchers in analyzing string-pulling video data. The user defines colors of body, ears, nose, hands, and string which are used to find respective masks using color-based image segmentation. Heuristics based algorithms are then used to identify and tag the body, ears, nose, and forehands. If automatic tagging fails, the user can manually tag any body part. Using the centroids and shapes of tagged body parts, the software estimates and plots their kinematic parameters such as body length and angle, head yaw, roll and pitch, and paths as well as speeds of both hands. The toolbox is open source and users can modify according to their specific needs.

Title: IronClust > Drift-resistant, real-time spike sorting based on anatomical similarity for high channel-count silicon probes

Authors: *J. J. JUN[1], J. MAGLAND[2], C. MITELUT[3], A. H. BARNETT[1];
[1]Ctr. for Computat. Mathematics, [2]Ctr. for Computat. Biol., Flatiron Inst., New York, NY;
[3]Columbia Univ., New York, NY

Abstract: Extracellular electrophysiology can record the activity of a large neural population with single spike resolution. Spike sorting is then needed to resolve individual cellular activities by grouping together similar spike waveforms distributed at a subset of adjacent electrodes. Silicon probes are widely used to measure the spiking activities from behaving animals, but the probes can drift in the brain due to animal movements or tissue relaxation following a probe penetration. Probe drift often causes errors in conventional spike sorting methods that assume stationarity in spike waveforms and amplitudes. However, some of the latest silicon probes offer whole-shank coverage by electrodes of sufficient density that algorithms could potentially compensate for such drift along the probe axis.We introduce a drift-resistant spike sorting algorithm, IronClust, for high channel-count, high-density silicon probes, which accurately handles both gradual and rapid drift. We exploit the fact that a linearly drifting probe revisits anatomical locations at later times. We apply density-based clustering to temporal subsets of the spiking events when the probe occupied similar anatomical locations. This anatomical similarity between disjoint time segments is determined from activity histograms, which capture spatial structures in the spike amplitude distribution on each electrode, prior to clustering. For each spiking event, the clustering algorithm (DPCLUS) computes the distances to a subset of its neighbors selected by their peak channel locations, and by anatomical similarity. Based on the k-nearest neighbors, one then finds the density peaks based on the local density values, and the nearest distances to the higher-density neighbors, and recursively propagates the cluster memberships toward a decreasing density gradient. The accuracy of our algorithm was evaluated using validation datasets generated using a biophysically detailed neural network simulator (BioNet), which generated stationary, slow monotonic drift, sinusoidal, and fast random drift. IronClust achieved ~8% error on the stationary dataset, and ~10% error on the gradual or random drift datasets, which significantly outperformed existing algorithms. We also found that additional columns of electrodes improve the sorting accuracy in all cases. By exploiting GPU code, IronClust achieves over 11x real-time sorting speed for 60 channels, which is over 2x faster than other leading algorithms. In conclusion, we present an accurate and scalable spike

sorting tool that is resistant to probe drift, by taking advantage of anatomically-aware clustering and parallel computing.

Title: Enhancing parametric models of neuroscientific data involving diverse covariance structures with the Union of Intersections (UoI) framework

Authors: *A. KUMAR, K. E. BOUCHARD;
Biol. Systems and Engin., Lawrence Berkeley Lab. and UC Berkeley, Berkeley, CA

Abstract: A pervasive but under-appreciated aspect of neuroscientific data is the presence of strong correlations between predictive features. For example, when estimating functional connectivity, there are often strong correlations between different populations of neurons. In the context of parametric estimation (e.g. linear regression), correlated design hampers both feature selection and estimation. The widely used Lasso tends to select only one out of a group of highly correlated features. Other estimators such as the Elastic Net exhibit a grouping effect, wherein clusters of correlated features will tend to be assigned similar coefficient values. These fundamental issues are often not appreciated by experimentalists, and jeopardize conclusions drawn from estimated models. In this empirical study, we demonstrate that Union of Intersections (UoI), a statistical-machine learning framework we have recently developed to enhance feature selection and estimation, exhibits state of the art performance on generic, sparse, correlated regression problems. The superior selection and estimation accuracy of $\text{UoI}_{\text{Lasso}}$ and $\text{UoI}_{\text{ElasticNet}}$ is demonstrated on synthetic datasets. We systematically vary the covariance matrix of predictors from a block diagonal structure to one with exponentially decaying off-diagonal elements. This approach contrasts with most methodological developments in this space, which address very specific covariance structures. Furthermore, we impose varying degrees of signal to noise, heterogeneity in the model coefficients, and model sparsity. Our numerical studies reveal a 'fundamental' tradeoff between false positive and false negative control. This tradeoff, modulated by the signal-to-noise ratio of the problem, bounds the selection accuracy attainable by known estimators. As the UoI framework aggressively controls for false positives through a form of stability selection, it is able to outperform competing algorithms in sparse settings. Moreover, $\text{UoI}_{\text{Lasso}}$ and $\text{UoI}_{\text{ElasticNet}}$ do not exhibit grouping effects, and are able to recover

heterogenous coefficient estimates, in agreement with the generative model. We validate our findings by estimating functional connectivity from rfMRI, human ECoG (speech cortex), rodent mECoG (auditory cortex), and NHP multi-single unit recordings (M1 during reaching), showing that UoI-based methods recover sparser models with no loss of predictive accuracy. Taken together, these results demonstrate the potential of the UoI framework to enhance the scientific interpretability of sparse parametric models involving correlated variables that frequently arise in data-driven neuroscience.

Title: Unsupervised extraction of dynamical features from noisy data with dynamical components analysis

Authors: *D. G. CLARK[1], J. A. LIVEZEY[1], K. E. BOUCHARD[1,2];
[1]Lawrence Berkeley Natl. Lab., Berkeley, CA; [2]UC Berkeley, Berkeley, CA

Abstract: Complex brain functions are produced by the dynamic coordination of many neurons. High-dimensional data from multi-neuronal recordings stand to elucidate these population-level dynamics. Linear dimensionality reduction methods provide a computationally-efficient way to extract relevant dimensions from such data, however widely used techniques which extract dimensions based on maximizing variance, e.g. Principal Components Analysis (PCA), are prone to extracting noise rather than dynamics. At the same time, quantifying the dynamical complexity of time series data is of interest in many domains, including neuroscience. Predictive information (PI), defined as the mutual information between the past and future, provides a robust quantification of time series complexity: PI is zero for purely random time series, saturates for purely regular time series, and can grow without bound for time series with rich dynamical structure. We present Dynamical Components Analysis (DCA), a linear dimensionality reduction method which discovers a subspace of high-dimensional time series data in which PI is maximized. Here, we describe DCA, demonstrate its superior ability to recover dynamics in synthetic data and evaluate its performance on neuroscience datasets. DCA's PI-based objective function can discriminate between noise (zero or small PI) and meaningful dynamics (large PI). Using synthetic examples, we contrast DCA with Slow Feature Analysis (SFA), which does not capture long-timescale dynamics, and Forecastable Components

Analysis, which maximizes temporal regularity rather than dynamical complexity. We apply DCA to neural datasets from motor cortex and hippocampus and demonstrate that the dimensions extracted by DCA allow for more accurate decoding of behavioral variables than those extracted by PCA and SFA, implying that DCA more robustly extracts underlying neural dynamics. Finally, we show that DCA can be used as a preprocessing step for popular latent variables methods such as GPFA and LFADS, dramatically reducing the runtime of these algorithms without changing their inferred structure. Overall, our results show that DCA is a powerful and computationally-efficient linear dimensionality reduction method for extracting dynamics from high-dimensional neural data.

Title: SpikeForest - A large-scale reproducible spike sorting validation platform with an interactive web interface

Authors: *J. MAGLAND[1], J. J. JUN[1], E. LOVERO[1], A. J. MORLEY[2], A. BARNETT[1]; [1]Flatiron Inst., New York, NY; [2]MRC BNDU, Univ. of Oxford, Oxford, United Kingdom

Abstract: Extracellular electrical recording is a popular and direct method to measure the simultaneous spiking activity of a large neural population. The key computational extraction of distinct neuronal units and firing times is known as spike sorting. However, there is a growing number of automated spike sorting codes, and much uncertainty and folklore about their accuracy in various experimental conditions. Several papers report comparisons on a case-by-case basis, but there is a lack of standardized measures and validation data. Furthermore, there is a potential for bias, such as sub-optimal tuning of competing algorithms, and a focus on one brain region or probe type. Without a fair and transparent comparison, genuine progress in the field remains difficult.
We address this challenge by developing SpikeForest, a reproducible, continuously updating platform which benchmarks the performance of spike sorting codes across a large curated database of electrophysiological recordings with ground truth. With contributions from over a dozen participating labs, our database includes hundreds of recordings, in various brain regions, with thousands of ground truth units (and growing). As well as extracellular recordings with paired intracellular ground truth, we include state-of-the-art simulated recordings, and hybrid synthetic datasets. We wrapped many popular sorting algorithms (including HerdingSpikes2, IronClust, JRCLUST, KiloSort, Kilosort2, MountainSort, SpyKING CIRCUS, and YASS) under

a common Python interface that performs automatic caching of results, and guarantees reproducibility via singularity containers and transparency of parameter choices. This also enables researchers themselves to install and run all tested sorters with a single interface. The large scale of our analysis demands an automatically updating nightly batch on a high performance compute cluster, where hundreds of sorting jobs are run in parallel (> 5000 CPU/GPU hours). Results are uploaded to a MongoDB database which is then accessed by our public-facing web site. This site allows intuitive comparison of metrics (precision, recall, overall accuracy, and runtime) across all sorters and recordings, and interactive visual "drilling down" into each sorting output at the single unit or event channel-trace level. The web technology is built on Node.js/React, and the D3 library for rendering.
In short, via reproducible ground truth studies, SpikeForest will continuously validate community progress in automated spike sorting, and guide neuroscientists to an optimal choice of sorter and parameters for a wide range of probes and brain regions.

Title: SpineYOLO: A web-based, deep learning tool for identification of dendritic spines

Authors: *M. S. SMIRNOV[1], B. SCHOLL[2], E. GONZALEZ[1], J. M. CHRISTIE[3], R. YASUDA[2];
[1]Max Planck Florida Inst. for Neurosci., Jupiter, FL; [3]Synapse Physiol. Group, [2]Max Planck Florida Inst., Jupiter, FL

Abstract: Abnormal density and morphology of dendritic spines are associated with many mental diseases. Since hundreds of molecular players are involved in the regulation of spine morphology, scalable and high-throughput tools to analyze spine morphology are necessary to understand the link between molecules and spine morphology. Toward this goal, we present SpineYOLO, an open source and online tool capable of automatically identifying dendritic spines in fluorescent tissue. SpineYOLO relies on a deep learning, end-to-end approach to minimize any need for parameter tuning. The algorithm is capable of identifying bounding boxes around dendritic spines with an average precision (AP_{50}) of 72%. We demonstrate that SpineYOLO is easily generalizable to different types of spines, including spines in mouse

hippocampal neurons, ferrets cortical neurons and Purkinje neurons, when combined with a straightforward one-click-per-spine data labeling tool. SpineYOLO can be used on a single computer, shared over a network, or accessed online via a web browser. This tool will be useful for high-throughput spine morphology analysis, and its performance will improve over time due to the collection of crowd-sourced training data through its web interface.

Title: SPARC initiative: Data alignment for proteomic, physiological, molecular and anatomical datasets from 36 research groups

Authors: G. PINE[1], T. GILLESPIE[2], ***A. BANDROWSKI**[1], S. TAPPAN[3], M. E. MARTONE[2]; [2]Neurosci., [1]UCSD, La Jolla, CA; [3]R&D, MBF Biosci. - MicroBrightField Inc., Williston, VT

Abstract: The SPARC (Stimulating Peripheral Activity to Relieve Conditions) initiative is a coordinated effort among 36 different research groups with the unified purpose to produce microscopic, genomic and physiological data that can be used to explore interactions of the peripheral nervous system and organs. In addition to the investigators, the consortium comprises of 3 cores: DAT, MAP and SIM. Consortium members are publishing their datasets through the DAT (data) core; datasets are enhanced by tools and processes available through MAP (mapping) core and a simulation platform will be provided by the SIM (simulation) core. Critical to success of such an ambitious project is a set of standards and best practices to ensure that data accruing from multiple, independent labs can be harmonized and integrated. The MAP core has created a SPARC-specific common ontology set, which uses community ontologies such as UBERON and FMA heavily, but extends them where this is needed by the SPARC investigators. The solution is to use interlex and SciGraph services, which work seamlessly over search applications, and to integrate access to these services within external and internal curation tools which all draw from a common ontology set even while that ontology set is being updated. Extension of MBF Bioscience software to support interlex and SciGraph services allows SPARC investigators to seamlessly utilize curated ontology sets at the time of initial annotation and enables simple resurfacing to SciGraph for missing term requests. Creating mechanisms to easily generate rich metadata enhances the quality and utility of all segmented data generated for the

SPARC program.
During the initial stage of the project, consortium members submitted 44 unique datasets. In tandem with these datasets, researchers published a total of 57 corresponding protocols to protocols.io. These datasets will be made available on the SPARC data portal 12 months after initial submission, but about 10 datasets will be published ahead of time in July 2019. Each protocol(s) will be linked with the dataset, once the data becomes public and vice versa. Overall experiences with the SPARC community has highlighted the benefit of adapting common and flexible data structures, to serve the needs of the consortium.

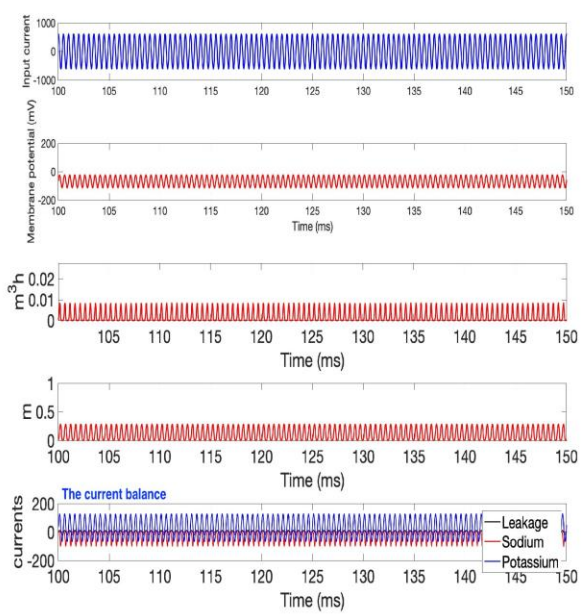
Title: A current balance phenomenon causes temporal interference stimulation

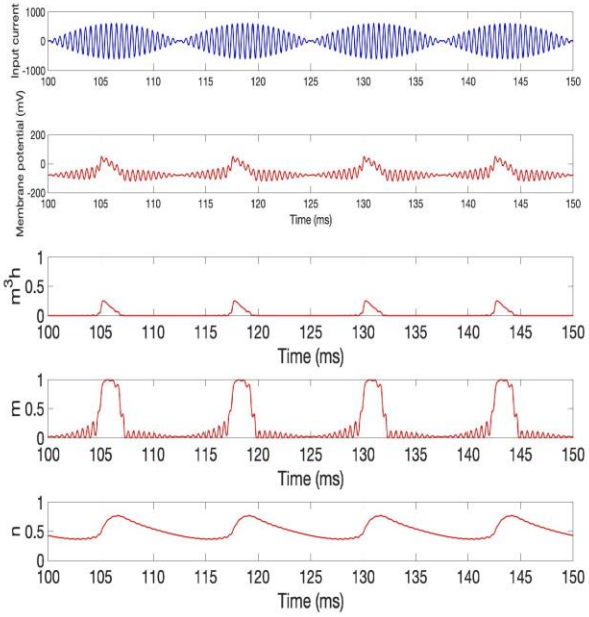
Authors: *P. GROVER[1], J. CAO[1], C. GOSWAMI[1], B. D. DOIRON[2];
[1]Carnegie Mellon Univ., Pittsburgh, PA; [2]Mathematcis, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Objective and Rationale: We use single neuron models to understand mechanisms behind Temporal Interference (TI) stimulation [Grossman et al., Cell 17] (aka "Interferential Stimulation" [Smith 71]). TI stimulation has created interest because of its ability to stimulate deep inside the brain without shallow stimulation. Despite decades of work, mechanisms of TI stimulation remain unclear. Understanding mechanisms can help improve the precision of TI stimulation [Cao, Grover, IEEE TBME'19].
Methods and Results: This work provides the first understanding of TI stimulation mechanisms using minimal single neuron models. We observe that both 2D neuron models (e.g. FitzHugh-Nagumo and Izhikevich's "simple" model) and 4D (Hodgkin-Huxley-type) neuron models exhibit TI stimulation for wide ranges of parameter choices. We observe that neurons (both 2D and 4D) that exhibit TI have an "accommodation-like" phenomenon: in 4D, a high-freq. inward current generated by opening and closing of fast sodium channels (in direct response to the pure sine current) is balanced by outgoing currents from relatively steady potassium (K+) channels (assisted by leakage) over a single sine cycle. Consequently, in response to high frequency pure sine currents, the membrane potential displays a stable subthreshold limit cycle. However, when the envelope is modulated at a sufficiently high slope, the K+ channel is slow to respond, while the sodium currents get a sharp boost, resulting in firing.
When a current imbalance exists for a pure sine input, the neuron does not exhibit TI stimulation

as it fires in response to both pure and modulated high-frequency sinusoids. Some 4D neuron models (e.g. excitatory pyramidal cells and HH-squid neurons) exhibit TI, whereas others (e.g. PV neurons) do not.
Conclusions: Our understanding of its mechanisms predicts that not all neurons will exhibit TI stimulation. Examined neurons complement this observation: PV neuron models do not seem to exhibit TI stimulation, whereas models of Hodgkin-Huxley squid neurons and excitatory pyramidal cells do exhibit TI stimulation.



(a) A neuron that exhibits TI stimulation does not respond to purely sinusoidal stimuli because of a current-balance (shown in last sub-plot).



(b) The response of the same neuron to amplitude modulated sinusoid shows stimulation.

Abstract: Aberrant neural oscillations hallmark the pathophysiology of numerous neurological and psychiatric disorders. Here, we first report a method to accurately track the phase of neural oscillations in real-time by a Hilbert transform that avoids the characteristic Gibbs distortion at the end of the signal, aka endpoint-corrected Hilbert transform (ecHT). The ecHT method maintains the same computational complexity class of the original Hilbert transform allowing implementation in simple digital hardware. We then used the ecHT method to show that the aberrant neural oscillation that hallmarks treatment-resistant essential tremor (ET), the most common adult movement disorder, can be noninvasively suppressed via transcranial electrical stimulation of the cerebellar activity at a fixed phase difference to the ipsilateral tremor movement. The suppression of the ET activity was sustained after the end of the stimulation and can be phenomenologically predicted, post-hoc, from the features of the tremor movement before the start of the stimulation. Finally, we used a highly-comparative time-series feature extraction (> 8000 features) with statistical learning and neurophysiological computational modelling to show that the suppression of ET activity can be mechanistically attributed to a disruption of the temporal coherence in the tremor movement that can be originated in a higher bursting entropy at the cortico-olivo-cerebello-thalamic circuitry. The suppression of aberrant neural oscillation via phase-locked driven disruption of temporal coherence may represent a powerful neuromodulatory strategy to treat neurological and psychiatric disorders.

Title: Neurons have unequal sensitivity to transcranial ultrasound neuromodulation

Authors: *X. NIU[1], K. YU[1], E. I. KROOK-MAGNUSON[2], B. HE[1];
[1]Biomed. Engin., Carnegie Mellon Univ., Pittsburgh, PA; [2]Neurosci., Univ. of Minnesota Syst., Minneapolis, MN

Abstract: Introduction Transcranial focused ultrasound (tFUS) is a noninvasive neuromodulation tool that can penetrate the skull and achieve high spatial specificity (mm). The goal of this work is to address the fundamental question of whether intrinsic cell-type specific factors such as ion channel distributions and dendritic morphology etc. can lead to difference in response to tFUS stimulation without introducing external assistive agents. We studied this question in wide type rats and optogenetics-tagged mice. Methods Single-element transducer (500 kHz) in pulsed mode was used on both a wild-type rat and opto-tagged mice models. We set the ultrasound pulse repetition frequency (PRF) at 5 levels, i.e. 30, 300, 1500, 3000 and 4500 Hz, and used 3D printed ultrasound collimators to guide the focused ultrasound wave unilaterally onto primary somatosensory cortex of the two rodent models. The sonication duration was maintained at 67 ms while keeping the cycle per pulse number constant throughout all the PRFs. 32-channel intracranial electrode was employed to record extracellular action potentials, and based on the action potential waveform, we separated the neurons with the temporal features into 2 major groups, regular spiking units (RSU, presumably as excitatory neurons) and fast spiking units (FSU, presumably as inhibitory neurons) in the wide-type rats. In order to validate the effect of tFUS on excitatory and inhibitory neurons, opto-tagged mice models were developed through breeding of transgenic animals to achieve cell-type specific expression of channel-rhodopsin. Neuron types in the mice model were identified through responsiveness to optical stimulation and were then tested using the 30 and 300 Hz PRF tFUS. In both models neuronal spiking rates were used to measure the response to tFUS. Results For the first time in *in vivo* rodent models, we found that at low PRF of 30 Hz, the excitatory neurons are significantly less responsive to the ultrasound stimulation than those with the PRF at 3000 Hz ($p < 0.005$) and the PRF at 4500 Hz ($p < 0.001$), whereas the spiking rates of inhibitory neurons do not change significantly across all PRF levels. In the opto-tagging mice model, the CamKII and PV neurons also demonstrate significantly contrasted spiking activities in response to the two levels of PRFs ($p < 0.05$). Conclusion Neurons exhibit intrinsic unequal sensitivity to tFUS. The ability to

noninvasively stimulate selected cell-types has a positive impact in understanding of the brain and ability to treat neurological disorders. Here we show early evidence that tuning tFUS PRF can preferentially target specific neuron types.

Title: Late enhancement of sustained attention with cortical priming prior to rTMS

Authors: *G. EDWARDS, F. CONTÒ, L. BATTELLI;
Ctr. for Neurosci. and Cognitive Systems@UniTn, Rovereto, Italy

Abstract: Low-frequency rTMS (LF-rTMS) to the intra-parietal sulcus (IPS) in the healthy hemisphere of patients with parietal lesion improves visual attention 30 minutes post-rTMS. It is hypothesized LF-rTMS inhibits the healthy hemisphere, causing upregulation of functional communication in the remaining attention network and increased attention performance. To aid clinical intervention, enduring effects are crucial. We hypothesize LF-rTMS effect on IPS may extend by controlling brain state through priming. Here, we prime the cortex using high-frequency transcranial random noise stimulation (HF-tRNS) prior to LF-rTMS, based on the hypothesis that HF-tRNS increases neuronal excitability. Experiment one tested four fMRI-guided stimulation protocols: 1) HF-tRNS & LF-rTMS, 2) LF-rTMS alone, 3) HF-tRNS alone and 4) Control. Sustained attention was recorded up to 94 minutes post-stimulation via bilateral multiple object tracking (MOT). MOT requires participants to track two moving discs among two moving distractor-discs in each visual field. Results showed an effect of stimulation on MOT performance ($p=0.024$). At 80-94 minutes after HF-tRNS & LF-rTMS, participants performed 7% better than Control ($p=0.015$). Priming with HF-tRNS over the IPS prolonged the LF-rTMS effect. In experiment two, we replicated experiment one and enhanced stimulation impact by requiring participants to perform MOT during HF-tRNS. MOT functionally activated bilateral IPS alongside external activation by HF-tRNS to boost priming. Specifically, MOT performance increased by 15.22% at 80-94 minutes following tRNS & rTMS relative to sham ($p=0.023$). Furthermore, MOT performance improved 13.56% following HF-tRNS without LF-rTMS at the 80-94-interval ($p=0.036$). Priming the cortex with behavior alongside HF-tRNS boosted the late attention increase found in experiment one following HF-tRNS & LF-rTMS. Further, the effect of HF-tRNS also intensified when applied with behavior. These results

suggest priming may be a useful tool in lengthening stimulation effects in clinical rehabilitation protocols.

Title: Temporal interference stimulation to activate respiratory motor pools

Authors: *M. D. SUNSHINE[1], E. NEUFELD[3], A. M. CASSARA[4], N. GROSSMAN[5], K. J. OTTO[2], E. S. BOYDEN[6], D. D. FULLER[1];
[1]Physical Therapy, [2]Univ. of Florida, Gainesville, FL; [3]Computat. Life Sci., IT'IS Fndn., Zuerich, Switzerland; [4]IT'IS Fndn., Zurich, Switzerland; [5]Dementia Res. Inst., Imperial Col. London, London, United Kingdom; [6]MIT, Cambridge, MA

Abstract: Temporal interference (TI) stimulation can activate neurons in deep brain structures using minimally invasive electrodes. Here we have adapted TI stimulation to target spinal respiratory neurons. Our overall hypothesis is that TI stimulation can target neuro-modulation to the ventral cervical spinal cord to regulate diaphragm activation during acute or chronic hypoventilation associated with opioid overdose or neurotrauma. We have systematically characterized, using experimental studies in adult rats and computational modeling approaches, the delivery of TI stimulation using epidural electrodes, in order to understand and optimize targeted diaphragm activation. We have been able to control the stimulation by focusing the interference maximum to the phrenic motor pool. Simulations were helpful in predicting and optimizing electrode locations and current ratios. A ratio of dorsal:lateral currents of about 2.0:0.8mA produced maximal diaphragm activation. Diaphragm activation with minimal blood pressure changes was achieved by varying the carrier frequency. To determine if TI acts via pre- vs. post-synaptic mechanisms, additional experiments were conducted used pharmacologic agents to block presynaptic input to phrenic motor neurons. Blocking glutamatergic receptors using intraspinal CNQX/AP5 delivery reduced the TI evoked response to 75±58%, 65±31%, and 53±21% of baseline using 100μA, 200μA, and 300μA lateral currents. Blocking glycine (strychnine) and GABA (bicuculine) receptors increased the evoked response to 168±81%, 143±64%, and 101±66% of baseline. Thus, both excitatory and inhibitory pre-synaptic inputs to phrenic motoneurons appear to be activated by T-I stimulation. We also validated the efficacy of TI stimulation following acute spinal cord injury (C2 hemisection) in anaesthetized rats. TI epidural stimulation could both activate and regulate diaphragm motor units after cervical spinal cord injury. We conclude that appropriately targeted TI can depolarize phrenic motor neurons with >50% of the evoked response resulting from direct motor neuron depolarization. The evoked diaphragm EMG response was dependent on the amplitude of the two TI currents; this observation helps constrain possible mechanisms of interaction underlying TI neuromodulation.

Title: Deep brain stimulation via temporal interference stimulation using implanted DBS electrodes. A feasibility study

Authors: *A. M. CASSARA[1], E. NEUFELD[1], H. BERGMAN[2], E. S. BOYDEN[3], N. GROSSMAN[4], N. KUSTER[1,5];
[1]IT'IS Fndn., Zurich, Switzerland; [2]Hebrew Univ., Jerusalem, Israel; [3]MIT, Cambridge, MA; [4]Imperial Col. London, London, United Kingdom; [5]ETHZ, Zurich, Switzerland

Abstract: Temporal Interference (TI) Stimulation has been considered a breakthrough in non-invasive-brain-stimulation (NIBS) due to the possibility to focus and steer stimulation in deep brain structures in a controlled way, and without stimulating brain regions close to electrodes or the skin. In this study, we performed an in silico feasibility evaluation to determine the potential of use TI in patients with implanted DBS electrodes to access a large variability of deep brain regions. Electromagnetic (EM) simulations within reference anatomical head models were used to calculate the E-field generated by DBS electrodes for different combinations of activated electrode pairs, different orientations of the DBS implant and site of implantation. We investigated the possibility to steer stimulation in regions proximal to single DBS electrodes, as well as the possibility to target more distant brain organs using multiple implanted DBS electrode (e.g. bilateral implants), such as the one between right and left sub-thalamic nuclei. We investigate and compare traditional E-field exposure by individual electrode pairs against the distribution of TI modulation envelop for input currents used in standard DBS applications, and we use neuroelectric models of realistic neurons and axons to investigate the impact of TI on the neuroelectric activity of realistic positioned neurons and fibers. Safety issues of unwanted stimulation of brain regions outside of designated targets are also evaluated. This study is the basis for forthcoming experimental measurements to advance treatment planning and technology development of TI hardware.

Title: Multi-locus transcranial magnetic stimulation for closed-loop brain stimulation

Authors: *R. J. ILMONIEMI[1], G.-L. ROMANI[2], U. ZIEMANN[3];
[1]Neurosci. and Biomed. Engin., Aalto Univ., Espoo, Finland; [2]Inst. for Advanced Biomed. Technologies, Gabriele D'Annunzio Univ. of Chieti-Pescara, Chieti, Italy; [3]Eberhard Karls Univ., Tübingen, Germany

Abstract: Current protocols to treat the brain with transcranial magnetic stimulation (TMS) almost exclusively target a single cortical spot, such as the left dorsolateral prefrontal cortex in the case of depression or the motor cortex in the case of neuropathic pain. Furthermore, in many cases, the treatment target is inaccurately defined, its location determined only by head-surface landmarks or by moving the TMS coil a certain distance from a location where stimulation produces motor responses. The resulting stimulation may then activate different functional sites in different individuals, causing variability in treatment efficacy.
We are developing technology (called multi-locus TMS or mTMS) for stimulating multiple cortical sites simultaneously or at arbitrary time intervals. Instead of predefining the stimulation sequence, we will use algorithms in a closed-loop mode so that the stimulation targets, stimulus timing and pulse intensity are determined by real-time EEG, muscle-activity, or behavioral measures. In this dynamic approach, we aim at modifying network connectivity or other properties of neuronal activity into desired directions, ultimately for therapeutic purposes to normalize dysfunctional network connectivity in neurological and psychiatric disorders.
With our 2-coil mTMS prototype, we have demonstrated automatic brain scanning, feedback-guided algorithmic motor-hotspot determination, and the possibility to investigate short-distance surround inhibition and facilitation mechanisms. Motor hotspot determination can now be done with far fewer pulses than with the conventional manual approach, much faster, more reliably, and without user bias. In our ConnectToBrain project (2019-2025) funded by the European Research Council, we will build a large mTMS coil array that covers most of the cortical mantle and allows one to administer to the brain electronically-controlled spatiotemporal TMS sequences. We will develop machine-learning methods to optimize treatment paradigms and will translate mTMS methodology into physiological and clinical studies.

Engin., Case Western Reserve Univ., Cleveland, OH; [9]Advanced Platform Technologies Ctr., Louis Stokes Cleveland Veterans Affairs Med. Ctr., Cleveland, OH

Abstract: Implanted neural stimulation devices, known as bioelectronic medicines, electroceuticals, or neuromodulation therapies, are successfully being used to treat a variety of disorders. Unfortunately, the complexity and invasiveness of the surgical procedures for implanting neural stimulation electrodes normally limits the availability of these therapies to patients that have failed conventional treatments. There is a critical need for electrodes that can be delivered through minimally-invasive procedures. To meet this need, we have developed the Injectrode, an electrode that can be injected as a flowable pre-polymer and cures in the body to form a conductive neural interface. Here, we also propose that the invasiveness of the procedure can be further reduced, compared to traditional implanted neural stimulation systems, by augmenting transcutaneous stimulation through the addition of an injected subcutaneous collector electrically coupled through intact skin to an external patch electrode.
Experiments were performed with Injectrode made from silver particles embedded in a silicone elastomer. Scanning electron microscopy and electrochemical testing was performed to assess the neuromodulation relevant material properties of the Injectrode. Acute *in vivo* testing of the Injectrode in a swine model of vagus nerve stimulation, after correcting for differences in impedance between the electrodes, showed a similar dose-titration for evoking decreases in heart rate compared to a LivaNova stimulation electrode. Additionally, transcutaneous stimulation of the vagus nerve through an Injectrode with a subcutaneous collector evoked consistent decreases in heart rate that did not occur during application of the same stimulation without the collector. By reducing invasiveness of the electrode and complexity of the surgical procedure, the Injectrode fills an unmet need for less invasive neuromodulation electrodes that can stimulate complex neural targets. Additionally, the capability of the Injectrode to augment transcutaneous stimulation using a collector has the capacity to further reduce the invasiveness and potential failure points of the system. For these reasons, the adoption of this technology could lead to novel and more widely applicable neuromodulation therapies.

Title: Connecting intrafascicular recordings, electromyography of the neck muscles, and functional magnetic resonance imaging during clinical vagus nerve stimulation in swine

Authors: E. N. NICOLAI[1,2], M. L. SETTELL[1,2], E. K. ROSS[3], J. K. TREVATHAN[1,2], B. E. KNUDSEN[1], A. L. MCCONICO[1], A. J. SUMINSKI[2], J. C. WILLIAMS[2], *K. A. LUDWIG[2]; [1]Mayo Clin., Rochester, MN; [2]Univ. of Wisconsin, Madison, WI; [3]Cala Hlth., Burlingame, CA

Abstract: Vagal nerve stimulation (VNS) is FDA approved for epilepsy, depression, cluster headache, and migraine with over 100,000 patients having received VNS implants to date. However, clinical studies suggest that activation of vagus afferent pathways for therapeutic effect do not occur prior to reaching therapy-limiting side effects such as throat pain, voice alteration, and dyspnea putatively associated with neck muscle activation. One method to assess vagal afferent engagement during clinical VNS is functional MRI (fMRI), as it can be performed non-invasively. However, the dose response to VNS measured via fMRI has not been directly connected to both intrafascicular (LIFE) recordings of vagal fiber activation and electromyography (EMG) of the neck muscles in a human sized animal model.
To address this gap, we used a clinical VNS electrode and clinically relevant stimulation parameters in an anesthetized swine model to compare the dose response curves of EMG and vagal LIFE recordings with fMRI obtained in a partially overlapping cohort. We correlated these responses to VNS induced heart rate (HR) changes and activation of the Hering-Breuer (HB) reflex. ‘A-fiber’ activation and associated EMG response were evident at low levels of stimulation (~0.2 mA), without BOLD fMRI changes. At clinically tolerable levels (<1.5 mA), placement of the VNS electrode can dramatically change physiological outcome (no HR/HB, HR, HB, HR+HB). When a HR decrease was achieved, there were dose dependent increases in negative BOLD signal. When a HB reflex was achieved, global changes in BOLD signal were observed including changes in brainstem structures associated with activation of vagal afferents. During lower stimulation amplitudes, that did not elicit a HB response, there was little to no

change in BOLD signal.
Neck muscle activation occurred at stimulus amplitudes lower than those required for afferent pathway activation. Putative B-fiber activation of preganglionic vagal efferents led to dose dependent increases in HR change and negative BOLD signal. Putative C-fiber afferent activation, which resulted in BOLD signal change consistent with those observed during clinical VNS, required stimulation amplitudes that caused visible neck muscle contractions AND specific electrode placement.

Abstract: Vagal nerve stimulation (VNS) is an FDA approved neuromodulatory or ‘electroceutical’ strategy for the treatment of epilepsy, cluster headaches, and treatment resistant depression that is also currently being explored as a therapeutic option across a broad range of clinical indications such as obesity, anxiety, arthritis, and gastrointestinal disorders. Indeed, the VNS clinical population continues to grow with over 100,000 patients to date despite the actual therapeutic mechanisms behind VNS remaining poorly understood. Separately, the recently described brain waste clearance systems, including the meningeal lymphatic and glymphatic systems, have gained increasing research interest for their roles in the maintenance of a healthy brain homeostasis. These systems have been of especial interest in the realm of neurodegenerative diseases and traumatic brain injury as they are responsible for the proper removal of metabolic waste products and misfolded proteins from the brain interstitium. Of note, the glymphatic system, which revolves around the influx and interchange of cerebrospinal fluid

(CSF) with interstitial fluid (ISF), is partially driven by cerebral arterial pulsations and shown to be sensitive to noradrenergic signaling. Given the known effects of VNS on systemic and cerebral hemodynamics as well as brain noradrenergic levels we hypothesized that VNS, delivered at clinically derived parameters, could affect the influx of CSF to the brain parenchyma. To test this, we used an *ex vivo* slice model to quantify the spread of a lysine-fixable tracer injected into the CSF system through the cisterna magna. We found that VNS significantly increased the degree of CSF dye penetrance (18.60% ± 1.98%) relative to naïve controls (10.75% ± 1.26%) and sham (13.05% ± 2.29%) and that there was no difference between the naïve controls and sham VNS groups. These results demonstrate a novel and previously unappreciated effect of VNS with potential therapeutically beneficial applications across a broad range of central nervous system pathologies.

Title: Effects of electrical stimulation of the infraorbital branch of the trigeminal nerve on oscillatory activity in the barrel cortex

Authors: *J. P. NESS[1], W. ZENG[2], P. PARMETT[1], J. KEGAL[1], S. K. BRODNICK[1], K. P. CHENG[1], L. KRUGNER-HIGBY[1], W. B. LAKE[3], K. A. LUDWIG[4], J. C. WILLIAMS[1], A. J. SUMINSKI[3];

Abstract: Over the past decade, electrical stimulation of various cranial nerves has been shown to be an effective adjunctive therapy for many neurodegenerative and neuropsychological diseases, and modulator of cognitive functions such as learning, memory and decision-making. This is especially true for the vagus and trigeminal nerves due to their direct access to neuromodulatory centers and arousal mechanisms. In particular, pairing stimulation of the vagus nerve with behavior is known to cause cortical reorganization that improves sensory discrimination, speeds the learning of motor tasks and drives functional rehabilitation after injury. It remains unclear, however, if trigeminal nerve stimulation (TNS) similarly modulates

cortical function. Here, we evaluate the hypothesis that electrical stimulation of the trigeminal nerve induces changes in cortical oscillations in the somatosensory cortex. Lewis rats (n = 5, all male) were chronically implanted with a custom nerve cuff electrode (1.5mm ID, 120μm wire diameter, 1.5mm spacing) on the infraorbital branch of the trigeminal nerve (IoN) and a 16 channel uECoG array (200um site diameter, 500um inter-electrode spacing) placed over barrel cortex. In 8 weekly sessions, we measured the cortical responses evoked by electrical stimulation (single cathode leading biphasic pulses, 200us phase duration, 50 - 300 uA current amplitude). We quantified the minimum stimulation current required to generate an evoked potential by comparing the peak to peak response magnitude to a baseline measured 20ms prior to the onset of stimulation. The threshold to evoke a cortical response decreased monotonically from week 1 to 4 and then remained stable in weeks 4 through 8. In parallel, we investigated the effects of TNS of oscillatory activity in the somatosensory cortex by measuring the local field potential (LFP) and computing the power spectra for separate 3 minute recordings before and after TNS and compared the total power in discrete frequency bands. Power in the gamma band (36-55Hz) decreased significantly following TNS, but we found no change in alpha/theta(6-12Hz) and beta (12-25Hz) power. This change in gamma power may reflect the mechanism by which stimulation of peripheral nerves modulates cognitive function.

Abstract: Transcranial direct current stimulation (tDCS) is a non-invasive technique that allows the modulation of cortical excitability. This modulation can be dissociated in immediate and long-term changes, with the first one referring to changes observed due to the interaction of the imposed electric field and the redistribution of intracellular ions in the neuron, and the later referring to changes that persist after electric current cessation and, therefore, mediated by protein, genetics and/or structural modifications. While immediate effects appear at the very moment of tDCS application, long-term effects need several minutes to take place. Because the mechanisms behind each one of these effects are partly unknown, the objective of this study was to deepen in such mechanisms. For this purpose, mice were prepared for chronic recording of sensory evoked potentials (SEPs) induced in the primary somatosensory cortex (S1) in response to whisker electrical stimulation before, during and after tDCS. S1-tDCS was performed at different current intensities for 5 s to test the immediate effects on SEPs, and during 20 min to analyze the long-term effects and expression of GAD65-67 and VGLUT1 after stimulation. 5 s of tDCS modulated the amplitude of the SEPs in a polarity and intensity manner. Anodal tDCS increased the amplitude of the SEPs up to a maximum of 41% for the maximal applied current, whereas cathodal tDCS decreased it up to a maximum of 26%. For 20 minutes of cathodal tDCS, a significant reduction in SEPs amplitude was induced together with a decrease in power spectrum between 10-100 Hz, and the effects were maintained for 40 minutes after tDCS cessation. For 20 minutes of anodal tDCS a significant increase in SEPs amplitude was observed together with an increase in power spectrum between 30-50 Hz, but these changes didn’t persist after tDCS cessation. The immunohistological analysis of the stimulated S1 brain regions showed a significant increase of GAD 65-67 immunoreactivity after cathodal stimulation but not after anodal or sham condition. No changes were observed in VGlut1 expression after anodal nor cathodal tDCS. The current results demonstrate a dissociation between immediate and long-term effects associated to tDCS of sensory cortex. Histological data suggest the implication of inhibitory mechanisms in the asymmetry of long-term effects consistent with electrophysiological results.

Title: Impact of cerebellar tDCS on motor performance and Purkinje cell activity in mice

Authors: *A. SANCHEZ-LOPEZ[1], S. OHMAE[1], J. MARQUEZ-RUIZ[2], J. F. MEDINA[1]; [1]Dept. of Neurosci., Baylor Col. of Med., Houston, TX; [2]División de Neurociencias. Univ. Pablo de Olavide, Seville, Spain

Abstract: Transcranial direct current stimulation of the cerebellum (CB-tDCS) has been used to alleviate motor impairments as well as to enhance different aspects of cognitive function. However, our understanding of the mechanisms of action of CB-tDCS is still in its infancy, particularly with regards to the neuromodulatory effects induced at the level of specific neural circuits *in vivo*. To address this question we have focused in a previously identified circuit in the mouse cerebellum, which is responsible for motor performance during an eyeblink conditioning task. Behavioral data indicates that application of cathodal CB-tDCS over lobule simplex of the cerebellar cortex causes an impairment of conditioned eyelid movements in a dose-dependent manner, whereas anodal CB-tDCS at the same site produces a subtle but very reliable enhancement at low density currents (<35.4 A/m^2) and impairment at higher density currents (70.8 A/m^2). Moreover, preliminary data obtained from Purkinje cells in this circuit indicates that CB-tDCS can be used to effectively modulate the resting state spontaneous firing rate in a polarity dependent manner. Altogether, our experiments provide the first glimpse at the local effects of CB-tDCS on the activity of Purkinje cells in a specific neural circuit of the cerebellar cortex, revealing how the polarity and intensity of the stimulation affect neural excitability to modulate behavior.

Abstract: Cerebellar transcranial direct current stimulation (cer-tDCS) is being used to modulate cerebellar function both in health and disease. Nevertheless, how external electric fields affect the different components in the cerebellar network remains to be elucidated. The aim of this study was to characterize the physiological mechanisms underlying short- and long-term effects associated to cerebellar tDCS in behaving mice. Mice were prepared for chronic recording of sensory evoked potentials (SEPs) in response to whiskers electrical stimulation, as well as single-cell activity in the CrusI/II region of the cerebellar cortex. Cer-tDCS in behaving mice was applied at different intensities for 10 s to test short-term effects, and during 20 min to characterize long-term effects on SEPs and expression of GAD65-67 and VGLUT1. In addition, neuronal juxtacellular recordings in vermis were made during cer-tDCS application in anesthetized mice and then, the recorded neurons were labeled with neurobiotin for morphological characterization. During the application of cer-tDCS, anodal and cathodal polarities increased and decreased, respectively, the amplitude of the trigeminal (T) component of SEPs, and slightly, yet reliably modulated the amplitude of the cortical (C) component in the opposite direction. Interestingly, Purkinje cell simple spike firing rate was modulated by cer-tDCS in a heterogeneous manner, observing an increase/decrease with anodal/cathodal stimulation in some of them, the opposite pattern in others, and no effects in the rest. Neurobiotin labeling showed that this diverse modulation largely depended on the axodendritic axis orientation of the Purkinje cells in the cerebellar layer with respect to the active electrode. However, despite the SEPs and Purkinje cells modulation during tDCS application, after cer-tDCS cessation no long-term effects were observed for the amplitude of SEP components, and accordingly no changes were observed in GAD65-67 nor VGLUT1 expression. Present results successfully demonstrate the immediate modulatory effects of cer-tDCS on cerebellar cortex activity in behaving mice. In addition, the experiments show the crucial importance of the Purkinje cells axodendritic axis orientation in the modulation of neuronal activity by cer-tDCS.

Title: Changes in evoked coherence in subregions of the striatum and substantia nigra pars reticulata in anesthetized rats

Authors: *H. LI[1], G. C. MCCONNELL[2];
[2]Biomed. Engineering, Chem. and Biol. Sci., [1]Stevens Inst. of Technol., Hoboken, NJ

Abstract: Introduction: Microelectrode recordings (MERs) during Deep Brain Stimulation (DBS) surgery are commonly used to verify and refine targeting of electrode placement. We hypothesized that changes in coherence spectra of stimulation evoked local field potentials (LFPs) between neighboring microelectrode recordings correlated with electrode position. We tested this hypothesis in two promising DBS targets in the Basal Ganglia: Substantia Nigra pars reticulata (SNr) and its subregions, medial SNr (mSNr) and lateral SNr (lSNr); striatum and its subregions, dorsal striatum (DS) and ventral striatum (VS). Methods: Fluorescently-coated single wire tungsten microelectrodes were lowered in anesthetized rat brain (step size of microdrive = 100μm). Stimulation was delivered 10s (amplitude = 100 μA; frequency = 0.5Hz; pulse width = 90 μs) at each depth and neural recordings were obtained during interpulse intervals. Coherence analysis of power spectrums (0-200Hz) of evoked LFPs was calculated between two adjacent depths after aligning the timestamps of stimulation. Borderlines of each brain region and its subregions were measured based on histology. Results: Electrodes penetrated through mSNr (n=6) and lSNr (n=6). Evoked coherence in mSNr showed a trend of low coherence dorsal to mSNr, high coherence within mSNr, and low coherence ventral to mSNr. Evoked coherence in lSNr showed a trend of high coherence dorsal to lSNr, low coherence within lSNr, and high coherence ventral to SNr. In total, 10 out of 12 trials (83%) showed significant difference between dorsal to SNr vs. within SNr; 9 out of 12 (75%) trials showed significant difference between within SNr vs. ventral to SNr. Overall, both mSNr and lSNr showed significant difference with the structures dorsal and ventral to them. Electrodes penetrated through DS (n=16) and VS (n=16). Evoked coherence showed a trend of high coherence in cortex, low coherence in DS, and high coherence in VS. In total, 14 out of 16 trials (87%) showed significant difference between cortex vs. DS, and 9 out of 16 trials (56%) showed significant difference between DS vs. VS. Overall, both DS and VS showed significant difference with cortex. DS and VS did not significantly differ, however, the same trend was observed in 14 out of 16 tracks. Conclusion: Our results suggest that coherence analysis of stimulation evoked LFPs can distinguish DBS targets from surrounding brain regions and lay the foundation for this technique to accelerate precise targeting during DBS implantation surgeries.

Abstract: The ability to probe the activity of neuronal networks can allow deciphering the fundamental processes in the brain and, eventually, help with the diagnosis and treatment of neurological disorders. All-optical probing requires two components: a light-controlled cell stimulation method and an imaging-based method for recording of neuronal activity. Optogenetics is currently a leader among optical stimulation methods. However, optogenetic stimulation is a complex phenomenon that inevitably affects cells due to the need for high expression levels of exogenous light-sensitive ion channels, their gating kinetics, and the activity of specific ions conducted by optogenetic actuators. Therefore, in certain cell systems (e.g., stem cell-derived neurons), it is not desirable to express exogenous proteins that might affect physiology of differentiating and maturing cells.
Our study offers an alternative optical stimulation method that enables fast and reversible optical stimulation of genetically intact neurons by taking advantage of optoelectronic properties of graphene. Previously, graphene materials have been successfully interfaced with various cell types in cell scaffolds, where graphene merely provides the passive structural support. In contrast, in this study, due to its ability to efficiently convert light to electricity, graphene can play an active role in interactions with live cells.
Here we present a novel optoelectrical biointerface for graphene-mediated optical stimulation (GraMOS) of cells via external light-controlled electric field [1]. Our GraMOS biointerface does not interfere with either genetic make-up of cells or their structural integrity, thus providing truly non-invasive stimulation. By performing imaging and electrophysiological experiments on hiPSC-derived neurons, we demonstrated that the GraMOS biointerface exhibits the excellent biocompatibility and the ability to optically trigger action potentials in neurons. Using geometrically patterning of GraMOS biointerfaces, we are evaluating the connectivity of neuronal networks under various experimental conditions.Graphene-mediated optical stimulation

is a powerful new method that can be used 1) to probe the existing neuronal activity, decipher the fundamental processes in the brain and, eventually, help with the diagnosis and treatment of neurological disorders; and 2) to elevate the neuronal activity to the new level that could enable activity-dependent neurogenesis, restore vision, and assist with deep-brain stimulation.

Title: A causal network analysis of neuromodulation in the cortico-subcortical mesolimbic network

Authors: ***S. QIAO**[1], K. BROWN[1], J. I. SEDILLO[2], B. FERRENTINO[1], B. PESARAN[1];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]NYU, New York, NY

Abstract: Modern neural technologies offer new ways to study and control brain networks. Neuromodulation refers to a spectrum of technologies that seek to achieve therapeutic effects by intervening to alter neural activity. It has broad and wide-ranging potential to treat drug-resistant neurological and neuropsychiatric disorders. Despite the progress, whether and how electrical stimulation can be used to treat, for example, cognitive impairment remains controversial. These hurdles reflect limitations in the conceptual framework for neuromodulation-based treatment. Clinical targets for therapeutic stimulation are increasingly viewed within a circuit-based model of neural dysfunction, which highlights the need to assess the network mechanism of action - how the intervention alters activity not just focally but across the network. Network neuroscience describes networks as nodes connected by edges to form graphs and other generalizations. The edges can have different weights, reflecting different connection strengths. Network neuroscience thus provides a framework for testing the neuromodulation hypothesis. Neuromodulation may involve suppressing or facilitating the weight of the edge between two nodes - the edge modulation hypothesis. Alternatively, neuromodulation may modulate the nodes themselves, suppressing or facilitating activity at those sites - the node modulation hypothesis.

Here, we test the network mechanism of action of a primary intervention using the concept of neural excitability to disambiguate edge- and node-modulation hypotheses. Unlike correlation-based estimates, neural excitability estimates edge weight casually by measuring the neural response to a secondary intervention - an isolated stimulation pulse. Recording from many sites during the secondary intervention measures network excitability in a causal network analysis. Performing the causal network analysis before and after the primary therapeutic intervention, a stimulation pulse train, allowed us to test the edge- and node- modulation hypothesis. We performed a causal network analysis across a large-scale cortico-subcortical mesolimbic network before and after delivering a short-burst tetanic microstimulation (TetMS) at sites in either gray matter or white matter. Our results indicate that short-burst TetMS overwhelmingly acts to disrupt processing across edges while processing within nodes remains relatively undisturbed. Together, our results have implications for the rational design of therapeutic patterns of closed-loop stimulation based on a circuit-level understanding of the neuropsychiatric conditions.

Col. of Med., Taoyuan, Taiwan

Abstract: Transcranial direct current stimulation (tDCS) is one of non-invasive technique for modulating neural plasticity which is considered having therapeutic potentials in neurological

and neuropsychological disorders. For the purpose of translational neuroscience research, a suitable animal model could be the best way to provide a stable condition for identifying the mechanism insights that help to explore therapeutic strategies. Here, we developed a focused brain stimulation protocol using tDCS on the motor cortex for modulating the motor excitability in anesthetized rats. The change in motor excitability was evaluated by the changes of motor evoked potential (MEP) elicited by a single-pulse epidural cortical electrical stimulus. To examine tDCS-elicited plasticity responses, immediately MEP changes and MEP input-output (IO) curve were measured at baseline and for 30 min after anodal tDCS or cathode tDCS. In the results, analogous to those observed in humans, the present experiments demonstrate long-term potentiation (LTP) and long-term depression (LTD)-like plasticity can be induced by tDCS protocol in anesthetized rats. We found that the MEPs were significantly enhanced immediately after 0.1 mA and 0.8 mA anodal tDCS and remained enhanced for 30 min compared to the baseline MEP. Similarly, the MEPs were only suppressed immediately and lasted for 30 min or more after 0.8 mA cathodal tDCS. No effect was noted on the MEP magnitude under sham tDCS stimulation. Furthermore, the IO curve slope was elevated following anodal tDCS and showed a trend towards diminished slope after cathodal tDCS. These results indicate that the developed tDCS schemes can produce consistent, rapid, and controllable electrophysiological changes in corticomotor excitability in rats. Our studies provided a step toward extending human brain stimulation protocols to translational research where motor plasticity can be manipulated in rats. This newly developed tDCS animal model would be useful for further exploring the mechanical insights and may serve as a translational platform bridging human and animal studies for establishing new therapeutic strategies in neurological disorders.

Title: Neural elements mediating side effects during cervical vagus nerve stimulation in the pig

Authors: *E. N. NICOLAI[1,2], M. L. SETTELL[1,2], E. K. ROSS[3], B. E. KNUDSEN[1], A. MCCONICO[1], N. A. PELOT[4], W. M. GRILL[4], J. C. WILLIAMS[2], K. A. LUDWIG[2]; [1]Mayo Clin., Rochester, MN; [2]Univ. of Wisconsin, Madison, WI; [3]Cala Hlth., Burlingame, CA; [4]Duke Univ., Durham, NC

Abstract: Stimulation of the vagus nerve (VNS) is FDA-approved for treatment of epilepsy and depression, as well as CE marked in Europe for multiple other conditions including heart failure. Despite widespread adoption and perceived efficacy, a post-hoc analysis of patients treated for heart failure using VNS showed that only 12% of patients experienced cardiac effects one year post-implant. This might be explained by evidence that 1) A-type nerve fibers responsible for muscle responses have lower stimulation amplitude thresholds than B-type nerve fibers mediating cardiac effects, and 2) stimulation amplitudes are limited in patients such that intolerable neck muscle responses do not occur. Therefore, lower threshold muscle responses may have prevented application of higher amplitudes required to achieve cardiac effects in clinical trials of VNS for heart failure. Understanding therapy-limiting side effects to VNS and finding ways to mitigate them are important challenges towards optimizing VNS for clinical practice.

To address this gap, we developed a swine model of VNS that utilizes the clinical LivaNova VNS electrode used in human patients. The swine model most closely matches the size of the vagus nerve and fascicular organization seen in humans. We hypothesized that neck muscle responses are mediated by somatic branches of the vagus—as opposed to direct electrical activation of the muscle fibers—and tested this using neuromuscular junction blocking agents, as well as systematic somatic vagus nerve branch transection. We measured compound nerve action potentials using intrafascicular electrodes placed within the vagus to identify activation of different nerve fiber types by conduction velocity. The downstream effects of nerve fiber activation, i.e. changes in heart rate and neck muscle responses (EMG), were measured using an arterial catheter and intramuscular electrodes, respectively.

Two pathways contribute to VNS-evoked neck muscle response: activation of nerve fibers in the recurrent laryngeal branch of the cervical vagus nerve at low amplitudes and in the superior laryngeal branch at higher amplitudes. This work represents a step towards mitigating intolerable side effects of VNS, thereby allowing maximization of intended target engagement.

Title: Evaluating the target engagement in focal transcranial magnetic stimulation (TMS) of the rat brain

Authors: S. CERMAK[1], K. PENG[1], Q. MENG[1], C. MEJIAS-APONTE[3], C. J. JORDAN[2], K. MOUSSAWI[4], Z.-X. XI[2], Y. YANG[1], *H. LU[1];

Abstract: Transcranial magnetic stimulation (TMS) is emerging as a potential treatment for neuropsychiatric disorders, including drug addiction. However, the nature, extent, and mechanisms of TMS effects remain speculative, and clinical outcomes are variable. Creating an animal model that can mimic human TMS conditions is of great value in better understanding these neurobiological mechanisms. Our lab recently developed a rodent TMS system that can induce suprathreshold focal stimulation of the rat and mouse brains (Meng et al., Brain Stim 2018). The purpose of this study is to map brain regions activated by TMS using Fos immunochemistry. Rats were implanted with a head-post on the skull, directing the TMS coil E-field toward the medial prefrontal cortex (mPFC), +2.2mm from bregma. TMS parameters were as follows: 10 Hz pulses alternating at 2s on and 6s off with a total of 1800 pulses, at either high power (455V, n=7) or low power (220V, n=4). Each experimental animal was paired with a control animal receiving sham TMS at 25V(n=11). Animals were perfused 90 minutes post-TMS. Brain slices were evaluated under brightfield 10x magnification for Fos expression at three slices along the anterior-posterior axis: AP +3.2mm, AP +2.2mm, and AP+1.2mm. Brain regions were identified by tracing them from corresponding atlas images. The brain regions of the mPFC that were counted were: M2, IL, PRL, CG1, and CG2. A customized ImageJ script was used to quantify regions by setting an intensity threshold of the image to contrast the Fos labeled cells. The cells were automatically counted based on circularity and size and confirmed by visual inspection. Compared with the sham group, animals receiving high power TMS showed significantly higher level of Fos expression, which was particularly prominent in the center of the stimulation region (A-P +2.2mm); within this region, all mPFC subregions (CG1, M2, IL, PRL) showed significantly higher Fos expression. One millimeter posterior to the stimulus focus (A-P +1.2mm), Fos activation was significantly higher only in CG1 of the high power TMS group compared to the sham group. One millimeter anterior to the stimulus focus (A-P +3.2), there was no difference in Fos expression between these two groups. There was no difference in Fos levels between the low power TMS group and the sham group. The higher level of Fos expression under the TMS focus region (A-P +2.2 mm) suggests that the coil is indeed focal in activating the mPFC. At lower power levels, stimulation may be insufficient to stimulate the target region. Ongoing work is to quantify appropriate TMS power levels that activate specific mPFC subregions. Title: An algorithm for predicting cortical activation by transcranial magnetic stimulation

Authors: G. ARABKHERADMAND[1], F. SALINAS[2], P. FOX[2], ***D. MOGUL**[1];
[1]Biomed. Engin., Illinois Inst. of Technol., Chicago, IL; [2]Univ. of Texas, San Antonio, TX

Abstract: Transcranial magnetic stimulation (TMS) is a powerful technique to noninvasively activate neurons in the brain. However, the relationship between TMS-generated electric fields (E-fields) and specific cortical responses is not well understood. The goal of this study was to investigate the relationship between induced E-fields and neocortical activation measured by metabolic responses. Human subject-specific detailed finite element models (FEM) of the head were constructed to calculate the distribution of induced cortical E-field vectors. Positron emission tomography (PET) recordings were made during concurrent TMS application as a measure of cortical activation. A functional model of local circuit connections was developed to study therelationship between applied magnetic fields and neocortical activation and was fitted to experimental data. Induced E-fields were decomposed into vectors normal and tangential to the cortical surface under the assumption that cortical pyramidal neurons and interneurons were principally activated by the corresponding field vectors, respectively. Using published cortical network connectivity properties in a computational model, neuronal sensitivities to relevant E-fields were fitted to the experimental PET data. Sensitivity of interneurons to induced tangential E-fields were found to be over twice as strong as pyramidal neuron sensitivity to induced normal E-fields which may help explain why cortical electrophysiological responses to TMS have specific sensitivities to coil orientation. Furthermore, this study produced an algorithm for predicting near-field electrophysiological responses in human neocortex with high accuracy (>95%) and specificity (>99%) that could provide an invaluable tool for planning of specific regional cortical activation critical in both research and clinical applications.

Title: Modeling the cellular effects of transcranial electrical stimulation on the cerebellum

Authors: *X. ZHANG[1,2,3], R. HANCOCK[2,3,4], S. SANTANIELLO[1,2,3];
[1]Biomed. Engin. Dept., [2]CT Inst. for the Brain and Cognitive Sci., [3]UConn Brain Imaging Res. Ctr., [4]Dept. of Psychology, Univ. of Connecticut, Storrs, CT

Abstract: Transcranial electrical stimulation of the cerebellum has raised increasing interest with a broad range of potential clinical applications, including Parkinson's disease, dystonia, essential tremor, and ataxia. Despite great promise, results have been inconsistent thus far, and an understanding of the cellular mechanisms of cerebellar transcranial electrical stimulation is still lacking. In this study, we leverage on the highly modular and homogeneous organization of the cerebellar cortex and a unique suite of computational modeling techniques to investigate the behavior of different cerebellar cell types under the electric field generated by transcranial electrical stimulation. Multi-compartment neuron models of granule cells, Golgi cells, Purkinje cells, and cerebellar interneurons, including stellate and basket cells, were paired with electric fields generated under several electrode montages using a realistic human head model and an established computational pipeline. For each cell type, changes in membrane potentials under the effects of the electric fields are simulated in NEURON and the resultant action potential initiation, propagation, and frequency are quantified. Finally, the cellular responses are integrated into a single-compartment network model of the olivo-cerebello-thalamic system to determine the effects of transcranial stimulation on the cerebellar output. Simulation results quantify the impact of the orientation and strength of the electric field onto the cerebellar output and pave the way towards the optimization of transcranial stimulation patterns for the treatment of movement disorders involving the cerebellum, such as essential tremor.

Abstract: There has been increased usage in the clinical application of non-invasive forms of neurostimulation to treat a wide variety of clinical conditions, such as stroke, epilepsy, and pain. Some types of non-invasive stimulation, such as transcranial magnetic stimulation (TMS), can directly activate populations of cortical neurons and have well described physiological and physical properties. Other forms of non-invasive stimulation, such as transcranial direct current stimulation (tDCS) do not directly depolarize neurons, but instead are thought to act more nebulously though alterations in cortical excitability by shifting membrane potentials to change the likelihood of neurons firing. How populations of individual neurons respond to this type of stimulation has not been systematically studied *in vivo*. Here, we present a study to determine the effects of tDCS on single-unit and LFP activity in motor cortex of freely moving, healthy rats. A total of nine rats were implanted with a 16-shank microelectrode array over M1 for neural recordings. To administer tDCS, two screws were embedded bilaterally in the skull over M1 to act as anodal and cathodal poles for tDCS, and two screws in the interparietal bone to act as electrode and tDCS ground. Each rat underwent up to 12 recording sessions testing six different randomized stimulation conditions (48 hour wash out period between conditions) varying in current intensity (maximum current density = 90.5 A/m2 at 0.4 mA) and polarity (anodal or cathodal). For each session, the rat was allowed to freely move about a behavioral box while neural activity was recorded before, during 20 minutes of continuous tDCS, and one hour after stimulation to look for changes in the patterns of neural activity. After analysis of 496 neural units across all rats, we found no effect of tDCS stimulation condition on firing rate or firing pattern. Restricting the analysis to the most responsive units, subtle, but statistically significant changes occurred only in the highest intensity anodal condition.

Title: Optimization of transcranial temporal interference stimulation of targets of interest using realistic human head models

Authors: ***S. RAMPERSAD**[1], B. ROIG-SOLVAS[1], M. YAROSSI[2], E. SANTARNECCHI[3], A. D. DORVAL[4], D. H. BROOKS[1];

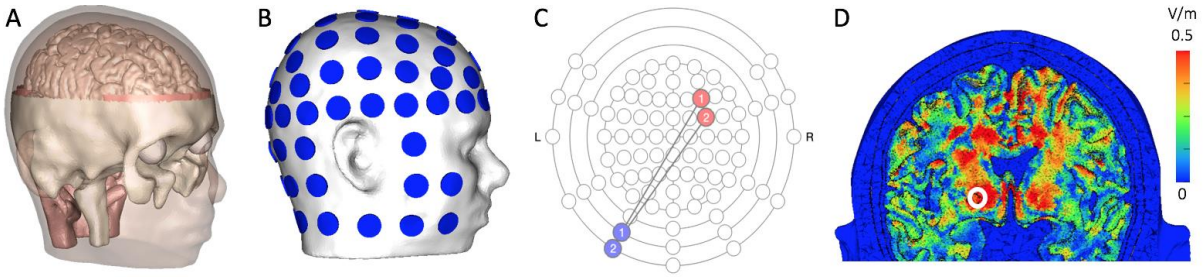
Abstract: Introduction Transcranial current stimulation (tCS) can noninvasively and transiently modulate neural activity and affect behavior. Stimulation of superficial brain regions in both healthy subjects and patients has shown promising results. Transcranial temporal interference of two oscillating currents (tTIS) has been suggested as a new form of tCS that could reach deep brain areas selectively. In a recent simulation study, we showed that tTIS electric fields can create local maxima in deep brain regions. Here, we present methods to optimize tTIS and tCS current injection patterns and compare results for several brain areas that are often targeted with deep brain stimulation, and superficial areas commonly targeted with traditional tCS.
Methods Individual finite element head models were made using MRIs from 10 healthy adults following informed consent; a subset of models included anisotropic brain conductivities. We placed 88 electrodes on each model, plus a reference. We simulated injecting 1 mA current between each electrode and the reference. The resulting fields could then be combined into any desired current injection pattern. We searched for optimal current patterns to stimulate target regions in hippocampus, pallidum, thalamus, motor cortex, prefrontal cortex and cerebellum. Both an exhaustive search over 146M current patterns and mathematical optimizations were performed for tTIS and tCS to select patterns that produced the highest mean field strength in each target area. Additional optimizations also constrained the field strengths in regions outside the target area.
Results Our approach successfully found current patterns that maximized stimulation in each target area for each head model. We present optimized results for several cases, assess

intersubject variability, and pool all results to deduce general guidelines for electrode placement. Conclusion Our results suggest that most deep and superficial brain areas can be reached by tTIS with field strengths similar to tCS, but tTIS allows greater selectivity.



Using a realistic human head model (A; 10 models were made with 6 tissue types each) with 88 possible electrode positions (B; standard 10-10 locations plus additional locations to cover neck and cheeks), we found the optimal tTIS current pattern (C; on an extended 10-10 schematic (top view of the head with each electrode represented by a circle), electrodes marked 1 (or 2) represent one current loop injecting current at one frequency) to maximize the electric field along the direction of the neurons in a spherical target area (white circle) in the right pallidum (D).

Abstract: Background: Chronic stress (CS) is associated with a decrease in pain threshold caused by the changes in neural pain circuits. It can be associated to glucocorticoid imbalance with alterations in neural circuitry. Inhibition of stress-induced pain-related neural changes by using techniques that safely induce neuro- plasticity such as transcranial direct current stimulation (tDCS) may prevent hyperalgesia triggered by CS. Objective: This study aimed to verify the effect of tDCS performed prior to CS exposure on nociceptive response. Methods: Thirty-two rats were distributed in the following groups: control; stress; sham-tDCS þ stress; and tDCS þ stress. Bicephalic active tDCS was performed for 8 consecutive days before the CS exposure. The pain threshold was evaluated using a hot plate and tail flick latency (TFL) tests. Results: The tDCS exposure increased the pain threshold on stressed rats. Conclusion: The data obtained indicate that the treatment with bicephalic active tDCS before chronic stress exposure prevents stress-induced hyperalgesia.

Title: Exploring depth spread of the induced electric field in transcranial magnetic stimulation with small parallel coils

Authors: *H. BAGHERZADEH[1], Q. MENG[2], J. BADJO[1], X. DU[3], L. HONG[3], F.-S. CHOA[1]; [1]Univ. of Maryland, Baltimore County, Baltimore, MD; [2]NIH IRP, Baltimore, MD; [3]Univ. of Maryland Sch. of Med., Catonsville, MD

Abstract: Recent years, noninvasive electrical stimulation-based treatments for neuropsychiatric disorders have been of high interest in both research and clinical studies. Among them, transcranial magnetic stimulation (TMS) is widely accepted as a safe and effective method. However, current TMS coils used for this purpose are not capable of stimulating targeted deeper brain regions due to the quick energy spread at deeper regions. Deep brain stimulation highly depends on the focality, intensity, and attenuation of the induced electric field at a distance away from the coils. In our previous works, we have shown that by increasing the diameter of a coil we can reduce the field strength decay rate of induced electrical field as a function of the depth away from the coil. In that work we have demonstrated that coils with different diameters will

produce different depth strength decay curves. However, increasing the coil diameter will require to use a larger magnetic core, which can be bulky and heavy. Furthermore, a larger diameter coil will have a larger inductance. If the coil inductance goes up, the induced electrical field power will drop when the bias voltage is kept constant. To obtain high electric filed strength at deep brain region, we have to reduce the coil inductance. In this work, we show that using a group of parallel-connected coils that have smaller diameters we can greatly enhance the output power and at the same time enjoy the same field strength decay rate as a function of penetration depth as a large diameter coil when the combined diameter of the group of coils are about the same as that of the large diameter coil. In addition to the advantages of smaller size and lighter weight, such an array of smaller coils can produce much higher filed strength compared with that of a single large diameter coil. For the purpose of analyzing and validating the behavior of the coils, Finite Element Method (FEM) calculations (COMSOL software) and experimental implementations and measurements were conducted.

Title: Transcranial focal electrical stimulation effect on neuronal activity mediated through early gene expression

Authors: L. A. BAUTISTA OROZCO[1], S. OROZCO-SUAREZ[1], L. L. ROCHA[2], ***W. G. BESIO**[3];

Abstract: Experiments were conducted to evaluate the effects of transcranial focal electrical stimulation (TFS), through tripolar concentric ring electrodes, on the expression of early genes, related to brain activity and neuromodulation. Male Wistar rats received TFS (300Hz, 200-μs biphasic square charge-balanced 50-mA constant current pulses for 2 min and 5 min); 3.5 minutes later the brains were extracted by craniotomy, the cortex (located just below the electrode) of 6 rats for the control group, and 6 TFS. RNA was extracted by the method of Trizol reagent (Life technologies) to be used in microarrays of the complete transcriptome for rat GeneChip R Rat Gene 2.0 ST Array ® of Thermo Fisher Affymetrix ®, which was processed in the microarray laboratory of the National Institute of Genomic Medicine (INMEGEN) SSA.

Microarray analysis was performed using: Transcriptome Analysis Console, PANTHER classification system and Cytoscape software, to determine the molecular functions that TFS exerts on genes.
The results with 2-minute stimulation demonstrated a significant difference in the expression of 39 genes, as compared with the control group. Of these 39 genes, 19 were overexpressed and 20 were under-expressed; the main pathways involved with overexpressed genes were: angiogenesis and the signaling pathway of VEGF, while the most under-expressed genes involved the signaling pathway of the nicotinic acetylcholine receptor and response to oxidative stress. For 5 minutes, the TFS group showed a significant difference in the expression of 1563 genes compared to the naïve rats not receiving TFS. The analysis of the possible signaling pathways in which the genes could be involved showed that there are 90 signaling pathways involved with the overexpressed genes and 53 pathways involved with the under-expressed genes. These pathways are related to inflammatory response, glutamatergic transmission, transport and metabolism of neurotransmitters, pathways related to neurogenesis and signal transduction, which accounted for the majority of genes involved. These results indicate that the 5-minute TSF affects more genes than the 2-minute stimulation and may be an alternative therapy in neurodegenerative processes, as epilepsy and Parkinson disease.

Abstract: Neural oscillations are associated with many cognitive functions, including consciousness-related processes such as sleep. Developing novel non-invasive brain stimulation techniques that can modulate specific oscillatory activity may be a viable approach for understanding functional causality of oscillatory rhythms in cognition, and developing novel treatment strategies for patients with disorders of consciousness. Among existing state-of-the-art techniques, repetitive transcranial magnetic stimulation (rTMS) induces frequency-specific but relatively short-lasting neuronal oscillations, whereas transcranial alternating current stimulation (tACS) primarily entrains endogenous oscillatory activity. In this study we investigate whether phase-synchronizing these two techniques may be a viable method in order to induce and entrain non-endogenous oscillatory rhythms in the human cortex. After assembling a control circuit that could precisely synchronize rTMS pulses with the phase of the tACS, we investigated whether combined alpha (10 Hz) rTMS and tACS to the prefrontal cortex (PFC) could induce sustained resting state PFC-alpha activity. 25 healthy participants took part in a single-blind, within-subject design. Resting state EEG was recorded at baseline before, immediately after, and 15 and 30 min after an 8 min stimulation block, in both eyes-open (EO) and eyes-closed (EC) conditions. 10 Hz tACS at 1 mA was applied through four bilateral electrodes over PFC and mastoid regions (EEG positions F3/F4, and TP9/TP10). 10 Hz rTMS at 70% AMT was delivered over positions F3/F4 with pulses aligned to the positive peaks of the tACS waveform. This combined protocol was compared to five control protocols: rTMS alone, tACS alone, sham rTMS combined w/sham tACS, combined rTMS+tACS during EC, and finally rTMS pulsed at the negative tACS peak. No effects were observed with sham rTMS+sham tACS. During both EO and EC states, PFC-alpha power increased the greatest (~30%) with the combined rTMS+tACS protocol (both during EO and EC) compared to the sham, with effects lasting up to 30 min. Slightly lesser increases were observed with the combined rTMS+tACS at the negative tACS peak, as well as short-duration effects of rTMS alone, while the weakest effects were observed for tACS alone. Our work demonstrates for the first time the feasibility of combined rTMS and tACS for enhancing non-endogenous oscillations. Further investigations are needed to unravel the mechanisms underlying these findings. Our study points towards the promising potential of integrating these protocols for functionally-relevant research and clinical applications.

Title: Luminance and pattern discrimination in visual cortex (V1) of transgenic Opto-mGluR6 mice

Authors: *A. BHATTACHARYYA[1], S. KLEINLOGEL[2];
[1]Inst. For Physiol., Bern, Switzerland; [2]Physiol., Bern, Switzerland

Abstract: Opto-mGluR6 is a chimeric protein composed of the light sensing extracellular and transmembrane domains of melanopsin and the intracellular, G-protein coupling domains of the ON-bipolar cell-specific metabotropic glutamate receptor, mGluR6. Until now, Opto-mGluR6 is the most light sensitive construct that can elicit a response roughly equivalent to the amount of light at dusk/dawn. Although recovery of vision in Opto-mGluR6 transgenic mice (Opto-mice) has been shown by performing *in vivo* optical imaging of the primary visual cortex (V1) from both hemispheres, there is no direct measure of visual acuity at the cortical level in the Opto-mice. To understand what the brain is actually visualizing we conducted *in vivo* extracellular recordings from the V1 middle layers and looked at the multi-unit activity (MUA) and visual evoked potentials (VEP). Responses were recorded and averaged for 40-50 stimuli. We consistently found robust light responses from the middle layers of V1 in response to blue light stimulation (470nm). Next we assessed if the Opto-mice can discriminate full field grating stimuli from equiluminant gray and had any measurable acuity. An average response profile showed a transient increase in firing during change in luminance or a change from grey to equiluminant. These data imply that the chimeric protein expressed in the bipolar cells of the Opto-mice can reliably and reproducibly mediate responses to light pulses. In particular, by using an image discrimination paradigm, we could show that Opto-mice cannot only distinguish luminance levels, but also identify patterns. Thus gene therapy with Opto-mGluR6 can be used as a potential approach to impart light sensitivity and pattern discrimination for visual restoration.

Title: Optogenetic calcium sensor, voltage indicator and chemogenetic mouse models available from the Jackson Laboratory

Authors: *J. BECKWITH, S. ROCKWOOD, C. LUTZ;
The Jackson Lab., Bar Harbor, ME

Abstract: Understanding neural circuitry in both normal and disease states is a priority of the biomedical community. To facilitate this, The Jackson Laboratory (JAX) offers an impressive array of genetically-engineered tools enabling scientists to monitor the neural activity of intact mouse brain. Top most in this tool box are mouse lines using optogenetic and transient-sensing (calcium-, voltage-) technologies. Opsins are light-activated proteins that alter membrane potential in neurons, so that stimulation with light allows rapid control of neuronal activity. Several mouse lines express improved/optimized opsins fused to fluorescent proteins. These include mice with channelrhodopsin expression directed by specific promoters. Additional control is available in mice with Cre- or Tet-dependent expression of channelrhodopsin or halorhodopsin.
GCaMP fluorescence in response to calcium is an indicator of cell activation. These include *Thy1*-promoter driven GCaMP6 transgenic lines and Cre or Tet-dependent GCaMP6 variants. Both cytosolic- and membrane-targeted GCaMP6 mice are available. Furthermore, mice with GCaMP8 expression in capillaries allow studying the blood/brain barrier.
Several intersectional strains utilize both Cre-lox and Tet-On/-Off functionality. Removal of a floxed-STOP allows Tet-dependent expression of channelrhodopsin (ReaChR/EYFP, ChR2*H134R/EYFP), GCaMP6s, GCaMP6f, RCaMP1.07, voltage-sensor (ASAP2s), bicistronic QuasAr voltage-indicator CheRiff channelrhodopsin (OptoPatch) or substrate-dependent reporters (APEX).
This set includes mice created by the Allen Institute for Brain Science, the Genetically-Encoded Neuronal Indicator and Effector (GENIE) Project (Janelia/HHMI), Duke/MIT and several others. Designer receptors exclusively activated by designer drugs (DREADDs) are mutant G-protein coupled receptors activated by the pharmacologically-inert molecule clozapine-N-oxide. Several chemogenetic strains have Cre- and/or FLP-inducible expression of DREADDs.
As extensions of MMRRC-JAX 5xFAD mouse line utility, recently available are the AD-BXD panel of F1 hybrid mice - an isogenic resource useful for studying the effect of genetic background/diversity on the 5xFAD transgenic model of Alzheimer's disease.
Offerings may be searched (**jax.org/mouse-search**). Researchers are encouraged to donate their mouse lines via a very short online form (**jax.org/donate-a-mouse**). Visit The Jackson Laboratory Resources for Optogenetics, Cre-dependent Optogenetic Tools and Cre Strains for Neurobiology (**jax.org/optogenetics**). JAX receives support from NIH, HHMI and private foundations.

Title: An open database for optogenetics in nonhuman primates

Authors: *S. TREMBLAY, C. REVSINE, M. PLATT;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Optogenetics has revolutionized neuroscience in small laboratory animals, but its impact on animal models more similar to humans, such as nonhuman primates, has been mixed. The viral transfection methods optimized for rodents do not translate perfectly to primates, whom have a bigger brain and a more complex immunological system. Thus, when designing an optogenetic experiment, primate researchers are left with scant evidence to decide on viral vectors, genetic promoters, opsins and reporter genes. To make evidence-based decisions in primate optogenetics, our community would benefit from a centralized database listing all attempts, successful and unsuccessful, at expressing opsin genes in the primate brain. Over the last year, we emailed every member of our community who reportedly attempted optogenetics in primates to ask for their contribution to a central database. On the day of writing this abstract (May 1st, 2019), thirty-five laboratories around the world accepted to contribute their data to the repository. The database listed more than 500 viral injection attempts in nonhuman primates, and is still growing. The resource is free for everyone to consult on, and to contribute to on the Open Science Framework website. The "NHP Optogenetics Open Database" provides a portal for nonhuman primate researchers around the world to share their results using optogenetics with their community, including negative unpublished results. It contains a detailed list of viral transfection attempts and their associated methods (viral constructs, injection technique, outcome measures, etc.). The goal is to avoid duplication of efforts within our community and to maximize success in applying optogenetics in nonhuman primates, with hopes of future applications in human patients.

Title: Optogenetically driven electromyographic response characteristics and modulation strategies for peripheral motor stimulation

Authors: *J. J. WILLIAMS[1], A. B. SCHWARTZ[3], A. VAZQUEZ[2];
[1]Systems Neurosci. Inst., [2]Radiology, Univ. of Pittsburgh, Pittsburgh, PA; [3]Dept Neurobiol, Univ. of Pittsburgh Dept. of Neurobio., Pittsburgh, PA

Abstract: Optogenetic stimulation of muscle activity via excitation of nerves genetically labeled with light-sensitive ion channels has recently emerged as a promising alternative to functional electrical stimulation for the purposes of reanimation of paralyzed muscle activity. While electrical stimulation has an extensive background of research data as well as clinical experience to guide the selection of stimulation patterns for muscle activation, the breadth of data available regarding muscle responses to peripheral optogenetic stimulation is comparatively basic. In this study, we sought to narrow this gap by examining electromyographic (EMG) and muscle force responses to single optical pulses, optical pulse trains of varying frequency, and pulse-width modulation of optical trains used to stimulate peripheral motor nerves in a Thy1-ChR2 transgenic mouse model. Normalized EMG responses to an optical pulse train demonstrated a consistent decay in magnitude with time constant proportional to optical pulse train frequency. Single electrical stimulus pulses could be tuned to elicit similar responses to optical stimuli, while responses to electrical pulse trains showed a slower decay rate with increasing frequency than matched optical stimuli. The impulse and frequency responses of EMG and force activity were then used to model an "effective optical stimulus" transformation in agreement with previous computational models of *in vitro* ChR2 kinetics. Finally, optical pulse trains utilizing either constant pulse width or pulse-width modulation were used to stimulate brief movements in anesthetized animals. Constant pulse-width trains initiated brief, jerky movements with a long refractory period, while modulating the optical pulse width in a sinusoidal fashion elicited smooth limb movements that could be repeated over a longer time period. These results from an animal model with "ideal" opsin expression highlight critical differences between peripheral optical and electrical stimulation that may make conventional electrical stimulation strategies incompatible with optical stimulation. Furthermore, we present an alternative optical stimulation approach aimed at producing smooth, functional movements in prosthetic applications.

Title: How does optogenetic modulation of the locus coeruleus affect the neuronal network activity in the cortex?

Authors: *D. MERCAN[1], M. POFAHL[2], N. NIKBAKHT[2], S. SCHWARTZ[1], H. W. BECK[2,3], M. FUHRMANN[3], M. T. HENEKA[1,3];

Germany; [2]Dept. of Epileptology, Univ. of Bonn, Bonn, Germany; [3]German Ctr. for Neurodegenerative Dis. (DZNE), Bonn, Germany

Abstract: Norepinephrine (NE) is one of the major neurotransmitters in the central nervous system. The synthesis of NE is mainly achieved by the locus coeruleus (LC), which sends projections almost to all brain areas including the cortex and hippocampus. The LC plays a role in modulating general arousal, selective attention, stress, sleep architecture, synaptic plasticity, learning and memory. It has been demonstrated that the LC is one of the brain regions that is first affected at earliest in Alzheimer`s Disease (AD). Thus, the levels of NE are decreased in the LC projection areas during AD pathology. Importantly, the reduction in NE concentration strongly correlates with memory loss and cognitive impairment in humans and animal models.
Our aim was to investigate the activity of cortical circuits in response to transient silencing of the LC via optogenetic modulation in both wild type and APP/PS1 mice. For this we used mice that selectively expressed halorhodopsin (eNpHR3.0) in tyrosine hydroxylase positive LC neurons. The mice were subjected unilaterally to light of 593nm wavelength through an implanted cannula to achieve inhibition of the LC. The neuronal activity was measured in the cortex before, during and after the inhibition of LC by examining calcium (Ca^{2+}) currents using two-photon *in vivo* laser scanning microscopy. For visualization of the Ca^{2+} currents GCaMP6, genetically-encoded Ca^{2+} indicator, was used.
Our simultaneous recordings of cortical Ca^{2+} transients revealed that photo-inhibition of the LC resulted in a significant decline in cortical neuronal activity for both wild type and APP/PS1 mice, while control animals did not show any changes in neuronal activity. These changes appear to be transient, as 1 hour after silencing we detected a slightly increased neuronal activity, which suggests a recovery of neurons after photo-inhibition.
In addition, using the same experimental strategy we also investigated whether optogenetic inhibition of the LC changes the structural plasticity of dendritic spines. In order to visualize dendritic spines Thy-1/YFP mice were used and spine density over time was imaged by 2-photon *in vivo* laser scanning microscopy. We observed that 2 days after the 1 hour inhibition, the number of lost spines increased and gained spines decreased, however control animals showed no change. These results suggest that LC silencing may affect the dynamics of dendritic spines in cortex
Our findings shed light on the important modulatory function of the LC on cortical neuronal network activity, which might be modulated through the structural plasticity of dendritic spines.

Title: Optogenetic activation of GABAergic cortical neurons as a robust method for reversible inactivation in macaques

Authors: *A. DE[1,2,3], Y. EL-SHAMAYLEH[4,5], G. D. HORWITZ[1,2];
[1]Physiol. and Biophysics, Univ. of Washington, Seattle, WA; [2]Washington Natl. Primate Res. Ctr., Seattle, WA; [3]Grad. Program in Neuroscience, Univ. of Washington, Seattle, WA; [4]Dept. of Neurosci., Columbia Univ., New York, NY; [5]Zukerman Mind Brain Behavior Inst., New York, NY

Abstract: Reversible inactivation techniques are valuable for elucidating links between neural activity and behavior. Pharmacological agents achieve robust inactivation but have limited spatiotemporal precision. In contrast, suppressive optogenetic tools achieve weak inactivation but have superior spatiotemporal precision.
To achieve robust and temporally precise inactivation of small (~1 mm^3) cortical regions in macaques (three male Macaca mulatta), we used an AAV vector carrying the channelrhodopsin-2 (ChR2) gene along with a mDlx5/6 enhancer sequence which restricts gene expression to cortical GABAergic cells (Dimidschstein et al. 2016). We vetted this approach in the primary visual cortex (V1), a well understood area of the cerebral cortex and an ideal testbed for probing the effect of neural inactivation on behavior.
Histological analyses confirmed that ChR2 expression was largely restricted to cortical inhibitory interneurons. Extracellular recordings confirmed that laser stimulation modulated spiking activity of neurons at the AAV injection sites. Some units were activated at short latency, consistent with direct activation. Others were suppressed, consistent with them receiving synaptic input from directly activated ChR2+ inhibitory interneurons. We assessed the behavioral efficacy of the optogenetic perturbation using a visually guided saccade task and a contrast detection task. In the contrast detection task, a Gabor stimulus appeared on half of the trials, and the monkey was rewarded for reporting this event with a saccade to a remote target. In both tasks, laser simulation was pseudorandomly delivered on half of the trials. On laser trials, visual sensitivity was reduced within receptive fields of the illuminated neurons, consistent with illumination activating inhibitory circuits and suppressing V1 output. Overall, we demonstrate the utility of AAV-mDlx5/6-ChR2 as a robust and spatiotemporally precise inactivation tool for revealing the effects of neural activity on behavior in macaques.

Title: Optogenetic manipulation of top-down feedback in mouse visual cortex

Authors: *A. BROGGINI, I. ONORATO, C. URAN, A. TZANOU, M. VINCK;
Ernst Strüngmann Inst., Frankfurt am Main, Germany

Abstract: Cortical feedback is thought to play an important role in many cortical processes such as attention and predictive coding. In this study we investigated how top down feedback (FB) projections from higher visual areas modulate neuronal activity in primary visual cortex (V1), and how this modulation depends on cortical layers and behavioral state. For this purpose, we recorded primary (V1) and secondary (V2) visual areas simultaneously with high-density silicon probes in awake, head-fixed mice placed on a running platform. In order to identify and later modulate connected visual areas, we used retrograde viral transfection in combination with microscopy. In a first experiment, we expressed the opsins Chronos or Channelrhodopsin (ChR2) in V2 FB neurons projecting to V1 trough injection of the respective retrograde virus in V1. This led to EYFP fluorescence expression in both areas which we used to position our laminar probes. We observed that optogenetic light stimulation in area V2, even at relatively low light intensities, led to an increase of the activity of V1 neurons throughout supra and infra-granular layers. This effect may have been mediated by a direct activation of FB neurons, but could alternatively be explained by antidromic activation of V1 axons. In a second experiment, we therefore used another viral strategy in which expression of ChR2 or Chronos was restricted to area V2. Specifically, we injected AAV-Cre with a retro-helper in area V1 and combined this with Cre-dependent expression of ChR2 or Chronos in area V2. Using the described viral strategy, we obtained localized expression of opsins in area V2. We performed simultaneous recording of V1 and V2 throughout all cortical layers guided by fluorescence patterns, and found closely overlapping receptive fields. With the double virus strategy, we did not find a general increase in V1 activity due to optogenetic activation of FB neurons in area V2. This indicates that optogenetic activation of higher areas using AAV retro-helper can lead to strong antidromic activation in lower areas, even at low light intensities. By analyzing the data from the second experiment, we show that optogenetic stimulation of FB neurons in V2 leads to a layer-specific pattern of activity enhancement and suppression in area V1.

Abstract: Neurons are highly polarized cells, with localised protein trafficking and expression providing dendrites, axon and soma with distinct structural, chemical and functional characteristics. Within the brain, densely interconnected networks formed by neurons give rise to further complexity. Data generated using transgenic approaches, which underlie much of modern neuroscience, can therefore be difficult to interpret without targeted subcellular expression of their protein actuators. One common method to direct transgene trafficking has been through fusion with targeting motifs derived from endogenously localised proteins. In studies presented here, we applied this approach to alter trafficking of the chloride-conducting 'GtACR2' opsin channel. Though having strong inhibitory effects at the soma and dendrites, differential ion flux through axonal GtACR2 has been found to elicit membrane depolarization rather than hyperpolarization. To avoid this axonal depolarization and achieve targeted somatic inhibition, we developed a GtACR2 variant fused with a trafficking motif from the potassium channel Kv2.1, previously shown to provide soma-restricted channelrhodopsin 2 (ChR2) expression. Initial studies expressing this construct from a recombinant adeno-associated viral (rAAV) vector in neurons of the rat pre-Bötzinger complex revealed greatly improved membrane trafficking and phenotypic effects of GtACR2-Kv2.1 compared to wild-type (WT) GtACR2 (n = 3 rats per construct). However, some axonal expression of GtACR2-Kv2.1 was still evident in brainstem and primary cultured hippocampal neurons. These findings are consistent with recent publications describing similar 'somatic' GtACR2-Kv2.1 fusion constructs, which despite reducing axonal expression relative to WT-GtACR2 under certain conditions do not provide exclusively somatic expression. Further rAAV vectors, expressing either GtACR2 or ChR2 fused with potential axonal or dendritic trafficking motifs, have been developed and are being characterised, particularly in ongoing studies of rat ventral respiratory column circuitry.

Successful identification of novel variants with targeted expression, along with GtACR2-Kv2.1-expressing vectors we have developed, will provide valuable tools in a range of neuroscience applications.

Neurobio., Hamburg, Germany; [3]Charité-Universitätsmedizin, Berlin, Germany

Abstract: Understanding the role of defined neuronal pathways in cognitive and behavioral processes requires techniques for spatially selective and temporally-precise in vivo manipulation of synaptic transmission. Powerful optogenetic tools have been developed that allow light-driven excitation of long-range projecting axons. Although temporally-precise inhibition of presynaptic terminals has proven challenging with conventional optogenetic techniques, chemogenetic tools have been shown to efficiently suppress synaptic transmission through activation of the Gi/o signaling pathway. We examined the expression and function of several Gi/o-coupled rhodopsins in mammalian neurons. We found that a mosquito rhodopsin, homologous to the vertebrate encephalopsin (OPN3), can effectively recruit Gi/o signaling in mammalian neurons. Illumination of axonal terminals expressing an enhanced variant of this rhodopsin (eOPN3) led to robust, light-sensitive and stable suppression of presynaptic neurotransmitter release. Activation of eOPN3 in autaptic hippocampal neurons decreased the size of evoked excitatory and inhibitory postsynaptic currents (EPSCs and IPSCs) and increased the paired-pulse ratio, indicative of reduced neurotransmitter release. In organotypic hippocampal slices, paired whole-cell patch-clamp recordings showed that activation of eOPN3 at Schaffer collateral presynaptic

terminals reduces the amplitude of EPSCs without inhibiting CA3 cell action potential firing. We further validated eOPN3 in vivo using extracellular recordings in the barrel cortex, demonstrating temporally-precise inhibition of responses to whisker stimulation during activation of eOPN3 in thalamocortical axons. Our findings demonstrate that eOPN3 can be used to selectively suppress synaptic transmission through direct illumination of axonal terminals. This novel optogenetic approach will be useful for studies exploring the functional consequences of silencing specific long-range axonal projections.

Title: Optogenetic tool for spatiotemporal RNA visualization and manipulation

Authors: *Y. D. RIANI[1], W. WANG[2];
[1]Life Sci. Inst., Ann Arbor, MI; [2]Univ. of Michigan-Ann Arbor, Ann Arbor, MI

Abstract: Optogenetic tools allow the manipulation of biological function using light and have transformed the way neuroscience research is conducted in the last decade. Photoactivatible Cas9, which is composed of a light sensing protein and a DNA binding module - CRISPR/Cas9, has enabled *in situ* regulation of DNA in a spatiotemporal manner. Many biological processes rely on regulation of mRNA translation at specific cellular locales. Therefore, RNA regulation, and not just DNA, must be considered. However, there are few reports on optogenetic tools for manipulating RNA's function. Here I introduce a rational design of light-switchable RNA binding protein for spatiotemporal visualization and manipulation of RNA. We choose Human PumHD (Pumilio Homology Domain) protein as the RNA recognition protein as PumHD is modular and can be designed to bind to any RNA sequences. For light regulation, we will incorporate the light sensing domain eLOV, an engineered version of the LOV2 domain that changes conformation effectively upon blue light irradiation. The goal is to design a light switchable PumHD that doesn't bind to target RNA in dark and only binds when light is administered. This way, visualization or manipulation of RNA would be achieved with minimal perturbation to normal physiological function. In this poster, I will show the design and optimization of the light switchable PumHD.

Title: Engineering a red-shifted genetically encoded glutamate sensor for two-photon imaging

Authors: *A. AGGARWAL[1], K. PODGORSKI[2];
[1]Dept. of Chem., Univ. of Alberta, Edmonton, AB, Canada; [2]Janelia Res. Campus, HHMI, Ashburn, VA

Abstract: Glutamate, a major neurotransmitter in the brain, is an important signaling molecule in biological organisms. Glutamate dysregulation is associated with stroke and neurodegenerative disorders including Alzheimer's disease. Genetically-encoded fluorescent protein (FP) indicators have emerged as powerful tools for studying neuronal circuits due to their specificity and high spatiotemporal resolution. Scientists from Janelia have developed an intensity-based glutamate sensing fluorescent reporter (iGluSnFR) constructed from Gltl domain and circularly permuted GFP. However, current variants are still hampered by several limitations including brightness, signal to noise ratio (SNR) for deep tissue imaging, and lack of spatial resolution. To address these fundamental challenges, efforts are being diverted to developing a new generation of iGluSnFR indicators that will enable deeper imaging into tissues using two-photon excitation with 1030-nm lasers. Recently, different variants of iGluSnFR with emission profiles ranging from blue to yellow were reported to improve upon the GFP based iGluSnFR. These new variants are brighter, have a higher spatial and temporal resolution, are more photostable, and allow imaging at kilohertz rates. The chromophore mutations from GFP iGluSnFR to Azurite FPlead to a blue emission profile, mTurquoise mutations lead to a cyan emission profile, and mVenus mutations on top of iGluSnFR lead to a yellow emission profile. Since the yellow Venus-based prototype also resulted in a red-shifted excitation that enables excitation with femtosecond fiber lasers, it is favorable to use Venus-iGluSnFR with 2P imaging due to its higher fluorescence change and brightness at 1030nm compared to the original iGluSnFR. We performed iterative directed evolution on top of Venus-iGluSnFR prototype and discovered nine unique variants with varying mutations that further red-shifted the current Venus-iGluSnFR excitation profile by 10nm. Two of these variants that have an excitation maximum at 518nm (1-photon) exhibit a glutamate-dependent response of 197% and 178%, at 1,030nm, and provide us with a starting point for a new line of red-shifted Venus-iGluSnFR's.Using these new variants of red-shifted Venus-iGluSnFR's, we hope to create a new iGluSnFR that researchers can use with 2-photon microscopy to investigate the physiological activity of organs, understand the signaling patterns deep within the tissue, and use to study the various disease states at the resolution and depth that is currently not possible.

Title: A novel optogenetic molecular probe for light-induced inhibition of vesicular release

Authors: ***J. WON**[1], C. J. LEE[2], W. HEO[3];
[1]KAIST/IBS, Daejeon, Korea, Republic of; [2]IBS, Daejeon, Korea, Republic of; [3]IBS/KAIST, Daejeon, Korea, Republic of

Abstract: Brain connectivity is composed of highly network which communicate each other: Neurons develop synapses, which is highly specialized structure and enabling exchange signals between each other. During these bidirectional communications between 'neurons and neuron', and 'neurons and glia', in a large percent of transmitters are released by secretory vesicles. Thus, manipulation of vesicle release technique is required to understand brain connectivity.
The current optogenetic approaches, such as archaerhodopsin or halorhodopsin, for synaptic inhibition do not directly inhibit the vesicular release, but indirectly by hyperpolarizing the membrane potentials. Moreover, recent studies raise the issue of unexpected calcium increase and synaptic release during archaerhodopsin or halorhodopsin activation.
In this study, we have developed genetically-encoded optical inhibition system, Opto-vTrap, for direct inhibition of vesicular exocytosis. We used optogenetic dimerizers based on plant *Arabidopsis* cryptochrome2 (CRY2) and cryptochrome-interacting basic-helix-loop-helix (CIB1) interaction that oligomerize each other under blue light (~488nm) illumination. We co-expressed cytosolic N-terminal domain of CRY2 (PHR), and N-terminus of CIB1 (CIBN) fused with vesicle-associated membrane protein (VAMP2) to allow direct interaction with exocytotic vesicles. Under confocal microscopy, we confirmed the light-stimulated reversible clusterization of vesicle in Opto-vTrap transfected Cos-7 cells within 5 minutes. Under TIRF microscopy, we observed complete inhibition of exocytosis of NPY-containing vesicles in Opto-vTrap transfected NS-1 cells under blue light illuminations. In Opto-vTrap virus injected hippocampal slice, electrically-evoked synaptic currents were decreased upon blue light without paired-pulse ratio (PPR) changes.
Not only in the neurons, but also in GFAP-promoter-driven Opto-vTrap virus injected mice, the frequency of astrocytic vesicle-mediated fast inward NMDAR-mediated currents was selectively and reversibly decreased upon blue light illuminations within 5 minutes.
Our study provides a novel optogenetic molecular probe for direct inhibition of both vesicular synaptic- and glio-transmission upon light stimulations. This system will be applied to excitable

neuronal cells as well as non-excitable cells, such as glial cells, without any need for hyperpolarization of the membrane potentials.

Abstract: Chemo-optogenetics has produced powerful tools for optical control of cell activity, but current tools suffer from a variety of limitations including low unitary conductance, the need to modify the target channel, or the inability to control both on and off switching. Using a zebrafish behavior-based screening strategy, we discovered “TRPswitch”, a photoswitchable non-electrophilic ligand for the transient receptor potential ankyrin 1 (TRPA1) channel. TRPA1 exhibits high unitary channel conductance, making it an ideal target for chemo-optogenetic tool development. Replacement of the TRPswitch azobenzene with azoheteroarene yielded TRPswitch-B, with improved photoswitching efficiency and longer thermal half-life. The TRPswitch compounds enable reversible and repeatable light-induced activation and deactivation of the vertebrate Trpa1b channel with violet and green light, respectively. The utility of TRPswitch compounds was demonstrated in larval zebrafish hearts exogenously expressing Trpa1b, where heartbeat could be controlled using TRPswitch and light. Therefore, TRPA1/TRPswitch represents a novel step-function chemo-optogenetic system with a unique combination of high conductance, high efficiency, activity against an unmodified vertebrate channel, and capacity for bidirectional optical switching. Overall, this TRPswitch/TRPA1

chemo-optogenetic system will be particularly applicable in systems where a large depolarization current is needed or sustained channel activation is desirable.

Title: Altering synaptic composition with a novel optogenetic approach

Authors: *A. BAREGHAMYAN[1], G. G. GROSS[1,2], X. LU[2], W. ZHANG[2], R. E. CAMPBELL[2], D. B. ARNOLD[1];
[1]USC, Los Angeles, CA; [2]Chem., Univ. of Alberta, Edmonton, AB, Canada

Abstract: We have generated a novel, recombinant, photo-activatable protein complex, with extremely low background activity in the dark. This system is based on the photocleavable protein PhoCl, whose amino acid backbone is cleaved following absorption of 400 nm light, causing a 13-mer peptide to be released from its C-terminus. Using mRNA display we have generated a 10 amino acid peptide (PhoCl binding peptide, Pbp) that binds with high affinity and specificity to the pocket that is created by release of the native C-terminus of PhoCl, thus creating PhoCl-containing Light Inducible Complex, PhLIC . Because there is virtually no cleavage of PhoCl in the dark, and because Pbp does not bind to uncleaved PhoCl there is negligible interaction between PhoCl and Pbp in the absence of light. To demonstrate the efficacy of this system we have targeted PhoCl to different subcellular locations such as to the Golgi, and shown that we can inducibly target protein fused to PBP to those locations with light. Furthermore, we have shown that using this system we can ablate inhibitory synapses in a light-dependent manner using a split version of the protein GFE3, which uses an E3 ligase targeted to inhibitory synapses to degrade Gephyrin. In the dark, ablation of Gephyrin by the PhoCl/GFE3 complex is undetectable, even when it has been expressed for over one week. Because of its low background activation, even over long periods of time, we believe that this system will be practical for applications requiring photo-activation *in vivo*. We are also extending the application of PhLIC to generate a light-inducible system for eliminating excitatory synapses.

Title: Photosensitive regulation of voltage-gated potassium currents

Authors: H. H. JERNG[1], J. PATEL[1], B. R. ARENKIEL[2], ***P. J. PFAFFINGER**[1];
[1]Neurosci., [2]Mol. & Human Genet. and Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Optogenetics provides exciting tools to activate or silence specific neuronal populations; however, what is lacking are good optogenetic tools to explore the roles that specific neuronal currents, such as voltage-gated potassium (Kv) channels play in shaping neuron and circuit function, and behavior. To create such a tool we engineered voltage-gated potassium (Kv) channels with the light-sensitive LOV domain of *Vaucheria frigida* Aureochrome 1 (VfAu1-LOV) fused to the N-terminus of the Kv channel T1 domain, which regulates Kv channel tetramerization, to create Opto-Kv channels. Using electrophysiological methods, we then tested these Opto-Kv channels in *Xenopus* oocytes and mammalian cells to characterize the light-dependence of channel expression. Our studies found strong induction of current with blue light for all tested mammalian and invertebrate Opto-Kv channels (aKv1, mKv1.1, mKv2.1, mKv3.1) of between 3.5-10x depending on the construct and expression system. Consistent with a regulation of channel assembly and trafficking, the induction and reversal kinetics were 5-10x faster in mammalian cells at 37 ^{o}C than Xenopus oocytes at 16 ^{o}C, with maximal current changes occurring within 1-3 hrs of the initiation or termination of blue light (A). We also found that a dominant negative construct Opto-Kv1(V400D) dramatically suppressed currents by 60-90% in a light dependent manner with a similar time course (B). Finally we tested if Opto-Kv1(V400D) expressed in mitral cells could produce light dependent olfactory behavioral effects similar to the Supersmeller phenotype seen with Kv1.3 knockout. Using a FLEx AAV to restrict expression of Opto-Kv1(V400D) plus P2A-FP to targeted CRE-expressing mitral cells (C), we found that 2-3 hrs of blue light exposure to the bulb was sufficient to produce a significantly increased sensitivity to a novel odor after desensitization to a structurally similar odor(D). In conclusion, Opto-Kv constructs provide a new way to examine the roles of normal Kv channels and disease-causing mutations in brain function and behavior.

Title: Wide-field multi-scale areal parcellation of neural circuits in mice

Authors: ***L. M. BRIER**, J. R. BUMSTEAD, H. B. BANKS, A. R. BICE, J. P. CULVER; Radiology, Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Improved parcellation of neural networks has been a goal spanning multiple decades of research in the functional MRI community in order to navigate the amazing complexity of the human brain. While advances in this realm [1] have led to higher-level organizational structures, increased statistical rigor, and reduced data complexity, the same mathematical development in the mouse brain, which is frequently studied to understand human conditions, has been lagging. To this end, we used functional concurrent optical intrinsic signal (fcOIS) and fluorescence

imaging combined with genetically encoded calcium indicators (GECIs, e.g. GCaMP6) to study mouse brain circuits in a cell-specific manner. Here, sequential wide-field illumination supplied by four LEDs (470nm, 530nm, 590nm, 625nm) was captured by a high-powered sCMOS censor (Andor Zyla) coupled with a 1X objective lens (Olympus MVX10, NA=0.25), which allowed for concurrent calcium and hemoglobin imaging with high spatial resolution across the whole cortex at 15 frames per second (fps). A large field-of-view craniotomy spanning from the anterior suture to lambda and 8mm laterally allowed for direct brain imaging and increased spatial resolution due to less light scattering medium in the imaging path. The unique design of the optical path allows for targeting various cell types using transgenic *Thy1*-GCaMP6 or virally injected *Aldh1l1*-RGECO mice for direct excitatory neuron or astrocyte recording, respectively. Specifically in the present work, wide field *Thy1*-GCaMP6 transients were recorded either during rest or various types of sensory/motor stimulation. During rest, functional connectivity (FC) maps were calculated and evaluated against commonly used mesoscopic metrics of recording whole-cortex brain activity [2]. The robustness of commonly used parcellation techniques, including a k-means clustering approach [3], across multiple spatial scales was evaluated. Further developments will allow for more sophisticated mathematical techniques to parse out more accurate cortical networks and how these networks deteriorate in different disease states.

Title: Mesoscopic imaging of optogenetically-evoked motor maps reveals patterns of cortical activation specific for movement category

Authors: *E. MONTAGNI, F. RESTA, G. DE VITO, A. SCAGLIONE, A. ALLEGRA MASCARO, F. S. PAVONE;

Abstract: Neuronal networks in living organisms are highly interconnected. Usually, to study their functional roles in healthy conditions, task-evoked neuronal responses are correlated with the behavioral readout in freely moving or head-fixed animals. Mapping of motor representation has been classically performed by inducing reproducible movement via serial electrical stimulation of targeted cortical sites. Recently, optogenetics proved to be a useful tool to manipulate targeted neuronal circuits using light. In parallel, the development of red-shifted genetically encoded calcium indicators (red-GECIs) like jRCaMP1a allowed to reduce the spectral overlap with the most common optogenetic actuator, ChR2. Combining these optical tools is possible to develop all-optical systems, which are smart approaches for long-term low-invasive studies of neuronal patterns. Here we developed a new all-optical system for motor mapping by combining simultaneous wide-field calcium imaging, optogenetic stimulation of neuronal activity and recording of behaviour in awake mice. Animals were double transfected with jRCaMP1a and ChR2 over one cortical hemisphere by local AAV injections. The laser beam for stimulation was displaced using Acousto-Optic Deflector (AOD). In this way, we were able to create temporal patterns of light delivered to the motor cortex. First, we characterized the functional response by performing single pulse optogenetic stimulation and we observed that evoked calcium signals increase at increasing laser power. Furthermore, we reproducibly induced two distinct complex behaviours: (i) grasping like movements and (ii) tap like movements by applying trains of optogenetic stimulation on the rostral forelimb area (RFA) and caudal forelimb area (CFA) respectively. The analysis of the calcium response induced by single site optogenetic stimulation showed that the spatio-temporal patterns of neuronal activity are specific and well separated for movement category. Preliminary experiment using complex optical patterns interference confirmed these results. We believe that our combination of techniques represent a fundamental tool to unravel the interplay of brain activity and motor control in healthy and pathological settings.

Title: Real-time neural feedback of mesoscale cortical gcamp6 signals using raspberry-pi

Authors: *P. K. GUPTA, T. H. MURPHY;
Dept. of Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Previous work has found that mice can learn to control specific neuronal ensembles using sensory (eg. auditory) cues (Clancy et al. 2014) or even artificial optogenetic stimulation (Prsa et al. 2017). Real-time neurofeedback of cortical mesoscale brain activity can be used in goal-directed training and learning. In the present work, we measure mesoscale cortical activity with GCaMP6s and provide graded auditory feedback (within ~100 ms after GCaMP fluorescence) based on changes in neuronal activation within a specified region of interest (ROI). We define a compact, low-cost optical brain-machine interface capable of image acquisition, processing, and conducting closed-loop auditory feedback for water reward experiments, using a multithreaded program on a single Raspberry Pi. The ROI activation level, calculated as the fraction of pixels that exceed their running baselines, determines the pitch of the audio feedback (1-24 kHz in quarter-octave steps). Water rewards are delivered if the activation level surpasses a preset threshold. To investigate learning in this context, water-deprived tetO-GCaMP6s mice (N=4) were trained for about 45-minute sessions per day for six days. Results across daily training sessions indicate that mice increase the number of brain-activity mediated water reward deliveries ($p<0.001$, over 6 days) even at increasing thresholds (25-80% activation of ROI pixels). Analysis of the reward-triggered brain activity (dF/Fo) over time indicated that mice progressively learned to activate the cortical ROI to a greater extent ($p=0.002$) than surrounding areas. In this regard, training increased the number of rewards($p<0.001$) and allowed all the mice to perform at a higher threshold ($p=0.002$). In contrast, randomizing the reward delivery led to a decline in % pixel activation in the ROI ($p=0.0015$). To determine the impact of auditory feedback on this type of cortical modulation, we trained mice with auditory feedback (AF, N=2) and with no audio feedback (NAF, N=2). We found that AF mice who received auditory feedback were able to increasingly modulate cortical activity and perform better than NAF mice ($p=0.009$). Additionally, AF mice showed persistently increased cortical activity in ROI over six days of recording ($p<0.0001$ daily; $p<0.0001$ overall) while NAF mice exhibited increase within the daily tasks ($p<0.01$) but it did not last over the days ($p=0.08$). In conclusion, we developed an open-source system for closed-loop feedback that can be added to experimental scenarios for brain activity training and could be possibly effective in inducing neuroplasticity.

Abstract: The major direction of developments in two-photon microscopy is to exploit the widening toolset of optogenetics to allow simultaneous stimulation and imaging in 3D which is an excellent approach to further understand mechanisms in the living brain. Efficacy of two-photon optogenetics is usually limited by single site stimulation. We sought to overrun this limitation using cutting-edge quasi-simultaneous two-photon photostimulation and Ca^{2+}-imaging.
We used a novel acousto-optical scanning solution which is controlling two laser lines with different wavelengths in three dimensions. Switching between the two lasers and scanning patterns happens almost instantaneously, making it possible to perform photostimulation and Ca^{2+}-imaging in an interleaved fashion. We used Thy1-Cre mouse line expressing soma-targeted ChrimsonR-mRuby2 and GCaMP6f.
By fine-tuning the scanning parameters, we were able to record every second frame for imaging during stimulation, which let us follow activity even during photostimulation. With this technique it is possible to affect and monitor at least 80 neurons in a desired 3D network. Accuracy of acousto-optical focusing also enables precise dendritic stimulation at even more sites than for cells. As a result, since interlaminar connection and dendritic computation are crucial features of cortical processing, with this method we can select, image and stimulate neuronal ensembles in a more sophisticated way than with conventional methods, taking us closer to dynamic cortical connection mapping and understanding of the main features of information processing. These results demonstrate for the first time the possibilities and effectiveness of acousto-optical focusing to perform *in vivo* quasi-simultaneous imaging and photostimulation of a desired neural network in large cortical volume with micrometer resolution.

Abstract: Over the past years, progress in opsin engineering and light delivering approaches have enabled neuroscientists to drive and read neural circuits with single action potential precision and cellular resolution, opening fascinating perspectives in both fundamental and medical neuroscience. Precisely, a large number of variants in microbial opsins have been recently screened or engineered in the laboratory, to fasten their kinetics, improve their conductance, confine their expression and shift their absorption peak. On the other hand, advanced wave front shaping approaches have been developed to optimize temporal resolution and precisely guide light through tissues using either scanning or parallel two-photon(2P) excitation. If joint progresses in these two fields have significantly widened the possible experimental configurations for 2P optogenetics, they have also made it more difficult to choose the combination of opsin and illumination configuration that better matches the experimental requirements. In this work, we investigated, experimentally and theoretically, the temporal dynamics of photoevoked currents using opsins with different kinetics and different 2P-illumination conditions. Specifically, by using fast (f-Chrimson), intermediate (CoChR) and slow (ReachR) opsins, we studied, in cell culture and brain slices, the role of opsin kinetics on the photostimulation under 2P-scanning and -parallel illumination. We then used 3- and 4-states models to reproduce the experimentally photoevoked currents under both illumination conditions. This characterization and the prediction of the model can provide crucial information to guide the opsin choice and development and to optimize the design of 2P optogenetics experiments.

Abstract: Vagus nerve interfacing is of interest due to its central role in parasympathetic regulation of the visceral organs, as well as its modulatory effects on the brain, which have been shown to influence epilepsy, depression and migraines. Electrical vagus nerve stimulation (VNS) has shown therapeutic effect in humans, yet it lacks the specificity for controlling and studying targeted pathways. In contrast, optical techniques may enable axon-specific neuromodulation using genetically targeted opsin expression and spatial patterning of the photo-stimulus. In addition to light-activated stimulation, calcium-sensitive fluorescent reporters such as GCaMP6 present a pathway for axon-specific optical recording of activity. We demonstrate *in vivo* photo-stimulation and two-photon GCaMP6 fluorescence imaging in the vagus nerve using a novel GRIN lens-coupled nerve cuff in the anesthetized mouse. A pulsed near-IR laser (1040 nm, 300 fs) was modified by a spatial light modulator (SLM) in the Fourier plane and focused by the microscope objective through a GRIN relay lens to the cervical vagus nerve. By actuating the SLM, spatially selected regions of axons could be differentially stimulated within the nerve. Mouse vitals were monitored with a MouseOx suite and used to detect physiological changes in response to photo-stimulation. We were able to induce differential modulations in heart rate, respiratory rate, and blood-oxygen saturation upon photo-stimulation of selective spatial regions

of the nerve. Additionally, we recorded two-photon GCaMP6 Ca^{2+} transients in vagal axons in response to both photo-stimulation and electrical stimulation.

Title: Cerebral hemodynamics are differentially regulated by excitatory and inhibitory neural circuits

Authors: J. LEE[1], A. BICE[2], Z. ROSENTHAL[2], J.-M. LEE[2], ***A. Q. B. BAUER**[1];
[1]Washington Univ. in St. Louis, Saint Louis, MO; [2]Washington Univ., Saint Louis, MO

Abstract: Neurovascular coupling relies on different populations of brain cells to regulate blood flow via vasoactive messengers[1]. Recent studies using optogenetics have shown that targeting all GABAergic neurons results in dilation followed by constriction[2] and increased blood flow despite suppression of neural activity[3,4]. However, it is currently unclear if specific subpopulations of GABAergic neurons independently regulate cerebral perfusion. Parvalbumin (PV)-expressing interneurons are the largest subpopulation of GABAergic interneurons[5], but the role of PV-interneurons in NVC has been less thoroughly examined. We combined optogenetics, laser speckle contrast imaging (LSCI), and optical intrinsic signal (OIS) imaging in awake mice to investigate how PV-circuits regulate local hemodynamics. Hemodynamic changes following photostimulation (PS) of the left barrel cortex in PV- (n=5) and Thy1-ChR2 (n=5) mice were measured using OIS-LSCI (Figs.1A,B). Thy1-circuit stimulation elicited robust local hemodynamic responses consistent with those following peripheral stimulation. However, activation of PV-circuits resulted in opposite responses, characterized by negative Δ[HbO], positive Δ[HbR], and negative Δ[HbT] changes (Figs.1C,D). Interestingly, we also observed reductions in CBF and CMRO2 following PV-ChR2 stimulation in contrast to that of Thy1-ChR2 (Figs.1C,D). We next tested how activation of PV circuits affected evoked responses due to whisker stimulation(WS). Simultaneous excitation and inhibition of left barrel cortex (WS+PS) resulted in a significant reduction of Δ[HbO] compared to that of WS only (Figs.1E,F). Our results demonstrate a role of PV-expressing interneurons in regulating the brain's blood supply. The flipped local hemodynamic activity following PV-circuit activation is consistent

with local oxygen consumption occurring simultaneously with vasoconstriction; an effect emphasized with concurrent WS and PS of left barrel cortex. Future work will investigate specific molecular mechanisms mediating these responses.

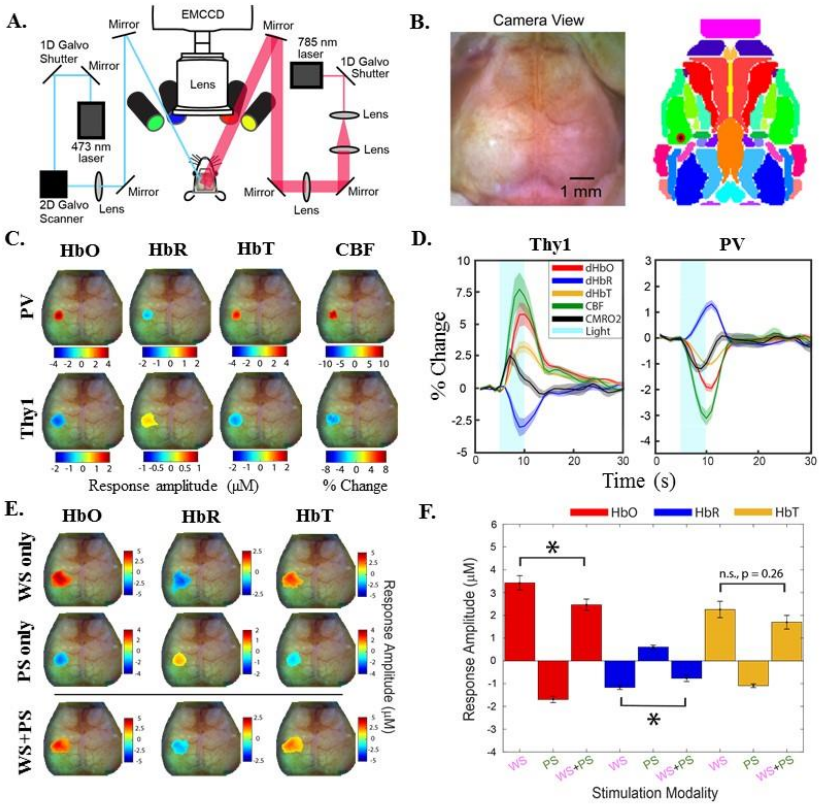

Figure 1. A. Opto-OIS-LSCI system. Prior to imaging, a cranial window was secured to each mouse with dental cement following scalp retraction. LEDs centered at 470nm, 530nm, 590nm, and 625nm illuminated the skull for Opto-OIS imaging. A 473nm laser (0.5mW, SLOC) and 785nm laser diode (50mW, ThorLabs) were used respectively for optogenetics and LSCI. A EMCCD camera (Andor iXon) collected diffuse reflected light for OIS with hemodynamic activity imaged at 20Hz or 10Hz for PV- or Thy1-ChR2 mice data collection respectively. **B.** Image showing camera view during imaging sessions (left) as well as the site of photostimulation (right). Photostimulation was delivered in 5ms pulses at 20Hz or 10Hz for PV or Thy1 stimulation respectively given the native firing rates of each cell population. All stimuli were delivered for 5s followed by 55s of rest. **C.** 50% of max thresholded peak [Hb] and CBF maps after PV- or Thy1-circuit PS. **D.** Time courses of changes in [Hb], CBF, and CMRO2 following PV- or Thy1-circuit PS. CMRO2 was calculated using concurrent measurements of CBF and [Hb]. **E.** 50% of max thresholded peak [Hb] maps after right whisker peripheral stimulation (WS), PS, or WS+PS. **F.** Quantification of peak hemodynamic response calculated by averaging thresholded areas shown in Figure 1E, n.s. = not significant, $*p < 0.05$
