Abstract: Glutamate is an excitatory amino acid in the central nervous system, and it plays crucial roles by binding to the NMDA receptor, AMPA/kainate receptor or metabotropic glutamate receptor. Recently, it has been reported that the pretreatment with CNQX, an AMPA/kainate receptor antagonist, attenuates acute itch induced by chloroquine, a pruritogen (Koga et al., 2011; Akiyama et al., 2014), indicating that the AMPA/kainate receptor is involved in pruriceptive processing. Interestingly, perampanel is an anticonvulsant that elicits its effect by attenuating the AMPA receptor activity (Zwart et al., 2014). Taken together with these previous data, it seems likely that perampanel may have the antipruritic effect; however, there is no available information on the antipruritic effect of perampanel. Thus, the objectives of the present study were determined to clarify whether perampanel exhibits the antipruritic effect on model animals with acute itch.
Pruritus elicits the desire to scratch. Therefore, pruritogen-induced scratching behavior was used to evaluate the effect of perampanel. Different concentrations of perampanel were administered into the subarachnoid space under isoflurane anesthesia, and then chloroquine (200 μg/ 50 μL), serotonin (10 μg/ 50 μL) and histamine (500 μg/ 50 μL) were subcutaneously injected into the nape of the neck. The numbers of scratching behavior after administration of chloroquine and serotonin were significantly attenuated by intrathecal administration of 5×10^{-4} μg/ 5 μL and 5 μg/ 5 μL perampanel, respectively, whereas there was little effect of perampanel on histamine-induced pruritus. These results indicate that the effects of perampanel on pruritogen-induced scratching behavior depend on pruritogens.
We thank Eisai Co., Ltd., Tokyo, Japan for their generous gift of perampanel.

Title: Role of keratinocyte STAT3 in itch

Authors: T. HASHIMOTO, K. SAKAI, G. YOSIPOVITCH, ***T. A. AKIYAMA**;
Univ. of Miami, Miami, FL

Abstract: Recent findings suggest that not only the interaction between pruritogens and peripheral pruriceptor terminals, but also the interplay among peripheral pruriceptor terminals, immune cells, and epidermal keratinocytes play roles in itch induction. STAT3 plays critical roles in the regulation of keratinocytes. The aim of this study was to elucidate the involvement of keratinocyte STAT3 in itch sensation. To examine the role of STAT3 in keratinocytes in vivo, we crossed Stat3 flox mice with K5CreERT2 mice, and tamoxifen was injected to delete STAT3 in keratinocytes. We initially assessed the in vivo effect of keratinocyte-specific STAT3 depletion on acute itch in mice. The acute itch was evoked by intradermally injecting either histaminergic or non-histaminergic pruritogen (histamine, serotonin, or chloroquine). All three pruritogens evoked scratching responses in control mice. Histamine-evoked scratching behavior was significantly attenuated in STAT3 conditional knockout (cKO) mice while serotonin- and chloroquine-induced scratching responses did not change. To determine whether pruritogens elevate intracellular calcium in keratinocytes, we performed calcium imaging experiments on keratinocytes. In keratinocytes from control mice, intracellular calcium gradually increased and reached a maximum level 90-150 sec after application of histamine and serotonin. However, chloroquine did not increase intracellular calcium. The increased responses of keratinocytes to histamine and serotonin were significantly reduced by STAT3 knockout, or TRPV4 inhibitor reported to inhibit histamine-evoked calcium responses of keratinocytes. To investigate whether STAT3 is involved in the regulation of TRPV4 expression, we performed immunostaining experiments on epidermal sheets. In epidermal sheets from control mice, TRPV4 was detected on the cell surface of keratinocytes. This signal was considerably weaker in keratinocytes of STAT3 cKO mice, while TRPV4 mRNA expressions were detected in the epidermal sheets from both control and STAT3 cKO mice. STAT3 may be involved in the trafficking of TRPV4 to the plasma membrane. Overall, these results indicate that keratinocyte STAT3 plays a major role in

histaminergic itch, but not nonhistaminergic itch, possibly through regulation of TRPV4 expression.

Title: Effects of rostral ventromedial medullary tachykinin 1 receptor (NK-1R) expressing neurons on the descending modulation of itch

Authors: *T. FOLLANSBEE[1], D. T. DOMOCOS[2], K. TAKANAMI[3], M. CARSTENS[1], E. E. CARSTENS[1];
[1]Neurobiology, Physiol. & Behavior, Univ. of California, Davis, Davis, CA; [2]Fac. of Biology, Univ. of Bucharest, Bucharest, Romania; [3]Mouse Genomics Resource Lab., Natl. Inst. of Genet., Mishima, Japan

Abstract: The rostral ventromedial medulla (RVM) is a brainstem structure that has been known for decades to be important in descending modulation of spinal pain transmission. However, whether these descending pathways also modulate the spinal transmission of itch is unknown. Within the RVM, a relevant class of cells -the ON cells - are thought to facilitate spinal pain transmission and exhibit a significant increase in firing prior to the onset of a nocifensive withdrawal reflex. Furthermore, ON cells respond to intradermal injection of pruritogens. RVM neurons with descending spinal projections express the neurokinin-1 (NK-1) receptor, and ON cells were shown to be excited by local administration of substance P (SP). We hypothesized that ON cells express the NK-1 receptor, and that activation of NK-1 receptor- expressing ON cells may have an inhibitory effect ion itch opposite to their pronociceptive action. To test these hypotheses, chemogenetic and pharmacological approaches were used to activate ON cells and determine whether itch- related behaviors were reduced.
Using electrophysiological single-unit recording methods in lightly anesthetized mice, the magnitude of responses of RVM ON-cells elicited by hindpaw pinch were significantly potentiated (~50%) following local injection of SP (0.5 µl, 10 nmol) through a cannula adjacent

to the recording electrode. This effect was maintained throughout the 60 min recording period. Saline microinjection had no effect. In behavioral experiments, intracranial microinjection of SP (0.5µl, 10nmol), as compared with saline, through an implanted cannula significantly reduced the mean number of hindlimb scratch bouts directed to the site of intradermal injection of histamine (106 to 60, $p<0.05$) or chloroquine (157 to 24, $p<0.05$) as compared with saline microinjection. We also used a chemogenetic approach, injecting AAV5: DIO-hM3Dq-mCherry into the RVM of NK-1R-cre mice. Consistent with the pharmacological approach, chemogenetic activation of RVM NK-1 receptor-expressing neurons significantly reduced pruritogen-evoked scratching behavior. In each DREADDs mouse we compared the number of scratch bouts elicited by histamine or chloroquine following systemic administration of saline (control) vs. clozapine (0.01mg/kg). Compared to controls, clozapine administration significantly reduced the mean number of scratch bouts evoked by intradermal injection of histamine (6 vs. 76, $p<0.05$) or chloroquine (34 vs. 139, $p<0.05$).
We conclude that activation of NK-1 receptor-expressing ON cells in RVM significantly reduces the spinal transmission of itch.

Title: High-resolution analysis of the tickle response and of self-tickle suppression in humans

Authors: *S. PROELSS, S. ISHIYAMA, E. MAIER, M. BRECHT;
Bernstein Ctr. For Computat. Neurosci. Berlin, Humboldt Univ. of Berlin, Berlin, Germany

Abstract: Ticklishness is an all too familiar experience to most, yet the physiological underpinnings of this sensation remain poorly understood. Here, we address this issue by systematically mapping out physiological changes in humans during tickling in high definition recordings with the aim to 1) establish a time series of processes that accompany ticklishness responses from first onset of external touch to vocalisation at different body parts, and 2) assess the effects of self-generated motion and touch in the suppression of ticklish responses. In a within-participant design, we assessed vocalisation latencies, acoustic vocalisation properties, preparatory changes (i.e., breathing) and activation of facial action units (Facial Action Coding System; Ekman & Friesen, 1978) in conjunction with self-reported ticklishness scores in response to tickling and self-tickle suppression.
Overall results show that greater self-reported ticklishness co-occurs with significantly faster

vocalisation latencies, further characterised by significantly heightened pitch during laughter. The first point of external touch is followed by an inhale at short latencies (down to <200ms) and onset of mouth opening commences at <150ms before vocalisation. Whilst body parts differ across subjects in these parameters, the emergent pattern remains consistent across participants. Intriguingly, we further show that self-touch suppresses a ticklish response to tickling applied by second person. Such self-touch suppression requires the establishment of 'true self-touch' at the ipsilateral side to the external point of touch, resulting in significantly increased response latencies or even absence of vocalisation and greatly diminished self-reported ticklishness. In contrast, sole execution of a tickling-finger-motion without touch at the ipsilateral or contralateral side to the tickle does not alter response latencies or perceived ticklishness. Notably, the here reported necessity of direct bodily contact is indicative for a role for inhibitory mechanisms during self-touch. Our data suggest that self-tickle suppression might be mediated by an inhibitory tactile mechanism acting on sensations within a body hemisphere. This explanation is simpler than conventional models, which often evoke motor mechanisms (such as efference-copy) or invoke a neural computation that distinguishes between self- and allo-touch.

Title: Determining the function of TRPC3 in allergic contact dermatitis induced itch

Authors: *K. BEATTIE[1], H. JIANG[2], M. MACVITTIE[1], Q. LIU[2], W. LUO[1];
[1]Neurosci., Univ. of Pennsylvania Sch. of Med., Philadelphia, PA; [2]Anesthesiol., Washington Univ. at St. Louis Sch. of Med., Saint Louis, MO

Abstract: Itch is an irritating sensation that triggers the desire to scratch. It is a major symptom of dermatological diseases including Allergic Contact Dermatitis (ACD), a disease characterized by rash formation and intense itch sensation. Although the pathophysiology of the immune response in ACD is well-characterized, the molecular mechanisms underlying the sensation of itch in ACD are still being elucidated.
Transient receptor potential (TRP) channels comprise a superfamily of proteins that form nonselective cation channels and function in a variety of sensory pathways, including itch. In this study, we focus on one of the TRP channels, TRPC3, and investigate its role in mediating or modulating itch sensation in ACD. Our lab previously characterized *TrpC3* knock out (KO) mice

and found that they exhibited no phenotypic differences in a variety of behavioral tests for acute pain and itch sensation. In contrast, pilot studies our collaborator's lab demonstrated that *TrpC3* KO mice showed a marked increase in scratching behavior in a mouse model of ACD. To confirm this finding, we induced CHS in 3 to 4-month-old male and female C57/B6 (*n*=10) and *TrpC3* KO mice (*n*=8) and observed that *TrpC3* KO mice scratched significantly more than aged-matched C56/B6 mice (no sex-differences were found). These results suggest TRPC3 plays a critical role in dampening pathological itch triggered by CHS. *TrpC3* is known to be expressed in both the immune and nervous system. To understand the mechanism through which TRPC3 acts in CHS, we are generating conditional KO mice of *TrpC3* in either immune or nervous system. We have examined epidermal thickness and immune cell infiltration in the epidermis of C57/B6 and *TrpC3* KO mice with and without CHS (H & E staining, n=3 for each group). Both genotypes showed a significant increase in epidermal thickness and cellular infiltration with CHS compared to control skin, and there was no significant difference between the genotypes. These results demonstrate that the amount of skin inflammation is not correlated with itch behavior. In summary, our results suggest a novel role for TRPC3 in modulating chronic itch in ACD, and the exact mechanism is under investigation.

Title: Skin microbiome induced release of an itch-inducing cytokine

Authors: *S. PITAKE[1], L. FLOWERS[2], E. GRICE[3], I. ABDUS-SABOOR[1];
[1]Biol., [2]Dermatol., [3]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Atopic dermatitis (AD) is a chronic inflammatory skin disease that affects approximately 15-20% of children and 3% of adults overall. The exact pathogenesis of AD is poorly understood; however, studies have shown that the skin microbiome plays a crucial role in maintaining the barrier function and preventing dysbiosis. Loss of structural integrity and alterations in commensal bacteria of skin leads to increased colonization of harmful bacterium such as *Staphylococcus aureus*, thus contributing towards progression of AD. Early clinical studies have also shown that topical application of some commensal strains (*Staphylococcus hominis* or *Roseomonas mucosa*) reduce severity of AD in some cases; but the underlying

mechanism remains unclear. In this study, we collected skin biopsies from young and adult human donors and inoculated primary keratinocytes with up to 40 different commensal and AD associated bacterial strains in a time dependent (24 and 72 hours) manner. The supernatants from keratinocyte-bacteria co-culture were assessed for the itch-inducing cytokine Thymic stromal lymphopoietin (TSLP) content by ELISA and we found a time dependent increase in TSLP release. Interestingly, in addition to previously reported AD associated strains, we identified several new bacterial strains which could contribute towards AD directly via TSLP release.

Title: Modulation of touch and itch by neuropeptide Y signaling within the dorsal spinal cord

Authors: *D. ACTON, X. REN, S. DI COSTANZO, A. DALET, S. BOURANE, M. GOULDING;
Salk Inst., La Jolla, CA

Abstract: The neurons of the dorsal spinal cord express a multiplicity of neuropeptides and their receptors, and these function to shape the transmission and transformation of cutaneous sensory information. Peptidergic signaling has been shown to be important in the regulation of the central transmission pathway for chemically evoked itch sensation. In this pathway, fast synaptic transmission is complemented by the excitatory actions of neuropeptides including substance P, natriuretic polypeptide b and gastrin releasing peptide, and by the inhibitory actions of dynorphin. Recently, we demonstrated that a separate pathway exists for the transmission of itch sensation evoked by mechanical stimuli, such as the light touch of an insect on the skin. This pathway is subject to inhibitory gating by dorsal horn interneurons that express Neuropeptide Y::Cre (NPY::Cre INs) (Bourane et al. *Science*. 2015), such that ablation of these neurons causes compulsive scratching in mice. Previously it was unclear whether this inhibitory regulation was mediated by GABA/glycine or by NPY itself. We have used extensive genetic and pharmacological interventions to determine the role of NPY signaling in the dorsal horn transmission pathways for touch, pain, and mechanical and chemical itch. NPY receptors are expressed by multiple neuronal populations in the central and peripheral nervous systems, and

previous studies of the influence of NPY signaling on somatosensory processing have been unable to pinpoint its sites of action. We have now assessed the contribution that NPY signaling within the dorsal horn makes to the regulation of the mechanical itch transmission pathway. Given observations that some patients with debilitating chronic itch have reduced serum levels of NPY, and that NPY levels are inversely correlated with the intensity of itch (Reich et al. *Acta Derm.Venereol.* 2007), determining the role of NPY in the inhibitory regulation of this modality is of considerable interest.

Abstract: Patients with liver diseases often suffer from chronic itch or pruritus, yet the itch-causing pruritogen(s) and their cognate receptor(s) remain largely elusive. Here, we identify a ligand-receptor pair, bile acids and orphan, primate specific MRGPRX4, underlying cholestatic itch. *In situ* hybridization and immunohistochemistry revealed that MRGPRX4 is expressed in ~7% of human dorsal root ganglion (hDRG) neurons and co-localizes with HRH1, a known itch-inducing GPCR. Bile acids elicited a robust Ca^{2+} response in a subset of cultured hDRG neurons. Intradermal injection of bile acids or a MRGPRX4 specific agonist induced significant itch in healthy human subjects. Surprisingly, application of a specific agonist for TGR5, a known sequence conserved bile acid receptor previously implicated in cholestatic itch in mice, failed to elicit Ca^{2+} response in cultured hDRG neurons, nor did it induce itch in human subjects. *In situ* hybridization and immunohistochemistry revealed that hTGR5 is selectively expressed in satellite glial cells, unlike mTGR5 (in mouse DRG neurons), likely accounting for the inter-species difference functionally. Finally, we found that plasma bile acids correlate well with cholestatic itch and the elevated bile acid level in itchy patients is sufficient to activate MRGPRX4. Taken together, our data strongly suggest that MRGPRX4 is a novel bile acid receptor that likely underlies cholestatic itch, providing a promising new drug target for anti-itch therapies.

Abstract: Chronic itch associated with diseases like atopic dermatitis impair the lives of patients and their family members. Studying the neuronal mechanism (s) to cause allergic itch will lay the

foundation to shed light on signaling processes that become unregulated and sensitized during chronic allergic skin disorders. Recently, many painful conditions (inflammatory and neuropathic pain) have been associated with integrin signaling. Following engagement with extracellular matrix proteins, integrin signaling influences numerous cellular processes including migration, proliferation, and death. However, the unique role of the integrin receptor in chronic itch associated with the allergic itch is unknown. Here, we employ cellular, molecular, physiological, pharmacological, mouse genetics and mouse behavioral assays to illustrate a new pathway that is possibly linked with the chronic allergic itch. We identify a novel endogenous ligand that induces itch and is evolutionarily conserved among several animals. Consistently, we find a novel receptor that is expressed and is functional in the DRG sensory neurons that is involved in itch and not in pain. Finally, we show ligand activation of DRG neurons releases the neurotransmitter NPPB to further transmit the signal to spinal cord neurons in the CNS. Our current working model predicts that a localized allergic response in the skin generates and releases ligand which transmits a signal through DRG sensory neurons, which further targets transient receptor potential (TRP)-channels downstream in the signaling pathways. Overall, we identify a novel endogenous mediator and the mechanism that are fundamental to neuronal responses during chronic allergic skin diseases. The future targeting of ligand/receptor may provide innovative strategies for the development of new drugs to treat chronic itch.

Title: A meta-analysis of sex and animal models used in pre-clinical itch research

Authors: *J. J. WHEELER[1], K. N. ALLEN-MOYER[2], S. K. MISHRA[1];
[1]Mol. Biomed. Sci., [2]Dept. of Statistics, North Carolina State Univ., Raleigh, NC

Abstract: Beginning in June 2015, the NIH has required researchers to include both sexes in preclinical research in biomedical sciences. Recent studies have indicated that neuroscience has historically been biased towards using male animals in preclinical research. Itch, a symptom of many diseases, is mediated by the nervous system; therefore, we were interested in whether itch research has the same sex biases as other neuroscience. However, there haven't been any studies to look at the use of both sexes in itch research or to determine if the itch sensation has any sex

bias. Therefore, we performed a meta-analysis on primary research articles indexed in the PubMed database that contained the terms “Itch” or “Pruritus” from August 2007 to December 2018. From these primary research articles, we collected the following information: the animal model used, type of itch (acute vs. chronic), the sex of the animals used, and whether sex was considered a variable. Further, we looked at the different strains of mice and rats used, species of non-human primate, and breed of dog used. We also looked at how the use of sex differed before and after the NIH’s 2015 mandate. We found that male animals were most likely to be used, regardless of the animal model used. Additionally, in research that used both male and female animals, researchers rarely tried to determine if their results were sex-dependent. We found that mice were the most frequently used animal model. We also determined that researchers using non-human primates were more likely to use both sexes and that researchers using rats were least likely to use females in their research. Overall, our report will provide a significant understanding of sex bias and its omission in itch research. Further, the information from this study will help guide researchers to consider this factor as an important variable in itch research.

Title: Cinnamaldehyde-evoked scratching in mice involves activation of TRPV4- and TRPV1- but not TRPA1-expressing sensory neurons

Authors: A. NGUYEN[1], T. FOLLANSBEE[2], D. T. DOMOCOS[3], M. IODI CARSTENS[4], ***E. CARSTENS**[5];
[1]Neurobiology, Physiol. and Behavior, [2]NPB, Univ. of California, Davis, Davis, CA; [3]Fac. of Biology, Univ. of Bucharest, Bucharest, Romania; [4]Dept Neurobiol, Physiol, Behav, U C Davis, Davis, CA; [5]Neurobiology, Physiol. and Behavior, Univ. of California Davis, Davis, CA

Abstract: Topical application of cinnamaldehyde (CA) elicits itch in humans. Intradermal cheek injection of CA in mice elicits dose-related scratching but little wiping, indicating itch. We previously reported that CA-evoked scratching behavior was reduced by ~50% in male and female knockout (KO) mice lacking TRPV1 or TRPV4, but not TRPA1. We presently used calcium imaging to investigate if dorsal root ganglion (DRG) cells of various genotypes are activated by CA and other itch and pain mediators. DRGs from wildtype (WT) and TRPV1KO, TRPA1KO or TRPV4KO mice were collected, acutely isolated, cultured and plated for

ratiometric calcium imaging using Fura-2. The TRPA1 agonists CA and allyl isothiocyanate (AITC; mustard oil) respectively activated 11.9% and 32.8% of DRG cells from WT mice. As expected, neither CA nor AITC activated any DRG cells from TRPA1KO mice. CA activated significantly fewer DRG cells from TRPV4KO mice (4%) compared to WT mice, consistent with the behavioral data in which CA elicited less scratching in TRPV4KO mice. However, compared to WTs, both CA and AITC activated significantly more DRG cells from TRPV1KO mice (17 and 38.7%, respectively), which is inconsistent with the behavioral data showing that CA evoked less scratching in TRPV1KOs. The higher percentage of CA- and AITC-sensitive DRG cells in TRPV1KOs may reflect a compensatory increase in TRPA1 expression in these mice. Since CA elicited normal scratching in TRPA1KOs, CA presumably acts independently of TRPA1-expressing sensory or epithelial cells. CA is a contact sensitizer that activates CD-1-restricted T cells. We therefore tested the type 2 cytokine, IL-4 (300 nM), which activated 10% of DRG cells from WT mice, 13.1% from TRPV1KOs, and 6.8% from TRPV4KOs. IL-4 appears to act via TRPA1, since IL-4 did not activate any neurons from TRPA1KOs. In conclusion, TRPA1 is not required for CA-evoked itch. CA may partly act via TRPV4 or a TRPV4-TRPV1 heterodimer in sensory neurons to elicit itch. CA may also have a TRPA1-independent immune effect leading to production of type 2 cytokines, although activation of DRG cells by IL-4 is TRPA1-dependent and thus does not appear to mediate CA-evoked itch.

Abstract: The dopaminergic neural system plays a crucial role in motor regulation as well as modulation and processing of somatosensory information. Although rats with neonatal dopamine depletion exhibit motor hyperactivity and have been utilized as animal models of attention deficit hyperactivity disorder, characterization of their responses to pain and itch stimuli during

adulthood have rarely been investigated. In the present study, we performed open field tests to confirm motor hyperactivity, and then investigated behavioral responses to pain and itch stimuli in adult rats with neonatal dopamine depletion. The neural responses to these stimuli were also examined through immunohistochemical analysis of c-Fos protein and electrophysiological analysis of extracellular recording of neural activity in the spinal dorsal horn. The rats that received intra-ventricular injection of 6-hydroxydopamine (6-OHDA) 4 days after birth showed a significant increase in the distance traveled in the open field tests during adulthood compared to the vehicle-treated rats. The 6-OHDA-treated rats showed a significant increase in the nociceptive behavioral response in the formalin test. The von-Frey filament and tail flick tests failed to reveal significant differences in withdrawal thresholds between the vehicle-treated and 6-OHDA-treated rats. The 6-OHDA-treated rats showed a significant decrease in itch-related behavior evoked by injection of serotonin (5-HT) into the hindpaw compared to the vehicle-treated rats. Significantly increased number of c-Fos-immunoreactive neurons was observed in the ipsilateral spinal dorsal horn to the formalin injection site in the 6-OHDA-treated rats compared to the vehicle-treated rats. There was no significant difference in number of c-Fos-immunoreactive spinal dorsal horn neurons evoked by the 5-HT injection into the hindpaw between the two groups. No significant differences in numbers of neural activities in the spinal dorsal horn evoked by von-Frey filament and the 5-HT injection applied to the hindpaw were observed between the two groups. These results suggest that the dopamine system is a crucial role in the development of somatosensory system including pain and itch, and the neural circuit in the spinal cord for itch is different from that for pain. The effects of neonatal dopamine depletion on somatosensory system depend on the modality. Supraspinal mechanism may be implicated in the modulation of itch-related behavior induced by the neonatal dopamine depletion.

Abstract: Chronic itch is a debilitating condition involving primary sensory neurons. Though several studies have been done in this field, the exact molecular mechanisms by which the itch signals are relayed from the peripheral nervous system to the central nervous system are not yet well understood. However, it is believed that the process of detecting the itch sensation and relaying it via the dorsal root ganglion (DRG) to the dorsal horn (DH) and other regions of the central nervous system involves cell to cell signaling molecules such as neuropeptides. In the current study, we employed a label-free mass spectrometry-based relative quantitation procedure to correlate the levels of various neuropeptides in the DH and DRG regions in mouse models of atopic dermatitis and dry skin. Using this approach, we were able to quantify over 400 peptides in the DRG and DH regions combined. Of these quantifiable peptides, 33 were found to be significantly changed ($p \leq 0.05$, adjusted for multiple testing corrections) between the treated and control models. Several peptides from neuropeptide precursor proteins such as proSAAS, proTachykinin-1 and proCGRP were among those that were significantly changed. Additionally, Substance P, a previously known peptide candidate for itch signal transmission, contributed towards differentiating between the treated vs. control replicates via principal component analysis (PCA) in the current study. Secondly, we compared the peptidomics results from the current study with a previous study performed on migraine model of mice. Though pain and itch are two distinct sensations, the exact mechanisms that differentiate these two are not completely understood. Here, we looked at the change in peptide profile levels from DH of mice treated for these two conditions to see if there are any peptide level differences associated with these two conditions. From a preliminary analysis, we found that 115 peptides were exclusively present in the pain model while 79 peptides were found only in the itch model. This suggests that a different set of peptides could potentially be involved in mediating these two disorders. Further investigation on the nature of these peptides and their relative levels of change should reveal greater details on the mechanism of itch.

Title: Closed loop brain machine interface modulation of acute pain in rats

Authors: *Q. ZHANG[1], R. TALAY[1], S. HU[3], Z. XIAO[4], B. CARAVAN[1], L. HU[1], Z. CHEN[5], J. WANG[2];

Abstract: Acute pain is triggered by noxious stimuli that induce changes in the neural responses of specific circuits at both single neuron and population levels. However, current diagnosis of pain remains based on behavioral reports rather than cellular mechanisms, leading to the risk of under or over-treatment. Our previous studies have shown that certain brain regions, such as the prelimbic prefrontal cortex (PL-PFC), can be optogenetically or electrically stimulated to provide analgesia. Continuous stimulation, however, can result in unwanted nonspecific side effects. To address these challenges, we have developed a prototype brain machine interface (BMI) for acute pain onset detection and for on-demand therapeutic stimulation in freely moving rats. Silicon probes assembled with custom-designed drives were implanted in the anterior cingulate cortex (ACC). In addition, an optic fiber was implanted in the PFC after AAV-CamKII-hChR2 injection. Mechanical or thermal stimuli were delivered to the hind limbs contralateral to recording sites. Online-sorted ensemble spike activity was used to train and test a Poisson linear dynamical system (PLDS) to detect the onset of acute pain and trigger PL-PFC optogenetic stimulation. Our preliminary data show that we can achieve real-time decoding with a true positive rate of >80% and a detection latency shorter than rat limb withdrawal latency. At the same time, real-time pain detection can reliably trigger PFC stimulation to attenuate pain behavior. The paw withdrawal latency is significantly increased after BMI treatment. In addition, rats prefer to stay in the BMI-associated treatment chamber during conditioned place aversion (CPA) testing. These results suggest that a closed-loop BMI is able to relieve both sensory and affective acute pain behavior. Furthermore, this BMI model could be used to study mechanisms of cortical pain circuitry and relate neural codes to behavior.

Title: Hyperexcitability of mPFC-NAc neurons in a mouse model of incision pain

Authors: *S. ZHOU[1], K. C. JONES[2], B. K. ATWOOD[3], P. L. SHEETS[4];
[1]Dept. of Pharmacol. & Toxicology, Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Indiana Univ. Sch. of Med., Greenwood, IN; [3]Dept. of Psychiatry, Indiana Univ. Sch. of Med., Indianapolis, IN; [4]Dept. of Pharmacol. & Toxicology, Stark Neurosciences Res. Institute, Indiana U, Indianapolis, IN

Abstract: Prescription opioid treatment of surgical procedure-related incisional pain has captured the national spotlight due to an alarming rise in opioid misuse and overdose. Before novel therapeutic pain strategies can be developed, cellular and circuit alterations to supraspinal pathways involved in both pain regulation and opioid reward must be resolved. The medial prefrontal cortex (mPFC) in rodents plays an important role in pain regulation. Using retrograde tracing strategies, we identified a major population of mPFC neurons that target the nucleus accumbens (NAc), a striatal region implicated in opioid reward. This corticoaccumbal pathway (i.e. mPFC-NAc) is involved in regulation of both pain and reward-driven behavior. Here we used the plantar incision model for surgical pain, which produced a significant reduction in 50% paw withdrawal threshold in response to von Frey fibers at post-operation days 1-4. Our preliminary whole-cell patch clamp data from acute brain slices show that retrogradely-labeled mPFC-NAc neurons from the incision group have higher frequency of current-evoked action potentials and lower voltage thresholds compared with the sham group. We are currently dissecting functional changes to mPFC-NAc neurons in surgical injury plus opioid-treated cohorts. Findings from this work will have important implications for how specific cortical circuits may underlie protective mechanisms against opioid addiction following surgical injury.

Title: Pain and brain oscillations in freely moving mice: Searching for an electrographic signature of pain

Authors: *J. ZHANG[1], S. PONSEL[1], M. PILZ[2], Y. YANOVSKY[1], J. BRANKAčK[1], A. DRAGUHN[1];
[1]Inst. of Physiol. and Pathophysiology, [2]Inst. of Med. Biometry and Informatics, Heidelberg Univ., Heidelberg, Germany

Abstract: Pain is one of the major public health concerns. However, an objective and reliable method for diagnosing pain is missing. Little is known how pain modulates brain oscillatory activities in both humans and animals. To investigate this, brain electrodes were implanted bi- and unilaterally into multiple pain-related brain regions of mice, including primary somatosensory cortex (S1), anterior cingulate cortex (ACC), insular cortex (Ins), ventroposterior lateral thalamus (VPL), parietal cortex (PAC) and olfactory bulb (OB). Electrographic oscillatory activity was recorded in freely moving animals in all brain regions, simultaneously with motor activity. Baseline recordings and controls after saline injections in one hind paw were compared to capsaicin injections which resulted in acute pain. We found increases of cross-frequency coupling (CFC) between low (1-12 Hz) and fast frequencies (80-120 Hz) in anterior cingulate cortex (ACC) and increases of coherence between specific brain regions in frequency ranges below 30 Hz. To distinguish between pain (capsaicin) and no-pain (saline) an elastic net model was applied using power, CFC and interregional coherence data separately and in combination. The elastic net permitted reliable detection of pain using three parameters, all in the frequency range below 30 Hz (which is mainly used in clinical EEG recordings in humans): Power spectrum densitiy between 6-12 Hz in ipsilateral OB, coherence at 6-12 Hz between ACC and PAC (both ipsilaterally), as well as coherence at 6-12 Hz between ipsilateral ACC and Ins. These parameters contribute to a classification with an area under the curve (AUC) of 0.74, which is significantly different from chance. These findings indicate a specific change of electrophysiological signals during acute pain in the mouse brain.

Title: High frequency oscillations (HFOs) as a promising neural signature in response to noxious stimulus

Authors: *Z. WANG, Y. B. PENG;
Dept Psychol, Univ. of Texas At Arlington, Arlington, TX

Abstract: High-frequency oscillations (HFOs) ranging between 80-600 Hz, is proved to be involved in normal brain function, such as, cognitive process, memory, and epileptic seizures. However, much less is known about whether HFOs are associated with pain process. In this study, we aim at exploring the HFOs features, mainly at 100-250 Hz and 250-500 Hz, in response to noxious stimulus, providing a promising neural signature of pain. We hypothesize that differential HFOs response will be detected after noxious stimulus in different brain regions, which contribute to different components of pain (e.g., anterior cingulate cortex (ACC) for emotion, and primary somatosensory cortex (S1) for sensory discrimination). Here, local field potential (LFP) was recorded from contralateral ACC, bilateral amygdala (Amg), and contralateral VTA simultaneously in male Sprague-Dawley rats (n=12). Firstly, HFOs were recorded through four electrodes localized in these four brain areas for 11 minutes as baseline. Then, rats were given 0.1mL formalin (3%) injection at the left hindpaw and continued recording for 60 minutes. Both Spike2 and MATLAB were used to analyze the generated data. A repeated measures analysis of variance (ANOVA) with LSD post-hoc test was conducted to compare the HFOs power difference: 1) between baseline and formalin periods; and 2) among these four regions. We found that the intensity of HFOs at 100-250 Hz was significantly increased after formalin injection ($p < .05$) in ACC, contralateral Amg, and VTA, which lasted up to 60 minutes, but not in ipsilateral Amg ($p > .05$). The intensity at 250-500 Hz was significantly increased ($p < .05$) in all four regions for up to 60 minutes. There was a main effect for brain regions, $F(1.35, 13.47) = 15.03$, $p = .001$. ACC responded more strongly than that of VTA, and bilateral Amg. However, for HFOs at 250-500Hz, there was no main effect for brain region, $F(1.17, 11.65) = 1.89$, $p = .197$, suggesting no significant differences responses among these four regions. In conclusion, significant intensity change of HFOs could be detected after formalin injection in various brain regions with different patterns, which demonstrated a promise that HFOs might be a new neural signature of pain.

Abstract: Chronic pain affects at least 100 million American adults. Treatment options remain limited and the most effective options, namely opioids, are linked to addiction and related mortality at an epidemic rate. Thus, novel, non-opioidergic treatment options are urgently needed and especially for neuropathic pain conditions. Epigenetic pathways that include modifications of histone proteins such as methylation and acetylation appear to be emerging as important determinants of chronic pain. However, despite recent progress, a comprehensive understanding of how histone modifications may impact chronic pain remains elusive. Rats with spared nerve injury (SNI) provide a validated rodent model for human chronic pain. We use this model to understand epigenetic mechanisms that control chronic pain. The SNI model induces mechanical allodynia (pain due to tactile stimuli that do not elicit a painful response under normal circumstances) as well as deficits in hippocampal function as measured by the novel object recognition assay an index of recognition memory. Inflammatory cells such as microglia, astrocytes and blood macrophages have been shown to play an important role in neuropathic pain in the SNI model. We will show how epigenetic histone modifiers decrease primary neuropathic pain-related behavior, expressed by tactile allodynia pain relief without motor or anxiety-like deficits, for an extended period of time, which also seems to be gender specific. We will further show immune cell and molecular signatures, transcriptional networks and functional pathways associated with epigenetic adaptations of the injured rat tissue. The study provides important insights into understanding the molecular mechanisms by which epigenetic factors control chronic pain and develops strategies targeting neuro-immune interactions to treat chronic pain.

Title: Gene expression profiling of the rat hippocampus during chronic inflammatory pain

Authors: A. ASH[1], E. KOKKINOS[1], D. NERLAND[1], G. BERENBEIM[1], B. WILKE[1], L. SEMKE[1], L. POINTS[1], M. GIRGENTI[2], R. DUMAN[2], *V. DURIC[1];
[1]Des Moines Univ., Des Moines, IA; [2]Yale Univ. Sch. of Med., New Haven, CT

Abstract: Up to 50% of all clinical chronic pain patients suffer from major depressive disorder (MDD), which is significantly higher than the incidence of approximately 7% within the general population. The exact neural events that link these two neurological illnesses are still largely unknown; however, it is thought that chronic pain may produce negative effects on different limbic brain regions similar to those seen with chronic stress. In the current study, we used a genome-wide microarray analysis to examine the genetic profile of the hippocampus from male rats exposed to 21 days of peripheral inflammatory pain. Functional group analysis has identified a number of significantly dysregulated genes with known roles in either neuroinflammation or neurodegenerative processes. Bioinformatic gene network/canonical pathways analyses have identified a significant network associated with the Akt (protein kinase B) as the main hub gene. Altered activity of Akt-related signaling pathways (e.g., PI3K/Akt/mTOR) has been previously linked to both the development of depressive state and antidepressant treatment. Furthermore, expression of several dysregulated genes of interest (i.e., Gzma, Gzmk, Mis18a, S100a9, CCL5, and Lrg1) was also assessed in other limbic areas involved in mood regulation, as well as in the brains of female rats exposed to the same 21-day pain paradigm. Ongoing studies are further investigating the expression of these target genes in pain animals with or without presence of the depressive-like behavioral phenotype (i.e., high vs. low responders). The results of this study further elucidate the presence of transcriptional alterations in the hippocampus during the chronic pain state. Additionally, the dysregulation of genes involved in neuroinflammatory and neurodegenerative processes in the limbic brain areas continues to strengthen the idea that these processes may be involved in the development of mood disorders during the chronic pain state.

Title: Lateral hypothalamic fast-spiking parvalbumin neurons modulate nociception through connections in the periaqueductal gray area

Authors: *J. N. SIEMIAN, C. B. BORJA, S. SARSFIELD, A. KISNER, Y. APONTE;
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: The lateral hypothalamus (LH) contains a diverse collection of cell types crucial for orchestrating behaviors that facilitate survival. Over the past decade, tremendous progress has been made on new methods that allow systematic characterization of the function and connectivity of these heterogeneous neuronal subtypes. While studies have begun to identify LH circuits that regulate food intake and reward-related behaviors, less attention has been given to the contributions of genetically-identified LH circuits that modulate nociceptive behaviors. Here we examined how lateral hypothalamic neurons that express the calcium-binding protein parvalbumin (PVALB; LH^{PV} neurons), a small cluster of neurons within the LH glutamatergic circuitry, regulate nociception in mice. Using optogenetics to modulate neuronal activity, we found that photostimulation of LH^{PV} neurons suppressed nociception to an acute, noxious thermal stimulus, whereas photoinhibition potentiated thermal nociception. Moreover, brain slice electrophysiology recordings using channelrhodopsin (ChR2)-assisted circuit mapping (CRACM) revealed that LH^{PV} axons form functional excitatory synapses on neurons in the ventrolateral periaqueductal gray (vlPAG), a critical brain region for pain modulation. Furthermore, photostimulation of LH^{PV} axons in the vlPAG suppressed nociception to both thermal and chemical visceral stimuli. Interestingly, this antinociceptive effect appears to occur independently of opioidergic mechanisms, as antagonism of mu-opioid receptors with systemically-administered naltrexone did not abolish the antinociception evoked by activation of this LH^{PV} to vlPAG pathway. Importantly, none of the optogenetic manipulations significantly affected locomotor activity or anxiety-like behavior as measured by the open-field and elevated plus maze tests, suggesting that the role of LH^{PV} neurons is likely specific to nociception. Similar to our results for these acute pain tests, photostimulation of either LH^{PV} somata or axonal projections in the vlPAG also significantly attenuated thermal and mechanical hypersensitivity induced by a model of chronic inflammatory pain. Together, these results directly implicate LH^{PV} neurons in modulating nociception, thus expanding the repertoire of survival behaviors regulated by LH circuits.

Title: Comparison of CANE-RV and EnvA-RV when using CANE to capture nociceptive neurons in VPM

Authors: *M. UMORIN, P. R. KRAMER;
Biomed. Sci., Texas A&M Univ. Col. of Dent., Dallas, TX

Abstract: Genetically capturing cell populations that are active in response to a specific stimulus at a specific time would allow researchers to study functional neuronal circuits at the cellular resolution. Existing techniques, like TRAP and TRAP2, require use of a hormonal analog that has the potential to interfere with hormonal signaling. Pain signaling is different in different sexes and, thus, the use of a sex hormone analog would likely interfere with the pain mechanisms. CANE is a recently developed method that does not use sex hormones for genetic capturing. Instead, it relies on a transgenic animal that expresses the TVA receptor after a neuron is activated. We used CANE to label neurons in the ventroposterior medial nucleus (VPM) of the thalamus after injection of CFA into the TMJ or in non-injected controls. Then CANE-RV and EnvA-RV were compared with respect to the number of secondary cells labelling and retrograde tracing. Both methods resulted in low background of starter cells in non-injected controls. However, CANE-RV use resulted a significantly higher number of presynaptic labelled cells in the non-injected controls and in the CFA injected animals. Both methods had a significantly higher number of starter and presynaptic sells in pain treatment vs controls. Use of CANE-RV resulted in higher ratio of presynaptic-to-starter cells in the VPM as compared to the use of plain EnvA-RV (15.8 vs 9.0). Thus, it is possible to use diverse expression constructs available in EnvA-pseudotyped rabies but the labelling rate would be much lower.

Title: Opioid antagonists attenuate NSAIDs-induced antinociception in anterior cingulate cortex of rats

Authors: *M. G. TSAGARELI[1], N. TSIKLAURI[1], N. TSAGARELI[1,2], I. KVACHADZE[2];
[1]Ivane Beritashvili Exptl. Biomedicine Ctr., Tbilisi, Georgia; [2]Tbilisi State Med. Univ., Tbilisi, Georgia

Abstract: Anterior cingulate cortex (ACC), which is activated by noxious stimuli, is involved in pain processing, the neural mechanisms of the ACC involvement in affective pain have yet to be elaborated. To study relation antinociceptive effects induced by non-steroidal anti-inflammatory

drugs (NSAIDs) with endogenous opioid system we treated experimental rats with opioid receptor antagonists, naloxone and CTOP in the ACC pre- and post-following microinjections with NSAIDs.
We measured nociceptive thermal paw withdrawal latencies and mechanical thresholds in rats' formalin test following microinjections of NSAIDs (diclofenac, ketoprofen, ketorolac and lornoxicam), saline or opioid receptor antagonists, naloxone and CTOP in the ACC. Five minutes following intraplantar formalin injection all animals showed a significant reduction in thermal paw withdrawal latency and mechanical withdrawal threshold compared to pre-baseline values. Fifteen minutes after formalin injection, diclofenac, ketoprofen, ketorolac and lornoxicam clearly showed antinociceptive effects of NSAIDs. When pretreated with naloxone and CTOP separately, we found a significant reduction of analgesic effects of NSAIDs as well as post-treatment of these completely abolished NSAIDs-induced antinociception.In summary, we demonstrated that microinjection widely used non-opioid, NSAID analgesics, diclofenac, ketorolac anad lornoxicam injected into the rostral part of the ACC, induced antinociception in rats. The present findings support the concept that NSAIDs-induced antinociception is mediated via descending endogenous opioid system.

Institute, McGill Univ., Montreal, QC, Canada; [7]Montreal Neurolog. Inst., Montreal, QC, Canada; [8]Douglas Res. Centre/McGill Univ., Montreal, QC, Canada

Abstract: Fibromyalgia (FM)[1] is a disorder characterized by generalized pain. The acid saline-induced muscle (ASM)[2] model is considered an acceptable animal model of FM with widespread chronic pain. Here we use non-invasive resting-state functional magnetic resonance (Rs-fMRI) neuroimaging[3] to investigate the impact of FM-like pain in the ASM model on whole brain neuronal communication. We test whether mice receiving intramuscular pH7.2 (control) and pH4.0 (FM) treatment show distinct functional connectivity (FC) patterns and strengths. Acquisition was performed in slightly anesthetised animals under resting state using a 7 Tesla Bruker animal MRI scanner with Cryoprobe. Independent component analysis (ICA) was performed and identified 97 components, which we anatomically annotated following the Allen mouse brain atlas. Correlation analysis revealed significant reduction of FC in several brain regions, with predominant effects for retrosplenial cortex (RSP) and periaqueductal gray matter (PAG) components, known as core centers of the default mode network(DMN) and pain, respectively. Seed-to-seed analysis (hypothesis-driven) was performed using 14 pain-relevant brain regions, and connectivity analysis showed highest FC reduction for the PAG seed. Seed-voxelwise analysis (hypothesis-driven) was also performed with a focus on PAG. We found reduced PAG FC with 13 Allen Brain Atlas-based regions, and quantification of these alterations showed highest FC modifications of PAG with habenula and thalamic areas, as well as insular, anterocingular and entorhinal cortices, all involved in aversive sensory and emotional processing. Finally, von Frey experiment[4] was performed 3 weeks after fMRI scanning to score the extent of generalized pain of each subject. Pain thresholds measures by paw withdrawal were significantly lower in the pH4.0 group compared to pH7.2 group. We then correlated pain sensitivity scores with the intensity of FC reduction between PAG and RSP seeds at individual subject level, and found a trend to positive correlation, suggesting that brain connectivity across these two seed may be relevant to the behavioural pain response. In conclusion, our FC analyses concur to demonstrate that FM like-induced pain reduces brain communication with predominant effects on general connectivity (DMN) and pain centers (PAG). Consistent with human data[5-6], this study established a signature of generalized pain in the brain and shows the potential for translational MRI approach to study a chronic pain condition.

Title: Imaging cortical circuitry during general anesthesia: Insights into cortical pain processing

Authors: *J. A. P. WEINRICH, M. X. BERNSTEIN, C. R. ANDOLINA, A. I. BASBAUM; Anat., Univ. of California San Francisco, San Francisco, CA

Abstract: BACKGROUND: General anesthetics work in a concentration-dependent manner on the central nervous system (CNS) to induce loss of consciousness and block the experience of pain. Interestingly, however, during nitrous oxide anesthesia and the initial stages of ether and isoflurane anesthesia, analgesia can be produced independently of loss of consciousness. In the present studies in the mouse, we monitored, over time, the *in vivo* activity of hundreds of individual cortical neurons during the induction to, and emergence from, general anesthesia. Furthermore, we compared the effects of isoflurane on bulk neural activity (pan-neuronally) versus isolated subpopulations of molecularly-defined cortical inhibitory interneurons (parvalbumin (PV+), somatostatin (SST+) or vasointestinal peptide (VIP+)). Our objective is to uncover the mechanisms through which a major volatile anesthetic, isoflurane, not only produces loss of consciousness, but also analgesia. **METHODS:** In adult mice, we monitored the activity of neurons in the anterior cingulate cortex (ACC), a region implicated in the affective component of pain. Spontaneous neural activity was continuously monitored before, during, and after isoflurane anesthesia. We used virally delivered genetically encoded fluorescent reporters of neural activity (GCaMP6f) expressed either (1) ubiquitously across neurons, or (2) specifically within molecularly-defined interneuron populations (PV+, SST+, or VIP+). Changes in GCaMP6f fluorescence captured via the Inscopix miniscopes. **RESULTS:** For induction and emergence, we find that inhibitory interneuron populations are more susceptible to the suppression of neural activity by isoflurane than the bulk population. During induction, both spontaneous neural activity and the percentage of active neurons decreases with increasing concentrations of isoflurane, however, inhibitory neurons are affected at much lower concentrations of isoflurane than the bulk population. Similarly, during emergence, neural activity resumes in at much higher concentrations of isoflurane for the bulk neural population than for inhibitory interneurons. **CONCLUSIONS:** Consistent with previous studies where the global activity of the cerebral cortex is decreased during general anesthesia, we found that isoflurane anesthesia decreases spontaneous activity within the ACC in a concentration dependent manner. However, our results clearly indicate that isoflurane-induced decreases in neural activity are not uniform across all neurons of the ACC. Rather, inhibitory interneurons exhibit increased susceptibility to isoflurane when compared to the bulk neuronal population.

Title: A partial connectome in mice of the thalamocortical input from a higher order thalamic nucleus, POm, to the secondary somatosensory cortical area, S2

Authors: *V. SAMPATHKUMAR[1], A. J. MILLER[2], S. SHERMAN[3], N. B. KASTHURI[2]; [2]Neurobio., [1]Univ. of Chicago, Chicago, IL; [3]Dept Neurobiol, Univ. Chicago, Chicago, IL

Abstract: Large volume serial EM "connectomics" has emerged as a key tool for understanding neural circuits. We applied this approach to study long distance thalamocortical connections between the higher order thalamic relay, POm, and the secondary somatosensory cortical area, S2, in the adult mouse. To trace the pathway, we injected a "cocktail" of 2 types of AAV into POm, the first to express Cre in POm neurons and a second expressing Cre-dependent APEX2 in the cytoplasm of the now Cre expressing neurons. Staining with osmium and DAB produced APEX2 electron dense precipitates, allowing us to perform multiscale EM imaging using the ATLUM approach [Kasthuri N, et al. (2015) Saturated reconstruction of a volume of neocortex. Cell 162:648-661] to reconstruct the connections of POm neurons in all layers of S2. We sampled a region of S2 that spanned the entire cortical depth of (~ 1mm x 0.5mm x 0.1mm). Cytoplasmic APEX2 expression reliably allowed for long range tracing of neuronal connectivity: APEX2 labeling was clear even in the finest axonal processes, including the upper layers of cortex, with no sign in reduction of signal from diffusion, fading, etc. 'Intersectional' viral labeling strategies in this pathway appear to not label neurons retrogradely since low resolution EM sections that span cortex show no sign of labeled cortical cell bodies. Thalamocortical synapses were found throughout all cortical layers. Furthermore, POm neurons primarily targeted spines on dendrites of the cortical neurons. Notably, each of these spines had a spine apparatus, an ultrastructural indication of strong synapses, whereas many unlabeled synapses were found on both spines without such an apparatus as well as dendritic shafts. Multiple spines on the same dendritic segments were commonly targeted by POm inputs, with up to 50% of such spines innervated by POm terminals, and individual POm axons typically provided multiple such inputs to the same dendritic segments. The question to be addressed is whether further examples

of thalamocortical inputs, including those from first order nuclei like VPm show similar or different features.

Title: The partial connectome of the layer 5 corticothalamic projection from primary motor and sensory cortex to the higher order somatosensory thalamic nucleus, POm

Authors: *M. S. SHERMAN[1], N. KASTHURI[2], V. SAMPATHKUMAR[2], A. J. MILLER[2]; [1]Univ. Chicago, Chicago, IL; [2]Univ. of Chicago, Chicago, IL

Abstract: Electron microscopy (EM) has been used for decades to study ultrastructural details of cells, including the connections of neurons. Recent advances have combined serial EM with specific cell labeling using engineered peroxidases to distinctly label neuronal types in EM datasets with electron dense precipitates (APEX2). We applied these approaches to characterize connections from layer 5 (L5) neurons in primary S1 and M1 to the higher order somatosensory thalamic relay, POm. We use Cre dependent AAV/APEX2 viruses injected into transgenic animals expressing Cre in L5 pyramidal neurons to label L5 corticothalamic pathways. Specifically, the AAVs producing APEX2 cytoplasmic labeling were injected into M1, and APEX2 mitochondrial labeling, into S1, and appropriate staining which produced APEX2 EM precipitates. We then analyzed the connections in POm using multiscale EM imaging [Kasthuri N, et al. (2015) Saturated reconstruction of a volume of neocortex. Cell 162:648-661]. Relatively few terminals have been found so far in our material from M1, and beyond noting that these were large and did not innervate the same cells as those innervated by S1 terminals, we do not further consider these. We found that labeled terminals from S1 showed characteristic large vesicle filled boutons, as predicted from reconstructions from other species. The labeled terminals are at the large end of the size distribution of all labeled and unlabeled terminals found in POm. These labeled terminals synapsed predominantly near the first branch point of dendritic trees. We find that &gt5% of the labeled large terminals participate in triads and that neurons in POm have

different connectivity patterns, some with only labeled giant synapses throughout the dendritic arbor, some with all unlabeled giant synapses, and some cells with mixed innervation. Thus, because of their size, termination initial dendritic branch points (and thus proximally on dendritic arbors), and occasional involvement in triadic arrangements, these POm terminals have the characteristics of "driver" synapse.

Title: Involvement of descending pain inhibitory system mediated by orexin/orexin 1 receptor in the regulation of central post-stroke pain

Authors: *W. MATSUURA[1], S. TOKUYAMA[2];
[1]Dept. of Clin. Pharm., [2]Kobe Gakuin Univ., Kobe, Japan

Abstract: [Aims]Central post-stroke pain (CPSP) is one of the secondary diseases of cerebral stroke. However, the detailed mechanism remains unclear. Recently, it is reported that orexin level of cerebrospinal fluid decreased in stroke patients and central administration of orexin-A reduces nociceptive responses in inflammatory pain model mice, suggesting that orexin play an important role in the regulation of CPSP. Furthermore, orexin 1 receptor (OX1R) is located in the rostral ventromedial medulla (RVM) and locus coeruleus (LC) which is nucleus of origin in the descending pain inhibitory system. In this study, we tested the involvement of orexin-A/OX1R in CPSP model mice.
[Methods]Bilateral carotid arteries of male ddY mice (5 weeks old) were occluded for 30 min (BCAO). Mechanical allodynia was evaluated by a von Frey filament test on day 3 after BCAO. The test was conducted at 10, 20, 30 and 60 min after the intracerebroventricular (i.c.v.) injection of orexin-A Prepro-orexin (orexin precusor) in the hypothalamus was analyzed by real-time PCR. SB334867 (OX1R antagonist) was administered i.c.v. injection 30 min before orexin-A injection. Yohimbine (α_2 receptor antagonist) and WAY100635 (5-HT_{1A} receptor antagonist) were administered intrathecal (i.t.) injection 15 min before orexin-A injection. Immunohistochemistry for OX1R and immunoreactivity for c-Fos (a neuronal activation marker) were observed in the RVM or LC on day 3 after BCAO.

[Results]The withdrawal responses to mechanical stimuli were significantly increased on day 3 after BCAO. Prepro-orexin in hypothalamus was significantly decreased as compared with sham. BCAO-induced mechanical allodynia dose-dependently suppressed by the pre-treatment of orexin-A. These effects of orexin-A were inhibited by the pre-treatment of SB334867, yohimbine and WAY100635. On day 3 after BCAO, OX1R was located and the c-Fos expression was induced in the RVM and LC after i.c.v. injection of orexin-A.
[Conclusion]These results show that BCAO induced-mechanical allodynia was controlled by descending pain inhibitory system mediated by orexin-A/orexin 1 receptor.

Title: Involvement of cerebral and spinal nicotinic acetylcholine receptor mediated system in the regulation of central post-stroke pain

Authors: *S. TOKUYAMA, W. MATSUURA;
Kobe Gakuin Univ., Kobe, Japan

Abstract: [Aims]Central post-stroke pain (CPSP) is one of the complications of cerebral ischemia and of neuropathic pain syndrome. The treatment of CPSP remains incomplete due to its resistance to both pharmacological and non-pharmacological therapies in approximately half of CPSP patients. Although CPSP is a serious condition, details pertaining to underlying mechanisms are not well known, making current standard treatments only partially effective. Recently, it is reported that nicotine suppressed infact area after stroke. Nicotine suppressed sciatic nerve injury induced mechanical allodynia. Nicotinic acetylcholine α4 receptor agonist injected into locus coeruleus (LC) suppressed inflammatory pain. In this study, we tested the effect of nicotine signaling on CPSP model mouse.
[Methods]Bilateral carotid arteries of male ddY mice (5 weeks old) were occluded for 30 min (BCAO). Mechanical allodynia was evaluated by a von Frey filament test on day 3 after BCAO. On day 3 after BCAO, nicotine intracerebroventricular (i.c.v.; 10 or 20 nmol/mouse) injected. Von Frey filament test was conducted at 10, 20, 30 and 60 min after nicotine injection. Yohimbine (α_2 receptor antagonist) was administered intrathecal (i.t.; 16 μg/mouse) injection 15 min before nicotine injection. Immunoreactivity for c-Fos (a neuronal activation marker) was

observed in the LC.
[Results]The number of escape behaviors, one of mechanical allodynia, against the stimulation induced by the von Frey filament was significantly increased on day 3 after BCAO compared with that in the sham group. BCAO-induced mechanical allodynia dose-dependently suppressed by the pre-treatment of nicotine. These effect of nicotine were inhibited by the pre-treatment of yohimbine. The c-Fos expression was induced in the LC after i.c.v. injection of nicotine on day 3 after BCAO.
[Conclusion]These results suggest that nicotinic acetylcholine receptors play an important role in the regulation of BCAO induced-mechanical allodyni. Our findings are helpful for better understanding of the pathological mechanism in CPSP.

Title: Role of Lipocalin-2 (Lcn2) in the limbic pain processing

Authors: E. KOKKINOS, A. ASH, D. NERLAND, B. WILKE, G. BERENBEIM, *L. SEMKE, L. POINTS, V. DURIC;
Des Moines Univ., Des Moines, IA

Abstract: Clinical studies have shown a high co-morbidity between different chronic pain conditions and major depressive disorder. The exact brain mechanisms connecting these two neurological illnesses are still largely unknown. Our recent whole genome microarray high-throughput profiling has identified lipocalin-2 (Lcn2) as one of the highest upregulated genes in the hippocampus of rats exposed to 21 days of peripheral inflammatory pain (i.e., hindpaw injections of Complete Freund's Adjuvant; CFA). Lcn2 is an iron-related protein whose function was previously linked to innate immune response, as well as regulation of the cell differentiation, maturation and death. Recent studies further suggest that Lcn2 may also play an important role in emotional behaviors and cognitive function through regulation of neuronal excitability and dendritic spine formation/maturation. However, to our knowledge, Lcn2 has not been previously implicated in the limbic pain processing. Thus, in the current study, we investigated the expression of Lcn2 gene in the affective pain neurocircuitry within specific limbic brain areas. In male rats exposed to the 21-day CFA pain paradigm, robust increases (~ 2 fold) in Lcn2 mRNA

levels were observed within the contralateral hippocampus, prefrontal cortex (PFC) and anterior cingulate cortex (ACC). Similar upregulation of the hippocampal Lcn2 gene was also observed in the female animals exposed to the same pain model. Ongoing studies in our lab are further examining the activity of Lcn2 gene in pain animals with or without presence of the depressive-like behavioral phenotype (i.e., high vs. low responders). Overall, the results of this study suggest that chronic pain activates Lcn2 within several different limbic brain regions, which may contribute to the neural mechanisms underlying the development of mood disorders associated with the chronic pain state.

Title: Cell type specific midbrain and extended amygdala contributions to sex differences in pain and drug use

Authors: *W. YU, T. KASH;
UNC Chapel Hill, Chapel Hill, NC

Abstract: Chronic pain and drug abuse are comorbid disorders that manifest with differing prevalence and severity in males and females. A mechanism that explains sex-specific pain and drug interactions has yet to be identified. Recent evidence from our lab suggests that dopaminergic neurons of the ventrolateral periaqueductal grey ($vlPAG^{DA+}$) contribute to the anti-nociceptive effects of morphine and alcohol use. Following up on these studies, we found that activation of $vlPAG^{DA+}$ terminals in a primary output region, the bed nucleus of the stria terminalis (BNST), relieves thermal and mechanical nociception in males but not females. This effect persists during pathological pain, with $vlPAG^{DA+}$/BNST activation attenuating heightened pain sensitivity following treatment with the inflammatory agent Complete Freund's Adjuvant (CFA). Downstream of $vlPAG^{DA+}$ neurons, we examined a population of pain- and alcohol-sensitive corticotropin releasing factor (CRF) neurons in the BNST. Genetic deletion of CRF from the BNST reduces thermal and mechanical nociception and potentiates alcohol consumption in male and female mice. *In vivo* miniscope calcium imaging of $BNST^{CRF+}$ neurons further reveal robust and synchronized recruitment of these neurons during acute exposure to pain and alcohol in both sexes. Taken together, these findings support the notion that $vlPAG^{DA+}$

and $BNST^{CRF+}$ neurons differentially contribute to sex-specific interactions of pain and drug use. This knowledge will be informative for future approaches to treating chronic pain and drug abuse, as it identifies new morphine- and alcohol-sensitive mechanisms that are capable of attenuating pain in both a sex-dependent and -independent manner.

Title: CGRP in the left amygdala reduces bladder pain in female mice

Authors: *H. ALLEN, A. COX, B. J. KOLBER;
Biol. Sci., Duquesne Univ., Pittsburgh, PA

Abstract: Urologic chronic pelvic pain syndrome (UCPPS) is among the most common visceral pain conditions in the United States, affecting between 5 and 10 million Americans and costing over $5 billion in healthcare annually. UCPPS patients experience debilitating symptoms that severely impact quality of life, including increased urgency and frequency of urination, intense and burning pain during bladder filling and voiding, referred pain in the back and pelvic area, and co-morbidities such as anxiety and depression. The underlying cause of UCPPS is largely unknown, and therefore treatments are poor and ineffective. Recent imaging studies have identified changes in cortico-limbic areas in UCPPS patients. The central amygdala (CeA) is a bilateral, mid-brain limbic region that processes both pain and emotion and can modulate bladder pain. Sensory neurons that relay information from the bladder to the CeA express high levels of calcitonin gene-related peptide (CGRP), a peptide with a well-established role in pain processing. Although there is ample evidence that CGRP is pro-nociceptive in the right CeA, a few studies indicate that CGRP may act anti-nociceptively in the left CeA. Here, we explored CGRP's contribution to the left CeA's anti-nociceptive role in the context of bladder pain using molecular and behavioral techniques. Immunohistochemical quantification of CGRP expression in the left and right CeA of control and bladder-sensitized mice revealed a significant decrease in CGRP expression in the left CeA of bladder sensitized animals. Additionally, infusion of CGRP into the left CeA of bladder-sensitized mice decreased abdominal mechanical sensitivity and visceromotor response to noxious urinary bladder distention for up to 60 minutes after injection.

Title: Parabrachial to central amygdala neural circuit for the modulation of pathological pain

Authors: *T. D. WILSON[1], A. ADKE[1], J. J. BECKER[3], S. MARTINEZ-GONZALES[1], Y. K. SUGIMURA[4], Y. CARRASQUILLO[2];
[1]NCCIH, [2]Natl. Ctr. for Complementary and Alternative Med., NIH, Bethesda, MD; [3]NCCIH, The Natl. Inst. of Hlth., Bethesda, MD; [4]Dept. of Neurosci., Jikei Univ. Sch. of Med., Minato, Japan

Abstract: Increasing evidence over the last several years supports the central nucleus of the amygdala (CeA) as a critical center for pain processing, the modulation of pathological pain and its related affective comorbidities. We have previously shown that the CeA can bidirectionally modulate pain like behaviors in a cell-type-specific manner. Anatomical and electrophysiological experiments have further demonstrated that nociceptive inputs into the CeA come from the lateral parabrachial nucleus (lPB). The functional contribution of the PB-CeA circuit to the modulation of pain-related behaviors, however, has not been established. To answer this question, we used intersectional approaches in combination with chemogenetics, optogenetic-assisted circuit mapping and behavioral assays. The sciatic nerve cuff model of neuropathic pain and the formalin model of inflammatory pain were used in mice to measure spontaneous pain-related responses to inflammation as well as hypersensitivity to cold, heat, pinch and tactile stimulation of the paw after nerve injury or paw inflammation. The results from our experiments specifically demonstrate that CeA cells expressing somatostatin and CeA cells expressing PKCδ receive monosynaptic inputs from the lPB. We also show that inhibition of CeA-projecting PB neurons decreases spontaneous responses to formalin as well as nerve injury-induced hypersensitivity to cold, heat and pinch stimuli. Interestingly, while hypersensitivity to tactile stimuli one day after paw inflammation was reversed by inhibition of the CeA-projecting PB cells, hypersensitivity two weeks after nerve injury was unaffected. Ongoing experiments aim at determining whether pain plasticity in the PB-CeA pathway is cell-type-specific. We also want to determine if the modulation of tactile hypersensitivity by this pathway is time-dependent or pain-type-specific (neuropathic vs inflammatory).

Title: Inhibition of neuropathic pain by glial regulation in the insular cortex

Authors: *S. CHOI[1,2], K. KIM[1,2], M. CHA[1], S.-K. HONG[3], B. LEE[1,2];
[1]Dept. of Physiol., Yonsei Univ. Col. of Med., Seoul, Korea, Republic of; [2]Brain Korea 21 PLUS Project for Med. Science, Yonsei Univ., Seoul, Korea, Republic of; [3]Div. of Bio and Hlth. Sci., Mokwon Univ., Daejeon, Korea, Republic of

Abstract: The insular cortex (IC), one of the brain areas that process motivational and emotional aspect of pain information. Studies on the role of neuroglia have been carried out in various pain researches, but the majority of researches have been done at the spinal cord. We hypothesize that glial cells may mediate the neuronal alteration through regulating synaptic physiology of cortical neurons in the IC. The aim of this study was to reveal the associations between neuroglia and neurons in the IC on neuropathic pain (NP) condition. Fluorocitrate (FC) and minocycline (MC) were bilaterally administered into the IC at different injection time points. We conducted two experiments, one is injection of FC (1 nM) and MC (20 uM) into the IC for 7 days (NP 0-7 days) and the other is application of drugs in the chronic pain stage (NP 8-14 days) for 7 days. The behavioral tests were performed before and after drug application. Western blot analysis was performed to evaluate expression changes of glial cells in the IC. As a result, the early inhibition model of glial cells showed analgesic effect as increasing mechanical thresholds. Especially, MC-treated group which belongs to early inhibition model showed a significant pain alleviation effect despite the drug withdrawal. The chronic pain stage inhibition model showed significant analgesic effect which was confirmed by behavioral tests during the period that FC and MC were applied. Interestingly, GFAP, increased as much as vehicle in the MC-treated group of the early inhibition model. These data suggest that glial cell regulation in the IC has a pain relieving effects during the development of chronic pain. Suppression of glial cells just after the nerve injury could delay the neuronal changes associated with chronic pain development. This study was supported by the Basic Research Program through the National Research Foundation (NRF) funded by the Ministry of Science and ICT (NRF-2015R1C1A1A01053484 and 2017R1A2B3005753)

Title: Chronic pain promotes integration of sensory and affective cortical circuits

Authors: *A. K. SINGH[1], Q. ZHANG[2], X. GUO[4], D. PATEL[4], R. TALAY[4], L. HU[4], E. ROBINSON[4], H. KEMPRECOS[4], E. MARTINEZ[4], Z. CHEN[1], J. WANG[3];
[1]New York Univ., New York, NY; [3]Anesthesiol., [2]NYU Sch. of Med., New York, NY; [4]New York Univ. Sch. of Med., New York, NY

Abstract: Pain is an integrated sensory and affective experience. Cortical mechanisms for this sensory and affective integration, however, are not known. Here we combine optogenetics with *in vivo* electrophysiology in free-moving rats to investigate a direct projection from the primary somatosensory cortex (S1), which receives and encodes the sensory information of pain, to the anterior cingulate cortex (ACC), an area crucial for processing the affective, or aversive, component of pain. We identify nociceptive information flow between these two regions and show that whereas only a small fraction (8%) of ACC neurons receives direct S1 inputs, these neurons display exceptional responsiveness to noxious stimuli. Furthermore, activation of S1 axon terminals in the ACC can recruit new ACC neurons to respond to noxious stimuli, as well as to increase the firing rates of the individual pain-responsive neurons. At the behavioral level, this direct S1 to ACC projection contributes to the aversive response to pain. Importantly, in the chronic pain state, there is an increase in the connectivity between these two cortical areas, as manifested by a higher number of ACC neurons that respond to S1 inputs and the magnified contribution of these neurons to the nociceptive response in the ACC. This increased cortical connectivity in turn contributes to enhanced aversive behavior associated with chronic pain. These results provide direct evidence for cortical integration of sensory and affective pain pathways; they also show that elevated cortico-cortical nociceptive information flow contributes to chronic pain and may thus be a target for neuromodulatory therapies.

Title: Posterior insular cortex encodes non-painful thermal perception

Authors: *M. VESTERGAARD[1], M. CARTA[1,2], J. F. A. POULET[1];
[1]Max-Delbrück Ctr. for Mol. Med. (MDC), Berlin, Germany; [2]Interdisciplinary Inst. for Neuroscience, CNRS, Univ. of Bordeaux, Bordeaux, France

Abstract: Fast and accurate perception of surface temperature is important for forming a somatosensory percept during object touch. Anatomical, functional imaging and lesion studies in humans and rodents have suggested different cortical areas are involved in non-painful thermal perception (Craig et al. 2000, Milenkovic et al. 2014, Bokiniec et al. 2018, Beukema et al. 2018, Greenspan et al. 2008), however, a consensus has not yet been reached. Here we used the mouse forepaw system to investigate the cortical processing of non-painful temperature stimuli. Widefield calcium imaging data indicate that a region of posterior insular cortex (pIC) is activated by brief (2s) warming and cooling of the forepaw. While responses to warming and cooling of the forepaw spatially overlap, responses to stimulation of different body parts are somatotopically organized. The widefield thermal response amplitude correlates with stimulus size but shows distinct temporal dynamics, with warming responses having a longer latency than cooling. Two-photon single cell imaging reveals that a partially overlapping population of neurons respond to cooling and warming with similar temporal dynamics to that observed at the population level. Finally, optogenetic manipulations in trained mice show that pIC is required for non-painful warm and cool perception. Taken together, our data suggest that pIC is the primary cortical region for non-painful thermal sensation.

Title: Modulating pain by auditory neural entrainment

Authors: *R.-J. HUNG[1], I. LOW[1], T.-F. LIN[1], H.-K. FU[3], H.-Y. LI[1], L.-F. CHEN[1,4,2], J.-C. HSIEH[1,4,2];

Abstract: Perception of pain is protective. However, when pain persists, it can become detrimental to one's emotion, cognition, and quality of life. Pain can be associated with a decrease of alpha power. People who are sensitive to pain are more likely to have lower peak alpha frequency. It has been shown that antecedent alpha-wave entrainment may decrease the subsequent experimentally induced pain intensity and pain-evoked potentials. This study aimed to investigate the efficacy and the central mechanisms of auditory neural entrainment (ANE) for pain modulation. We hypothesized that ANE can induce alpha oscillations in the neural substrates for pain processing and thereby reduce pain intensity. Twenty-nine healthy volunteers (mean age 25.24 ± 3.82 years; 14 males) were recruited in this study. The study was a within-subject design. All participants received 15-min auditory stimuli as ANE protocol and underwent pressure pain tests (Medoc, Israel) as a model of chronic pain. In experimental condition, subjects listened to the binaural beats during ANE phase; in control condition, subjects listened to the pure tone during ANE phase. Electroencephalographic signals were recorded during the experiment using a 64-channel actiCAP system (Brain Products, Munich, Germany). ANE-induced analgesia was statistically examined using Wilcoxon's signed-rank tests. Almost all participants developed more intensified pain during the second pain test as compared to the first pain test (possibly due sensitization). However, listening to the binaural beats lessened the degree of sensitization in 15 participants (responders). In addition, the responders showed significantly higher peak alpha frequency after ANE in parietal ($Z = 2.31$, $p = .02$) and occipital ($Z = 2.07$, $p = .04$) regions. Our study unveiled different phenotypes and EEG endophenotypes for ANE-analgesic effect.

Title: Zona incerta stimulation in humans differentially modulates perception of heat pain and thermal grill sensation

Authors: *C. W. LU[1], D. E. HARPER[2], S. E. HARTE[3], P. G. PATIL[4];
[2]Chronic Pain & Fatigue Res. Ctr., [3]Dept Anesthesiol., [4]Neurosurg., [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Deep brain stimulation (DBS) for the treatment of pain classically targets sensory thalamus, periaqueductal gray, and periventricular gray matter. Long term success rates of DBS treatment of neuropathic pain due to stroke, peripheral neuropathy, and brachial plexus injury, are unsatisfactory. Strong cytoarchitectural, animal, and clinical evidence point to zona incerta as a promising new target for analgesic neuromodulation. This study directly examines the effect of zona incerta stimulation on perception of heat pain and thermal grill sensation in human volunteers. Parkinsonian patients with subthalamic DBS implants traversing zona incerta were asked to rate perceived pain evoked by heat or thermal grill stimuli applied to the volar forearm. Pain ratings with and without concurrent DBS were compared to determine the analgesic effects of zona incerta neuromodulation. Preliminary results show decreases in evoked heat pain and increases in thermal grill pain during DBS. These results suggest that zona incerta DBS may differentially modulate perception of heat pain and thermal grill sensation, encouraging further investigation of zona incerta as a DBS target for treatment of pain.

Title: Early postnatal exposure to general anesthesia agent causes chronic neuropathic pain via activation of mTOR signaling pathway in pain circuits

Authors: *Q. LI, R. P. MATHENA, N. EREGHA, C. D. MINTZ;
ACCM, Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Previous studies raise a concern that childhood exposure to general anesthetics (GA) may produce cognitive deficits. Our animal studies indicated that early exposure to isoflurane (Iso) causes lasting impairments in learning and memory functions and impedes neuronal development and myelin formation in the mouse hippocampus. Iso aberrantly increases the activity of mTOR and treatment with rapamycin (Rapa), an inhibitor of the mTOR, restores the developmental abnormalities resulting from this exposure. Here we ask whether Iso might also alter the development of the sensory pathways mediating pain perception, which are regulated by mTOR activity. At P7, 14 mice were exposed to 1.5% Iso and 7 were separated from the dams to serve as controls. From P21-P35, Rapa or vehicle was injected (i.p.) to Iso exposed mice. During P56-P63, pain behavior tests (von Frey, tail flick, and formalin injection) were performed and mice were sacrificed at P63. Sections of brain and L4-6 spinal cord (SC) were immunostained (IHC; n=4) and fresh tissue of insular cortex (IC) and dorsal SC were conducted for Western blotting (WB; n=3) with following antibodies: c-fos, p-S6, NeuN, p-mTOR, t-mTOR. In pain behavior tests, Iso significantly decreased hind-paw withdrawal threshold (1.9 g vs. 1.6 g, $p<0.05$) and time to tail-flick (10.2 sec vs. 7.6 sec, $p<0.05$). Rapa treatment reversed these effects (von Frey: 1.8 g; tail flick: 9.9 sec, $p<0.05$). Following formalin injection in hind paw, Iso exposed mice spent increased time licking the injection site (314.3 sec) compared to controls (233.4 sec, $p<0.05$); and Rapa decreased this time (265.1 sec) during phase II (15-30 min). IHC revealed 12.1/mm^2 c-fos+ nuclei in control IC and 79/mm^2 in Iso group ($p<0.001$); and Rapa decreased this number to 31.6/mm^2 ($p<0.01$). 75.4/mm^2 p-S6+ neurons were seen in control and 161.3/mm^2 in Iso group ($p<0.05$). This number was decreased in Rapa treated mice (92/mm^2, $p<0.05$). In dorsal SC (lamina I+II), the number of p-S6+ neurons was increased by Iso (2/mm^2 vs. 4.77/mm^2, $p<0.01$) and it was restored with Rapa (2.5/mm^2, $p<0.05$). WB results indicated that ratio of band intensity of phospho-mTOR over total-mTOR increased with Iso compared to control in IC (29.4% vs. 103.6%, $p<0.001$), and decreased with Rapa (58.7%, $p<0.05$). Iso exposure to early developmental mice causes aberrant increase in neuronal activity, mTOR signaling, and expression of key excitatory synaptic receptors in the IC and superficial dorsal SC in adult. Rapa treatment attenuates these effects. Chronic hyperalgesia is observed in Iso exposed mice and Rapa rescues this function. Together these data suggest early GA exposure may alter the development of pain pathways.

Title: The effect of GlyT2 inhibitors on glycinergic neurotransmission in the spinal cord dorsal horn

Authors: *C. A. NATALE[1], T. RAWLING[3], S. N. MOSTYN[1], K. AUBREY[2], R. J. VANDENBERG[1], M. J. CHRISTIE[1];
[1]Pharmacol., [2]Pain Mgmt. Res. Inst., Univ. of Sydney, Sydney, Australia; [3]Mathematical and Physical Sci., Univ. of Technol. Sydney, Sydney, Australia

Abstract: Evidence suggests that nociceptive and innocuous somatosensory pathways are kept separate within the spinal cord dorsal horn due to the presence of a feed-forward glycinergic gate. In animal models of neuropathic pain this glycinergic function is decreased resulting in allodynia, a condition in which a usually innocuous stimulus is perceived as painful. A novel way of treating this condition is to enhance glycinergic neurotransmission within the dorsal horn, thereby reinstating the glycinergic gate. Here we investigate the ability of a novel class of GlyT2 inhibitors, derived from the endogenous lipid, N-Arachidonyl glycine, to inhibit the GlyT2 subtype of glycine transporters (GlyT) and enhance glycine signalling. This work aims to identify how these novel inhibitors effect glycinergic neurotransmission in the spinal cord dorsal horn in a normal physiological state as well as in animal pain models. The lumbar enlargement section of the spinal cord was removed from anaesthetised rats and sliced using a vibratome. Cell responses to exogenous glycine application were recorded from interneurons in lamina II of the spinal cord dorsal horn via whole-cell patch-clamp electrophysiology. A novel GlyT2 inhibitor known as Oleoyl-D-Lysine was compared to the previously characterised GlyT2 inhibitors, ORG25543 and ALX1393. Both the exogenous and tonic glycine responses are increased in the presence of ORG25543 and ALX1393. In contrast, the novel inhibitor, Oleoyl-D-Lysine had no effect on the current induced by exogenous glycine, but did stimulate a significant increase in tonic current. For both ORG25543 and Oleoyl-D-Lysine the increase in tonic current was positively correlated with the size of the exogenous glycine response, with statistically significant increases in tonic current being present in cells with glycine responses of 200pA or greater. ALX1393 did not follow this trend. Overall these results show that all 3 GlyT2 inhibitors tested reach their desired target in spinal cord slice recordings, as they are able to enhance glycinergic neurotransmission. The difference in effect of ALX1393, ORG25543 and Oleoyl-D-

Lysine is likely linked to different mechanisms employed by each drug to inhibit GlyT2. We will further investigate the effects of Oleoyl-D-Lysine and its mechanism of action to understand its potential as an alternative treatment for allodynia and neuropathic pain.

Title: Expression analysis of BEGAIN mRNA and protein in the nervous systems

Authors: *T. KATANO[1], K. KONNO[2], K. NISHIDA[1], M. WATANABE[2], K. SAKIMURA[3], S. ITO[4], T. KOBAYASHI[1];
[1]Kansai Med. Univ., Hirakata, Japan; [2]Hokkaido Univ. Sch. of Med., Sapporo, Japan; [3]Brain Res. Institute, Niigata Univ., Niigata, Japan; [4]Osaka Med. Col., Takatsuki, Japan

Abstract: Expression level of synaptic proteins are regulated in the physiological and/or pathological state. In our previous study, we identified brain-enriched guanylate kinase associated protein (BEGAIN) as an increased protein in the PSD fraction of the spinal dorsal horn after spared nerve injury. In the spinal cord, BEGAIN protein was highly localized at the synapse of dorsal laminae IIi-IIIo and it was not detected in the ventral horn. However, BEGAIN-positive neurons were detected in both ventral and dorsal horn of the spinal cord by *in situ* hybridization. In order to clarify this discrepancy between protein and mRNA, we carried out expression analysis of BEGAIN. In mice, two splice variants of BEGAIN (Began-203 and 204), which may encode proteins as 619 and 824 amino acids, respectively, have been demonstrated (Ensemble database; http://asia.ensembl.org/index.html). To confirm the expression of these splice variants, we performed quantitative RT-PCR for each splice variant and western blotting in the hippocampus, spinal ventral horn, dorsal horn and dorsal root ganglia, and detected both variants in all the tissues by quantitative RT-PCR. Western blotting using anti-BEGAIN antibody demonstrated that Begain-203 of approximately 68 kDa was expressed in the hippocampus and spinal dorsal horn, but not ventral horn and dorsal root ganglia. On the other hand, Begain-204 of approximately 90 kDa was not detected in any tissue by western blotting. These results demonstrate that the expression pattern of BEGAIN protein differs from that of

RNA (coding and non-coding) in mouse. Further analyses of these splice variants may clarify the translational control of BEGAIN in the nervous systems.

Title: Sex specific effects of paclitaxel on genes expression in prefrontal cortex

Authors: ***L. LIANG**, J.-X. WEI, F. GAO, B. NAGENDRA, L. TIAN, H.-R. WANG, L. XU, F.-Q. HUO, S. LU;
Xi'An Jiaotong Univ. Hlth. Sci. Ctr., Xi'an, China

Abstract: Background: Neuropathic pain and cognitive impairment are most popular adverse effects of chemotherapy drugs in nervous system. More recently, paclitaxel has been found to be related to peripheral neuropathy and cognitive impairment in various domains including working memory, information processing speed, and visual attention. Prefrontal cortex (PFC) is one of the area which is fragile to chemotherapy drugs and contributes to pain and cognitive function. However, the role of PFC in paclitaxel induced-cognitive impairment and peripheral neuropathy are not clear, and there is currently no treatment for this condition. The purpose of this study was to examine the gene expression changes of whole transcriptomes in PFC in the development of chemotherapy-induced cognitive impairments and neuropathic pain. Methods: Chemotherapy-induce neuropathic pain and cognitive impairment were established by intraperitoneal injections of paclitaxel (4 mg/kg) as 4 consecutive injections every other day. Mechanical pain behavior was examined by recording paw withdrawal frequencies (PWFs) in response to 0.16g calibrated von Frey filaments. Cognitive function was examined by new object recognition test and Morris water maze test. RNA-Seq assay and an in-depth gene expression analysis was performed to determine the effect of paclitaxel treatment on genes expression in the PFC in both male and female mice. RT-qPCR was used to verify genes expression in subareas of PFC including medial PFC and ventrolateral orbital cortex in both sexes. Results: Mice with paclitaxel injection showed significant mechanical pain hypersensitivities, impaired cognitive function in new object recognition test and Morris water maze test. Analysis from paired control and paclitaxel-treated PFC showed that total 1798 DEGs were differentially expressed by paclitaxel treatment in male

and female mice. There is an increased tendency for genes related to inhibitory synaptic transmission while a decrease in genes related to excitatory synaptic transmission. Conclusions: This study suggests that paclitaxel-induced genes expression changes may be related to neuropathic pain and cognitive impairments. Precise mechanisms in sex dimorphisms may help to improve the translational relevance to clinical populations.

Title: An EEG-AI classifier of chronic pain

Authors: *M. M. EDHI[1,2], J. LEVITT[1], K. S. SCARFO[1], A. G. CARAYANNOPOULOS[1], J. W. GU[3], K. H. SRIVASTAVA[3], B. A. CLARK[3], R. ESTELLER[3], C. Y. SAAB[1,2]; [1]Neurosurg., Rhode Island Hosp., Providence, RI; [2]Carney Inst. for Brain Science/Brown Univ., Providence, RI; [3]Boston Scientific, Valencia, CA

Abstract: Due to the pain epidemic and related opioid crisis, the development of pain biomarkers is urgently needed. We hypothesized that electroencephalography (EEG) contains physiological information relevant to pain, which could be leveraged to build a diagnostic algorithm. We obtained resting state EEG from 3 groups of human subjects: G1) healthy (n=20), G2) chronic lower radiculopathy pain (n=20, visual analogue scale or VAS >5, aged and gender matched to healthy), and G3) chronic lower back pain (n=17, VAS >5, treatment-resistant pain and candidates for spinal cord stimulation). First, we investigated differences between G1 and G2 in the following categories: power spectra in single channels, coherence between channel pairs, and phase amplitude coupling between frequency band pairs, however, results showed no statistical difference. We then trained a support vector machine (SVM) algorithm which resulted in a cross-validated binary classification accuracy of 80% and greater than 100% of randomly shuffled training and testing iterations. Second, we investigated the performance of a SVM trained on data from G1 and G2 using 'test' data from G3. The SVM predicted G3 to fall within the G2 class with 100% accuracy, suggesting that the EEG features in these patients are distinct from those in healthy subjects. Third, we trained a SVM using data from G1, G2 and G3, resulting is 3-way SVM classification with 70% accuracy and leave-one-out cross validation. We

concluded that, while conventional statistics show no difference in standard wavelet analysis of EEG, some of these features nonetheless contain pain-related information that enables a computer algorithm to predict clinically distinct pain states.

Title: Dorsal raphe nucleus glutamatergic neurons innervate mesolimbic system and regulate chronic pain

Authors: *S. HU, D. LIU, Q. ZHANG, J. YANG, M. ABDUL, S. XIA, J. CAO;
Jiangsu Province Key Lab. of Anesthesiol., Xuzhou Med. Univ., Xuzhou, China

Abstract: Numerous researches have indicated that the mesolimbic system, consisting of ventral tegmental area (VTA) and nucleus accumbens (NAc), plays a vital role in the modulation of chronic pain. Our previous study has suggested that the maladaptations in VTA-NAc dopaminergic (DA) neurons can mediate the pathophysiological processes of nociception. However, the mechanisms by which the VTA DA neurons are over-activated under nociceptive condition are still unclear. Here, we demonstrated the dorsal raphe nucleus (DRN) neurons innervated VTA-NAc DA neurons with the tans-synaptic tracing strategy mediated by modified rabies virus. The vitro electrophysiological recordings confirmed that the spontaneous firing rates of DRN neurons innervating VTA-NAc DA neurons (DVN) were increased in a mouse model of chronic pain (sciatic nerve chronic constriction injury, CCI). In naïve mice, photoactivation of the DVN was sufficient to induce a nociceptive phenotype which could last

for 2 days when repeated photoactivation was given. We also validated that the DRN were mostly glutamatergic (GLU) rather than serotonergic (SER). In parallel, photoinhibition of the DRN-VTA GLU pathway relieved pain in CCI mice. Meanwhile, photoactivation of this pathway mimicked pain-like behavior in naïve mice. However, DRN-VTA SER pathway was incapable of eliciting the same effects which were driven by the GLU pathway. Besides, the EPSCs in VTA-NAc DA neurons were increased by stimulation of VTA-projecting DRN neuronal terminals with optogenetics, which could be blocked by bath perfusion of artificial cerebrospinal fluid containing NBQX. In addition, increased amplitude and decreased paired-pulse ratio (PPR) of light-evoked EPSCs were observed in the VTA-NAc DA neurons in CCI mice. The AMPA/NMDA ratio of VTA-NAc DA neurons innervated by DRN neurons was increased. Furthermore, the intra-VTA injection of NBQX reversed the nociceptive phenotype induced by photoactivation of DVN but AP-5 could not express the same effect. Hence, we conclude that the GLU innervations from the DRN to mesolimbic DA neurons are involved in nociception modulation. Both glutamate released from presynaptic DRN neurons and glutamate receptor on postsynaptic VTA-NAc DA neurons can mediate the modulatory roles of the DRN-VTA-NAc pathway in chronic pain. Our results provide a potential target for therapeutic intervention for chronic pain.

Title: Suppression of the inhibitory amygdala-parabrachial pathway contributes to chronic pain

Authors: C. RAVER, O. UDDIN, Y. LI, Y. JI, N. CRAMER, R. MASRI, *A. KELLER; Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The parabrachial nucleus (PB) is a midbrain area involved in acute pain transmission. PB communicates with diverse brain regions controlling sensation, homeostatic functions, and emotional processing, including the central nucleus of the amygdala (CeA). We have recently shown, in rats, that PB neural activity is amplified after chronic constriction injury of the infraorbital nerve (CCI-ION), a model of neuropathic pain. Here, we test the hypothesis that decreased inhibitory input from CeA to PB contributes to PB neuronal amplification, and to chronic pain. Adult male and female animals were randomly assigned to CCI-ION and control

groups; experimenters were blind to their condition. Anterograde and retrograde tracers in mice and rats revealed a dense inhibitory projection from CeA to PB. We used RNA-scope to neurochemically identify PB-projecting CeA neurons, finding that they include somatostatin, dynorphin, and corticotropin releasing hormone positive neurons. Whole-cell patch clamp experiments confirmed that inputs from CeA to PB are inhibitory, and, critically, that this inhibition is suppressed in CCI-ION conditions. Corroborating our previous findings in rats, PB neural activity is increased *in vivo* in CCI-ION mice. Finally, we show the functional relevance of this pathway: pain behaviors increase in rats after suppressing the inhibitory CeA to PB pathway, and pain behaviors are relieved by activating the projection in CCI-ION animals. These findings suggest that changes in the CeA to PB pathway could be a major driver in developing and maintaining chronic pain.

Title: Modulation of mechanosensory vibrissal responses in the trigeminocervical complex by stimulation of the greater occipital nerve

Authors: *N. GARCÍA MAGRO[1], Y. MARTIN[2], P. NEGREDO[1], A. NUNEZ[1], C. AVENDANO[1];
[1]Autonoma Univ. of Madrid, Madrid, Spain; [2]Francisco de Vitoria Univ. CIF – G80480197, Pozuelo de Alarcon, Spain

Abstract: Referred and refractory cervico-cephalic pain is a subject of growing interest because of its high prevalence and severity. The discovery of an area of convergence of afferents from occipital and trigeminal nerves in the upper cervical and medullary dorsal horn provided an appealing substrate to study the neural mechanisms of these painful conditions. Anatomically, this area, known as 'trigeminocervical complex' (TCC), extends from the spinal caudal trigeminal nucleus (Sp5C) to segments C_2-C_3 in the spinal cord[1]. Neuromodulation of occipital or trigeminal nerves has become widely used as a treatment for chronic refractory neurovascular headaches as migraine or cluster headache. The stimulated nerves project to the upper cervical spinal cord or brainstem, where they coincide with other afferents coming from vessels or other

tissues of the regions affected. In this study we aimed at investigating the acute effects that the electrical stimulation of the greater occipital nerve (GON) elicited on the responses of neurons in the TCC to the mechanical stimulation of the ipsilateral vibrissal pad. Experiments were performed on urethane-anesthetized adult male Wistar rats. Following a laminectomy, Sp5C and the upper two segments of the spinal cord were exposed. Unit recordings were obtained from neurons in laminae I-III of the TCC. The GON was isolated and stimulated unilaterally by a monopolar electrode. The responses to the stimulation of vibrissae by 20 ms air pulses were analyzed before and after GON stimulation. Recordings were acquired and analyzed with Spike 2 software. Stimulation of the GON generated a short-lasting response in Sp5C. The stimulation of GON 100 ms before the vibrissal stimulation caused a 33% facilitatory effect on the response to vibrissae in controls. This facilitation was dependent on NMDA receptors, being blocked by local injection of 1µl of AP5 (50µM). Under these conditions, an inhibitory effect was unmasked, which was dependent on the activation of $GABA_A$ receptors and was blocked by the local application of bicuculline (1µl , 20 mM). Currently in progress, a similar recording-stimulation study is carried out on rats showing trigeminal neuralgia-like condition induced by chronic constriction of the infraorbitary nerve. In these animals, the GON-induced facilitation of vibrissal responses disappears, being replaced by inhibitory effects. These results show that, at least in acute settings, the stimulation of GON is able to modulate the responses in TCC to sensory input from a distant location, and that this modulation is changed in rats that present a chronic facial pain.

Title: Role of α_5GABA_A receptors in diabetic neuropathy and modulation of the Hoffmann reflex and primary afferent excitability

Authors: J. HERNÁNDEZ-REYES[1], A. SALINAS-ABARCA[2], G. VIDAL-CANTÚ[2], G. RAYA-TAFOLLA[1], D. ELÍAS-VIÑAS[3], V. GRANADOS-SOTO[4], *R. DELGADO-LEZAMA[1]; [1]Physiology, Biophysics and Neurosci., [2]Dept. de Farmacobiología, [3]Ingeniería Eléctrica, Cinvestav, IPN, CDMX, Mexico; [4]Dept. De Farmacobiologia, Cinvestav, Coapa, Ciudad de Mexico, Mexico

Abstract: There is evidence that the loss of spinal GABAergic inhibition participates in painful diabetic neuropathy. However, the role of extrasynaptic α_5 subunit-containing $GABA_A$ (α_5GABA_A) receptors in this process is unknown. The purpose of this study was to investigate the role of α_5GABA_A receptors in diabetes-induced tactile allodynia, loss of rate dependent depression (RDD) of the Hoffmann reflex (HR) and modulation of primary afferent excitability. A combination of behavioral (threshold withdrawal), electrophysiological (HR, RDD and excitability test) and immunohistochemical techniques was used in this study. Experiments were carried out in female Wistar rats. Intraperitoneal administration of streptozotocin (STZ) induced tactile allodynia. Intrathecal injection of α_5GABA_A receptor inverse agonist, L-655,708, produced tactile allodynia in naïve rats whereas it reduced allodynia in STZ-treated rats. In healthy rats, electrical stimulation of the tibial nerve at 5 Hz induced RDD of the HR, although intrathecal treatment with L-655,708 (15 nmol) abolished RDD of the HR. STZ induced the loss of RDD of the HR, while intrathecal L-655,708 (15 nmol) restored RDD of the HR. For the excitability test the antidromic compound action potential (cAP) was evoked in the tibial nerve by the intraspinal electrical stimulation at the level of the lumbar enlargement. The sural and the peroneal nerves were used as a conditioned stimulation. The interstimulus interval of 30 ms between the conditioned and the test stimulation was selected to assess the action of L-655708 on the phasic and tonic excitability of primary afferent fibers. L-655,708 (15 nmol) increased tonic excitability of the primary afferents without affecting the phasic excitability produced by the primary afferent depolarization. α_5GABA_A receptors were immunolocalized in superficial laminae of the dorsal horn and L4-L6 DRG. STZ increased mean fluorescence intensity and percentage of neurons expressing α_5GABA_A receptors in dorsal horn and L4-L6 DRGs in ten-week diabetic rats. Our results suggest that spinal α_5GABA_A receptors modulate the HR, play an antinociceptive and pronociceptive role in healthy and diabetic rats, respectively, and are tonically active in primary afferents.

Title: TLQP-62, a neuropeptide upregulated by nerve injury, facilitates spinal BDNF release

Authors: *A. G. J. SKORPUT[1], J. L. COOK[1], R. GORE[1], M. S. RIEDL[1], L. VULCHANOVA[2];
[1]Univ. of Minnesota, Minneapolis, MN; [2]Neurosci., Univ. of Minnesota Dept. of Neurosci., Minneapolis, MN

Abstract: BDNF-dependent central sensitization contributes to the development and maintenance of mechanical allodynia in rodent models of neuropathic pain. The signaling mediators leading to increased BDNF bioavailability and its cellular source remain controversial. The neuropeptide TLQP-62 is derived from the precursor protein VGF (non-acronymic), which in the superficial dorsal horn of the spinal cord is localized predominantly in primary afferent central processes. Peripheral nerve injury induces rapid and robust upregulation of VGF in primary afferent neurons, and an increase in the level of TLQP-62 in the spinal cord. Exogenous TLQP-62 application induces potentiation of glutamatergic responses in the spinal cord and calcium transients in primary afferent neurons. Several lines of evidence suggest a functional relationship of TLQP-62 and BDNF in hippocampus. For example, TLQP-62 induces BDNF-dependent plasticity that functions in learning and memory. In addition, VGF signaling increases the expression of BDNF, and vice versa in an autoregulatory feedback loop. Based on these observations, here we test the hypothesis that TLQP-62 facilitates the release of spinal BDNF. Using an *in-situ* ELISA approach, we are examining the effect of TLQP-62 on BDNF release from spinal cord slices, cultures of dorsal root ganglion (DRG) neurons, and cultures of adult spinal microglia. Our results are consistent with TLQP-62-induced facilitation of activity-dependent release of BDNF from spinal cord slices and DRG cultures. This suggests that BDNF bioavailability in the spinal cord following peripheral nerve damage may be the result of increased TLQP-62 levels. In combination with our previous work, these results suggest that TLQP-62 and BDNF may participate in an autoregulatory feedback loop that maintains a state of heighted synaptic plasticity in the spinal cord dorsal horn to facilitate central sensitization and the manifestation of tactile allodynia.

Title: Alterations in pre limbic - periaqueductal grey functional connectivity regulates the temporal development of neuropathic pain in rats

Authors: *R. DRAKE, R. APPS, A. PICKERING, B. LUMB;
Univ. of Bristol, Bristol, United Kingdom

Abstract: The descending pain modulatory system (DPMS) regulates acute pain and its maladaptation is thought to be important in chronic pain. However, the cause of this maladaptation is not well understood. The medial prefrontal cortex (mPFC) and midbrain periaqueductal grey (PAG) are key components of the DPMS with the PAG orchestrating modulation of nociceptive processing within the spinal dorsal horn via brain stem nuclei. Brain imaging studies in humans show functional connectivity changes between the mPFC and PAG during endogenous pain modulation and alterations in this functional connectivity that is related to chronic pain development. However, it is not known whether these alterations are causally related to the development of the chronic pain. To address this question of causality, we selectively transduced pre-limbic cortex-PAG projection neurones with both channelrhodopsin2 and the inhibitory DREADD, hM4Di using a retrograde CAV-Cre + Cre-dependent AAV strategy. This allows selective activation and inhibition of neurones in rats undergoing sensory testing. In uninjured animals, optoactivation (20Hz, 10ms) of PL-PAG neurones produced a bi-lateral increased in thermal withdrawal latency (Stim vs no-stim, 10.9±0.8 vs 8.6±0.7 seconds, p=0.0006, paired t-test, n=7) but had no effect in control rats (no CAV-Cre, n=4). Systemic clozapine-N-oxide (2.5mg.kg^{-1} i.p), DREADD agonist, had no effect on withdrawal latencies to thermal stimulation in either group. The same animals had tibial nerve ligation (under recovery anaesthesia) to produce a neuropathic pain model (chosen because of its gradual (~1 week) progression which is dependent on descending inhibitory noradrenergic control (Hughes et al 2013)). DEADD inhibition of PL-PAG projections revealed the contribution of PL-PAG communication to the pain phenotype. At early time points (day 3-7), inhibition unmasked a latent mechanical hypersensitivity (day 3 von Frey withdrawal threshold vehicle vs CNO, 10.3±2.5 vs 2.9±1.6g, p=0.02, Two-Way RM ANOVA with Sidak's post-test, n=4) but not in control animals. Conversely, systemic CNO delivery at late time (21 days post-TNT) points had little effect on mechanical withdrawal thresholds in experimental or control animals which is consistent with the concept that the DPMS fails over time in this model and implicating the PL-PAG causally in the development of the neuropathic pain phenotype.

Title: A cortico-accumbens CRF-ergic circuit for pain sensation

Authors: *W. ZHAO[1,2], X. WANG[1,2], Y. MA[1,2], G. ZHANG[1,2], Y. YU[1,2], B. FAN[1,2], J. YANG[1,2], A. MANNAN[1,2,3], H. ZHANG[1,2], J.-L. CAO[1,2,3];

Abstract: Corticotropin-Releasing Factor (CRF) is a neuropeptide which is closely related to pain perception. However, the mechanism through which it regulates pain behaviors, especially at the microcircuit level remains to be unknown. The nucleus accumbens (NAc), an important target brain region of CRF heavily influence the pain modulation in animal and human being studies. The present study was designed to screen the sources of CRF-ergic projections in the NAc, and to explore the potential functional role of interested CRF-ergic pathways in modulating pain sensation. To determine the upstream sources of CRF-ergic projections in the NAc, a retrograde adeno-associated virus (AAV) encoding CRF promoter with an enhanced green fluorescent protein tag was injected into the NAc of naïve mice. Our immunofluorescent staining in consecutive whole brain slices demonstrated that the medial prefrontal cortex (mPFC) was the predominant source of NAc CRF-ergic projections. To investigate whether artificially activating the cortico-accumbens CRF-ergic projection in the NAc was sufficient enough to induce pain-like behaviors, AAV-encoding Cre-recombinase with CRF promoter and Cre-inducible Channelrhodopsin (AAV-DIO-ChR2) were injected into the NAc and mPFC respectively, to target the projection-specific cortico-accumbens CRF-ergic neurons. Behavioral tests that were repeated at the interval of 5-days (10Hz 15mW 10ms) demonstrated that the optical activation of the cortico-accumbens CRF-ergic projections in the NAc decreased the thermal paw withdrawal latency (PWL) and 50% mechanical paw withdrawal threshold (50%PWTs) in naïve mice. In neuropathic pain mice in which chronic constrictive injury (CCI) of the sciatic nerve was performed shows a significant increase in c-fos protein within cotico-accumbens CRF neurons, indicating hyperactivity of this circuit in pathological pain. In our proceeding inhibitory optogenetic experiment, replacing AAV-DIO-ChR2 with Cre-inducible Halorhodopsin (AAV-DIO-NpHR), increased PWL and 50% PWT were observed when the yellow laser was turned on. Interestingly, the analgesic effect observed above could also be achieved by pharmacologically antagonizing CRF receptors in the NAc. Ongoing experiments are more exploring the role of NAc CRF receptor in mediating the pain behaviors induced by activating the cortico-accumbens CRF circuit. In summary, these studies identified the previously unknown circuit for regulating pain sensation of the CRF-ergic neurons that project from mPFC to NAc, and these studies also

help in providing the novel molecular targets for translational drug development for chronic pain treatment.

Title: Tn pain relief leads to a bilateral volumetric increase in hippocampal subfields

Authors: *A. NOORANI[1], S.-P. HUNG[1], J. ZHANG[1], M. HODAIE[2];
[1]Krembil Res. Inst., [2]Neurosurgery, Toronto Western Hosp., Univ. of Toronto, Toronto, ON, Canada

Abstract: Hypothesis
Trigeminal neuralgia (TN) is the most prevalent type of chronic neuropathic facial pain. Recent findings suggest that the limbic system, specifically the hippocampus (HC), is involved in processing of chronic pain, and associated with decreased HC volume. However, there are few models that can adequately study the structural changes in the HC in chronic pain. TN serves as a unique model to assess these alterations after successful pain relief as it is highly amenable to surgical treatment. We hypothesize that relief of pain status results in a volumetric HC increase, in particular subfields important in connecting the pain circuits to HC such as Cornu Amonis 2 (CA2) and CA4.
Methods
Patients with T1 anatomical imaging before and 6 months after surgical treatment were retrospectively studied. FreeSurfer 6.0 was used to segment the HC subfields and a residual approach was employed to account for individual variability. HC subfield volumes were contrasted between responders (75% pain reduction) and non-responders at pre and post-surgery using standard T-test.
Results
71 TN (45F, age = mean ± SD, 66.1 ± 12.5) patients were grouped as 46 responders (29F, age = 65.0 ± 12.3), and 25 non-responders (16F, age = 68.3 ± 12.7). Unique subfield HC changes

related to pain relief consisted in a contralateral volumetric increase in GC (P=0.048) and CA4 (P=0.047) in responders. Ipsilaterally, molecular Layer (P=0.030), GC (P=0.007), CA2/3 (P=0.018), and CA4 (P=0.006) showed a volumetric increase in responders.

Conclusion

Our findings suggest that there are HC subfields volume increases associated with TN pain relief, characterized by a bilateral increase in CA4 and GC. Considering the known association between chronic pain, stress and associated HC structural abnormalities, our data points to a dynamic nature of HC subfields. Furthermore, we suggest that these structural alterations may relate to increased neuronal density/neurogenesis in HC.

Abstract: Proliferation and activation of microglia have been implicated to play an important role in the development of neuropathic pain following peripheral nerve injury. We have taken a molecular therapy approach to attenuate microglial proliferation to alleviate neuropathic pain. Colony stimulating factor-1 receptor (CSF1R) is crucial for microglial proliferation. We generated an adeno-associated viral vector (serotype 9) expressing a non-functional soluble CSF1R (AAV9/sCSF1R) as a decoy to block the binding of CSF1 to CSF1R. AAV9/sCSF1R and the control vector AAV9/GFP were intrathecally injected into the lumbar spine of adult C57BL/6 mice. Two weeks later, these mice were subjected to partial sciatic nerve ligation or sham operation. Normal mice and mice with sham operation or sciatic nerve ligation without viral injection were also used as controls. Before and after the surgery on sciatic nerves, mice were tested for mechanical pain sensation. Animals were sacrificed 3 weeks post operation. GFP and sCSF1R were found to be highly expressed in lumbar DRG and spinal cords in AAV9-injected mice. Significant increase in the number of macrophages in lumbar DRG and microglia

in the dorsal and ventral horns of lumbar spinal cords were observed in the mice subjected to sciatic nerve ligation or AAV9/GFP injection plus nerve ligation. In the AAV9/sCSF1R injected mice with sciatic nerve ligation, the microglial densities in the dorsal and ventral horns and macrophage density in DRG were significantly lower compared with the mice subjected to sciatic nerve ligation or AAV9/GFP plus nerve ligation, indicating that sCSF1R expression is able to limit the microglial and macrophage proliferation induced by nerve ligation. Behavioural test showed that sCSF1R expression significantly reduced the nerve ligation-induced mechanical allodynia. The results implicate that over-expression of sCSF1R may represent a novel approach in long-term alleviation of neuropathic pain.

Title: Role of the interaction between GluN2B subunit and PSD-95 in neuropathic pain after peripheral nerve injury

Authors: *Y. KIM[1,2], Y. YOON[1,2];
[1]Dept. of Physiol., [2]Neurosci. Res. Inst., Korea Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: N-Methyl-D-aspartate receptor 2 (NMDAR GluN2) has glutamate binding sites, especially GluN2B subunit located at sensory regions in central nervous system such as the forebrain and the spinal dorsal horn. Therefore, blocking of GluN2B is gaining attention to reduce neuropathic pain with minimal side effects. However, the signal transduction associated with GluN2B in neuropathic pain is not well known. L5 spinal nerve was ligated using 6/0 silk (L5 SNL) under the isoflurane inhalation in male Sprague-Dawley rats (220-250 gram). We analyzed the temporal changes in GluN2B, its phosphorylation residue at Ser1303 and Tyr1472 in the ipsilateral side of the dorsal spinal cord after SNL. Protein expression of GluN2B increased from 6 hours to 4 days and p-Ser1303 expression increased up to 2 weeks after injury. Co-immunoprecipitation was used to examine the interaction between p-Ser1303 and CaMKII, PKC or PSD-95, respectively. The interaction between p-Ser1303 and CaMKII was robustly enhanced from 6 hours to 4 days, and that between p-Ser1303 and PSD-95 was increased from 4

days to 2 weeks after injury. Mechanical paw withdrawal threshold was measured before and after intrathecal administration of relevant drugs. Inhibitors of GluN2B or CaMKII more effectively increased mechanical paw withdrawal threshold in the early phase than the later phase, and reduced the interaction between p-Ser1303 and PSD-95 at that time. These results demonstrate that GluN2B translocation onto the postsynaptic density may play a role in the long term maintenance of neuropathic pain.This work was supported by the Korea Science and Engineering Foundation (KOSEF) grant funded by the Korea government (MEST) (NRF-2017R1D1A1B04035645) and the Korea University Fund (K1220201).

Title: Low threshold-afferent-driven inhibition of spinal lamina I neurons

Authors: Y. ANDRIANOV[1,3], D. SHEVCHUK[1,3], N. TRETIAK[1,3], B. V. SAFRONOV[4], N. V. VOITENKO[1,3], ***P. V. BELAN**[2,3];

Abstract: Spinal lamina I neurons receive inputs from nociceptive Aδ- and C-fiber afferents and relay these inputs to the supraspinal pain processing centers. Pre- and postsynaptic inhibition of these neurons play an important role in processing of painful stimuli. Although the low-threshold fibers are believed to mediate both types of inhibition, their roles in shaping the input-output characteristics of lamina I neurons is poorly understood. Here, we did the whole-cell patch-clamp recording from lamina I neurons in an isolated spinal cord preparation with an attached dorsal root. We have developed a novel method to evoke the Aδ/C-fiber-mediated EPSCs and IPSCs with or without simultaneous activation of the low-threshold fibers. Our results show that the low-threshold afferents can mediate a complete or partial pre- and postsynaptic inhibition of the mono- and polysynaptic Aδ- and C-fiber inputs to lamina I neurons. Different combinations of the low-threshold-afferent-driven presynaptic inhibition were present in the majority of lamina

I neurons, whereas the postsynaptic inhibition was rare. Importantly, the low-threshold-afferent-driven inhibition controls the number of action potentials generated by the lamina I neurons. Thus, we demonstrate that the pre- rather than postsynaptic low-threshold-afferent-driven inhibition shapes the output characteristics of lamina I nociceptive neurons.

Title: Alleviation of neuropathic pain by the inhibition of mTOR complex in the insular cortex

Authors: *K. KIM[1,2], S. CHOI[1,2], M. CHA[1], S.-K. HONG[3], J. LEEM[1], B. LEE[1,2];
[1]Dept. of Physiol., Yonsei Univ. Col. of Med., Seoul, Korea, Republic of; [2]Brain Korea 21 PLUS Project for Med. Science, Yonsei Univ., Seoul, Korea, Republic of; [3]Div. of Bio and Hlth. Sci., Mokwon Univ., Daejeon, Korea, Republic of

Abstract: In the pain matrix, the insular cortex (IC) is mainly involved in discriminative sensory and motivative emotion. Recent studies have shown that the mTOR kinase is major regulator of protein synthesis and it could be involved in the regulation of synaptic plasticity and memory formation in the central nervous system. This study was conducted to determine the changes in pain behavior and downstream effectors by mTOR inhibition. In addition, the dynamic changes in the spatiotemporal patterns of the IC activities were analyzed and compared before and after inhibition of mTOR complex in the IC after nerve injury. Under isoflurane anesthesia, the neuropathic surgery was conducted to Sprague-Dawley rats and the rats were anesthetized with isoflurane. The behavioral tests were performed before and after microinjection of mTOR inhibitors (Torin1 and XL388) and vehicle. To assess the spatiotemporal patterns of the IC activities, the optical imaging was conducted. The response of neuronal activities was recorded and these signals were analyzed. Western blot was carried out in order to ascertain the expression changes in mTOR and its downstream effectors. As a result, mTOR inhibitors showed the pain-relieving effect four hours after microinjection of mTOR inhibitors in behavioral test. In optical imaging, the Torin1- and XL388-injected groups showed decreased signals and reduced activation area contrary to the vehicle group. The phosphorylation of downstream effectors of mTOR complex, such as P70S6K and 4EBP, were significantly increased in the vehicle-treated

group. However, they were decreased in the Torin1- and XL388-treated groups. The other phosphorylated downstream effectors of mTOR complex, Akt and PKCα, also increased in the vehicle-treated group while significantly reduced in the mTOR inhibitor-treated groups. In addition, the expression level of phosphorylated mTOR significantly increased in the vehicle-treated group but, it was decreased in the Torin1- and XL388-treated groups. These findings suggested that the pain-relieving effect of Torin1 and XL388 was manifested by modulation of mTOR complex. This study was supported by the Basic Research Program through the National Research Foundation (NRF) funded by the Ministry of Science and ICT. (NRF-2015R1C1A1A01053484 and 2017R1A2B3005753)

Abstract: Chronic pain can result in social and psychological problems such as inability to work, disrupted social relationship, depression and suicidal thoughts. Chronic pain is difficult to manage, due to incomplete understanding of the complex modulating pathways in nociception and the side effects that limit the use of conventional analgesics such as NSAIDs and opioids. A major cause of chronic pain is osteoarthritis (OA), affecting 10% to 15% of people aged above 60 worldwide (WHO; 2013), is characterized by the loss of joint cartilage that leads to chronic pain and loss of function in the knees and hips. Through HPLC analysis of small peptides in pooled cerebrospinal fluid (CSF) from 20 OA patients, we identified a peptide metabolite of secretogranin V (7B2) protein, designated 7B2CT. 7B2 is involved in the maturation and activation of prohormone convertase 2 (PC2). 7B2CT, however, inhibits the activity of PC2. To activate PC2, 7B2CT peptide which is 31 a.a. (amino acids) in length must be cleaved by PC2 in the secretory granules into two fragments, 7B2CT-N (N-terminal, 18 a.a.) and 7B2CT-C (C-terminal, 13 a.a.). To quantify these peptides in individual patient's CSF, we employed liquid

chromatography coupled with mass spectrometry (LC-MS) and optimized the methodology to detect 7B2CT, 7B2CT-N and 7B2CT-C using 10ul of individual patient's CSF per run. Comparison between the CSFs of OA patients with chronic pain and control subjects without pain indicated that 7B2CT levels were significantly elevated in Asian OA pain patients in a small sample size trial (n=4; T-Test; $p<0.01$). Next, we investigated the binding site(s) of 7B2CT-N and 7B2CT-C by using biotinylated-7B2CT-N and biotinylated 7B2CT-C peptide to bind to mouse brain section in a binding assay. We found that 7B2CT-C, but not 7B2CT-N, binds strongly to the thalamus region of the mouse brain suggesting that 7B2CT may also bind in this brain region. Our findings suggest that 7B2CT may be a novel biomarker for OA chronic pain and 7B2CT (and its metabolites) may be involved in induction and/or maintenance of OA pain by acting as a neuromodulator released from the CNS during chronic pain in OA. These data may help in the isolation of an interacting partner for 7B2CT and in the development of a new class of anti-nociceptive drugs.

Title: Comparing the firing patterns of superficial dorsal horn neurons evoked by robotically automated and human manual brushing and Von Frey hair stimulation

Authors: *D. C. LEE[1], J. E. LEE[2], K. LEE[1], Z. KAGAN[1], K. BRADLEY[1];
[1]Nevro, Redwood City, CA; [2]ANCroid Robotics, Agua Dulce, CA

Abstract: Investigations into the response of spinal dorsal horn (SDH) neurons to afferent inputs typically employ various types of mechanical stimulation to peripheral structures (e.g., a rodent paw). Most often, these stimuli are applied manually to a receptive field; manual application may contribute to inconsistent variation in the parameters of the stimulus: temporal timing, duration, location, etc. We compared the spinal dorsal horn neural response between manual and custom robot-based brushing/Von Frey stimulation system.A robot with four degrees of freedom was programmed to brush the hind paw of an anesthetized rat. Multichannel electrodes were placed in the ipsilateral SDH (lamina II-III, the spinal segment L4-6) to monitor single unit firings evoked by a similar brushing motion and Von Frey stimulation performed by the robot and from a trained examiner. The robot brushing was programed to brush in an arc motion at different depths (0.5, 1, 2 and 3mm), speeds (50, 100 and 200mm/s) and directions (proximal to distal vs. distal to proximal). Von Frey hair stimulation was applied with 2, 6, 10 and 15g hair for 1.5s.

Qualitatively, automated brushing and Von Frey generated consistent and repeatable patterns of multiunit SDH activity. Manual forward brushing was most similar to the automated brushing with depth=2mm, speed=100mm/s in terms of firing rate and duration. Manual Von Frey duration had during of 0.76±0.12s with intension of 1 s stimulation duration, while automated Von Frey had duration of 1.4±0.02s. Mean firing rate from manual Von Frey was ~10% higher than automated stimulation. Interestingly, it appeared that most recorded neurons, activated by manual brushing or Von Frey hair were also fired by automated brushing, but certain neurons were activated more by manual mode or the other. Standardization of the sensory stimulus using this novel robot tool may allow for fewer trials of applied afferent input and greater sensitivity to detect subtle changes in response in sensory experiments or intervention such as spinal cord stimulation.

Title: S1PR1 induced mechano-hypersensitivities are mediated by alterations in adenosine signaling

Authors: *F. LAURO, L. A. GIANCOTTI, Z. CHEN, T. M. DOYLE, C. M. HARADA, D. SALVEMINI;

Abstract: Chronic pain is a global burden and unfortunately its treatments are frequently insufficient or non-existent. Underlying mechanisms that drive molecular pain pathways remain to be defined and new therapeutic targets are needed. We have recently reported that intrathecal (i.th) injection of sphingosine-1-phosphate (S1P) in rodents causes mechanical and thermal hypersensitivities by activating the S1P1 receptor subtype (S1PR1). Conversely, blocking S1PR1 through genetic and pharmacological approaches, inhibit the development of neuropathic pain states. We have also demonstrated that S1PR1 activation engages molecular signaling pathways downstream of the nucleotide-binding oligomerization domain-like receptor protein 3 inflammasome (NLRP3) leading to the production of the potent inflammatory and

neuroexcitatory cytokine, interleukin-1β (IL-1β). Recent studies suggest that IL-1β can increase the expression of adenosine kinase (ADK). ADK is the key intracellular enzyme regulating intra- and extracellular adenosine concentrations and is regarded as the essential "upstream" regulator of adenosine neurotransmission; increased ADK activity reduces adenosine signaling. We found that mechano-allodynia caused by i.th injection of IL-1β was blocked by an ADK inhibitor (ABT702). Reduced adenosine signaling at the A3 adenosine receptor subtype (A3AR) in the spinal cord contributes to the development of neuropathic pain states; selective A3AR agonists are potent analgesics. The interactions between sphingolipids and adenosine signaling are not known. Here, we show that the ability of S1PR1 antagonists to reverse neuropathic pain (caused by constriction of the sciatic nerve), is prevented by an A3AR antagonist suggesting the existence of potential cross talks. In support, we found that the development of mechano-allodynia caused by i.th. injection of a selective S1PR1 agonist was blocked by an ADK inhibitor; this led to reduced activation of NLRP3 activation. Collectively our data provides a first evidence of a functional connection between S1P and adenosine signaling and suggest that S1PR1 antagonists may exert their beneficial effects by restoring adenosine signaling at the A3AR warranting further investigations.

Title: Calcineurininhibition increases glutamatergic input to spinal dorsal horn neuronsand pain hypersensitivity through α2δ-1-bound NMDA receptors

Authors: *Y. HUANG, S.-R. CHEN, H. CHEN, Y. LUO, H.-L. PAN;
Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Abstract: Calcineurin inhibitors such as tacrolimus (FK506) is clinically used as immunosuppressants in organ transplant patients. However, these drugs can cause severe pain in some patients, commonly referred to as calcineurin inhibitor-induced pain syndrome (CIPS).

Although calcineurin inhibition increases NMDA receptor (NMDAR) activity in the spinal cord, the underlying mechanism remains unclear. In this study, we showed that systemic administration of FK506 in mice significantly increased the frequency of miniature excitatory postsynaptic currents (EPSCs) in spinal dorsal horn neurons and potentiated the amplitude of NMDAR-mediated EPSCs monosynaptically evoked by dorsal root stimulation and puff NMDA elicited currents in dorsal horn neurons. These effects were blocked by inhibiting α2δ-1 with gabapentin or α2δ-1Tat peptide, which interrupts the interaction between α2δ-1 and NMDA receptors. In α2δ-1 KO mice, treatment with FK506 failed to increase NMDA receptor-mediated glutamatergic input to spinal dorsal horn neurons. FK506 treatment significantly increased the amount of α2δ-1-NMDAR complexes at synaptic sites in the spinal cord. Furthermore, FK506 treatment-induced tactile allodynia and mechanical hyperalgesia were largely reduced in α2δ-1 KO mice and in mice with GluN1 conditional KO in primary sensory neurons. In addition, systematic administration of gabapentin or intrathecal injection of α2δ-1Tat peptide reversed pain hypersensitivity in FK506-treated mice. Together, our findings indicate that α2δ-1-bound NMDA receptors mediate calcineurin inhibition-induced synaptic NMDA receptor hyperactivity in the spinal cord and pain hypersensitivity.

Abstract: The dorsal horn of the spinal cord (DH) is the first relay center of somatosensory information originating from the periphery. In the superficial DH laminae I-II, nociceptive information is processed by a complex network of excitatory and inhibitory interneurons whose function and connectivity remain poorly understood. In this study, we examine the role of calretinin-expressing interneurons (CR neurons) in the processing of innocuous and noxious sensory inputs. These neurons are mainly located in lamina II, where they receive direct inputs from the central endings of nociceptive fibers and polysynaptic inputs from touch-sensitive Aβ fibers. Their activation by either chemogenetic or optogenetic stimulation produces mechanical

allodynia and nocifensive behaviors. Furthermore, we examined the position of CR neurons in the circuitry of the DH in which there are ideally positioned to modulate pain projection neurons in lamina I. In conclusion, we propose a new neuronal pathway in which CR neurons are positioned at the junction between nociceptive and innocuous circuits and directly ascending pain pathways of the dorsal horn.

Title: Defining pre- and post-synaptic Ca^{2+} signaling in the spinal cord in pain sensitization

Authors: *A. KEYES[1], C. WARWICK[1], L. SHUTOV[1], V. KROTOV[3], P. BELAN[3], Y. USACHEV[1,2];
[1]Pharmacol., [2]Iowa Neurosci. Inst., Univ. of Iowa, Iowa City, IA; [3]Mol. Biophysics, Bogomoletz Inst. of Physiol., Kyiv, Ukraine

Abstract: Chronic pain affects approximately 100 million Americans and only a minority of patients experience satisfactory relief of their pain with currently available pharmaceutics. One type of chronic pain caused by direct injury to the nerve is called neuropathic pain, and it affects ~10% of the overall population. Despite the prevalence, the underlying mechanisms of neuropathic pain are not well-defined, and better understanding of the mechanisms that promote central sensitization after injury could lead to better treatment of this condition. Among various mechanisms, central sensitization, or the enhancement of synaptic transmission in the spinal cord, is thought to be especially important in the pathogenesis of neuropathic pain. Primary afferents, responsible for transducing painful stimuli, terminate in the spinal cord at what is called the first sensory synapse. This synapse is a key regulator of pain signaling, and aberrant processes at this synapse can lead to an amplification of pain. As most studies have only examined the post-synaptic signaling of this synapse via patch-clamp recordings, the critical questions regarding the role of presynaptic changes in Ca^{2+} signaling in central sensitization have not been addressed. Furthermore, there are many questions remaining regarding the relationship between pre- and post-synaptic changes in Ca^{2+} signaling and Ca^{2+} signaling in microglia in central sensitization. We have developed a method to examine Ca^{2+} signaling in the spinal cord

with high spatial (~0.5 μm) and temporal (~100 ms) resolution using an *ex vivo* intact spinal cord preparation and multiphoton microscopy. Using this method, we are able to simultaneously monitor pre- and post-synaptic Ca^{2+} signaling in intact spinal cord from the mice that express Pirt-GCaMP3 in central terminals of primary afferents and Thy1-RGECO in dorsal horn neurons, and Ca^{2+} signaling in mice that express GCaMP5G-TdTomato in microglia. This approach will facilitate our ability to define pre- and post-synaptic mechanisms of central sensitization in the spinal cord.

Title: Neuromodulation of pain processing in the dorsal horn circuit

Authors: *P. SACRÉ[1], G. DRION[1], Y. GUAN[2], S. V. SARMA[3];
[1]Electrical Engin. and Computer Sci., Univ. of Liège, Liège, Belgium; [2]Anesthesiology/CCM, [3]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: Almost one of five adults suffer from chronic pain. Today, chronic pain is primarily treated with neuropharmacology, which may have negative side effects (e.g., addiction to narcotics), and lose efficacy after long-term use. Alternatively, chronic pain is also treated with neurostimulation—such as spinal cord stimulation or deep brain stimulation—which has great potential but has been associated with suboptimal efficacy and limited long-term success as its mechanisms of action are unclear. Understanding the mechanisms of pain processing to predict its modulation by therapies is therefore essential toward pain management, yet current computational models suffer from several limitations. They are either too simple (such as the static gate control theory) and lack fundamental dynamical functions of the dorsal horn circuit, or they are too complex (such as high dimensional conductance-based models) and lack the functional intuitions that are necessary for the design of new treatments as their analysis becomes untractable. Using mathematical models that combine computational economy and physiological interpretability, we investigated how the cellular and synaptic mechanisms in the dorsal horn circuit—the first central relay station for pain processing—contribute to its function.
At the cellular level, deep dorsal horn neurons can switch their intrinsic firing properties—tonic discharges, plateau potentials, or rhythmic bursting. This change in neural activity is captured in

our model by a modulation of the balance between negative and positive conductances in distinct timescales. A first ultraslow variable acts as a positive feedback (ultraslow regenerative ionic channels) and is responsible for the acceleration in the depolarized state and the deceleration in the hyperpolarized state. A second ultraslow variable acts as a negative feedback (ultraslow restorative ionic channels) and is responsible for the interburst period. In addition, at the circuit level, these firing modes correspond to specific functional states of information transfer at the circuit level in which dorsal horn neurons can faithfully transmit, greatly enhance, or block the transfer of nociceptive information. Our tractable model is a new step forward in understanding the early stages of pain processing in normal and pathological conditions and creating a testbed for finding potential targets of novel drugs or neurostimulation.

Title: Multidimensional approach of experimental chronic neuropathic orofacial pain: From behavioral to neuronal correlates

Authors: *C. D. MONTES-ANGELES, E. PERRUSQUIA-HERNÁNDEZ, R. D. ANDRADE-GONZÁLEZ, I. O. PÉREZ-MARTÍNEZ;
Univ. Nacional Autonoma De Mexico, Estado de Mexico, Mexico

Abstract: Chronic orofacial neuropathic pain (CNOP) is defined as an alteration of the trigeminal somatosensory system. Injuries from dental treatments, cancer and accidental injuries are the main causes of the development of this disease, which can involve modifications in both peripheral and central nervous system. The CNOP causes a decrease in the quality of life of who suffers in different dimensions, such as sensory, emotional and cognitive. From this multidimensional approach, it has been found that CNOP produces sensory impairment, depression and inability to adapt to the requirements and challenges of the environment. The aim of this project is to set the foundations for multidimensional assessment in a mouse CNOP model. All of the procedures presented were performed in accordance with the ethical standards of the National Autonomous University of Mexico committee on animal experimentation. Following a constriction injury of mental nerve in C57BL/6 mice, spontaneous and evoked nocifensive responses were assessed, in order to characterize the development of allodynia and hyperalgesia, sensory signs of CNOP. Responses during the escape/avoidance paradigm reflect

the emotional component of pain as a sign of emotional adaptation to environment. Behavioral paradigms assessed the adaptation to unexpected stimuli (switch task) and to changes in the environmental requirements (set-shifting and reversal-set-shifting tasks). These evaluations show that there are cognitive alterations after the CNOP. The present work provides the behavioral basis for the cortical and subcortical study of neuronal activity associated with cognitive adaptation processes when there is CNOP. The authors declare that they do not have conflict of interest.

Program, Hosp. for Sick Children, Toronto, ON, Canada

Abstract: Chronic pain has been labelled the silent health epidemic afflicting hundreds of millions of people worldwide. The most debilitating and poorly treated form of chronic pain is neuropathic pain. Existing treatments for chronic neuropathic pain are minimally effective and may be contributing to the current opioid crisis. The lack of novel therapies is directly related to the complex nature of pain signaling. Our previous work has revealed that there are multiple different cellular and molecular mechanisms that form the basis of pain processing in rodents. These critical differences are also susceptible to genetic variability and are sexually dimorphic. DNA methylation is one of the main mechanisms for sexual differentiation in the CNS. We evaluated the DNA methylome in spinal cord and periaqueductal gray (PAG) of male and female Sprague Dawley rats after spared nerve injury (SNI) by reduced representation bisulfite sequencing (RRBS). We selected methylated regions using Methyl Kit that were considered to be differentially methylated regions (DMRs) by the following criteria: adj. p.val <0.05,

differential methylation > |10%|, and width >3 CpG. Enrichment analysis was then performed on DMRs using Genomic Regions Enrichment of Annotations Tool (GREAT). Here we report that in spinal cord, 2,811 and 6,144 genomic regions are differentially methylated between males and females for naïve and SNI conditions, respectively. GREAT linked these regions to 3,486 and 6,005 genes, 2,371 of which are shared by the two condition. In the PAG, we found 5,448 and 3,631 genomic regions are differentially methylated between males and females DMRs for naïve and SNI conditions, respectively. These DMRs are linked to 5,627 and 4,265 genes, respectively, 2,684 of which are shared. We observed robust sex specific DNA methylation in both spinal cord and PAG in the naïve state and, after SNI, both tissue methylomes were altered in sex specific manners. Together, our findings support a hypothesis that DNA methylation is important for the sexual differentiation of the CNS and may be the foundation for sex differences in neuropathic pain mechanisms.

Title: Susceptibility and resistance to chronic pain: Sex is important

Authors: *M. R. GUIMARÃES, C. MIRANDA, A. M. CUNHA, S. ROQUE, M. ESTEVES, N. D. ALVES, N. SOUSA, M. CORREIA-NEVES, A. ALMEIDA, H. LEITE-ALMEIDA; Neurosci. Res. Domain, Life and Hlth. Sci. Res. Inst. (ICVS), Braga, Portugal

Abstract: Chronic Pain (CP) is an integrative phenomenon that results from dynamic interactions between sensory and emotional, motivational and cognitive domains. In fact, several studies using rodent models of CP revealed adaptations in brain regions related with anxiety, depression, cognitive dysfunction and nociception. However, little is known about their cross-relations prior to injury. In this work we aim to evaluate behavioral and immunological parameters associated with CP resistance/susceptibility in male and female rats.Male and female Sprague dawley (SD) rats were used in all experiments since 15% of these animals do not

manifest pain-related behaviors. Prior to installation of a modified spared nerve injury (mSNI), sociability (SB - neutral arena), emotional (EPM, elevated-plus maze; FST, forced swimming test) and impulsivity decision making (VDS, variable delay-to-signal) were assessed. Then, mechanical allodynia (proxy of neuropathic pain) was measured weekly to evaluate the progression of hypersensibility. After 4 weeks blood was collected for fluorescence-activated cell sorting (FACS) and the sucrose preference (anhedonia) test was performed.We observed that: 1) mSNI promotes a wide range of mechanical allodynia thresholds particularly in males; 2) High threshold (HT) animals are at baseline less depressed and more social; 3) HT animals had higher hedonic behavior than LT. We also show that females are more prone to develop hypersensitivity than males although no sex differences were observed between male and females in GFAP staining in spinal cord. Finally, resistance to pain manifestation was associated with increased sociability and decreased depressive-like behavior prior to the pain-triggering injury and with lower levels of T lymphocytes. Overall, our experiments show that in pain protection after a neuropathic injury is associated with better emotional state and lower levels of T lymphocytes, indicating that immune system and emotional state are crucial for pain manifestation.

Title: Resolving the molecular identity and connectivity of amygdalar neural ensembles active during pain

Authors: *D. J. BERG, C. CHEN, B. AHANONU, M. CHEN, S. QUAKE, M. SCHNITZER, G. SCHERRER;
Stanford Univ., Palo Alto, CA

Abstract: The amygdala critically contributes to emotional valence assignment during pain experience. By means of time-lapse *in vivo* calcium imaging and neural activity manipulation in freely behaving mice encountering noxious stimuli, we recently identified a neural ensemble that encodes pain unpleasantness in the basolateral amygdala (BLA) (Corder, Ahanonu, et al., 2019). Here we examined the connectivity of this BLA neural ensemble using viral tracing methods and the transcriptome of individual BLA neurons constituting the ensemble with single cell RNA-sequencing.
We first induced Cre activity in BLA nociceptive neurons, using TRAP2 mice injected with intraplantar formalin or stimulated with pinprick. To trace inputs to and from BLA nociceptive neurons, we injected the BLA with GFP-expressing mutant rabies viruses with retrograde transsynaptic spread properties combined with helper adeno-associated viruses. Additionally, we used adeno-associated viruses to express GFP and synaptophysin-mRuby to visualize BLA nociceptive neuron cell bodies and their axon terminals. We found that the BLA nociceptive ensemble receives convergent synaptic input from several brain regions, including the anterior cingulate cortex (ACC) and insular cortex, which are thought to play an important role in pain affect. We determined that outputs of the BLA nociceptive ensemble includes the ACC, nucleus accumbens, claustrum and striatum.
To identify novel therapeutic targets, we sequenced the transcriptomes of individual nociceptive BLA neurons. TRAP2 mice were crossed with Ai14 mice (*Rosa26*$^{LSL\text{-}tdTomato}$), to fluorescently label neurons active during pain. To distinguish and positively select tdTomato+ BLA nociceptive neurons, we microdissected the BLA, dissociated neurons, and acquired labeled neurons using fluorescence-activated cell sorting (FACS). We generated high-quality full-length gene expression profiles of individual neurons using Smart-seq2 and Illumina sequencing. Initial scRNA-seq experiments and unsupervised clustering analysis shows amygdalar subpopulations expressing known markers, including *CamKIIa* and the negative-valence marker gene *Rspo2*, and reveals the molecular architecture of amygdala neurons that encode pain emotional component. This transcriptomic analysis will provide a comprehensive catalog of surface proteins specifically expressed by BLA neurons encoding pain unpleasantness for the development of therapeutics to treat pain affect.

Title: Maladaptive cortical plasticity associated with neuropathic pain after SCI

Authors: *G. H. BLUMENTHAL[1,2], V. BRACCHI-RICARD[3], B. NANDAKUMAR[1], J. R. BETHEA[3], K. A. MOXON[1];
[1]Biomed. Engin., Univ. of California, Davis, Davis, CA; [2]Dept. of Biomed. Engin., [3]Dept. of Biol., Drexel Univ., Philadelphia, PA

Abstract: The role of the primary somatosensory cortex (S1) in the development of chronic neuropathic pain (CNP) remains unclear. Some studies have shown that increased cortical reorganization is associated with increased intensity of CNP, and that alleviation of some CNP symptoms can be achieved through reduction or reversal of this maladaptive plasticity. Conversely, others have shown that CNP is associated with a preserved representation of the painful region of the body. Much of this research was conducted in human subjects with variable injuries using neuroimaging methods, and was limited in that the painful region of the body was not directly stimulated. A well-controlled animal study would help shed light on the role of cortical plasticity in the development of CNP. To address this, we used a rat model of mid-thoracic (T10) spinal cord contusion injury in which a proportion of animals developed at-level CNP, allowing for a comparison of cortical reorganization in the S1 of injured animals that developed CNP to injured animals that did not. This is important because it allows us to control for the confounding factor of injury. Animals were tested for at-level CNP once a week for 5 weeks post-injury. At-level CNP was assessed by probing the dorsal trunk with a 26g von Frey filament within a body grid system, allowing us to precisely and consistently stimulate the trunk across all animals and localize the painful region to thoracic dermatomes. Aversive supra-spinal responses were measured. Animals were then separated into experimental groups based on the presence or absence of at-level CNP. At week 6, animals in both groups underwent sensory mapping in which receptive fields were measured from cortical cells both within and surrounding the putative trunk S1. In a separate cohort of animals, fresh tissue from S1 was analyzed to assess differential regulation of genes related to plasticity using RNAseq followed by qPCR. In our model, at-level CNP alone developed in dermatomes T4-T10 in 19% of animals, while 66% of animals developed no CNP anywhere. The remaining animals developed pain in the forepaws and/or hindpaws. In assessing S1 reorganization, we found that in animals that developed at-level CNP, the representation of the painful region of the trunk expanded into the putative representation of the forelimb when compared to both injured animals without CNP as well as naïve controls. Additionally, in animals with at-level CNP, mRNA from genes associated with both CNP and plasticity such as P2X7R were upregulated in S1 compared to injured animals without CNP and naïve controls, suggesting that this reorganization may be in part due to transcriptional changes at the cortical level.

Title: The role of dopamine in the processing of chronic pain signals in the mouse prefrontal cortex

Authors: *S. HUANG, E. GAMBETA, C. THOMAS, N. GODFREY, Z. ZHANG, S. BORGLAND, G. ZAMPONI;
Hotchkiss Brain Institute, Univ. of Calgary, Calgary, AB, Canada

Abstract: The medial prefrontal cortex (mPFC) is a brain region involved in coordinating consciousness and is important in mediating pain arousal. Previous studies have revealed that the mPFC undergoes plasticity during development of chronic pain. Pain and reward systems encode opposing motivational salience value, however, through a shared neuronal circuit. Dopamine is a key neuromodulator in the reward system and has been implicated in the modulation of the pain axis. The mPFC receives dopaminergic inputs, and stimulation of these inputs has been shown to modulate the plasticity of the mPFC and aversive behavior. In this study, we use optogenetic approaches in conjunction with a transgenic mouse line to selectively activate dopaminergic inputs in the mPFC during neuropathic pain states. We found that phasic but not tonic optogenetic activation of these dopaminergic inputs significantly reduced mechanical hyperalgesia. Conditional place preference tests of affective pain consistently showed that mice with neuropathic pain exhibit a preference to chambers in which they were conditioned with optogentically released dopamine. Furthermore, c-fos expression suggested that this modulation is mediated by activation of mPFC principal neurons. This is in accordance with previous findings showing that decreased activity of principal neurons has a causal relation to chronic pain. Together, our findings indicate a novel role of mPFC dopamine signaling in pain modulation.

Title: Dual GABA/acetylcholine basal forebrain input on a specific periglomerular cell subtype in the olfactory bulb

Authors: *D. DESAINTJAN;
INCI, UPR 3212, CNRS, Strasbourg, France

Abstract: GABAergic and cholinergic long-range projections from the basal forebrain (BF) potentially orchestrate inhibition in the olfactory bulb with synaptic connections on diverse interneuron subtypes in multiple layers. In the glomerular layer, BF afferents provide a prominent GABAergic synaptic input onto three subclasses of type 2 periglomerular (PG) cells (Sanz Diez et al., JPhysiol 2019). The impact of these inputs is unclear as previous studies concluded that GABA is depolarizing in PG cells but could nonetheless be inhibitory by shunting excitatory signals. To further investigate this question, BF modulation of PG cells spiking activity was examined using loose cell-attached recordings. BF axons were stimulated using optogenetics in olfactory bulb slices from adult mice. ChR2-EYFP was selectively expressed in BF neurons using stereotaxic virus injection in dlx5/6-cre mice. This led to the expression of ChR2-EYFP in multiple populations of BF GABAergic neurons as well as in cholinergic neurons that are known to be also GABAergic. Despite the high connection rate found in dlx5/6;ChR2-EYFP mice, light stimulation (1 ms) had no noticeable effect on a majority (>50%) of the recorded PG cells which were totally silent or fired only occasionally. PG cells that were modulated by the light-evoked BF input had diverse responses. In a minority of cells, BF inputs were excitatory and induced a single time-locked action potential (n=8) or a single delayed action potential (n=11). However, in the majority of cells (n=70), the firing was transiently inhibited by the BF input. Firing inhibition persisted in the presence of antagonists of the glutamate, nicotinic or muscarinic receptors but was abolished by gabazine, an antagonist of the $GABA_A$ receptors (n=12). The duration of this inhibition was highly variable across PG cells (range 100-900 ms) and in a subset of neurons (n=32), spiking inhibition was followed by a robust increase of firing. Increase in spike frequency peaked ~1 s after the light stimulus and lasted several seconds. This excitation persisted in the presence of gabazine or of NBQX/D-AP5 but was blocked by atropine or scopolamine, two antagonists of mACh receptors (n=9). This dual GABA/ACh modulation of firing was recorded in 7 cells that were then characterized in the whole-cell configuration. All were regularly firing type 2 PG cells, responding to the stimulation of the olfactory nerve with a long-lasting barrage of EPSCs (duration >1s) and to the stimulation

of the BF axons with a slow IPSC (decay 195±50 ms). Thus, the results identify a specific subtype of type 2 PG cells as the selective target of GABA and ACh inputs from the BF.

Title: Protein kinase inhibitor beta may be a specific marker for mitral cells in the olfactory bulb

Authors: A. KOLDAEVA[1], C. ZHANG[1], S. TAKAHASHI[2], H. MATSUNAMI[3], *I. FUKUNAGA[1];
[1]OIST Grad. Sch., Tancha, Onna, Japan; [2]Univ. of Tsukuba, Ibaraki, Tsukuba, Japan; [3]Howard Hughes Med. Inst. - Duke Univ., Durham, NC

Abstract: In many sensory systems, streams of information processing become segregated even at early stages. In investigating what information is conveyed and how distinct streams are used to guide behavior, molecular markers for distinct cell types are often indispensable. In the olfactory system, the information stream is thought to first segregate in the olfactory bulb (OB) into at least two streams, conveyed by mitral and tufted cells (MCs and TCs). These two neuron classes differ in anatomical and physiological properties, thus suggestive of unique gene expression patterns. MCs and TCs are likely to play distinct roles, but no specific driver mouse line for MCs exists yet. Here we took advantage of recent advances in single cell expression profiling to search for a marker that distinguishes MCs from TCs. We obtained the expression patterns of mouse OB neurons from a publicly available single-cell RNAseq data (Zeisel et al., 2018). To identify a potential mitral cell marker, we searched for a gene that is expressed reliably by MCs, but not TCs. We defined a putative MC cluster to be one that expresses Tbx21, but has the lowest CCK expression levels. Of the 10,745 OB cells analyzed, 1,682 cells expressed CCK and 47 cells expressed Tbx21, with some overlap between two populations. The CCK expressing cells constitute a large cluster among the OB cell population with sub-clusters, some of which may correspond to distinct types of TCs. We found no clear candidate marker that distinguishes these sub-clusters. On the other hand, we found 66 genes that are more abundant in the putative MC cluster. Of the candidate genes, we found that protein kinase inhibitor beta (Pkib) may be a specific marker for MCs. Using a threshold (7 counts), we found that Pkib is expressed in 72% of the putative MCs, and in 0% of the putative TCs. Immunohistochemistry and in-situ hybridization for Pkib confirm that, indeed, Pkib is present densely in the majority of cells in the

MC layer, but only at low levels or not at all among cells in other layers. We have generated a knock-in mouse where IRES-Cre is inserted immediately after Pkib open reading frame, and are currently testing its suitability as a mouse line for investigating unique contributions that MCs make in olfactory processing.

Title: Flexible categorization in the mouse olfactory bulb

Authors: *E. KUDRYAVITSKAYA, E. MAROM, D. PASH, A. MIZRAHI;
Dept. of Neurobio., The Edmond and Lily Safra Ctr. For Brain Sci. (ELSC), The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Categorical perception is a canonical feature of sensory systems. In earlier studies of category perception learning, distinguishable objects on each side of the category boundary are often treated as the same. In real life, however, even when we spontaneously group two items into the same category, we do not necessarily treat them as identical for all purposes. In our study, we tested the impact of learning on category formation in the mouse OB. We first examined how odour category is represented in the mouse OB using two-photon calcium imaging of Mitral Cells (MCs) in head-fixed awake mice. We imaged MCs responses to morphed monomolecular odours Ethyl Butyrate (EB) into Ethyl Tailgate (ET), through a series of intermediate mixtures (100/0, 90/10, 80/20, 20/80, 10/90, 0/100). We show that in naïve mice OB, MCs respond naturally in a categorical manner by grouping morphed odour stimuli based on the relative stimulus strength. MCs activity pattern changed abruptly with the morphing from one odour to another, consistent with known literature.
We next investigated wherever neurons in the OB could encode category information in a flexible way, could previously grouped stimuli be learned apart, and can primary category responses be changed with task demands. To answer these questions, we challenged mice with two learning tasks that use the same odours in different categorical logic. 1. An easy, 1-descision boundary task where animals learned to classify binary odour mixtures in two groups according to the dominant component in the mixture. 2. A hard task with multiple decision boundaries intermingled along the space of binary odour mixtures. We show that mice were able to learn

both tasks with the high accuracy and also switch between the tasks. Moreover, our data shows that odor representations by MCs are flexible, switching between the two different categorical schemes. Specifically, when mice were engaged in the 1-descision boundary task, MC odour responses reflected the perceptual boundary. This sharp 2-category transition was completely abolished in the multi boundary task and new task specific boundaries were formed instead. Our data thus underscores that categorical representation of odours in the mouse OB is dynamic and can be reorganized following learning.

Abstract: The characterization of population dynamics in mammalian sensory and motor circuits at single spike resolution has been challenging due to the discrepancy between the laminar, stratified architecture of neuronal networks and the axial arrangement in electrophysiological probes providing sufficiently large numbers of recording sites. To address this problem, here we used CHIME (CMOS hosted in-vivo microelectrodes), a technique allowing high signal-to-noise, parallel recordings from 100s-1000s of electrical recording sites over large areas at sub-millisecond time resolution to record population activity from distributed

populations of principal cells in the mouse main olfactory bulb. High signal-to-noise ratio (<10μV noise floor) was achieved due to the high conductivity of core metals in glass-ensheathed microwires allowing for the realization of ultrathin metal cores (down to <1 um) and negligible stray capacitance. The metal recording sites were electrodeposited with gold and IrOx to maximize the specific recording area. This enabled ultra-low access impedance with a geometric recording area of 1-2 μm. Damage to the blood-brain-barrier upon insertion was found to be minimal by post-hoc histology. Our results show that combining microwire bundles and CMOS arrays allows for a highly scalable neuronal recording approach, which addresses the need for application-specific electrode site arrangement as well as the mismatch between the three-dimensional architecture of the brain and largely two-dimensional microfabrication techniques.

Title: Hebbian model of the structural plasticity in the olfactory bulb

Authors: J. H. MENG[1], S. SAHA[2], K. SAILOR[2], P.-M. LLEDO[2], *H. RIECKE[1];
[1]Applied Mathematics, Northwestern Univ., Evanston, IL; [2]Lab. for Perception and Memory, Pasteur Inst., Paris, France

Abstract: How animals can learn to discriminate between different sensory stimuli, e.g. similar odors, is an intriguing question. In rodents, the olfactory bulb, which is the first brain area to receive sensory input from the nose, exhibits structural synaptic plasticity even in adult animals: reciprocal connections between excitatory mitral cells and inhibitory granule cells are persistently formed and eliminated. Here we present a Hebbian-type model to understand how this synaptic structural plasticity can contribute to the learning of discrimination tasks by enhancing differences between representations of similar odors.Recent work on spine fluctuations has shown that the experimentally observed age-dependence of spine stability can arise from a Hebbian mechanism that stabilizes synapses connecting strongly active cells [1]. Further, spine dynamics in the olfactory bulb is correlated with the activity of pre-synaptic mitral cells and post-synaptic granule cells [2, 3]. Based on these experiments, we assume that synaptic structural plasticity follows Hebbian-type rules: co-activation of a mitral and granule cell pair leads to the formation of a synapse connecting them; if the mitral cell is highly active, but not the granule cell, the connecting synapse is removed; if the mitral cell activity is low, the synapse is unchanged. In addition, the total number of synapses of each granule cell is limited.Here we first show that our model can explain the striking experimental observation [4], that upon familiarizing the animal with a pair of very similar odors the difference between the bulbar representations of these odors is enhanced, while learning a pair of dissimilar odors reduces their differences. Correspondingly, the number of mitral cells that respond differently to the dissimilar odors decreases, but it stays the same for the similar odors. Second, the model quite generally leads to a bimodal distribution of granule cell activity, which is also seen in ongoing experiments. Third, our model predicts that the learned bulbar network structure will be remembered unless additional, interfering discrimination tasks are presented.

Title: Cholinergic modulation of local and top-down GABAergic inhibition in the olfactory bulb

Authors: P. S. VILLAR, *R. HU, R. C. ARANEDA;
Biol., Univ. of Maryland, College Park, MD

Abstract: Precise regulation of an extensive network of interneurons in the olfactory bulb is crucial to odor processing, with the largest population corresponding to granule cells (GCs). Regulation of GCs occurs by the cooperative action of local and top-down inputs to GCs that fine-tune the encoding of odor signals. Within the GC layer, local GABAergic neurons, the deep short-axon cells (dSACs), are thought to provide inhibition to distal processes of GCs suggesting they control dendritic excitability in CGs. We have previously shown that long-range GABAergic projections originating in the basal forebrain (BF) are a source of important inhibition to GCs, with an innervation pattern that suggests perisomatic inhibition of GCs. Despite the importance of these inhibitory mechanisms in GCs, little is known of their regulation. Interestingly, the distribution pattern of BF cholinergic and GABAergic fibers shows extensive overlap in the GC layer, suggesting that acetylcholine can regulate inhibition onto GCs. To explore this possibility, we examined the effect of muscarinic acetylcholine receptor (mAChRs) activation on spontaneous inhibitory currents in GCs (sIPSCs). Under resting conditions, GCs exhibit a low frequency of events (0.23 ± 0.05 Hz, n=29), with an average amplitude of 17.5 ± 1.8 pA. Bath application of the non-selective mAChRs agonist muscarine (Mus; 10 µM), produced a significant increase in sIPSC frequency (control, 0.25 ± 0.05 Hz; Mus, 0.39 ± 0.5 Hz; n=11, p=0.02), which we hypothesized occur by an increase in inhibitory inputs from dSACs. In agreement with this possibility, application of Mus depolarized dSACs, an effect that is abolished in the presence of a selective M3-mAChR antagonist (4-DAMP 100 nM) (Mus, $\Delta V = 5.7 \pm 1.1$ mV; Mus + 4-DAMP, $\Delta V = 0.3 \pm 0.5$ mV; n=4, p=0.03). Importantly, 4-DAMP blocked the increase in sIPSCs frequency in GCs elicited by Mus (Mus, 0.28 ± 0.07 Hz; Mus + 4-DAMP, 0.31 ± 0.08 Hz; n=7, p=0.2). To examine the cholinergic modulation of BF inhibition to GCs, we expressed channelrhodopsin in BF GABAergic neurons. In contrast to the muscarinic effect on local inhibition in GCs, activation of mAChRs reduced the amplitude of the optogenetically evoked IPSCs from GABAergic axons (control, 116 ± 7 pA; Mus, 25 ± 7 pA; n=4, p=0.0009). This reduction in amplitude was blocked by AFDX-385 (300 nM), an antagonist of M2/M4 mAChRs. These results indicate that the activation of the BF cholinergic neurons can locally regulate the inhibition of GCs. We propose that the selective activation of M2/M4 and M3 mAChRs can produce a shift in the weight of top-down perisomatic vs. local distal GABAergic inhibition in GCs.

Title: Dynamics of spike time encoding in the olfactory bulb

Authors: *J. C. WERTH, T. A. CLELAND;
Psychology, Cornell Univ., Ithaca, NY

Abstract: Gamma oscillations are generated within the earliest central circuits of the olfactory system, and reflect synchronized activity across ensembles of principal neurons, such as the mitral and tufted cells (collectively, MTCs) of the olfactory bulb. The regulation of spike timing in these neurons - particularly including the synchronization of spikes in activated ensembles - and the phases of these spikes with respect to the underlying gamma oscillations are potentially critical bases for neural information coding. Understanding the fundamental mechanisms underlying these phenomena is therefore essential for understanding the construction of olfactory representations. However, it remains unclear which aspects of this dynamical regulation of spike timing are important for odor encoding and olfactory bulb function, in part due to the limited capacity to control the intensity and timecourse of odor delivery on fine spatial and temporal scales.
We investigated the spike-timing properties of MTCs using an *in vitro* bulbar slice preparation mounted on a 120-channel planar multielectrode array (MEA), while delivering “artificial odor” stimuli using spatiotemporally patterned optogenetic stimulation. These “artificial odor” stimuli evoke persistent gamma oscillations in the local field potential and also narrow the phase constraint of MTC action potentials with respect to gamma. Individual MTCs varied considerably in their responses to stimulation; while the mean phase constraint across all recorded MTCs increased significantly, clearly some MTCs became strongly phase-locked while others were relatively unaffected. Importantly, the MTCs that became phase-locked to the gamma oscillation depended on which “artificial odor” was presented. We present and discuss several alternative metrics for the spike timing-dependent analysis of MTC activity.

Abstract: Olfactory information processing requires the coordinated activity of neuronal circuits in multiple brain regions, including the olfactory bulb and peduncle which represent the first stages of processing of olfactory sensory inputs. These circuits contain multiple cell types with functional roles defined by their morphology, connectivity, and gene expression. Although recent single cell transcriptome (scRNA-seq) analyses identified cell types in the olfactory bulb by their patterns of gene expression, it remains unclear how these patterns are established and regulated through development. Here, we integrated large-scale single-cell transcriptomic with epigenomic datasets to investigate the molecular signatures of neurons in the olfactory bulb and peduncle. The accessibility of chromatin and the methylation status of genomic cytosines (DNA methylation) can influence transcription factor binding, leading to functional changes in gene expression. The Center for Epigenomics of the Mouse Brain Atlas (CEMBA), a BRAIN-Initiative funded consortium of laboratories, has produced a dataset that includes single cell resolution profiles of DNA methylation (snmC-seq, >5,000 cells) and chromatin accessibility (snATAC-seq, >40,000 cells) in the olfactory bulb and peduncle. We used these data to identify cell types by their epigenomic landscape, including multiple distinct types of granule cells and periglomerular cells in the olfactory bulb, several types of peduncle-specific inhibitory neurons, and a broad variety of excitatory neuron types. By comparing gene body DNA methylation with gene expression, we verified that these cell types are consistent with those determined by recent single-cell transcriptomic atlases as reported in Tepe et al. (2018) Cell Reports and Zeisel et al. (2018) Cell. For each cell type, we identified putative gene regulatory elements (enhancers) by overlapping sites of low DNA methylation with regions of open chromatin. These regions contain DNA sequences recognized by transcription factors that regulate cell type identity in the olfactory bulb and peduncle. Using scRNA-seq datasets from the olfactory bulb and peduncle generated by the Comprehensive Center on Mouse Brain Cell Atlas at the Allen Institute for Brain Science, we found cell type specific expression of genes regulated by the predicted cell type specific enhancers. In this study we have produced the first epigenomic-based cell atlas of

neurons and identified key sites of regulation for cell type identity in two key sensory processing areas, the olfactory bulb and peduncle.

Title: A search for neural metrics of odor identity perception

Authors: *H. NAKAYAMA[1], D. RINBERG[2];
[1]NYU Langone Med. Ctr., New York, NY; [2]Neurosci. Inst., New York Univ., New York, NY

Abstract: In the mammalian olfactory bulb, stimulus information from individual olfactory sensory neurons is transmitted into anatomically localized structures called glomeruli. Odorants evoke stimulus-specific spatiotemporal patterns of glomerular activation. One of the central questions in sensory neuroscience is how similarities between patterns of neural activity is related to perceptual differences between sensory stimuli. Here, we propose potential metrics of the spatiotemporal patterns of glomerular activation and develop a behavioral paradigm to test perceptual odor similarities and their relationship to the neural metrics.
We performed wide-field calcium imaging of odor responses from a larger number of glomeruli at high temporal resolution (~100 glomeruli at 100 frames/sec). Since potential neuronal metrics for odor identity perception are supposed to be concentration-invariant, we compare different metrics based on the stability across odor concentration changes. We found that the rank order of response onset latencies of glomeruli is more stable than other neuronal metrics including mean or peak level of activations.
To assess the relevance of different metrics of glomerular activation odor percepts, we designed a novel odor generalization task for mice that allows us to measure perceptual similarities between odors. Mice were trained to discriminate a target odor from many non-target odors at variable concentrations. Subsequently, novel odors are presented, and their perceptual similarities to the target odor are evaluated based on the similarities in behavioral readouts. We find consistent changes between behaviors and some of neural metrics. Our approach for the

combination of neuronal and behavioral measurement of similarity enables systematic investigation and dissociation of potential neural codes for odor perception.

Title: Dynamic inhibition of mice olfactory bulb output by the anterior olfactory nucleus

Authors: R. MEDINACELI QUINTELA, L. WALLHORN, J. BAUER, ***M. ROTHERMEL**; RWTH Aachen Univ., Aachen, Germany

Abstract: The anterior olfactory nucleus (AON) is the most anterior part of the olfactory cortex. Its extensive connections to lower and higher brain centers render the AON an interesting model system. Here, we examined the effect of AON modulation on olfactory processing both on a cellular and a behavioral level in anesthetized and awake mice.
First, we tested for behavioral consequences of extrinsically modulating AON activity. Mice implanted with an optical fiber targeting ChR2-expressing AON neurons were trained to report the presence of odorants. Stimulated optically, without odorant presentation, these mice failed to lick showing that activation of AON neurons in awake animals was probably not perceived as an odorant equivalent cue. AON activation during odorant presentation however, reliably suppressed odor detection. This AON mediated effect was constant across odors and concentrations. Testing different optical stimulation durations revealed that the AON modulates odor detection on a fast timescale.
In order to shed light on potential mechanisms, we next investigated if top-down projections from the AON modulate olfactory bulb (OB) output neuron activity using electrophysiological recordings in anesthetized mice. Optogenetic activation of AON axon terminals in the OB led to a significant decrease in odor evoked mitral/tufted (MT) cell spiking. The population time course showed a fast reduction of MT cell activity during light stimulation that was followed by a long lasting increase, reminiscent of OB offset responses. AON stimulation effects were independent of the strength and polarity of the odorant response and were observed across a variety of odors. Averaged normalized sniff-triggered spike histograms showed a decrease in both baseline and peak spike rate, consistent with an AON mediated effect on odor sensitivity rather than an influence on signal-to-noise ratio.

Taken together, the strong inhibition of MT cell activity observed during electrophysiological recordings might explain the suppression of odor detection observed in the behavioral experiments. These results support the hypothesis that the AON acts as a strong source of top-down input to the OB. Future experiments will focus on studying the effects of light-driven AON inhibition on OB output.

Col. London, London, United Kingdom

Abstract: Determining the spatial organization of odorant receptor (OR) gene expression in the mouse olfactory bulb (OB) can reveal important insights into OB subdomain structure, define neighbor relationships among glomeruli, and characterize odorant-OR interactions *in vivo*. However, only a few glomeruli have been genetically identified thus far. Here, we use Spatial Transcriptomics (ST) to develop a comprehensive map of glomerular identity in the OB. Spatial Transcriptomics provides visualization and quantification of gene expression in individual histological sections of tissue. mRNA capture probes with spatial barcodes are printed in spots on a glass slide and sections of OB tissue are placed on the printed microarrays. mRNA from the tissue is captured by the barcoded probes and sequenced. This sequence information is then aligned with the printed spots, resulting in a spatial map of gene expression in the tissue. Here, we will present preliminary data that validate ST as capable of accurately and precisely determining the identity of GFP-tagged glomeruli in OB sections of transgenic mice. We will also present ST arrays with improved spatial resolution and show that improved specificity of OR detection can be obtained by using degenerate OR capture probes. Finally, our preliminary

results show that, by performing ST on all sections of the OB, we are able to construct a three-dimensional map of gene expression and glomerular identity.

Abstract: Most sensory systems are topographically organized, where sensory neurons and projections are spatially arranged, and their functional properties systemically vary with their spatial position. By contrast, in the olfactory system, neurons and connections exhibit a spatially scattered and disordered pattern, which supports the generalization that functional similarities and positions in the olfactory system are not associated with each other. However, in the olfactory bulb (OB), mitral and tufted cells receive input from sensory neurons through glomeruli, which converge on axons of olfactory receptor neurons expressing the same receptors, to form a spatially arranged glomerular map on the surface of the OB. Whether the position of neurons in the OB conveys functional information and/or contributes to the odor coding remains unknown. In order to gain insights into OB spatial properties, we implanted 16-channel multi-electrode arrays to the ventral mitral cell layer along the anterior-posterior axis of the mouse OB.

A wide-area of neural population activity was recorded in head-fixed awake mice while eight monomolecular odorants were presented. Decoding analyses revealed that odors were represented with diverse odor-dependent spatial patterns across the OB. Some odors were accurately decoded within a specific local region while others required the involvement of broad regions. The data and the associated analysis support the idea that spatial positions of neurons in the OB may be associated with their function in encoding odor identity.

Title: MCHR1 localizes to primary cilia of olfactory bulb granule cells and modulates glomerular responses to odors

Authors: *K. R. JASSO[1], J. M. ROSS[2], H. KULAGA[4], M. L. FLETCHER[3], R. R. REED[5], J. C. MCINTYRE[1];
[1]Neurosci., Univ. of Florida, Gainesville, FL; [2]Anat. and Neurobio., [3]Anat. & Neurobio., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN; [4]Johns Hopkins Univ., Baltimore, FL; [5]Dept Molec Biol & Genet., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Sensory perception relies on the detection of external stimuli, but is dependent on modulation of the involved cells from periphery to brain. This process allows stimulus detection to match the demands of an organisms metabolic and hormonal states. Olfactory sensory neurons send axons that innervate the olfactory bulb (OB) where they transmit information about environment odors. Centrifugal innervation of the OB from several brain regions modulates this process, altering responses to odors. An area that has received limited research is hypothalamic modulation of signaling in the OB although hypothalamic neuronal populations, including melanin-concentrating hormone receptor (MCH) neurons, innervate the OB. MCH is known to regulate several olfactory-related behaviors, such as food finding and mating. In rodents there is a single MCH receptor, MCHR1, which is enriched in neuronal primary cilia. Cilia are

evolutionarily conserved organelle that functions as a signaling center projecting from nearly every cell type. While ciliary signaling is critical for neuronal development, the role of primary cilia in regulation of neuronal function, or neuromodulation, is less clear. A detailed anatomical understanding of MCHR1 expression in the OB is required to elucidate its potential modulatory effects on olfactory signaling. Using antibody labeling, we find that MCHR1 localizes to cilia of interneurons in the granule cell and glomerular layers. To further confirm this, and generate a potential tool for future studies, we used CRISPR/CAS9 to fuse mCherry to the n-terminus of MCHR1 (mCherry:MCHR1). Expression of mCherry:MCHR1 matches that of endogenous MCHR1, localizing to the primary cilium of granule cells and a subset of periglomerular cells. MCHR1, and mCherry:MCHR1, is not detected in the primary cilia of mitral cells, the primary output neurons of the olfactory bulb. To test the neuromodulatory role of MCHR1 in olfactory signaling, we have performed functional imaging experiments of the OB in response to odorant stimulation. Using epifluorescence imaging, we find that glomerular responses are enhanced following administration of an MCHR1 antagonist, SNAP-94847, ($t(157) = 5.425$, $p < 0.0001$) while application of MCH decreases glomerular responses ($t(99) = 10.98$, $p < 0.0001$). Together these data suggest that MCH/MCHR1 signaling contributes to modulation of olfactory function. Furthermore, our newly generated mouse line will aid in studying the role of MCHR1 in other brain regions and will aid in determining the importance of ciliary localization in modulating neuronal function.

Abstract: The logic of neural processes is encoded by physiological events mediated by nm-sized synapses that are distributed across mm-scale volumes of brain tissue. Therefore, a holistic approach bridging those temporal and spatial gaps is required in order to obtain a mechanistic understanding of brain function.
Here we describe a correlative experiment that involves *in vivo* physiology, rapid, high-resolution synchrotron X-ray tomography (SR-CT) and serial block-face volume electron microscopy (EM) to study neural computation in the first processing stage of the mammalian olfactory sensory system: the glomerular columns in the olfactory bulb (OB).
The projection neurons of the OB have a several µm-thick apical dendrite reaching into the glomerulus that defines the neuron's input signal. Their cytoplasm incorporates heavy metals poorly compared to the immediate neighbouring tissue, allowing to trace and resolve dendrites in near-micron-resolution histological datasets. This structural signature could be retrieved from neurons with known physiology by using a correlative *in vivo* - to - SR-CT - to - EM approach: We presented an array of 48 odours *in vivo* while recording the activity of a neuronal population of interest, surrounding a genetically-identified glomerulus, using volume 2-photon microscopy. Then, that same circuit was dissected, landmarks recorded and the tissue was stained with heavy metals. At this point, SR-CT could deliver datasets in which projection neuron apical dendrites could already be traced across 3*3*0.6 mm-sized samples, providing key contextual information of the underlying neural circuit. Finally, these samples were trimmed down to ~1mm^3 cubes so targeted regions could be imaged at nm resolution with EM. We show that consecutive imaging with these techniques is possible and can be conducted efficiently.
Combining SR-CT with volume EM holds significant promise for the wider systems neuroscience research. Here, we report biologically-relevant features in other brain areas that can be resolved by this technique: axon bundles in the striatum and CA1 pyramidal neuron apical dendrites in the hippocampus. With several synchrotron sources across the world being upgraded to provide higher flux and increased number of beamlines for biological imaging, SR-CT can become a tool to bridge scales for neuroscience research in a routine manner.
Altogether, we present an efficient correlative workflow that allows interrogating a neural circuit of interest from both the functional and ultrastructural level, bridging volume *in vivo* physiology of hundreds of neurons, sub-µm histology across several mm^3 and volume ultrastructure at the nm scale.

Title: Functional role of NRG1/ErbB4 signaling in odor discrimination

Authors: *Z. TAN[1], Y. LIU[1], F. LIU[3], W. XIONG[1], L. MEI[2];
[2]Dept. of Neurosci., [1]Case Western Reserve Univ., Cleveland, OH; [3]DNRM, Augusta Univ., Augusta, GA

Abstract: ErbB4 and its receptor neuregulin-1 (NRG1) are both risk genes of schizophrenia and major depression disorder. The NRG1/ErbB4 signaling has been implicated in neural development, GABA release regulation, and synaptic plasticity. Mutation of either NRG1 or ErbB4 leads to behavioral deficits that are associated with schizophrenia. Schizophrenia patients also show olfactory system syndromes. Here we show that ErbB4 is highly expressed in olfactory bulb (OB), in particular in GABAergic neurons that are not positive for parvalbumin, calretinin, calbindin, and tyrosine hydroxylase. The ErbB4+ neurons in the OB can be classified into three distinct groups, each with unique electrophysiological properties, integrated into different local circuits and potentially have distinct functions. Group1 neurons receive direct input from olfactory sensory neuron (OSN); Group2 neurons receive input from external tufted cell; and Group3 neurons do not receive direct input from OSN. Projection neurons (mitral and tuft cell) in the OB receive direct input from ErbB4+ cells. Importantly, NRG1 increases GABA release onto mitral cells, which might be a mechanism of impaired odor discrimination of Erbb4-/- mice. Thus, NRG1/ErbB4 signaling modulates GABA release in the OB, which is critical for odor discrimination.

Abstract: Oscillatory synchrony and temporal coding are prominent features of olfactory processing: information about olfactory stimuli is encoded by populations of transiently synchronized neurons whose identities progressively change across oscillation cycles. We found that responses of olfactory receptor neurons (ORNs) in the locust are more complex than previously documented. ORNs respond to odor stimuli with multiple distinct response types (i.e., onset responding, offset responding, and inhibitory). Further, each response type undergoes a different form of sensory adaptation, with onset responses decreasing, and offset responses increasing, during high frequency or lengthy odor pulses. During natural plume-like stimuli, odor filaments arrive at the animal with varying frequencies and durations. Using computational models of an ORN array implementing different receptor types with properties tuned to match those recorded *in vivo*, we found that the variety of the ORN response types and adaptation properties substantially improve classification performance for plume-like stimuli. We further examined how information from the ORN array interacts with a well-characterized mechanism of plasticity in the antennal lobe (AL): fast odor learning mediated by progressive buildup of stimulus specific synaptic inhibition. We found that distinct ORN response types are critical for orchestrating complex temporal patterning across the population of AL neurons, and that fast odor learning in the AL is required for the maintenance of robust temporal coding during plume-like stimuli. Our study predicts that a combination of receptor adaptation at the periphery and inhibitory facilitation in the AL formats olfactory information into an efficient — complex and robust — spatiotemporal code.

Abstract: Establishing causal links between patterns of neuronal activity and perception is crucial for understanding brain function. The mouse olfactory system is emerging as an ideal model for investigating spatiotemporal neuronal coding, given its ease of access for recording and manipulation, as well as its behavioral relevance for the animal. Recent studies have revealed that fine temporal scales are essential to olfactory information processing, but it is unknown which precise features of this code are behaviorally accessible. Recently, we developed a system for simultaneous large-scale 2-photon calcium imaging and holographic optogenetic stimulation in the olfactory bulb of awake, behaving mice, permitting recording and manipulation of groups of neurons at cellular and single action potential resolution, with millisecond precision. With this system we have measured odor-evoked activity in broad populations of mitral and tufted cells (MTCs), the projection neurons of the olfactory bulb, as well as interneurons and demonstrated the use of this system for closed-loop optogenetic feedback, mimicking natural, stimulus-evoked activity temporally patterned across an intrinsic biological rhythm (respiration). We performed a series of theory-driven experiments to establish the basic rules of MTC code readability by higher brain areas. Specifically, we ask what features of spatiotemporal neuronal activity in the olfactory bulb are *detectable* and *discriminable* by downstream circuits to guide behavior. We found that mice can detect single action potentials evoked synchronously across <20 olfactory bulb neurons, while ruling out detection of indirect effects using a novel optical sham-photostimulation technique. Additional experiments explored how this sensitivity changes as a function of synchrony, respiration phase, cell type and the odor tuning of targeted neurons. Finally, we characterized the effects of rapid and longer-term plasticity induced by cellular stimulation and behavioral training on network activity.

Title: Optophysiological mapping of synaptic inputs to adult-born granule cells in the olfactory bulb

Authors: *J. L. WALLACE[1], J. D. ZAK[2], V. N. MURTHY[3];
[1]Mol. and Cell. Biol., [2]Mol. & Cell. Biol., [3]Harvard Univ., Cambridge, MA

Abstract: New neurons appear only in a few regions of the adult mammalian brain and form synapses with preexisting cells to become integrated into functioning circuits. Adult neurogenesis is abundant in the rodent olfactory bulb (OB), where new neurons assume the identity of inhibitory interneurons, including granule cells. Adult-born granule cells (abGCs) receive feedforward inputs from both the principal cells of the OB (mitral and tufted cells) as well as feedback synapses from olfactory cortex. However, it is still unclear how these synapses are formed and refined in an input-specific manner to contribute to the functional activity of these cells *in vivo*, which we recently characterized (Neuron 96:883). By expressing channelrhodopsin in either feedforward or feedback inputs to abGCs in OB slices, we now describe the pattern of synaptic development and refinement of these inputs and relate this to action potential output in abGCs. We find that feedback inputs develop early, and there is no significant change in the amplitude of optogenetically-evoked minimal excitatory postsynaptic potentials or the estimated number of fibers converging onto single abGCs over development. Furthermore, activation of these inputs can already evoke action potentials in young abGCs (7-10 days after viral labeling of migrating neuroblasts). Functional feedforward inputs can also be detected in some cells at this stage and we are currently characterizing their spatial extent using patterned illumination with single-glomerulus resolution. These experiments will uncover the time course of development of different synaptic inputs to abGCs under normal conditions and under controlled perturbations.

Title: Active sampling optimizes processing of fluctuations in odor concentration

Authors: A. PARABUCKI[1], A. BIZER[2], ***R. SHUSTERMAN**[3];
[1]Neurobio., Weizmann Inst. of Sci., Rehovot, Israel; [2]Univ. of Haifa, Haifa, Israel; [3]Inst. of Neurosci., Univ. of Oregon, Eugene, OR

Abstract: We actively shape our sensory input through our sampling behavior. Further, we adjust our sampling behavior to *optimally* sample an area or object of interest. However, the benefit of this flexibility in sampling behavior is unknown - does it facilitate sensory processing? In olfaction animals control sniff rate: in rodents, sniffing varies between 2 to 10 Hz. However, how modulating sniff rate benefits neural processing is not known.
Increases in sniff rate are especially prominent during odor tracking tasks. Odor tracking entails sampling and comparing odor concentrations across various points in space and time. Consequently, to track odors animals should have an ability to compare odor concentrations across sequential sniffs (hereafter referred to as ΔC_t). Our recent work has revealed that ΔC_t representation begins in the OB. A subset of mitral/tufted cells (MTCs), the projection neurons of the OB, respond to odor concentrations in a history-dependent manner (Parabucki et al., 2019).
Here we show that fast sniffing improves ΔC_t processing in the olfactory system. Sniff rate strongly affects the processing of time-varying input, enhancing the contrast between concentrations. When we present identical concentration on two consecutive cycles, the odor information acquired during the second sniff cycle is redundant and therefore it is filtered out during fast sampling. Further, we predict that faster sniffing will improve the behavioral perception of ΔC_t.

Title: Phase referenced LFP power carries information on odor identity in proficient animals in the olfactory bulb

Authors: *J. LOSACCO, D. RESTREPO;
Cell & Dev. Biology, Neurosci. Program, Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: The accurate perception of odor identity can influence everything from quality of life to survival itself. The local field potential (LFP) in olfactory bulb (OB) represents a loose gestalt of the odor in terms of incoming sensory signal as well as top-down modulation of the odor's representation.
We studied the LFP in awake, behaving mice performing the go no-go odor discrimination task where the thirsty mouse learns to respond to the rewarded stimulus to obtain a water reward. In the past it was shown that single unit neural activity and LFPs measured in the OB carry information necessary to differentiate odorants. Here we studied whether aligning the LFP power to the phase of the theta oscillations makes a difference in the ability to predict odor identity. We used a Hilbert transform to obtain the phase of theta oscillations and wavelet analysis to quantify the power of high frequency oscillations. In addition, we used phase amplitude coupling (PAC) analysis to assay changes in the strength of coupling of high frequency bursts with theta oscillations. High frequency/theta PAC has been shown to occur for oscillations in the OB (Rojas-Libano et al., 2014).
We found that as the animal learns to differentiate the odorants the variance of the peak theta angle for bursts increases for the unrewarded odorant. We then determined the proficiency of prediction of the odorant using linear discriminant analysis (LDA) using the LFP power referenced to either the peak or the trough of the mean amplitude distribution over theta phase. We find that LDA for peak-referenced LFP power predicts the odorant when the animal is proficient for odorant discrimination. Prediction is closer to shuffled control when the animal is naïve, or when the LDA is performed with the trough-referenced LFP power.

Abstract: Although mice can navigate and locate resources using turbulent airborne odor plumes how they achieve this is poorly understood. One of the main challenges for animals navigating in these regimes is the intermittent contact with odor stimuli in a fluctuating plume. Population activity at the glomerular level is thought to help process this complex spatial and temporal information and create representations that can be used for effective navigation and source localization. However, how varying levels of intermittency impact odor representation in the first stages of the mouse olfactory system is not known. Using a miniaturized odor sensor combined with wide field calcium imaging techniques in head-fixed mice we precisely tracked plume dynamics and investigated glomerular response profiles in response to this fluctuating input. We found multiple distinct representations of intermittent plumes in the olfactory bulb, with some glomeruli reliably signaling intermittent plume contact at short timescales (seconds) and others signaling over longer time courses (tens of seconds). We will discuss how these results apply to navigation across a variety of odor landscapes and present data connecting intermittency-based processing to the physics of odor transport within a variety of environments that mice encounter during natural foraging behaviors.

Title: The olfactory bulb contributes to the accommodation of odor responses: The input-output transformation

Authors: *D. A. STORACE[1], L. B. COHEN[2];
[1]Florida State Univ., Tallahassee, FL; [2]KIST Ctr. for Functional Connectomics, Yale Univ. Dept. of Cell. and Mol. Physiol., New Haven, CT

Abstract: Humans and other animals exhibit adaptation to odorants. It remains unclear whether the olfactory bulb, the brain structure that mediates the first stage of olfactory information processing, participates in generating this perceptual adaptation. Olfactory bulb glomeruli are regions of neuropil that contain input and output processes; olfactory receptor neuron nerve terminals (input) and mitral/tufted cell apical dendrites (output). Differences between the input and output of a brain region define the function(s) carried out by that region. We compared the activity signals from the input and output to repeated odor stimulation across a range of odorant concentrations. Repeated odor stimulation of the same concentration resulted in a decline in the output maps, while the input remained relatively stable. These results suggest that the mammalian olfactory bulb may also participate in the perception of adaptation. This approach was previously used to show that the bulb contributed to the perception of concentration invariance of odor recognition and should be useful for understanding the role of the olfactory bulb in additional olfactory perceptions.

Title: Estrogen regulates olfactory glomerular development and neuronal activity of the olfactory bulb via specific glial progenitor cells

Authors: *A. TAKESONO, P. SCHIRRMACHER, M. J. WINTER, A. SCOTT, J. M. GREEN, O. LEE, H. WAI, T. KUDOH, C. R. TYLER;
CLES, Biosci., Univ. of Exeter, Exeter, United Kingdom

Abstract: In vertebrates, estrogen plays critical roles in the development and function of neurons in the developing brain, however, the precise cellular mechanisms promoting these functions are unclear. Employing the use of the Ca^{++} sensor transgenic zebrafish line, elavl3:GCaMP6s, we found that estrogen signalling has a crucial role in regulating neuronal activity in the olfactory

bulb (OBs). We show that estrogen suppresses intrinsic neuronal activity in regions of the anterior forebrain, notably in the olfactory bulb (OB), and conversely an estrogen receptor antagonist hyper-activates this neuronal activity during embryo development. Using an ERE:GFP transgenic zebrafish line we show that estrogen responsive cells in the brain of embryo-larvae predominantly occur in the OBs suggesting these cells (we have named estrogen-responding olfactory bulb/EROB cells) may regulate OB neuronal activity. Interestingly, EROB cells are not neurons but a type of glial progenitor cell. Ablation of the EROB cells supresses the estrogen-mediated neuronal inhibition in the OB and also impedes OB glomerular development. This occurs through a failure to establish terminal connections between olfactory sensory neurons and the OB glomeruli. We further show that altering estrogen activity during embryogenesis disrupts the olfaction-mediated avoidance response in later larval stages. Our findings thus reveal a novel mechanism in which estrogen regulates neuronal development and activity through specific glial progenitor EROB cells in the OB.

Title: Contextual changes of olfactory bulb dynamics by cortical inputs

Authors: *C. L. LINSTER[1], L. M. KAY[2];
[1]Neurobio. and Behavior, Cornell Univ., Ithaca, NY; [2]Dept. of Psychology, The Univ. of Chicago, Chicago, IL

Abstract: Olfactory bulb networks integrate sensory information conveyed by sensory neurons with “internal” information conveyed by cortical and neuromodulatory areas. The role of neuromodulatory inputs to the OB has been widely studied experimentally and computationally and coherent ideas about their function exist. In contrast, information conveyed by cortical areas to the OB is sparse but increasing due to new experimental techniques. We here use our fully developed OB-cortex model to systematically investigate the computational impact of cortical to bulbar projections. We include known details of this projection such as target neurons, transmitter released and receptors and investigate unknown parameters such as the distribution of these projections, ratios of inputs to different cell types, timing of inputs with respect to bulbar

dynamics. Our model shows that cortical inputs can have strong effects on bulbar signal to noise ratio, bulbar dynamics and bulbar odor representations. These effects depend strongly on cortical dynamics and activation, with cortex receiving olfactory as well as contextual inputs. We specifically show that beta-range dynamics can be generated in the PC due to intrinsic pyramidal cell properties: cortical feedback to OB interneurons can then entrain bulbar dynamics in the beta range. Interestingly beta range dynamics in the PC depend on feedback interactions between pyramidal cells, assumed to be strengthened during olfactory learning. As a consequence, beta oscillations in the PC and OB emerge during learning and are dependent on cortical feedback projections to the OB, as shown experimentally by Martin and Ravel (2004). Our modeling suggests a locus for beta range dynamics in the PC, imposed on OB by feedback projections, whereas gamma range dynamics would be based in OB and imposed onto PC.

Title: Elaborating the role of olfactory bulb granule cell excitation in gating beta oscillations

Authors: *Z. ZHENG[1], *L. M. KAY[2];
[1]Inst. for Mind and Biol., [2]Dept. of Psychology & Inst. for Mind and Biol., Univ. of Chicago, Chicago, IL

Abstract: The local field potential (LFP) of the rat olfactory bulb (OB) exhibits two distinct regimes of oscillations associated with different physiological and behavioral contexts. Gamma oscillations (40-100Hz) are associated with either odor sniffing (65-100Hz) or alert immobility (40-65Hz), and beta oscillations (15-30Hz) occur after learning and odor sensitization. Previous modeling and experimental work suggests that gamma oscillations arise from the local dendrodendritic synaptic interaction between the excitatory mitral cells (MCs) and inhibitory granule cells (GCs). However, beta oscillations require intact top down inputs to enhance GC excitability but are also generated at the dendrodendritic synapse. In particular, increasing GC excitability prolongs the activation of the NMDA receptors and voltage dependent calcium channels (VDCCs), which can mediate graded inhibition at the beta frequency because of their slow decay time constants. Our current, more detailed, model investigates specific processes (at different levels of abstraction) that regulate GC excitability to show their differential impacts on

the network oscillation. The model contains single compartment MCs receiving external input, and two-compartment GCs, which can receive cholinergic modulation or input from the piriform cortex (PC) as the top down input. The PC current is modeled either as constant, sinusoidal, or Poisson. The model suggests two distinct regimes within the beta band, high (25-30Hz) and low (20-25Hz), attained by different processes and/or modifications to the parameters. Not all means of increasing excitation lead to the most observed 20 Hz beta oscillation. Increasing excitation on GCs initially produces high power in low gamma frequency but eventually drives the network to oscillate in the high beta frequency range, unable to produce the low beta. Sinusoidal PC currents or a Poisson PC synaptic current with a sinusoidal firing rate, by contrast, can entrain the LFP, provided the driving frequency is in the beta-low gamma range, which is consistent with the experimental result that the LFPs of PC and OB have high coherence in the beta-low gamma but not in the high gamma range. Finally, ACh modulation can also slow down the network and produce 20Hz oscillation.

Title: Effects of olfactory bulb dynamics on cortical odor responses

Authors: *O. D. ESCANILLA[1], K. MAMA[1], M. EINHORN[2], T. A. CLELAND[2], C. LINSTER[3];
[2]Psychology, [3]CPL & Neurobio. and Behavior, [1]Cornell Univ., Ithaca, NY

Abstract: Olfactory bulb (OB) networks integrate afferent information conveyed by sensory neurons with “internal” information conveyed by cortical and neuromodulatory areas. The roles of neuromodulatory inputs to the OB have been widely studied, both experimentally and computationally, yielding clear proposals about their respective functions. Our computational modeling studies suggest a strong influence of bulbar dynamics and spike synchronization on cortical odor responses and dynamics. Behavioral data have shown that changes in bulbar processing evoked by manipulating bulbar neuromodulatory activity affect olfactory memory acquisition, specificity and duration. Modeling work has suggested that the loci of some of these memories are in brain areas receiving direct input from the OB. We here test these hypotheses by

recording electrical field potentials in the OB as well as unit activity in the piriform cortex (PC) while locally manipulating olfactory bulb neuromodulatory activity in awake, behaving rats. Rats were tested in a custom-designed cage equipped with pressure sensors and olfactometer inputs enabling the recording of respiratory activity and precise odor delivery without the need for prior behavioral conditioning. We recorded OB and PC activity in response to odor presentations while locally infusing cholinergic, noradrenergic and serotonergic agonists and antagonists. We observed changes in OB field potentials reflecting changes in spike synchrony and oscillatory dynamics, and correlate these with changes in PC spike responses. For example, when cholinergic tone in the OB is increased by infusing neostigmine, cortical odor responses increase in frequency. We then incorporate this information into the computational model to investigate how changes in OB dynamics and cortical responses modulate odor learning and to make detailed behavioral predictions.

Title: The logic of olfactory bulb outputs revealed by high-throughput single-neuron projection mapping using sequencing

Authors: *Y. CHEN[1], X. CHEN[1], J. M. KEBSCHULL[1], A. NARASIMHAN[1], A. KOULAKOV[2], A. M. ZADOR[3], D. F. ALBEANU[1];

Abstract: The olfactory bulb relays information about odor objects represented by olfactory sensory neurons through its output neurons, the mitral and tufted (M/T) cells, to higher brain areas. These areas have been proposed to perform distinct functions ranging from odor detection and localization, guiding spatial navigation to odor identification and innate, or learned, stimulus value assignment. Understanding the logic of information flow from the bulb to the rest of the brain is crucial for unraveling the computations performed by olfactory circuits.
Current state-of-the-art microscopy-based neuroanatomy is limited in throughput, and therefore difficult to scale up for robust statistical analysis of neuronal projections at cellular resolution.

Using MAPseq, a novel high-throughput method for mapping single-neuron projections via barcode sequencing, we investigated the single-cell projection patterns of 2,250 mitral and tufted cells (5 mice) on both the dorsal and ventral surface of the olfactory bulb. Our data recapitulate the distributed, but distinct projection patterns of mitral and respectively tufted cells cells previously observed using single-neuron tracing. Furthermore, we identified structured modules of projections from mitral cells to distinct domains along the anterior-posterior axis of the piriform cortex. These modular structures contained well-defined collaterals to non-piriform areas, and were reproducible across animals. Currently, we are further validating the projection patterns observed by single-neuron tracing using oblique light sheet microscopy. Our results indicate that information flows from the bulb to higher brain areas in a structured, non-random fashion.

Title: MTK analysis of interactions between crista junctions in "tethered" and "untethered" regions of mitochondria in the subcuticular plate region of type I vestibular hair cells

Authors: N. LABAN[1], A. KAMBALYAL[2], R. BAHARI[1], G. PERKINS[4], ***A. LYSAKOWSKI**[3];
[1]Dept. of Biol., [2]Dept. of Econ., [3]Dept. of Anat. and Cell Biol., Univ. of Illinois at Chicago, Chicago, IL; [4]NCMIR, Univ. of California at San Diego, San Diego, CA

Abstract: Cytoskeletal tethers connecting mitochondria to other organelles such as the endoplasmic reticulum have been well studied and are known to have an important role in molecule and ion transport (Pernice et al., 2018). However, the existence and function of tethers connecting mitochondria to other mitochondria are not as widely confirmed. We have observed such tethers in mitochondria bordering the stereociliar rootlets of a type 1 vestibular hair cell. These mitochondria were three-dimensionally reconstructed using electron microscope tomographic images and the 3D modelling program, IMOD (Kremer et al., 1996). The tomograms and models show a collection of mitochondria whose lamellar cristae are aligned forming what seems to be a mega-mitochondrial structure. Tethers were observed in some neighboring regions between these mitochondria and absent in others. Using the MTK function

of IMOD, a proximity nearest neighbor analysis was conducted to examine the relationship of neighboring crista junction pairs that were separated by two outer mitochondrial membranes and the intramembranous space. To confirm the presence of these novel connecting structures, the distances between crista junctions of neighboring mitochondria in a tethered zone were compared to distances found in an untethered zone by analyzing the histogram and data produced by the MTK function. It was observed that crista junctions in the tethered regions were in closer proximity compared to the crista junctions in the untethered regions. Thus, tethers between mitochondria allow for the flow of ATP and Ca^{2+} ions through an alignment of cristae from adjacent mitochondria, along with an alignment of their crista junctions. Both observations were made in mitochondria below the cuticular plate in type I vestibular hair cells. Increased production and concentration of ATP in this region could feed ATP into the cuticular plate for the regeneration of stereociliar rootlets or provide energy for the mechanotransduction process.

Title: Structural and functional characteristics of mitochondria in efferent boutons

Authors: *V. BABU[1], N. LABAN[2], J. KULAGA[2], J. LESUS[2], G. PERKINS[4], A. LYSAKOWSKI[3];
[1]Biol. Sci., [3]Dept. of Anat. & Cell Biol., [2]Univ. of Illinois at Chicago, Chicago, IL; [4]Natl. Ctr. for Microscopy and Imaging Research, Univ. California at San Diego, San Diego, CA

Abstract: The synthesis of ATP, the primary energy source in the body, is an important role played by mitochondria in every cell of the body. Inner ear vestibular hair cells have especially high energy demands because they have a high resting discharge. ATP is produced by ATP synthase found in mitochondrial cristae. Because little research has focused specifically on inner ear mitochondria, this study investigates the structural and functional differences among mitochondrial subpopulations in inner ear hair cells. Three different populations of vestibular mitochondria are found: large ones under the cuticular plate in central type I hair cells, medium-sized ones in hair cells, afferent boutons and calyces, and small mitochondria in efferent boutons. In this study we focused on the third population, those in efferent boutons. We used IMOD software (Univ. Colorado) to create 3D reconstructions of electron microscopic (EM)

tomograms. Mitochondria in efferent boutons have been shown (Lysakowski et al., SFN Abst, 2017) to have the smallest surface areas and volumes of the mitochondrial subpopulations. We find that the small, densely packed mitochondria in efferent boutons possess only tubular cristae that are polarized towards dense core vesicles (DCVs). Cristae have been shown to interact with the inner mitochondrial membrane at points termed crista junctions (CJs) (Rabl et al., JCB 185:1047, 2009), and polarization occurs when more CJs are on the side of the mitochondrion facing a specific structure than on the side facing away. Thus, CJs likely enable transport of ATP and Ca^{2+} to regions of interest; for example, mitochondria in efferent boutons are polarized towards DCVs likely because they serve as a calcium stores and energy sources for vesicle release. Furthermore, we also found cytoskeletal tethers connecting DCVs and mitochondria in efferent boutons. To further investigate this association between DCVs and mitochondria, we used MTK (a proximity density analysis function in IMOD) to measure the level of interaction between CJs, DCVs, and tethers. Surprisingly, there was no polarization of CJs toward the active zone. In conclusion, efferent boutons are densely packed with mitochondria that appear to provide energy for DCV release, if not synaptic transmission.

Title: Structural differences in mitochondria adjacent to the cuticular plate in vestibular hair cells

Authors: *H. SATTAR[1], V. BABU[2], K. ARIAS[2], M. PATEL[2], J. KULAGA[3], J. LESUS[3], G. PERKINS[4], A. LYSAKOWSKI[3];
[1]Dept. of Bioengineering, [2]Dept. of Biol., [3]Dept. of Anat. & Cell Biol., Univ. of Illinois at Chicago, Chicago, IL; [4]Natl. Ctr. for Microscopy and Imaging Res., San Diego, CA

Abstract: In mitochondria, cristae have been shown to interact with the inner mitochondrial membrane at points termed crista junctions (CJs) (Rabl et al., J Cell Biol 185:1047-63, 2009). These CJs likely enable transport of ATP and Ca^{2+} to regions of interest. A previous study observed CJ polarization in the auditory brainstem towards synapses that require large amounts of energy (Perkins et al., J Neurosci 30:1015-26, 2010). This study aims to investigate the structural and functional similarities among mitochondrial populations in inner ear hair cells, specifically with regard to CJs. IMOD software (Kremer et al., J Struct Biol 116:71-6, 1996) was

used to create 3D-reconstructions of mitochondria in order to analyze crista junction density with respect to structures with higher energy demands. Two models of type I hair cell mitochondria from a previous study (Lysakowski et al., SFN Abstracts, 2017) were used in this study to compare structural qualities in mitochondria in the hair cell subcuticular region. Two of the type II hair cell mitochondria in the present study that face the cuticular plate have already been reconstructed and a few more are in the process. To determine if the type II hair cell mitochondria were polarized towards the cuticular plate, we counted the number of crista junctions on the sides of the mitochondria facing towards and away from the CP using our 3D model. The CJ density on the side of the mitochondria associated with the CP was found to be significantly larger than that of the side facing away. This is similar to what was observed in type I hair cells and shows that this subpopulations of mitochondria with different sizes in different cell types possess a similarity in the presence of CJs, which may promote a similar function of delivering ATP. This occurrence in type I and type II hair cells differs to what has been observed in ribbon-associated mitochondria CJs. The polarization of the CJs suggest that they are a structural entity representing energy molecule output and delivery systems.

Title: Phase-locking of calyx-bearing vestibular afferent neurons and the role of quantal and non-quantal transmission

Authors: *M. M. IVERSEN[1], B. R. POPE[1], R. D. RABBITT[2];
[1]Univ. of Utah, Salt Lake City, UT; [2]Bioengineering, Univ. of Utah, Salt Lake Cty, UT

Abstract: Introduction
Dimorphic and calyx-only vestibular afferent neurons respond to auditory frequency (AF) sound and vibration by firing action potentials at precise times relative to the stimulus waveform (phase-locking). Calyx-bearing afferents synapsing on type I hair cells respond to AF stimuli up to several kilohertz, and are much more sensitive than bouton-only afferents synapsing on type II hair cells[1]. A unique feature of these AF sensitive afferents is that they receive both quantal (Q)

and non-quantal (NQ) transmission from hair cells[2]. It is unknown how, or if, these two forms of synaptic input combine to excite AF phase-locked action potentials in vestibular afferent neurons. In this report, we examine *in silico* the potential contributions of Q and NQ transmission to AF phase-locking in vestibular afferent neurons.

Methods

An integrate-and-fire model of a space-clamped vestibular afferent neuron was constructed with appropriate thresholds and after-hyperpolarization characteristics[3]. Q and NQ synaptic inputs from vestibular hair cells modulated at auditory frequencies were used to drive action potential generation. The NQ input was simulated using a compartmental model of ionic buildup in the synaptic cleft and modulation of a passive NQ current[4,5]. The quantal input was simulated with quantized, log-normally distributed, excitatory postsynaptic currents (EPSCs) with modulated multiquantal release (MEPSCs)[6,7]. The potential contributions of non-quantal and quantal inputs were examined numerically.

Results

Simulations indicate that Q transmission is principally responsible for phase-locking in the auditory frequency range and NQ transmission improves response fidelity by moving the voltage toward action potential threshold. Q synaptic inputs phase-lock with high vector strength at auditory frequencies and increase in strength when stimulus level dependent multi-quantal release is included. The NQ current has a cycle-by-cycle component that is present at low frequencies, but drops off as frequency increases, possibly indicating NQ's importance in low-frequency signal transmission.

Conclusion

Results offer an explanation why calyx-bearing vestibular afferents are the most sensitive to AF sound and vibration, and why these afferent neurons are preferentially excited in clinical tests that use AF stimuli.

Title: Histamine potentiates ASIC currents in isolated neurons of the vestibular ganglia of the rat

Authors: *R. VEGA[1], S. SÁNCHEZ[3], E. SOTO[2];
[1]Inst. of Physiol., [2]Benemerita Univ. Autonoma De Puebla, Puebla, Mexico; [3]Inst. of Physiol., Benemerita Univ. Autonoma de Puebla, Puebla, Mexico

Abstract: The Acid Sensing Ion Channels (ASIC) are ligand-dependent ion channels activated by pH changes that belong to the family of ENac/DEG (Epithelial Sodium Channel/Degenerin). ASICs are involved in a large number of processes such as pain, auditory and visual processing, memory and learning, and also in pathological processes such as epilepsy and cerebral ischemia among others, this makes them targets of interest to be studied. It has been shown that ASICs are expressed in vestibular afferent neurons so they could be participating in the modulation of the excitability of these neurons. A significant number of peripheral vestibular disorders still lack a complete physio-pathogenic explanation and adequate pharmacological treatment. Histamine is a neurotransmitter whose effect is mediated by at least four receptors (H1-H4). Histamine antagonists have been used as a treatment for vestibular disorders although its peripheral mechanism of action is unclear. It has recently been shown that histamine and related amines modulate the ASIC current in heterologous systems. Therefore, we proposed to study the effects of histamine on the ASIC current of vestibular afferent neurons of the rat. The experiments were performed using the patch clamp technique in the whole cell configuration to record native ASICs present on vestibular ganglia neurons. To activate the ASIC currents neurons were perfused by a puff of acid solution (5s, pH 6.1). To determine the effect of histamine ASIC currents were recorded in control and then perfused during 55 s with histamine (1nM and 1 M) and co-perfused during 5s with the acid pH. We found that the co-application of histamine 1 nM and 1 μM with the acid pH increased the ASIC current 10.1 ± 2.3% (n = 6) and 31.3 ± 7.0% (n = 8). To determine whether or not histamine receptor activation mediates potentiation of the ASIC currents, we used GDP-β-S blocker (500 μM) we found that the potentiating effect of histamine does not change (49.0 ± 6.8%, n = 7) with the G protein inhibitor, which suggests that the effect of histamine on the ASIC current is not mediated by activation of second messengers, as it would happen if it were mediated by the activation of histamine receptors. Based on these results, we conclude that histamine enhancement of the ASIC current seems to be due to a direct interaction between the ASIC and histamine. Who significant is this action is in the overall effect of histamine is still not defined but surely should be taken in consideration while studying amine related drugs.

Abstract: The peripheral vestibular system transmits sensory information with two populations of primary vestibular afferent neurons (VAN), which differ in the regularity of action potential (AP) timing. The two kinds of AP timing (regular and irregular) represent different encoding strategies (rate and temporal encoding, respectively) that are optimized for different kinds of sensory information. *In vivo*, the differences between regular and irregular VANs may reflect synaptic inputs as well as diverse intrinsic ion channel expression. In isolated VANs, the difference in regularity correlates with differences in firing patterns evoked by current steps: regular neurons respond with sustained firing and irregular neurons with transient firing. We use isolated VANs to examine whether differences in voltage-dependent sodium (Na_V) currents contribute to differences in step-evoked firing patterns. Previous work indicates expression of all Na_V channel α and β subunits and at least 4 transient (inactivating) Na_V currents with different voltage dependence and time course. We are testing whether VAN Na_V currents also occur in persistent and resurgent forms, which are smaller, non-inactivating Na_V currents. In whole-cell recordings, some VAN expressed persistent Na_V current in response to slow voltage ramps, and other VAN expressed resurgent Na_V current in response to repolarizing voltage steps after a depolarization. These non-inactivated modes of Na_V current may help to depolarize VAN after each spike, promoting the sustained firing that distinguishes regular VAN, and ultimately shape sensory encoding strategies in the vestibular inner ear.

Title: Infrared photo-sensitivity is modulated by TRPV4 in type I vestibular hair cells in *in vivo* rat model

Authors: *F. M. RACITI[1], W. JIANG[2], S. RAJGURU[3];
[1]Cell. Physiol. and Mol. Biophysics, [2]Biomed. Engin., Univ. of Miami, Miami, FL; [3]Biomed. Engin. and Otolaryngology, Univ. of Miami, Coral Gables, FL

Abstract: Pulsed infrared radiation (IR) is being investigated as a non-invasive technique for altering the activity of excitable cells such as nerves and muscles. However, the mechanism of action of IR and its target have not yet been fully explained. Previous studies suggest that IR induces intracellular [Ca2+] changes as a result of activation of temperature-dependent Transient Receptor Potential (TRP) channels. We hypothesized that IR-activation of TRPV4 channels modulates Ca2+ release from intracellular compartments leading to glutamate release from vestibular hair cells and the observed excitatory and inhibitory post-synaptic responses.To define the contributions of different cell types and the mechanism of light stimulation in the vestibular neuroepithelium, we combined measurements of the vestibulo-ocular reflex during pulsed IR stimulation with local pharmacological treatments in adult female rats. Bilateral eye movements were recorded and characterized during pulsed IR stimulation (λ=1860nm, 200μs, 200Hz, various radiant exposures) of vertical semicircular canals in vivo in a rat model to assess the activity of the vestibular system. Here we show that IR - evoked responses are reduced when the neurotransmission between vestibular hair cells and the afferent neurons is impaired upstream after the local perfusion of Neomycin (100 mM) and downstream with AMPA/kainate receptor antagonist CNQX (100 μM). Further modulation of the eye movement evoked by the IR is observed when Kv7 conductance, specific of calyx - ending afferents, is targeted with low doses of KCNQ antagonist XE991 (1mg/Kg). In accordance with previous studies performed in in vitro SGNs we report the colocalization of the temperature-dependent Transient Receptor Potential (TRPV4) and the endoplasmic reticulum. Furthermore, we recorded significant decrease in the IR - evoked eye movement after inactivation of the temperature-dependent Transient Receptor Potential (TRPV4). IR-responses reduced significantly when the temperature of the vestibular

neuroepithelium has been lowered below TRPV4 activation threshold (<26°C) with the local perfusion of temperature-controlled artificial perilymph as well as after the perfusion of TRPV4 channel blockers (GSK2193874 and HC067047) at different concentrations.Altogether, our findings show that IR stimulation modulates the activity of type I vestibular hair cells and we demonstrate the pivotal role of the endoplasmic TRPV4 in the IR activation of the vestibulo-ocular motor pathway in vivo.

Title: Modelling neurotransmission at the vestibular hair cell synapse

Authors: *A. GOVINDARAJU[1], I. H. QURAISHI[2], A. LYSAKOWSKI[3], R. EATOCK[4], R. M. RAPHAEL[1];
[1]Dept. of Bioengineering, Rice Univ., Houston, TX; [2]Dept. of Neurol., Yale Sch. of Med., New Haven, CT; [3]Dept. of Anat. & Cell Biol., Univ. of Illinois at Chicago, Chicago, IL; [4]Neurobio., Univ. of Chicago, Chicago, IL

Abstract: In vestibular sensory epithelia of amniotes, afferent neurons form large cup-shaped synaptic terminals (calyces) on type I hair cells and small bouton terminals on type II hair cells. Type I hair cells transmit to calyces by two mechanisms: release of glutamate from vesicles (**quantal - Q**) and flow of ions from the hair cell into the cleft and the postsynaptic calyx (**non-quantal - NQ**). Details of this complex transmission remain unknown, and the relevant compartments (cells and synaptic cleft) are hard to access, hindering the measurement of ion concentrations and electric potentials. As a complementary approach, **we are creating a mathematical model of the vestibular hair cell-calyx synapse (VHCC model) with the goal of predicting and accounting for both Q and NQ transmission modes and their interactions.**
The VHCC model is implemented as a 2D axisymmetric parametric surface in COMSOL with dimensions of hair cell and calyx geometry taken from electron micrographs. It incorporates specific locations and surface densities of hair cell and calyceal ion channels (MET, HCN, K_V, Ca_V, Na_V; as shown by immunocytochemistry and whole-cell recordings) and pumps (Na-K ATPase, KCC), membrane capacitance, measured or estimated channel conductances, and channel activation times. The input to the model is a step deflection of the hair bundle. To model

the dynamic behavior of the system, the VHCC model uses expressions for K^+ and Na^+ electrodiffusion in the cleft, simplified Hodgkin-Huxley-style ion currents based on whole-cell recordings, stochastic vesicle release, and the cable equation for voltage change along the fiber between the synapse and spike initiation zone.
The VHCC model can mimic firing patterns found in experimental voltage and current recordings. The model incorporates the distinctive low-voltage-activated conductance of type I hair cells ($g_{K,L}$) and postsynaptic HCN channels, which permit Na^+ and K^+ flow and are critical to NQ transmission (Contini et al. J Physiol 595:777, 2017). Model simulations confirm that removing either HCN channels or $g_{K,L}$ blocks NQ transmission. The model also predicts spatio-temporal gradients in K^+ and Na^+ within the synaptic cleft. Manipulations that increase maximal KCC-mediated K^+flow out of the synaptic cleft or reduce the calyx to the size of a bouton terminal reduce cleft K^+ accumulation, NQ transmission, and afferent spike rate. Thus, **the VHCC model supports findings and hypotheses implicating $g_{K,L}$ and g_{HCN}, K^+ accumulation in the cleft, and calyx morphology as factors in NQ transmission.**

Title: GABA and GABA receptors in zebrafish sensory hair cells and lateral line afferents

Authors: J. O'KEEFE[1], E. BACHE[2], M. SCHWEHR[1], ***C. P. TORO**[2];
[1]Linfield Col., McMinnville, OR; [2]Sarah Lawrence Col., Bronxville, NY

Abstract: The neurotransmitter gamma-aminobutyric acid (GABA) plays complex and incompletely understood roles in the inner ear. Decades of experimentation have provided evidence of GABA and numerous GABA receptor subunits in the cochlea and vestibular labyrinth, but the source and target of GABA within these tissues is varied. In the cochlea, GABA is an autoinhibitory transmitter released from cholinergic efferent neurons early in development. In the vestibular labyrinth, some data suggest GABA is an efferent neurotransmitter, but uniquely, in tissues of multiple species, GABA is synthesized by a subset of hair cells, likely those that also release glutamate. The function of GABA release from hair cells has not yet been fully described. The zebrafish lateral line is an established model with which to study hair cell physiology in general, but neuromast hair cells are most closely related

to those of the vestibular system. Consistent with this similarity, early studies of the toadfish and *Xenopus* lateral line demonstrated peripheral synthesis of GABA and modulation of afferent activity by GABA. We have begun to characterize GABA circuitry in the larval zebrafish lateral line to determine if it is an appropriate model with which to better understand the role of GABA in the vestibular periphery. Using RT-PCR, we detected the expression of 22 out of 23 GABA receptor genes in 5 dpf larvae. 17 of those were expressed in both head and trunk tissue samples, consistent with the expected expression pattern of lateral line genes. We have begun to identify which of those 17 genes are expressed in the lateral line via *in situ* hybridization. No discernible lateral line expression of *gabra3, gabra4* or *gabra6b* was detected. By contrast, our data show expression of *gabrb2, gabrb3, gabrg2,* and *gabbr1a* by afferent neurons in the lateral line ganglia. These genes code for ionotropic $GABA_AR$ and G protein coupled $GABA_BR$ subunits, suggesting complex sensitivity of afferent neurons to GABA. With immunohistochemistry, we confirmed that $GABA_BR$-expressing cells innervate neuromasts, and have terminals that co-localize with postsynaptic densities. Further, neuromast hair cells appear to be the local source of GABA: antibodies that bind Gad1/2 and GABA localize to them. Our data are consistent with hair cell modulation of afferent activity via GABA release. The zebrafish lateral line thus appears to be a suitable tissue with which to model GABA signaling by vestibular sensory hair cells.

Title: Targets of cholinergic terminals within vestibular sensory epithelia

Authors: *J. J. SALDATE[1], F. E. SCHWEIZER[2], L. F. HOFFMAN[1];
[1]Head & Neck Surgery, [2]Neurobio., UCLA - Geffen Sch. of Med., Los Angeles, CA

Abstract: Efferent vestibular neurons represent a centrifugal feedback circuit projecting to labyrinthine sensory epithelia. Analyses of efferent projection loci provide insight into the likelihood of potential cellular interactions of this cholinergic feedback. For example, we recently found that the density of efferent terminals was greater in the region of utricular epithelia harboring enhanced calyceal KCNQ4 expression. This suggested that if cholinergic

input was mediated through muscarinic receptors it could represent a mechanism to tune the m-current and modulate sensory input from type I hair cells. However, we found a relative paucity of efferent terminal projections directly onto afferent calyces, indicating that the circuit elements supporting such a tuning mechanism did not dominate the efferent landscape. Through this analysis we observed that efferent terminals aggregated in intraepithelial space below the base of afferent calyces. The objective of the present study was to investigate the cellular targets of the non-calyceal projection loci. This was achieved by exploring the projection loci onto calyces, afferent projections, and type II hair cells using immunohistochemistry and high-resolution microscopy. Presynaptic cholinergic terminals were labeled with antibodies targeting vesicular acetylcholine transporter (VAChT), while postsynaptic structures were labeled with antibodies for β3-tubulin (calyces and parent dendrites) and otoferlin (type II hair cells). Utricles and cristae from C57BL/6 mice were immunostained, mounted intact, and interrogated with confocal microscopy to determine the spatial relationships between pre- and postsynaptic components of efferent circuitry. While VAChT-positive projections terminated near type II hair cells, afferent calyces, and parent dendrites, most were associated with type II hair cells, including their basolateral extensions. VAChT terminals also targeted parent dendrites below the calyx bases. These findings indicate that the principal targets of centrifugal feedback are likely type II hair cells and signal integration sites of afferent neurons. This circuit would modify direct inputs from type II hair cells onto afferent boutons, or the inputs from type II hair cells onto the lateral face of the afferent calyx.

Title: Intense noise exposure impacts rats' balance beam performance

Authors: ***W. KING**[1], C. E. STEWART[2], D. BAUER[3], M. BATTERSBY[5], S. T. KATZ[3], E. G. BEEKMAN[4], R. A. ALTSCHULER[6];

Abstract: The vestibular system plays a critical role in detection of head movements and orientation with respect to gravity, and is essential for normal postural control. Due to their anatomical proximity to the cochlea, the otolith organs are exposed to sound pressure and are at risk for noise overstimulation. Irregularly discharging vestibular afferents are sound-sensitive (Murofushi & Curthoys, 1997) and important components of descending vestibulo-spinal pathways (Bilotto et al., 1982). The vestibular short-latency evoked potential (VsEP) reflects the activity of irregular afferents (Jones et al., 2011) and noise-induced attenuation of this response is associated with a reduction in calyx-only afferent terminals in the vestibular periphery (Stewart et al., 2018). The goal of the current study is to correlate changes in VsEP responses caused by noise exposure with changes in rats' ability to cross a narrow balance beam. Adult male and female Long-Evans rats (400-500g) were exposed to 120dB SPL noise (0.5 - 4 kHz) for six hours on a single day. Motor performance was assessed before and up to 28 days after noise exposure with a balance beam crossing task. Balance beam crossings were analyzed for crossing time on each trial and for variability of crossing time across trials on each day. Twenty-eight days after noise exposure, VsEP responses were obtained in response to head jerks ranging from 0.32 - 5.5 g/ms. Rats were then euthanized for tissue analysis. Post exposure VsEP data were compared with control VsEP responses obtained prior to noise exposure.One day after noise exposure, animals were able to perform the balance beam task successfully. However, day-by-day and within day balance beam crossing times exhibited greater variability after noise exposure when compared to control data. Furthermore, across the tested population, there was a tendency for mean crossing time to gradually increase. Crossing times were longest 7-14 days post noise exposure and remained elongated until sacrifice 28 days post exposure. These data suggest a subtle vestibular-mediated motor impairment after noise-induced injury to the vestibular periphery. *Supported by VA RR&D 1I01RX001986, NIDCD R21 DC015097, T32 DC000011, F32 DC017063-01.*

Title: Noise-induced injury to saccular affrents is associated with decreased vestibular nerve activity as assessed by the VsEP

Authors: *C. E. STEWART[1], A. KANICKI[1], D. BAUER[1], H. HAQUE[2], R. A. ALTSCHULER[1], W. KING[1];
[1]Kresge Hearing Res. Institute, Dept. of Otolaryngology-Head and Neck Surgery, [2]Col. of Literature, Science, and the Arts, Univ. of Michigan, Ann Arbor, MI

Abstract: While it is well accepted that the cochlea is sensitive to sound and susceptible to acoustic over-exposure, vulnerability of the vestibular portion of the inner ear to noise is less established. Previous work identified a reduction in striolar calyx endings in the sacculus, associated with abolishment of vestibular short-latency evoked potential (VsEP) responses to small head-jerk stimuli 21 days after noise exposure (Stewart et al., 2018). The current studies extended these findings by measuring VsEP responses to larger head jerk stimuli 28 days after noise exposure, and by examining regions of interest containing the entire width of the striola, identified as the region of the sacculus containing calretinin-immunopositive calyceal endings. Adult male and female Long-Evans rats were exposed to 120 dB SPL band-limited noise (0.5 - 4 kHz) for six hours on a single day. Before and for up to 28 days after noise exposure, VsEP responses to small (0.32 g/ms), moderate (2.2 g/ms), and large (5.5 g/ms) head-jerk stimuli were evaluated. Ears were then dissected and end organs were collected for immunostaining with a calretinin antibody to evaluate noise-induced changes in the sacculus. After noise exposure, VsEP responses to weak (0.32 g/ms) head jerk stimuli were abolished and responses to larger (2.2 and 5.5 g/ms) head jerk stimuli were attenuated. This attenuation was correlated with a reduction in the number of calyx-only afferent endings in the sacculus. Noise exposure was also associated with reduced calretinin immunostaining of striolar calyces. Across all sacculi, the number of calretinin-immunopositive calyceal endings decreased with increasing distance from the striolar mid-line, suggesting that this population of afferent terminals was not evenly distributed across the central region of the sacculus. This finding may be related to the apparent narrowing of the striolar region of the sacculus observed in noise exposed sacculi. These data build upon our previous work showing not only fewer calyceal terminals within the striolar region of the sacculus, but also a narrowing of the striolar region of the sacculus which correlates with reductions in VsEP amplitude.

Title: Responses to infant vocalizations in mouse oxytocin neurons

Authors: *S. VALTCHEVA[1], R. C. FROEMKE[2];
[1]NYU Sch. of Med., New York, NY; [2]Otolaryngology, NYU Med., New York, NY

Abstract: Healthy maternal sensitivity is characterized by the ability to reliably interpret and respond to infant signals, thus initiating appropriate caregiving responses. Motherhood is a dramatic natural experience but little is known about the specific circuits and neural mechanisms supporting the recognition of different infant cues. Recent studies from our lab (Marlin et al., 2015; Mitre et al., 2016) showed that the neurohormone oxytocin promotes long-term plasticity of neural responses to infant sounds in mouse auditory cortex in vivo. Release of oxytocin from the paraventricular nucleus (PVN) of the hypothalamus might help induce recognition of different infant cues such as cries. However, it remains unknown if infant vocalizations can activate oxytocin neurons. Here we performed in vivo cell-attached and whole-cell recordings from PVN oxytocin neurons in awake mice to investigate their responses to auditory stimuli. We used channelrhodopsin-assisted patching (Munoz et al. 2014) to record from optically-identified oxytocin neurons in maternal mice. We found that oxytocin neurons reliably respond to pup calls, but not to behaviorally-irrelevant pure tones. Interestingly, repeated presentation of pup calls specifically induced a gradual increase in tonic firing of individual oxytocin neurons but not of other PVN neurons. Using cell-type specific rabies virus tracing, we identified thalamic inputs which may drive auditory responses in oxytocin neurons. We further tested the strength of these connections by channelrhodopsin-assisted circuit mapping (Petreanu et al., 2007). We describe a novel noncanonical auditory pathway potentially relaying acoustic information about social sounds to PVN oxytocin neurons. Finally, we mapped populations of PVN neurons that are activated by pup calls or suckling via the immediate early gene c-fos and if these neurons were magno- or parvocellular. Our data suggest that oxytocin neurons differentially integrate auditory and somatosensory information which may be critical for the recognition of different infant cues, and for mediating peripheral and central oxytocin release.

Title: Role of top-down inputs in auditory cortex during vocalization in marmoset monkeys

Authors: J. TSUNADA, ***S. J. ELIADES**;
Dept. of Otorhinolaryngology, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: Human speech is a sensory-motor process involving auditory self-monitoring to control vocal production and ensure accurate communication. Monitoring auditory feedback during vocal production allows one to quickly adjust speech to compensate for perceived changes in vocal output, a control behavior shared with many animal species. The auditory cortex has been implicated in this self-monitoring process based upon previous studies showing both a suppression of the auditory cortex during vocal production as well as sensitivity to changes in vocal feedback. However, the mechanisms of this vocalization-induced suppression in auditory cortex remain poorly studied. We recorded neural activity from the auditory cortex of marmoset monkeys while they produced self-initiated vocalizations, analyzing both spiking activity and local field potentials. We found that previously-demonstrated pre-vocal suppression of neural firing is associated with an increase in low-frequency theta-band activity. We further show that, for many neurons, the magnitude of pre-vocal spiking suppression correlates with the acoustics of the subsequent vocalization. These findings suggest that this pre-vocal input to the auditory cortex, presumably a top-down signal, contains specific information predicting the expected sound of a vocalization, consistent with current models of feedback vocal control. Additionally, we found that gamma-band oscillation activity increases during vocalization, in contrast to suppression at single- and multi-unit levels. This dissociation between spiking activity and local field potentials further implicates local processing within the auditory cortex as a possible mechanism of vocalization-induced suppression.

Title: Variant-independent representation of zebra finch songs in the auditory forebrain

Authors: *M. DONG[1], D. I. NATANOV[2], M. MOHSEN[2], D. S. VICARIO[3];
[1]Psychology, [2]Rutgers Univ., New Brunswick, NJ; [3]Rutgers The State Univ. of New Jersey, Piscataway, NJ

Abstract: Invariant neural representation of a given natural sound that is produced with variations is important for identifying specific signals used in vocal communication and individual recognition. For example, the same word spoken in different situations can be acoustically different. However, listeners still perceive it correctly. To investigate how variant-independent representation emerges in the auditory system, we recorded neural responses from multiple sites bilaterally in both the primary thalamo-recipient auditory area (Field L2) and a secondary area (caudo-medial nidopallium, NCM) of awake zebra finches while presenting naturally-produced variants of the songs of individual male zebra finches. The response temporal profiles for different variants at individual recording sites were more similar to each other in NCM than in Field L2. Moreover, in NCM, the response temporal profiles for different variants converged with passive exposure to repeated playbacks, but changed little in Field L2. In addition, a population-level analysis of response magnitude also showed that responses to different variants in NCM were more similar to each other than in Field L2. Together, these results suggest that invariant representation of zebra finch song variants emerges hierarchically in the auditory forebrain. Because variant-independent representation can be essential for word recognition, findings in the zebra finch model may provide insights into basic neural mechanisms that serve speech perception.

Title: Selective decoding of communication sounds in lateral belt auditory cortex

Authors: *J. D. DOWNER, C. E. SCHREINER, B. J. MALONE;
UCSF, San Francisco, CA

Abstract: Anatomical differences among primate auditory cortical fields are well established but a comprehensive understanding of functional differences lags behind. To analyze functional differences between auditory cortical fields, we presented 4 stimulus sets, including both

synthetic and communication sounds, while recording single unit activity in core and lateral belt auditory cortex of 2 awake squirrel monkeys. Synthetic sounds were sinusoidally amplitude modulated broadband noise (AM) and sinusoidal frequency-modulated (FM) sweeps, each presented across a range of modulation frequencies (2-96 Hz). Communication sounds were squirrel monkey vocalizations (MV), with 2 exemplars for each of 13 vocalization classes, and human speech (HS) (10 repeated sentences from the TIMIT corpus). For each recorded unit, we measured trial-by-trial stimulus decoding accuracy separately for each stimulus set. Across stimulus sets, units in core fields exhibit significantly greater average decoding accuracy across all stimuli within the set relative to units the lateral belt. However, while a unit's overall decoding accuracy for a stimulus set may be low, it may still selectively decode individual stimuli within the set at high accuracy. Therefore, we separately analyzed decoding accuracy of units with the highest single-stimulus decoding accuracy, irrespective of average decoding accuracy. We then compared decoding accuracy for each stimulus set between the best-decoded 5 stimuli for these selective sub-populations. For synthetic stimuli (AM and FM), the selective sub-population of core units' average decoding accuracy significantly exceeded that of the lateral belt, as it did for overall decoding. However, for communication stimuli (MV and HS), the sub-population of selective units in the lateral belt exhibited significantly greater average decoding accuracy relative to core. These results indicate a key functional difference between core and lateral belt auditory cortex: whereas core units carry more overall stimulus information, sub-populations of lateral belt units selectively carry high information for communication sounds.

Title: Auditory memories for communication calls in zebra finches

Authors: *K. YU[1], W. E. WOOD[2], I. N. RICE[3], A. A. PRASAD[3], F. E. THEUNISSEN[2];
[1]Helen Wills Neurosci. Inst., [2]Dept. of Psychology, [3]UC Berkeley, Berkeley, CA

Abstract: In the zebra finch vocal repertoire, songs and distance calls are highly idiosyncratic vocalizations that are used to identify behaviorally relevant conspecifics, such as parents, siblings, or mates. However, it is unknown whether zebra finches are capable of memorizing the songs and calls produced by the many individuals in a colony, and what brain networks are

involved in this process. We hypothesized that the higher auditory areas CM and NCM play an important role in forming and storing these general auditory memories. In this study, we first performed behavioral experiments to assess the memory capacity of zebra finches for conspecific songs and distance calls. We then performed lesion experiments to determine the role of CM and NCM in the formation and storage of these auditory memories.
To test the memory capacity of zebra finches, we used an operant conditioning paradigm in which birds are trained to recognize non-rewarded vs rewarded stimuli consisting of conspecific songs and distance calls. We found that zebra finches have an extraordinary memory capacity; at least 16 songs and 12 distance calls from distinct individuals could be recognized in this task. To localize the brain regions involved in the storage, recall, and formation of these memories, we performed bilateral neurotoxic lesions in secondary auditory areas CM or NCM either before or after operant conditioning. Preliminary results suggest that CM is not critical for the recall or formation of these auditory memories; NCM lesions are ongoing. These experiments will reveal whether these secondary auditory regions are required for auditory memory in the context of vocal communication. Further work is needed to assess the possibility that these structures are individually sufficient for this and other auditory memory related tasks.

Title: Genetic and physiological segregation of excitatory vs inhibitory cell types in songbird auditory cortex

Authors: ***J. A. SPOOL**[1], G. SCARPA[1], M. MACEDO-LIMA[1], Y. MOROHASHI[2], Y. YAZAKI-SUGIYAMA[3], L. REMAGE-HEALEY[4];

(OIST) Grad. Univ., Okinawa, Japan; [4]Psychology and Neurosci., Univ. of Massachusetts, Amherst, Amherst, MA

Abstract: Cortical circuits are highly organized to process complex sensory inputs. In mammals, inhibition quickly quenches excitatory transmission to achieve highly time-locked responses to sensory stimuli. This type of feed-forward inhibition circuit motif relies on distinct classes of

cortical neurons, mainly narrow-spiking, inhibitory interneurons and broad-spiking, excitatory projection neurons. In other vertebrates such as songbirds, the organization of cortex appears highly dissimilar to mammals and yet has a similar capacity for processing complex sensory stimuli. For example in the caudomedial nidopallium (NCM), neurons are highly selective for particular features of learned conspecific vocalizations (i.e., song). Based on developmental and functional studies, NCM is considered analogous to mammalian secondary auditory cortex. However, the circuit mechanisms by which NCM processes complex ethologically-relevant auditory stimuli remain unknown. To test predictions from mammalian auditory cortex, we employed AAV viral constructs to target calmodulin-dependent protein kinase II (CAMKII) and glutamate decarboxylase (GAD) selective promoters in NCM to express channelrhodopsin within putative excitatory and inhibitory neurons, respectively. Using extracellular optrode recordings we then photoidentified infected single units *in vivo*, and obtained their waveform and auditory response properties to song. We found a striking segregation of broad vs. narrow waveforms in CAMKII+ and GAD+ single units respectively, suggesting that, as in mammalian cortex, an important component of NCM circuit architecture may be feed-forward inhibition to rapidly quench excitation. Whole cell patch clamp recordings of infected cells revealed a similar segregation of phasic vs tonic responses in CAMKII+ and GAD+ neurons, respectively. Stimulus selectivity, physiological properties, and comparisons with mammalian auditory cortex in these distinct populations of NCM neurons will be discussed. Support from NINDS.

Title: Degraded auditory and visual speech affects theta synchronization and alpha power differently

Authors: *A. HAUSWALD[1], A. KEITEL[2,3], S. RÖSCH[4], N. WEISZ[1];
[1]Univ. of Salzburg, Salzburg, Austria; [2]Univ. of Dundee, Dundee, United Kingdom; [3]Univ. of Glasgow, Glasgow, United Kingdom; [4]Paracelsus Med. Univ., Salzburg, Austria

Abstract: Understanding speech can pose a challenge, especially when speech is perceived as degraded, for example when using a hearing aid. Findings on brain dynamics involved in

degraded speech comprehension are mixed. We therefore investigated the effects of degraded continuous speech on three measures: intelligibility, theta synchronization, and alpha power. Additionally, we tested another commonly experienced degradation, namely that of blurred vision during visual speech perception (lip reading). Participants listened to unimodal auditory speech and watched unimodal visual speech with three different levels of degradation in a behavioural and an MEG experiment. In the auditory condition, intelligibility declined with declining clarity, implemented by fewer vocoding channels. Theta speech-brain synchronization increased with lower clarity in left auditory regions, while alpha power showed a widespread decrease. We assume that listening effort, which should be strongest for challenging conditions, led to both effects. The idea of a common process driving both measures is also consistent with the finding that increased synchronization (for stronger degradation) was associated with lower alpha power, mainly in right temporal regions. In the visual condition, intelligibility declined with increasing blurriness of the speaker's face. Theta lip-brain synchronization in bilateral visual areas decreased with degradation, while alpha power did not change, indicating that the blurry visual stimulus could not be compensated for by neural mechanisms. Together, these findings illustrate multi-layered neural mechanisms of degraded auditory and visual speech comprehension and suggest fundamental differences between both modalities.

Title: Speech encoding from simultaneous ECoG recordings of human temporal plane and lateral temporal cortex

Authors: *L. S. HAMILTON[1,2,3], Y. OGANIAN[1], E. F. CHANG[1];
[1]Neurosurg., Univ. of California, San Francisco, San Francisco, CA; [2]Neurol., [3]Communication Sci. and Disorders, Univ. of Texas at Austin, Austin, TX

Abstract: Speech processing involves the transformation of information from acoustic to phonetic and higher-order linguistic categories. Intracranial recordings have contributed significantly to understanding this transformation, however limitations in surgical exposure have precluded simultaneous high-density sampling from core and surrounding auditory cortices. Our previous work has demonstrated encoding for acoustic-phonetic features, spectrotemporal modulation, and intonational pitch tuning in superior temporal gyrus (STG), as well as a posterior region of the STG that is specialized for detecting acoustic amplitude onsets, but how this relates to processing in core auditory cortex is less well understood. Here, we present a functional characterization of the entire human auditory cortex, including the core and surrounding belt/parabelt areas. We overcame previous limitations by using direct recordings from the surface of temporal plane after surgical microdissection of the deep recesses of the Sylvian fissure when indicated for clinical purposes (peri-Sylvian epilepsy or insular tumors). We obtained simultaneous high-density recordings from patients with high-density electrode grids over the temporal plane (including Heschl's gyrus, planum temporale, and planum polare) and also over the lateral superior temporal gyrus in the left hemisphere. We then recorded neural responses while participants listened to natural speech sentences and non-speech pure tone stimuli. We fit models combining acoustic and linguistic stimulus representations to predict neural responses. We also compared latencies across different auditory fields and functional areas. Speech activated much of the temporal plane and STG, including belt and core areas. Heschl's gyrus and planum temporale exhibited strong, narrow-bandwidth tone responses, and strong responses to speech, while phonetic feature representations dominated in mid-STG. This study provides a comprehensive characterization of feature encoding for speech across the human auditory cortex at high spatiotemporal resolution.

Title: Neural representations of birdsongs across distinct processing regions of auditory cortex

Authors: *J. M. MOORE[1], S. A. SHAMMA[2], S. M. WOOLLEY[1];
[1]Psychology, Columbia Univ., New York, NY; [2]Univ. of Maryland, College Park, MD

Abstract: Vocal communicators rely on auditory perception to extract social information from the environment. For example, songbirds recognize conspecifics, tutors, and mates based on the acoustic features of songs. The encoding of these vocalizations in auditory cortex is hierarchical; spike rates in each successive processing stage are progressively more selective for salient sounds. However, it is unknown to what extent changes in auditory coding across regions impact the neural representation of vocal sounds. Moreover, it is unclear if coding specializations in auditory cortex extend to the specific properties of learned stimuli, such as the tutor song. A common approach to quantifying coding specializations is to measure neural tuning for specific acoustic features in vocal sounds, but this method suffers from a bias toward parameters selected *a priori* and failure to isolate correlated features. Here, we used a stimulus reconstruction method that eliminates these limitations to determine how well song features can be recovered from evoked auditory cortical responses. In zebra finches (*Taeniopygia guttata*), we recorded the spiking activity of single neurons in the four major regions of auditory cortex (intermediate, superficial, deep, secondary) in response to 15 songs from 3 species. First, we clustered single-neuron response patterns according to their temporal profiles and found that the number of cell clusters increased in successively higher areas of the network hierarchy. Second, we examined whether neural responses could reconstruct conspecific songs more accurately than the songs of two closely related species. Third, we tested whether the neural representation of tutor song differed from those of other conspecific songs in each region. Reconstruction of individual songs from cortical activity revealed circuit-level transformations in coding specificity for species and tutor song in the auditory cortex.

Title: Cell types and connectivity of a vocalization-selective auditory cortical region in the songbird

Authors: *J. A. EDWARDS, S. M. WOOLLEY;
Psychology, Columbia University's Zuckerman Inst., New York, NY

Abstract: Neural encoding of behaviorally relevant sounds, such as speech or other vocalizations, results from successive processing stages as signal information travels from the

periphery throughout the cortex. In songbirds, that learn and produce complex vocalizations for social communication, neurons in the deep layers of the auditory cortex respond selectively to acoustic features of species-specific vocalizations. Deep cortical neurons may therefore occupy a key position in the synaptic pathway through which social information is extracted from auditory cues. However, the cell types and connectivity of the deep region of the auditory cortex in songbirds remain poorly characterized. We used nanoinjections of the bidirectional tracer cholera toxin subunit B, and an adeno-associated viral vector driving fluorescent protein expression, to visualize deep cortical neurons and their projections in adult male zebra finches. We find that the deep region of the primary auditory cortex (Field L3) receives the majority of its afferents from superficial (Field L1 and caudal mesopallium, CM) cortical layers, suggesting that response selectivity for conspecific song arises after at least six synaptic processing stages, bypassing a direct connection with the anatomically adjacent thalamorecipient region, L2. We further show that Field L3 neurons cluster into distinct morphological types, which may map to a known distribution of electrophysiological signatures of putative interneurons and projection neurons. While we find that Field L3 projects widely to the caudal medial pallium, terminal fields are densest in two regions: the "shelf" of HVC and the "cup" of the robust nucleus of the arcopallium (RA). Results suggest that the neural representation of birdsong that originates in the deep regions of primary auditory cortex undergoes a superficial cortical "pre-processing" step, and then diverges into three pathways, two of which could influence singing behavior by virtue of their close spatial proximity to song pre-motor nuclei.

Title: Characterization of neural dynamics during tutoring in the zebra finch

Authors: *A. H. BAHLE[1], E. L. MACKEVICIUS[2], N. DENISSENKO[1], M. S. FEE[1];
[1]Brain & Cog Sci. / McGovern Inst., MIT, Cambridge, MA; [2]Columbia Univ., New York, NY

Abstract: In the zebra finch, young males learn to produce a robust imitation of an adult male tutor song, a process dependent on exposure to the tutor during an early sensitive period. Generating a stable and persistent tutor song memory during this period is central to the imitation process because birds eventually learn to precisely reproduce the tutor song’s acoustic structure.

The production and refinement of this imitation is thought to be controlled by a combination of basal ganglia dependent reinforcement learning and the growth and splitting of chains of neural activity in the motor system. Splitting of the motor representation is a fundamental part of song learning because it provides a neural substrate for each target syllable, ensuring that there is a one-to-one correspondence between syllables in the tutor song and the developing imitation. While this correspondence is necessary for song learning, it remains unclear where information about the tutor song is stored and how this information is coupled to the motor system. Likewise, while reinforcement learning has been a powerful framework for understanding the gradual refinement of song syllables, it is unknown how neural circuits for song evaluation are set-up during tutoring. To address these questions, we used a miniaturized head-mounted microscope to record the population activity of auditory-motor song regions in juvenile zebra finches throughout the tutoring process. By tracking individual neurons responses to tutoring across days we characterize how the dynamics of neural populations represent the tutor song and how these dynamics change as a function of experience.

Title: Intracranially recorded neural activity in auditory cortex elicited by simple sounds and during naturalistic verbal interactions in children

Authors: *A. E. RHONE[1], M. STEINSCHNEIDER[2], B. F. SNOAD[1], K. V. NOURSKI[1], C. K. KOVACH[1], B. J. DLOUHY[1];
[1]Neurosurg., Univ. of Iowa, Iowa City, IA; [2]Albert Einstein Col. of Med., Bronx, NY

Abstract: Neurosurgical interventions for remediation of medically intractable epilepsy in children have become a viable clinical option in pediatric patients. A companion presentation (Steinschneider et al., SFN 2019) examines basic response properties of auditory cortex on Heschl's gyrus. Here, we examine neural activity recorded from lateral superior temporal gyrus (STG) and other fronto-temporo-parietal areas. All studies were approved by the NIH and the University of Iowa Institutional Review Board. Informed consent was provided by the children's

parents or legal guardians. Verbal or written assent was obtained from the children. Subdural grid electrodes were placed over the lateral STG in three right-handed subjects (ages 9, 13, and 14). One subject had left and two had right hemisphere coverage. Analysis focused on local field potentials and event-related high gamma power (70-150 Hz). Stimuli included a wide variety of sounds including tones, click trains, speech and environmental sounds. Additionally, children engaged in a question-answer dialog based on that used previously (Nourski et al, 2016, Front Hum Neurosci 10:202) and a structured version of the children's card game "Go Fish." Neural activity elicited by sounds was maximal on the lateral STG near the transverse temporal sulcus. Activity was seen for all sound types, though speech generally elicited more widespread responses than pure tones and click trains. Responses to human vocalizations and environmental sounds (Belin et al, Nature 2000, 403:309-12) were similar in magnitude. Consonant-vowel syllables elicited local field potentials that differed between voiced and unvoiced consonants (5 ms and 40 ms voice onset time, respectively). Naturalistic interactions were characterized by a widespread activation within and beyond auditory cortex, including prominent responses in parietal areas when the subjects heard number words.We conclude that responses to isolated word and nonword stimuli on the lateral STG are similar to those seen in adults. Furthermore, preliminary results provide proof of concept that naturalistic interactive tasks are feasible in children undergoing invasive monitoring for treatment of their medically intractable epilepsy and can be used to probe auditory cortical function.

Title: Perceptual constancy of naturalistic sounds in macaques

Authors: *L. LEMUS, J. MELCHOR, I. MORÁN, T. FIGUEROA;
Cognitive Neurosci., Univ. Nacional Autonoma De Mexico, Mexico, Mexico

Abstract: Perceptual constancy, of say, a word, is the ability to recognize it regardless of physical variations produced by different speakers. However, the acoustic attributes holding up of the perceptual constancy of naturalistic sounds are not well understood. We trained two rhesus monkeys to recognize many naturalistic sounds as a target or as a nontarget sounds. After

training, we presented versions of the learned sounds that were not previously heard by the monkeys. The monkeys were able to recognize such sounds consistently to their putative categories. Our results not just validate their capacity to perform in complex acoustic tasks, setting a promising perceptual model to study the neural bases of sound perception, but more importantly, suggest that the most salient spectrotemporal metrics of sounds uphold for the perceptual constancy of naturalistic sounds.

Title: Encoding of natural sounds in the aging human auditory cortex

Authors: *J. ERB, L.-M. SCHMITT, J. OBLESER;
Inst. of Psychology, Univ. of Lübeck, Lübeck, Germany

Abstract: Recent advances in computational modelling of fMRI data have furthered our understanding of how the spectro-temporal modulations in natural sounds become represented in the human auditory system. Here, we ask whether and how cortical responses to these acoustic features change over life span. We acquired 3T-fMRI data while a group of young (n = 33, aged 18 - 32) and older adults (n = 21, aged 51 - 74) listened to a story presented against a competing stream of resynthesized natural sounds (0 dB SNR). We modelled the fMRI responses in auditory cortex as a function of the spectro-temporal modulations contained in the sound mixture, that is, temporal rate, spectral scale and frequency. In a fourfold cross-validation procedure, we used ridge regression to derive single- and multi-voxel modulation transfer functions (fMRI encoding and decoding) and compared those across age groups. Results from the encoding model indicate that topographical best feature maps are preserved in the aging auditory cortex: Tonotopic maps showed the typical mirror-symmetric frequency gradients along Heschl's gyrus in both age groups. Decoding sound features from auditory cortex yielded highest accuracies (obtained as Pearson's *r* between predicted and actual acoustic features) at frequencies of 230 - 580 Hz (median $r = 0.52$), scales of 0.25 cyc/oct ($r = 0.5$), and rates of 4 - 8 Hz ($r = 0.42$), irrespective of age. Although average decoding accuracies were comparable, we found age differences in tuning width: Tuning to temporal rate was sharper in young than in older participants. These results indicate that tuning to temporal modulations broadens in the aging auditory cortex.

Title: Fundamental response properties of auditory cortical activity in Heschl's gyrus of children as observed from direct intracranial recordings

Authors: *M. STEINSCHNEIDER[1], A. E. RHONE[2], K. NOURSKI[2], C. KOVACH[2], B. DLOUHY[2];
[1]Albert Einstein Col. of Med., Bronx, NY; [2]NEUROSURGERY, Univ. of Iowa, Iowa City, IA

Abstract: Improvement in technology and techniques has led to a greater use of neurosurgical interventions for remediation of medically intractable epilepsy in children. To clarify developmental features of audition, investigations into fundamental functional properties of auditory cortex in children have been initiated. These studies follow on the heels of previous investigations in adult patient-subjects (reviewed in Nourski, Laryngoscope Investig Otolaryngol 2017, 2:147-56), permitting comparisons between auditory cortical physiology in children and adults. Seven children were studied (3-18 years of age). All studies were approved by the NIH and University of Iowa Institutional Review Board. Informed consent was provided by the children's parents or legal guardians. Verbal assent was obtained from children ages 5-9, and written assent was obtained for older children. The 3-year-old child was studied only with passive presentation of stimuli and in the presence of a parent who could terminate research activities at any time. The 18-year-old provided his own informed consent. Depth electrodes targeting posterior insular cortex for seizure monitoring were placed in all subjects, permitting recordings from Heschl's gyrus or its immediate vicinity (4 left hemisphere, 5 right hemisphere). Click trains (repetition rates 25-200 Hz), pure tones (frequencies 0.25-8 kHz, and stop consonant-vowel syllables were presented. Analyses focused on local field potentials and event-related high gamma power. In common with adult subjects, response latencies progressively increased and high gamma power progressively decreased from posteromedial towards anterolateral Heschl's gyrus. Individual cortical sites were generally broadly tuned but did exhibit spectral preferences within the frequency range of the tones. Similar to adults, frequency-following responses (FFR) elicited by click trains were generally observed for rates up to 50-100 Hz and were maximal at the most posteromedial sites. FFR to the fundamental frequency of the

speech syllables (~100 Hz) was especially prominent in posteromedial Heschl's gyrus. We conclude that many fundamental properties of neural activity recorded from Heschl's gyrus are similar to those seen in adult subjects from early childhood onward.

Title: Left auditory cortex learns the statistics of infant distress sounds

Authors: *J. SCHIAVO[1], S. VALTCHEVA[2], S. C. SONG[3], R. C. FROEMKE[4];
[1]New York Univ. Med. Ctr., New York, NY; [2]Skirball Inst., NYU Sch. of Med., New York, NY; [3]New York Univ. Langone Med. Ctr., New York, NY; [4]Otolaryngology, NYU Med., New York, NY

Abstract: Sensitivity to variability in low-level features enables generalization across sounds that vary across individuals, such as vocalizations. Statistical learning enables a sensitivity to feature regularities and distributions. While the neural correlates of statistical learning have been well studied, the mechanisms underlying the sensitization of the auditory cortex to relevant statistics are poorly understood. Here, we use behavioral approaches in mice, together with *in vivo* 2-photon imaging and whole-cell recordings, to examine how the maternal brain learns the statistics of infant vocalizations. While these calls have distinct acoustic features from adult calls, they are variable across individuals. We therefore hypothesize that retrieving females are sensitive to key statistics for generalization. Importantly, since pup-naïve virgins do not behaviorally respond to calls, but will retrieve following maternal experience, we can utilize this behavior to assess the plasticity mechanisms underlying sensitization of virgin auditory cortex to vocalization statistics. We assessed the categorical boundary of pup calls in the temporal domain by speeding or slowing call rate. We first assessed the behavioral response boundary in maternal animals in a Y-maze. Retrieving females preferred to approach speakers playing pup calls temporally modulated at the ethological rate compared to morphs outside this range. Using *in vivo* two-photon imaging, we found that excitatory neurons in core auditory cortex of experienced virgins responded invariantly to morphs within the natural range, but do not generalize across statistics in naïve virgins. Inhibitory neurons in naïve cortex were broadly

tuned, resulting in a mismatch in excitatory and inhibitory tuning. *In vivo* whole-cell recordings showed strong excitatory drive across prototypical calls in both groups, but a drop in excitatory drive across morphs in naïve females. *In vitro*, inhibition more strongly adapted in left auditory cortex of females at repetition rates around the natural call rate, indicating an intrinsic sensitivity to stimuli at these timings. We then tracked excitatory and inhibitory populations using 2-photon imaging during cohousing, and found that excitatory and inhibitory populations matched 24 hours post-retrieval. Finally, to determine if females generalized based on feature distributions experienced during learning, we manipulated the sensory environment during co-housing by playing out-of-category calls. Both behavioral responses and cortical responses generalized to these statistics post-retrieval, indicative of experience-dependent statistical learning.

Title: Neural correlation codes for sound identification and categorization: The contribution of sound spectrum and envelope correlation structure

Authors: *X. ZHAI[1], M. SADEGHI[1], F. KHATAMI[4], F. HE[2], D. PEDRICK[3], H. L. READ[3], I. STEVENSON[3], M. A. ESCABI[3];
[1]Electrical and Computer Engin., [2]Biomed. Engin., [3]Univ. of Connecticut, Storrs, CT; [4]Neurolog. surgery, Univ. of California, San Francisco, CA

Abstract: In natural sounds, spectro-temporal modulations are highly structured and varied, and the envelopes are correlated both across frequencies and time. Here we tested how the sound spectrum and correlation structure of natural sounds is reflected in the firing rates and correlation structure of neural ensembles, respectively, and how each of the neural representations (place rate code vs. neural correlations) contribute to a sound identification and categorization task. Five texture sounds (crackling fire, bird chorus, crowd noise, running water and rattling snake) were delivered to unanesthetized rabbits and neural activity was obtained from the auditory midbrain (the inferior colliculus, IC) using multi-channel neural recording arrays. We demonstrate that the correlated firing between frequency organized recording sites in the IC are modulated by each of the tested sounds and these neural correlations can be used to decode and identify sound textures. Specifically, stimulus-driven spectro-temporal correlations were measured across the frequency organized recording array and a naïve Bayes classifier was

applied to the ensemble correlation activities to identify the delivered sounds. The classifier was able to decode and identify these original sounds approaching near perfect accuracy (~90%). Furthermore, control tests indicate that the neural response correlation is largely invariant to changes in the sound spectrum. Preserving the modulation content of each sound while removing the sound spectrum (equalizing all sounds for 1/f power spectrum) did not have a major effect on the neural correlations or the classifier performance. However, firing rates changed substantially and the firing rate classifier performance was substantially reduced. On the other hand, removing the modulation content while preserving the original power spectrum led to a reduction in the classification accuracy for the correlation classifier. Next, we tested the neural correlation classifier on a three-sound categorization task (fire, water, and speech) with multiple exemplars (6 exemplars per category). The neural correlation structure for each sound was more similar within a category than across categories such that the classifier was able to decode and categorize the sounds with very high accuracy (>90%). These findings suggest that the coordinated firing in auditory midbrain ensembles is largely invariant to changes in the sound spectrum and thus can serve as a highly informative neural signal for identification and categorization.

Title: Encoding vocalizations in background sounds at the cocktail party and in the woods

Authors: *D. PEDRICK[1], X. ZHAI[2], F. HE[3], I. STEVENSON[3], M. A. ESCABI[3];
[1]Biomed. Engin., [2]Electrical & Computer Engin., [3]Univ. of Connecticut, Storrs, CT

Abstract: Separating foreground sounds from background noise has long been the focus of the cocktail party conundrum. The goal of this study is to determine how the spectrum and modulation content of a background sound mask the neural encoding of a foreground vocalization. To evaluate the ability of certain sounds to mask vocalizations, natural and man-made background sounds were used as maskers (speech babble, construction noise, multi bird calls, babbling water, etc). Neural responses were recorded from the un-anaesthetized, head fixed Dutch Belt rabbit, in response to foreground vocalizations (speech and bird song) in the presences of the original and perturbed background sounds. To isolate the masking effects due to

spectrum content, background sounds were *phase randomized*, which preserves the original sound spectrum but removes the modulation content. Alternatively, the modulation masking effect was isolated by *spectrum matching* all the background sounds to pink noise (1/f spectrum). This manipulation preserves much of the modulation content. Single neuron spiking data from the Inferior Colliculus in response to vocalizations paired with original, spectrum matched and phase randomized background sounds was analyzed to determine how the encoding of the foreground sound was affected by different background conditions. Shuffled correlogram procedures were used to isolate the background driven and vocalization driven components of the neural activity. Background driven activity was obtained by shuffling correlograms across frozen background sound segments with unfrozen foreground vocalizations (same background sound excerpt, different foreground excerpts). Alternately, foreground driven activity was obtained by shuffling correlograms across frozen foreground sound segments with unfrozen backgrounds (same foreground sound excerpts, different background excerpts from the same recording). Preliminary results show that spectrum of the background sound has a strong modulatory effect on the response firing rates. On the other hand, the modulation content of the background sound affects the reliability and precision of firing of both the foreground and background response. Thus, the sound modulation spectrum can influence the detailed temporal firing pattern to foreground sounds beyond what is expected for pure spectral masking. The findings suggest that high-order modulation content of sounds is affecting the neural representation of vocalizations in a variety of natural and man-made background sounds and thus is a critical acoustic cue for detecting signals in the presence of noise.

Title: The auditory dorsal pathway mirrors the semantic hierarchy of speech prediction

Authors: *L.-M. SCHMITT[1], J. ERB[1], S. TUNE[1], A. RYSOP[2], G. HARTWIGSEN[2], J. OBLESER[1];
[1]Dept. of Psychology, Univ. of Lübeck, Lübeck, Germany; [2]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: When poor acoustics challenge speech comprehension, listeners are thought to increasingly draw on semantic context to predict upcoming speech. However, previous research focused mostly on predictions derived from isolated speech material with short timescales of context (e.g., sentences). We here ask how the human brain builds up predictions when confronted with a multitude of timescales characteristic of natural speech. In a 3-T fMRI study, healthy participants (N=60, 18-74 years) listened to a one-hour natural narrative embedded in a competing stream (0 dB SNR) of resynthesized natural sounds. To model semantic predictability at five timescales corresponding to a logarithmic increase in context length (i.e., 1-24 content words), we computed the similarity between the word2vec embedding of each content word in the story and each timescale's average word embedding. In an initial analysis of data from 30 younger participants, we mapped the timescales of semantic predictability onto the BOLD signal using voxel-wise ridge regression within a fourfold cross-validation scheme. We found that the timescales of semantic prediction are organized along an auditory dorsal processing hierarchy: increased activity in the posterior portion of superior temporal gyrus is tightly coupled to short informative timescales, whereas parietal regions like the temporo-parietal junction and angular gyrus are most responsive to long informative timescales. Furthermore, brain areas most responsive to long timescales largely overlap with the dorsal default mode network. Next, we will use a measure of semantic predictability fine-tuned to the unique hierarchical structure underlying the context of each word by incorporating a deep neural network trained to determine the probability of an upcoming word given the semantics of a timescale.

Title: The contribution of stimulus-driven and noise correlation for neural decoding and identification of texture sounds

Authors: X. ZHAI[1], I. STEVENSON[2], ***M. A. ESCABI**[2];
[1]Electrical & Computer Engin., [2]Univ. of Connecticut, Storrs, CT

Abstract: The amount of information conveyed by neural ensemble about a sensory stimulus is critically dependent on the correlation structure of its neural activity. On the one hand, stimulus driven correlations between neurons are often thought of as form of redundant encoding with

limited encoding capacity and reduced efficiency. Alternately noise correlations, i. e., coordinated firing due to network activity unrelated to the sensory stimulus are often thought of as a form of noise that limit the classification accuracy of neural population codes. Using multi-channel neural recording arrays to record neural responses to natural sound textures in unanesthetized rabbits we demonstrate that correlated firing between frequency organized neural ensembles in the auditory midbrain (inferior colliculus) can be used to recognize sounds. To explore the contribution of stimulus driven and noise correlations for decoding the sound texture identity, we developed a noise-less and a single-trial classifier. The noiseless classifier excludes the noise correlations and thus sets an upper bound on the classification accuracy provided by the stimulus driven correlation structure. The single trial classifier, by comparison, requires that both the noise and stimulus driven correlations be taken into account. Unlike noise correlations, which are mostly unstructured (diagonalized) and vary little with the sound, stimulus driven correlations are highly stimulus dependent and their time-frequency structure was quite diverse and informative for the classification task. The noiseless classifier approached near perfect identification accuracy (average 90%) using stimulus-driven correlations only and sets an upper bound on the classification accuracy. Although the average single-trial classification performance was on average lower (70%), individual penetrations were found that approached near perfect accuracy (90%). This reduction in the classification accuracy was accurately accounted for by the noise correlations. When noise correlations are not included as part of the single-trial classifier model, single trial performance drops to near chance (20%). Furthermore, performance was highly correlated with the signal-to-noise ratio (SNR) of the neural correlations: classifier performance was higher for recording locations with higher SNR. Thus, unlike previous studies which have proposed that correlated firing is generally detrimental, these findings suggest that stimulus-driven correlations can be quite informative for sound identification whereas noise correlations limit the classification performance (supported by NIDCD R01DC015138).

Title: Temporal context invariance reveals neural processing timescales in human auditory cortex

Authors: *S. V. NORMAN-HAIGNERE[1], L. K. LONG[2], O. DEVINSKY[6], W. DOYLE[7], G. M. MCKHANN[3], C. A. SCHEVON[4], A. FLINKER[6], N. MESGARANI[5];

Abstract: Natural sounds like speech and music are structured at many timescales, but it remains unclear how these diverse timescales are cortically represented. Do processing timescales increase along the putative cortical hierarchy? What timescales are used to code speech and music? Is there hemispheric or anatomical specialization for processing particular timescales? Answering these questions has been challenging because there is no general method for estimating integration periods: the time window within which stimulus features alter the neural response. Here, we introduce a simple experimental paradigm (the "temporal context invariance" paradigm) for inferring the integration period of any time-varying response. We present sequences of natural sound segments in which the same segment occurs in two different contexts. We then measure how long the segments need to be for the response to become invariant to the context. By applying this paradigm to human electrocorticography data from epilepsy patients (broadband gamma power), we map neural processing throughout primary (near Heschl's Gyrus) and secondary regions (superior temporal gyrus) of human auditory cortex. This map reveals a clear gradient in which integration periods grow from ~100 ms in primary auditory cortex to ~300/400 ms in secondary auditory cortex. Using a separate dataset of responses to a diverse set of natural sounds, we then test what information can be decoded from populations of electrodes with different integration periods. We find that spectral information is best decoded from short integration period electrodes (<200 ms) while sound categories (speech & music) are best decoded at longer timescales (>200 ms). These results provide support for hierarchical models, demonstrate the timescale at which speech and music selectivity first emerge, and validate our method.

Title: Electrophysiological responses of the medial vestibular neurons to serotonin application

Authors: *M. SHINO, O. NIKKUNI, Y. TAKAYASU, K. CHIKAMATSU;
Otolaryngology Head and Neck Surgery, Gunma Univ. Grad. Sch. of Med., Maebashi, Japan

Abstract: The medial vestibular nucleus (MVN) located at the brainstem is involved in the velocity- position integration for horizontal eye movement. MVN plays an important role in occurring nystagmus as a center of vestibulo-ocular reflex (VOR) in cooperation with the prepositus hypoglossi nucleus (PHN). Serotonin synthesized in the raphe nucleus of the brainstem is a monoamine neurotransmitter and is widely distributed in the central nerves systems. As serotonin modulates emotion, sleep, and pain, its agonists are used for depression or migraine, and abrupt withdrawal from serotonergic drugs, such as selective serotonin reuptake inhibitor (SSRI) causes vertigo and dizziness frequently. Serotonin is also involved in vestibular compensation after unilateral vestibular dysfunction. In this study, to elucidate the neuronal mechanism between vertigo and serotonin, we investigated electrophysiological membrane properties of the MVN neurons to serotonin administration by whole-cell patch-clamp recordings in the young Wistar rats. In response to bath application of 40 microM serotonin, frequency modulation of spontaneous firing of the MVN neurons was classified into three types, decreased, increased, and stable type. Next, three parameters of the spike, the half-width of the spike, the time to peak afterhyperpolarization (AHP), and the amplitude of AHP were measured. Half-width was extended in firing decreased type, shortened in firing increased type, and no significant change in firing stable type. The time to peak AHP was a similar change in each firing types, extended in firing decreased type, shortened in firing increased type, and no change in firing stable type. The amplitude of AHP was shallowed in both firing decreased and increased type, and no change in firing stable type. Spontaneous inhibitory postsynaptic current (sIPSC) examined in voltage-clamp mode, was significantly increased by serotonin administration and completely abolished by additional application of picrotoxin and strychnine. These results indicated the probability that serotonin modulates the membrane properties of MVN neurons resulting in some effect on the vestibular system.

Abstract: In the current study, the inner ear of the sea lamprey was examined by scanning electron microscopy to elucidate some morphological findings of the ear in this species. The major emphasis of the study was to characterize the hair cell stereocilia bundle types and their morphological polarity in the canals' cristae. We revealed that there are three types of hair cells in the canal cristae according to their stereocilia bundle morphology. Type 1 hair cells, in which the kinocilium is slightly longer than the tallest stereocilia, was located along the medial banks of the crista. Type 1 kinocilia were of uniform polarity and pointing laterally (ampullipetal). Type 2 hair cells, in which kinocilia were much longer than the stereocilia, was most abundant in the central region of the crista with a fewer number scattered variably in the lateral zone. The polarity of Type 2 hair cells was variable and exhibited all orientations. Type 3 hair cells were found to have extremely long kinocilia (40-50 microns in length) with extremely short stereocilia. Type 3 hair cells were distributed along the peripheral, central and lateral zones of the crista. We demonstrated that the hair cell polarity in the canals' cristae of the lamprey is not uniform as previously described. Rather, a substantial population of hair cells have diverse polarity where all orientations are represented. The physiological significance of this diverse polarity and relationship to vestibular function will be discussed.

Title: Vestibular neurons with direct projections to the solitary nucleus in the rat

Authors: E. K. CHAPMAN, A. H. GAGLIUSO, G. P. MARTINELLI, ***G. R. HOLSTEIN**; Neurol., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Vestibular input to central autonomic nuclei includes projections influencing homeostatic regulatory functions such as gastrointestinal motility, respiration, heart rate and blood pressure. Two of these are direct pathways from caudal vestibular nuclear neurons to the rostral and caudal ventrolateral medullary regions, key relays in the baroreflex pathway. These pathways are comprised of distinct glutamatergic and GABAergic components, some of which co-localize imidazoleacetic acid ribotide (IAA-RP), an endogenous neuromodulator that binds to I1 imidazoline receptors and modulates blood pressure. The solitary nucleus (SolN) is also important for autonomic function, receiving general visceral afferent input that terminates with high topographic specificity in the intermedio-caudal region, a critical area for control of homeostatic activity. SolN also receives input from the vestibular system, providing an additional vestibulo-autonomic route for altering autonomic activity in response to changes in posture and head movements. The goal of this study was to visualize the chemical anatomy of vestibular nuclear neurons with direct projections to SolN.
Anterograde (PhaL) and retrograde (FluoroGold) tract tracing were combined with neurotransmitter and modulator immunolabeling in 12 adult male Long-Evans rats. Direct, sparsely branched but highly varicose axonal projections from neurons in the caudal vestibular nuclei to SolN were observed. The vestibular neurons giving rise to these projections were primarily located in ipsilateral medial vestibular nucleus. The cell bodies were intensely glutamate immunofluorescent and their axonal processes contained vesicular glutamate transporter 2, indicative of glutamatergic neurotransmission. IAA-RP co-existed in the glutamate-immunofluorescent, retrogradely-filled vestibular cells. The vestibulo-solitary neurons were encapsulated by axo-somatic GABAergic terminals suggesting that they are under tight inhibitory control. The results establish a chemoanatomical basis for transient vestibular activation of the output pathways from the caudal and intermediate regions of SolN. In this way, changes in static head position and movement of the head in space may directly influence heart rate, blood pressure and respiration, as well as GI motility. This would provide one anatomical explanation for the synchronous heart rate and blood pressure responses observed following peripheral vestibular activation, disorders such as neurogenic orthostatic hypotension, and the nausea and vomiting associated with motion sickness.

Title: An intersectional viral-genetic strategy for selective targeting of vestibular efferent neurons in awake behaving mice

Authors: *V. W. K. TUNG, A. J. MURRAY;
Sainsbury Wellcome Ctr. for Neural Circuits and Behaviour, Univ. Col. London, London, United Kingdom

Abstract: The brain learns about both the external environment and its own body movement through the activation of sensory receptors in the periphery. However, information from these peripheral sensors can be modified by the actions of central circuits through the actions of efferent pathways. In the vestibular system, the efferent vestibular nucleus (EVN) projects to the periphery and can modify the firing of sensory hair cells and afferents. However, the logic and by which the brain recruits the EVN to modify incoming vestibular signals is still unclear.
In order to probe the function of the EVN in awake-behaving animals we developed an intersectional viral strategy for selective targeting of these neurons. Mouse EVN neurons are cholinergic and co-express the neuropeptide calcitonin gene-related peptide (CGRP). We developed and adeno-associated virus construct that utilises a fragment of the CGRP-promoter to drive expression only in CGRP-positive cells. We combined this promoter with the cre-dependent expression of the recombinase FLPo. Stereotaxic injection of this AAV into the brainstem of ChAT::Cre mice results in the selective expression of FLPo in the EVN. Co-injection of flp-dependent AAV constructs allows for the selective visualisation and manipulation of EVN activity.
By combining viral injections with the injection of the retrograde tracer fluorogold into posterior or horizontal canal, we show that viral expression is restricted to the EVN. This strategy was sufficient to direct the expression of GCaMP6s to EVN neurons for fiber photometry recordings during mouse behaviour. Ongoing experiments are aimed at probing the behavioural effect of EVN perturbation through the selective expression of tetanus toxin light chain blocking the synaptic transmission of EVN neurons.

Title: Gain scaling adaptation in vestibular thalamus

Authors: *G. MCALLISTER[1], J. CARRIOT[1], J. X. BROOKS[1], H. HOOSHANGNEJAD[2], K. E. CULLEN[2], M. J. CHACRON[1];
[1]Physiol., McGill Univ., Montreal, QC, Canada; [2]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: Growing evidence shows that thalamus sensory neurons dynamically adapt their response functions to efficiently encode natural sensory stimuli with changing properties. In particular, natural stimuli tend to contain low-frequency changes in amplitude, which often induce adaptive gain scaling in thalamus neurons. This gain scaling increases the dynamic range of neural responses and increases neural coding accuracy. Gain control has been demonstrated for many sensory systems including visual contrast, visual motion, and somatosensory responses, but not clearly for the vestibular system. Previous studies have found that vestibular stimulation resulting from natural self-motion display highly variable amplitude ranging up to 450 deg/s and 4 G. However, whether (and if so, how) central vestibular neurons adapt in order to encode such a large dynamic range remains unknown to date. Here we investigated how neurons within the ventral posterior lateral thalamus adapt to changes in stimulus amplitude. We recorded extracellular single-unit neural responses within the ventral posterior lateral thalamus of rhesus macaque monkeys (2 male, 1 female) during whole-body yaw rotations. Stimuli were sinusoidal carrier rotations at 1-8 Hz, modulated with square-wave (0.1 Hz) or triangle-wave (0.033 Hz) envelopes. We calculated the time-dependent neural gain using a sliding window linear regression, averaged across envelope cycles. To describe the net effect of stimulus amplitude on gain, we measured the rate of gain change as the amplitude increases linearly (for the triangle-wave envelope functions). Moreover, to detect gain adaptation, we measured the gradual gain change following the amplitude step (for the square-wave envelope functions). We found that neural responses to amplitude steps were strongly nonlinear and that neural gain adapted significantly following the amplitude step. Gain scaled inversely with peak amplitude; this scaling consisted of an initial rapid component followed by a gradual adaptive decrease over 2-5 seconds. Moreover, neural responses to linearly increasing amplitudes between 5 and 100 deg/s were also nonlinear as the gain was decreased three-fold. Specifically, gain decreased exponentially with increasing peak amplitude, and with a greater time constant at higher rotation frequencies. We hypothesize that the adaptation uncovered helps to increase the dynamic range of ventral posterior lateral thalamus neurons in order to more efficiently encode natural self-motion stimuli with variable amplitude.

Title: Focused infrared radiation of vestibular end-organs evokes changes in heart rate and blood pressure

Authors: *D. RICE[1], S. RAJGURU[2], G. R. HOLSTEIN[3], G. P. MARTINELLI[4];
[1]Biomed. Engin., [2]Biomed. Engin. and Otolaryngology, Univ. of Miami, Coral Gables, FL;
[3]Depts Neurol, Neurosci, Anat/Cell Bio, [4]Dept. Neurol., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: In the present study, we have developed the application of pulsed infrared neural stimulation (INS) focused on the vertical semicircular canals as well as the otolith organs *in vivo* in a rodent model and characterized the resultant physiological modulation of heart rate (HR), blood pressure (BP) and heart rate variability (HRV). Long wavelength pulsed IR (1863nm) unilaterally targeted the posterior canal or utricle macula of anesthetized rats and cardiovascular responses evoked via the activation of the vestibulo-sympathetic reflex (VSR) were measured by a small animal single-pressure implantable device (DSI pressure sensing technologies, HD-S10) inserted into the femoral artery. Eye movements were simultaneously recorded using a custom-modified video-oculography system (ISCAN Inc.) to orient the optical fiber in the correct position. Post mortem micro-computed tomography was used to confirm the site of stimulation, the distance of the fiber from target structures, and orientation of the beam *in vivo*. The results were compared to contemporary electrical stimulation activation of the VSR. Stimulation of the posterior semicircular canals using frequency-modulated IR resulted in significant cardiovascular responses. Overall, the decrease in BP ranged from 3.5 to 19 mmHg and the decrease in HR ranged from 7.5 to 70 bpm (n=17). In at least half of these animals, the high to low frequency ratio of heart rate variability (HRV) increased during IR stimulation, suggesting activation of the sympathetic nervous pathway. IR directed unilaterally at the utricular macula also evoked characteristic vestibular-ocular reflex (VOR) eye movements. However, contrasting the posterior canal results, frequency modulated IR stimulation of the utricular macula failed to evoked significant changes in BP, HR, and HRV.

Title: Effect of vestibular stimulation by rotation on motor activity rhythm

Authors: *F. PASQUIER[1], N. BESSOT[1], T. MARTIN[1], A. GAUTHIER[1], J. BULLA[2,3], P. DENISE[1], G. QUARCK[1];
[1]Normandie Univ, UNICAEN, INSERM, COMETE, GIP CYCERON, 14000, Caen, France; [2]Dept. of Mathematics, Univ. of Bergen, Bergen, Norway; [3]Dept. of Psychiatry and Psychotherapy, Univ. Regensburg, Regensburg, Germany

Abstract: Background: All mammal organisms display a daily cyclic variation in a number of physiological functions. While light represents the main stimulus for entraining mammalian circadian rhythms, recent literature raises the hypothesis that vestibular afferents could influence the biological rhythms. Animal and human studies have revealed anatomical and functional links between the vestibular system and the central biological clock generating biological rhythms. Moreover, animal data suggest that vestibular stimulation has an impact on biological rhythms synchronization, but this hypothesis was never tested in human subjects. The present study aims to test the impact of the vestibular stimulation induced by a rotary chair on the motor activity rhythm of young healthy adults. Method: Thirty-four healthy adults (aged 23,32 ± 2.57 years ; 13 women and 21 men) were recruited. Each subject underwent an Off Vertical Axis Rotation (20 min, 60°/s, 15° axis tilt) session and a sham session in a counterbalanced order; all in the late afternoon, on the same day of the week, and at the same hour to avoid any weekly or diurnal variations. Subjects wore an actigraph on the non-dominant hand during all the protocol. Actigraphy measurements started one week before the first session to have a baseline, and stopped a week after the second session. Results: Statistical analysis demonstrated a significant decrease of activity level in the evening following vestibular stimulation (161.71 ± 45.73 mvts/min) compared to sham (207.97 ± 86.86 mvts/min) and baseline (194.67 ± 98.00 mvts/min) conditions. Also, the peak time of the motor activity rhythm presented a significant advance in phase (-1.15 h) two days after the stimulation session ($p < 0.005$) compared to sham and baseline conditions. Discussion: This research reinforces the hypothesis of the implication of vestibular afferents on the motor activity rhythm in human. It corroborates the findings of alteration in circadian rhythms in vestibular-deficient patients. These results suggest the use of vestibular stimulation as a new method in circadian rhythms rehabilitation.

Title: Vestibular perceptual neuronal substrate coding strategies for representing natural self-motion

Authors: *J. CARRIOT[1], G. MCALLISTER[1], H. HOOSHANGNEJAD[2], I. MACKROUS[1], J. X. BROOKS[1], K. E. CULLEN[2], M. J. CHACRON[1];
[1]McGill Univ., Montreal, QC, Canada; [2]The Johns Hopkins Univ., Baltimore, MD

Abstract: Self-motion is sensed by the vestibular system, contributing to automatic reflexes and spatial perception. While it is generally accepted that sensory systems have adapted their coding strategies to the statistics of natural signals, how the vestibular system processes natural self-motion is largely unknown because artificial (e.g., sinusoidal) stimuli have been typically used to date. Natural stimuli frequently display complex spatiotemporal characteristics. It is commonly assumed that, through both evolutionary and developmental processes, sensory neurons are adapted to the statistical properties of the stimuli to which they are exposed. This has led to the proposal that sensory systems optimally process natural stimuli by removing redundancy which is commonly referred to as whitening as the neural response then contains equal power at all frequencies (i.e., is “white”). While we have shown that VN neurons optimally encode natural self-motion through temporal whitening, how this information is decoded remains poorly understood. Here, we investigated how neurons within the ventral posterior lateral (VPL) Thalamus, which receive direct input from neurons within the vestibular nuclei (VN) and project to cortical structures respond to natural self-motion stimuli. Our results show that vestibular Thalamic neurons, contrary to VN neurons, do not display whitening. Indeed, their response power spectra were not constant as a function of frequency and instead resemble those of afferents. Our results therefore suggest that VPL neurons do not act as mere relays information relays. Rather, they show that information as to the head motion’s detailed time course is actively decoded in VPL before being transmitted to cortical structures. We hypothesize that such decoding is required for accurate self-motion perception.

Title: Effect of galvanic vestibular stimulation on motor activity rhythm in human

Authors: ***G. QUARCK**, F. C. PASQUIER, N. BESSOT, A. GAUTHIER, P. DENISE;
Univ. of Caen- COMETE-INSERM, Caen, France

Abstract: Background: Light is the dominant synchronizer to entrain circadian rhythms to 24h period. Also, non-photic stimuli play a role in biological rhythmicity. Human and animal studies demonstrated anatomical and functional links between the central biological clock and the vestibular system. Hypergravity negatively impacts temperature and locomotion rhythms of rats. In human, swinging protocols have demonstrated a positive effect in the wake-sleep transition. However, while literature demonstrates the impact of vestibular information on biological rhythmicity, the effect of vestibular stimulation on motor activity rhythm was never tested. Galvanic Vestibular Stimulation (GVS) is a non invasive, safe and useful tool to stimulate vestibular afferents. The present study targets the impact of GVS on the motor activity rhythm human. Method: 25 subjects participated in this study (11 women, 14 men aged 35,08 ± 9,78). Each subject underwent 2 sessions: a sham and a vestibular stimulation session, in a counterbalanced order. The sessions took place at midday, and were scheduled on the same day of the week (2 weeks in between), and at the same hour to avoid any diurnal or weekly variations. During the GVS a direct current (1mA) was applied on the mastoid processes for twenty minutes. Activity level was registered by actigraphy during all the protocol. Subjects continuously wore the actigraph on the non-dominant hand, starting one week before the first test session (baseline) and stopped a week after the second session.Results: Statistical analysis did not reveal significant differences in motor activity between the three conditions (sham, vestibular stimulation, baseline). Also, we did not observe any modifications of activity level during hours following the vestibular stimulation compared to sham or baseline conditions. Discussion: The expected results were a phase change in circadian rhythms and, in particular, the rhythm of motor activity, in the same way that afternoon physical activity practice can induce a significant phase advance on melatonin secretion. Our study demonstrated that daytime GVS did not induce phase shift in motor activity, but another study in our laboratory showed that afternoon vestibular stimulation using a rotatory chair did lead to a phase advance. We have now to explore if the

GVS is not efficient to induce biological rhythms modifications or if the protocol used is not suitable. Further research is necessary to test the impact of GVS on biological rhythms using a modified protocol.

Title: Stochastic noise differentially affects neuronal subtypes within the medial vestibular nucleus *in vitro*

Authors: S. STEFANI[1], P. BREEN[2], J. SERRADOR[3], M. SCHUBERT[4], *A. J. CAMP[1];
[1]Univ. of Sydney, Sydney, Australia; [2]Marcs Institute, Western Sydney Univ., Sydney, Australia; [3]Rutgers New Jersey Med. Sch., Newark, NJ; [4]Johns Hopkins Med., Baltimore, MD

Abstract: Background: Stochastic resonance is a phenomenon whereby sensitivity to sub-threshold signals is modified via low amplitude noise application. Application of stochastic noise has been shown to improve visual, auditory, vestibular and cardiovascular functions within humans.
Objective: Here we aim to determine how stochastic noise effects the gain and phase dynamics of individual medial vestibular nucleus neurons *in vitro*.
Methods: All experimental materials and procedures were approved by the University of Sydney Animal Ethics Committee. All experiments were performed in 3 - 5 week-old male and female C57BL/6 mice. Whole-cell current-clamp recordings of individual MVN neurons were made at room temperature from 200 μm transverse tissue slices. Recordings were made in response to a suite of depolarising current steps (6 steps, 10 pA/step) with stochastic, sinusoidal or stochastic + sinusoidal noise or without noise (control). Spike rate vs current plots were produced and the slope of the line of best fit used to quantify neuronal gain. Neuronal type was characterised objectively based on their afterhyperpolarisation (AHP), and blind to the experimenter. Phase dynamics of neuronal firing was determined by analysing the timing of action potentials in accordance with the sinusoidal stimulus peaks.
Results: In 25/45 MVN neurons stochastic noise produced a significant alteration in neuronal gain when compared with the no noise control condition. In 12 of these neurons this difference was expressed as an increase in neuronal gain and in 13 of the cells, neuronal gain was reduced. Type A ($n = 12$) and C ($n = 6$) MVN neurons increased in gain (A; $p < 0.05$, C; $p = 0.06$), whilst type B ($n = 20$) were unchanged. Phase dynamics of MVN neuron was unaltered in all neuron

subtypes.
Conclusion: The sensitivity of MVN neurons can be influenced by the application of stochastic noise. Importantly this data suggests that the impact of stochastic noise is differential - that is, type A and C neurons appear most sensitive to stochastic noise. This differential may provide a "normalisation" mechanism to modulate the overall sensitivity of the vestibular system and as such may be useful in the development of therapeutic devices to treat those suffering from balance dysfunction.

Title: Structural connectivity patterns of visual-vestibular brain areas PIVC and PIC

Authors: *A. L. BEER[1], M. BECKER[1], S. M. FRANK[1,2], M. W. GREENLEE[1];
[1]Inst. für Psychologie, Univ. Regensburg, Regensburg, Germany; [2]Dept. of Cognitive, Linguistic & Psychological Sci., Brown Univ., Providence, RI

Abstract: Visual-vestibular integration is a key feature of human self-motion perception. The parieto-insular vestibular cortex (PIVC) and the posterior insular cortex (PIC) are relevant brain areas of the visual-vestibular network. Here, we examined the white matter connectivity of PIVC and PIC with intra-hemispheric cortical areas by probabilistic tractography based on diffusion-weighted magnetic resonance imaging in 20 human brains. PIVC and PIC were defined functionally using stimulation with caloric vestibular and visual motion cues in individual subjects during functional MRI. Our results showed high track probabilities for connections with PIVC in the lateral sulcus including the anterior insula, the inferior frontal cortex, the central sulcus, the superior frontal cortex, the cingulum, the intraparietal sulcus, the parieto-occipital sulcus, and parts of the calcarine sulcus. For connections with PIC high track probabilities were found in the supramarginal gyrus, superior temporal sulcus, inferior parts of the central sulcus, the intraparietal sulcus, the parieto-occipital sulcus, and also in parts of the calcarine sulcus. These findings replicate and extend previous results from our group showing that PIC and PIVC share connectivity with several cortical areas, whereby PIC exhibits stronger connections to posterior and PIVC to anterior parts of the cortex. Such connectivity could support multisensory integration for self-motion perception.

Title: Encoding strategies of natural self-motion in the early vestibular pathway

Authors: ***I. MACKROUS**[1], J. CARRIOT[2], K. E. CULLEN[3], M. J. CHACRON[1];
[2]Physiol., [1]McGill Univ., Montreal, QC, Canada; [3]Dept. of Biomed. Engin., The Johns Hopkins Univ., Baltimore, MD

Abstract: The vestibular system generates reflexes that are vital for gaze and posture stabilization, as well as for accurate spatial perception and motor control. Yet, most previous studies of self-motion processing by vestibular neurons have used artificial (e.g., sinusoidal) stimuli whose properties fundamentally differ from those experienced during natural everyday activities. Here we investigated how neurons in the vestibular nuclei (VN) encode naturalistic self-motion. Prior studies have shown that different cell classes within the VN project to different downstream areas and mediate reflexive versus perceptual behavioral responses. Specifically, vestibular-only (VO) neurons project to the ventral posterolateral (VPL) nucleus of the Thalamus, thereby mediating self-motion perception, as well as to the spinal cord, mediating vestibulo-spinal reflexes. In contrast, position-vestibular-pause (PVP) as well eye-head (EH) neurons project to eye motoneurons within the abducens nucleus and mediate reflexive behaviors such as the vestibulo-occular reflex (VOR). We found that many neurons responses were matched to natural stimulus statistics such as to optimally encode them through temporal whitening. Interestingly however, a subpopulation of VN neurons, identified for each cell type, showed response power spectra that that did not whitened, but instead followed the statistics of natural self-motion. Neuronal variability predicted the degree of optimal coding in that, more irregular neurons displayed greater whitened responses. Further, we found that the tuning properties of PVP neurons were sufficient to account for temporal whitening while this was not the case for EH and VO neurons (Mitchell et al. 2018). For these 2 latter neuron types, both neuronal variability and tuning were required to account for the different observed degrees of optimized coding. Overall, our results show that not all neurons within VN perform optimally encode of natural self-motion stimuli. We hypothesize that the output of neurons that do not temporally whiten enables the proper decoding of the optimized information carried by temporally whitened responses by downstream brain areas. As such, our results have important

implications for understanding how optimized coding is achieved by early vestibular pathways. Specifically, they suggest that similar coding strategies are used to transmit information about self-motion for both vital reflexes as well as self-motion perception.

Title: Development of membrane properties of vestibular neurons in perinatal mice

Authors: *C. J. DUBOIS, L. CARDOIT, F. M. LAMBERT, M. THOBY-BRISSON;
Inst. de Neurosciences Cognitives et Intégratives d'Aquitaine, université de Bordeaux, Bordeaux, France

Abstract: The neuronal vestibular network is involved in postural reflexes by integrating sensory vestibular inputs into *ad hoc* fast corrective motor actions. While most studies have focused on features of the mature vestibular network, the acquisition of the electrophysiological properties required for proper integration of vestibular inputs during early development remained unknown. Moreover, the ontogeny of these properties on distinct vestibulo-motor pathways had yet to be determined. Here we describe the membrane properties of vestibular neurons from embryonic stage E14.5 to postnatal day 5 in mice. We focused on two functionally distinct groups: the vestibular neurons that project to the contralateral vestibular nucleus (commissural neurons) and those projecting to the spinal cord *via* the Lateral VestibuloSpinal Tract (LVST neurons). At E14.5, vestibular neurons from both groups were unable to generate spike trains, even upon injection of depolarizing currents, suggesting an immature phenotype. At E15.5, more than 80% of the neurons still exhibited immature features. From E16.5 to P5, both commissural and LVST neurons progressively acquired the ability to sustain spike trains in response to depolarizing currents and could be classified similarly to mature preparations as type A or type B neurons according to the absence or the presence of a double after hyperpolarization, respectively. In the LVST population the proportion of type A neurons progressively increased to reach about 70% by P2-P5 whereas this proportion remained stable at 60% in the commissural group from E16.5 to P5. For type B neurons, their proportion remained stable (around 30%) from E16.5 to P5 in the LVST, but were detected only after birth in the commissural group. Functionally, most of the type A neurons of both groups and commissural type B neurons were spontaneously active at rest, while LVST type B neurons were all silent. Morphologically, only

type B neurons of both groups exhibited developmental changes with an increase in the number of neurites after birth. Altogether, our results show that vestibular neurons acquire their electrophysiological identity after E14.5 onwards and that the maturation of their membrane properties is not uniform across the different functional subgroups of vestibular neurons.

Title: Characterization of intrinsic membrane properties of vestibulospinal neurons through xenopus development

Authors: *A. OLECHOWSKI-BESSAGUET[1], L. CARDOIT[2], M. THOBY BRISSON[3], F. M. LAMBERT[4];
[1]CNRS UMR 5287, [2]Univ. of Bordeaux, Bordeaux, France; [3]Univ. De Bordeaux, CNRS UMR 5287, Bordeaux Cedex, France; [4]INCIA UMR 5287, CNRS Univ. of Bordeaux, Bordeaux, France

Abstract: Central vestibular neurons (2°OVN) involved in vestibulo-motor pathways present distinct intrinsic membrane properties in relation to specific vestibular functions in a given sensory-motor reference frame. Neuronal and behavioral remodeling that occur during amphibian metamorphosis represent a relevant plasticity model to investigate this functional vestibular organization. In adult terrestrial frog, two groups of 2°OVN were described according to their discharge dynamic: Phasic neurons exhibiting a high-frequency burst of 1-3 spikes, with monophasic AHP and tonic neurons firing continuously spikes with a biphasic AHP. These 2°OVN sub-populations act as band-pass and low-pass neuronal filters, respectively. Nonetheless this characterization was established on unspecified 2°OVN and so far nothing is known about the maturation of their features trough the frog metamorphosis.
This study aims to investigate 1/ intrinsic membrane properties of 2°OVN from identified vestibular pathways and dedicated to a precise vestibulo-motor command and 2/ their developmental maturation when the posturo-locomotor system is completely re-organized. The lateral vestibulo-spinal tract (LVST) produces vestibulospinal reflexes involved in postural control. Intrinsic membrane properties of LVST 2°OVN were characterized in larval (stage 53-

55) and juvenile *Xenopus laevis* aquatic frog. Rhodamine dextran (RDA) crystals were applied in the rostral hemi-cord to label ipsilateral brainstem vestibulo-spinal neurons by retrograde tracing. Patch-clamp recordings of RDA^+ LVST neurons were performed on 300µm transversal brainstem slices. Discharges dynamics were obtained in response to positive current step injections (+50pA to +300pA). Both developmental stages exhibited classical phasic (1-3 spikes) and tonic (continuous firing) LVST neurons. A third class of neurons was found with intermediate firing pattern (>3 spikes but not continuous) and varying discharge dynamics. Most of the recorded neurons presented a biphasic AHP and action potentials duration was larger in larvae than in juvenile.
This study depicts a functional link between 2°OVN neuronal properties and sensory-motor transformation produced by a given vestibular circuit and its developmental maturation.

Title: On the organization of electrical coupling between inferior olive neurons, and its influence on synchronized rhythmicity

Authors: *N. VRIELER[1], M. Y. UUSISAARI[2], Y. YAROM[1];
[1]Hebrew Univ. of Jerusalem, Jerusalem, Israel; [2]OIST, Kunigami-Gun, Japan

Abstract: The synchronicity in the rhythmic activity patterns produced by the inferior olive (IO) network is thought to be highly relevant to the cerebellar computation. While this synchronicity is known to depend on the dendro-dendritic gap junction (GJ)-coupling between IO neurons, it is unclear how this electrical coupling can allow specific subpopulations of neurons to synchronize their rhythmic subthreshold oscillations (STOs), rather than causing the entire network to act together. In the work presented here, we explore the possibility that spatio-temporal synchronicity patterns are inherent to the organization of the electrical coupling between IO neurons. Using a combination of morphological and electrophysiological data from mouse IO neurons collected in *in vitro* patch clamp experiments, we characterize the relationship between electrical dendro-dendritic coupling and intrinsic physiological response properties. Our results suggest that subsets of neurons with densely overlapping dendrites form anatomical clusters in the IO network, while other neurons form sparser connections across clusters. The morphological

and electrophysiological data together support the intriguing possibility that the networks' anatomically clustered neurons are wired to maintain steady rhythmic activity. Meanwhile, large-scale synchronicity patterns in the network may be mediated by the neurons connecting across clusters.

Title: Orientation-dependent bias on connectomes in cat's secondary visual cortex

Authors: ***R. LUSSIEZ**[1], A. OUELHAZI[2], S. MOLOTCHNIKOFF[3];
[1]Univ. of Montreal, Montreal, QC, Canada; [2]Sci. Biologiques, Univ. De Montreal, Montreal, QC, Canada; [3]Sci. Biologiques, Univ. de Montreal, Montreal, QC, Canada

Abstract: As previously demonstrated in numerous studies, the cat's visual cortices V1 and V2 are functionally organized, following an orientation column pattern. However, the stimulus-evoked response does not exclusively rely on this orientation selectivity, but also on the complex interplay between orientation columns and cortical layers. This complex interplay can be revealed by examining the neuronal circuits, also called connectomes. It has been shown that for a same cell-assembly in V1, the connectome (functional connections between neurons) changes depending on the visual orientation, presented as a sine-wave grating (Bharmauria, 2015). As V2 shares the same organization than V1, our aim in this study is to investigate the stimulus-dependent connectomes in V2. Using electrophysiological multi-unit recordings in V2, we recorded the neurons' electrical activity in both supra- and infragranular cortical layers of an adult head-fixed anesthetized cat. Spike-trains cross-correlations were computed to study functional connections between simultaneously recorded neurons. Similarly to V1, we observed a change in network connections depending on the presented orientation. Moreover, and quite interestingly, oblique orientations close to cardinal orientations (22.5°, 67.5°, 112.5°, 157.5°) generate a higher number of functional connections. We hypothesize that while cardinal orientations (0° and 90°) are overrepresented in the visual cortex, these oblique orientations require an additional emergence of functional connections to be effectively processed in relation to dominant cardinal orientations.

Title: A comparison of columnar and laminar neuronal distribution in human and macaque V1

Authors: *V. GARCIA-MARIN, J. G. KELLY, M. J. HAWKEN;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Neuronal density is thought to be critical to understanding the architecture of the cortex. One question that is central to the generality of cortical structure is the number of neurons in a cortical column through the depth of cortex. In the current study we compared the neuronal numbers in an ocular dominance column (ODC) in monkey and human primary visual cortex (V1). In human V1 previous studies have reported different neuronal densities; ranging from 18 to 123 x 10^3 neurons/mm^3. First we reevaluated the neuronal density in human V1 using immunohistochemistry and an automatic quantification method that we previously used in monkey V1 (Kelly & Hawken, 2017). Using antibodies to uniquely identify all the neurons (anti-NeuN) is a more specific approach than using Nissl staining. Using immunofluorescence confocal microscopy for NeuN and DAPI (a general cell marker), followed by post-imaging automatic segmentation, we quantified the distribution of neurons in 7 humans (14 columns). The average density across layers was 75 x 10^3 neurons/mm^3 and 159 x 10^3 DAPI cells/mm^3. Obtaining accurate neuronal density is an important step in establishing a link between processing modules in different species. In V1, the ODC is an important module that contains the processing for the full range of orientations at a range of spatial scales for one eye. Using the data obtained from our current study along with our data from macaque V1 (Kelly & Hawken, 2017; Garcia-Marin et al., 2019) and the ODC size in human and macaque, we estimated there were 159 x 10^3 neurons in one human ODC compared to 69 x 10^3 in one macaque ODC. Further, we estimated that were 1261 minicolumns per ODC for human and 625 minicolumns per ODC for macaque. Using the total number of neurons per ODC, we estimated that there were 127 neurons per minicolumn in human and 111 neurons per minicolumn in macaque. These estimates suggest that at the finest columnar scale - the minicolumn - there is a close match in the number of neurons between human and macaque. Yet at the meso-scale the human cortex has about 2.3 times the number of neurons per ODC than in the macaque even though the density of neurons in human cortex is about 1/3 of the density in macaque.

Title: Cortico-cortical axons of the visual cortex are not myelinated

Authors: *J. ROY, E.-M. FRIGON, D. BOIRE;
Dept. d'anatomie, Univ. Du Quebec A Trois-Rivieres, Trois-Rivieres, QC, Canada

Abstract: Myelin ensheathment increases transmission speed and could also improve synchronicity of signals despite differences in length of axonal paths to reach a specific target. Myelin distribution along the length of single axons of the cerebral cortex is poorly know. Although both myelinated and unmyelinated axons are present in both grey and white matter, the identity of the myelinated fibers at the single axon level is widely ignored. Moreover, myelin sheath can vary in length and thickness along a same axon. Typically, it is believed that in the CNS, axons connecting distant brain areas are wrapped in myelin. In addition, there are observations of myelinated local and recurrent axon collaterals of cortical pyramidal neurons. A recent study has reported that most myelinated fibers of the rodent cortex are axons of parvalbumin positive GABAergic interneurons. The objective of this study is to see the myelination pattern of visual cortex cortico-cortical projection axons in the mouse. Iontophoretic injections of the anterograde tracer, *Phaseolus vulgaris* leucoagglutinin (Phal), were performed in the visual cortex of C57BL/6J mice. After one-week survival, brains were harvested and cut. Myelin (myelin binding protein MBP) and Phal were revealed by immunohistochemistry. Confocal microscopic analyses of colocalization (proximity) of the axonal and MBP labeling showed that most of the visual cortex efferent axons are not myelinated. Most projections to ipsilateral cortices travelled through the gray matter whereas those to contralateral cortices travelled through the white matter. No myelinated grey matter axons were observed. Moreover, it was also noted that the orientation and morphology of the Phal labeled axons didn't correspond to the myelin labeling patterns. Myelin labeling in the mouse cortex appears as a regular columnar radial pattern of axonal bundles crossed by tangential horizontal fibers, while the Phal labeled axons had oblique orientations and travelled up and down between the myelinated fibers. The lack of colocalization in addition to morphology, suggest that most ipsilateral corticocortical projections in the mouse are through unmyelinated fibers.

Title: Complete synaptic coverage of dendrites of calcium-binding protein expressing GABAergic interneurons in mouse primary visual cortex

Authors: *P. TALAPKA[1], Z. KOCSIS[2], L. D. MARSI[1], V. E. SZARVAS[1], Z. F. KISVARDAY[1];
[1]Dept. of Anatomy, Histology and Embryology, Univ. of Debrecen; Fac. of Med., Debrecen, Hungary; [2]Neurosci. Res. Group, MTA-DE, Debrecen, Hungary

Abstract: Despite a vast number of well-organized datasets concerning the morphological, electrophysiological and synaptic properties of GABAergic inhibitory interneurons (INs), quantitative data on single cells as to their synaptic connectivity with other members of the neural network are quite rudimentary. Our major goal is to generate a quantitative electron microscopic (EM) database of the complete synaptic coverage of major subtypes of INs in the mouse primary somatosensory (S1) and visual (V1) cortices. Here we report our newly-developed immunohistochemistry-correlated EM method proved successful in allowing of tracing long dendrite segments originating from the parent soma. This method generates utmost ultrastructural quality which is free of deficits caused by the immunohistochemical procedure. 60 μm thick coronal vibratome sections were collected from tissue blocks containing cortical areas S1 and V1. Adjoining sections were reserved for EM analyses ("non-labelled") and stained for a particular GABAergic subtype marker ("labelled"), respectively. Thereafter, we utilized the "mirror" technique which rests on the precise identification of "mirror" cells which are cut in half by the sectioning plane of adjoining sections. Calbindin-D_{28K} (CB), calretinin (CR) and parvalbumin (PV) immunopositive INs were chosen from different layers of mouse V1, identified in the "non-labelled" sections and embedded in resin blocks. 50 nm ultrathin serial sections covering the whole thickness of the vibratome sections (~1200) were collected, processed for transmission EM analyses and documented typically at x30 k magnification. Section loss was less than 3%. Three dendrites, belonging to CB, CR or PV containing INs were traced (photographed) and reconstructed in 3D. We were able to determine the main synaptic parameters: distribution and exact distance of excitatory and inhibitory synapses from soma location, surface area and volume of the presynaptic boutons, morphometric parameters of vesicles, surface extent of the active zones. Here we provide the first complete quantitative

analyses of synaptic coverage of dendrites belonging the calcium-binding protein containing IN subtypes in the mouse neocortex. Supported by the Human Brain Project (785907-SGA2).

Title: Whole-brain reconstruction and classification of single spiny neurons in the neocortex of mice

Authors: *Y. WANG[1,2], P. XIE[1], X. KUANG[2], Y. LI[2], E. SHEN[1], P. LESNAR[1], A. FEINER[1,3], Y. WANG[3], H. KUO[1], Y. YU[1], Z. ZHOU[1,4], H. GONG[4], Q. LUO[4], H. PENG[1], J. HARRIS[1], H. ZENG[1];
[1]Allen Inst. for Brain Sci., Seattle, WA; [2]Wenzhou Med. Univ., Wenzhou, China; [3]Shanghai Univ., Shanghai, China; [4]Huazhong Univ. of Sci. and Technol., Wuhan, China

Abstract: Excitatory spiny neurons are the majority in neocortex , which have been intensively studied and defined into many types in different layers using brain slices with structures especially axons severed. The full neuronal morphologies are still unknown for most neuron types. To describe and classify these neurons based on complete morphologies, we performed computation-assisted morphological reconstructions to obtain full dendrites and axons of single neurons across all layers of multiple cortical regions using NL360 and Vaa3D-TeraVR from a high resolution whole brain image stack (>10K images, 0.2 x 0.2 x 1 micron at XYZ axis) acquired with a two-photon fluorescence micro-optical sectioning tomography system (2p-fMOST). We sparsely labeled neurons using tamoxifen-inducible Cre driver lines (Gnb4-CreERT2 and Cux2-CreERT2) crossed to a bright GFP reporter (Ai139, Ai140 and Ai166). Based on whole brain reconstruction, especially long axonal projections, we describe several preliminary results for neurons across cortical layers. (1) Ipsilateral-projecting pyramidal cells (PCs) typically target multiple cortical and sub-cortical regions; those of the same type have mostly shared target regions. (2) Contralateral-projecting PCs typically form an axon cluster around soma and also project to the homotypic region of contralateral hemisphere, forming

another axonal cluster. (3) Most PC types have ipsi- and bi-lateral projection subtypes, but only bilateral subtypes were found in some regions (such as L3TPCs in MOp, L6bPCs in AIv, L2/3TPCs and L4SSCs in AUD). (4) Axonal morphologies of L4 neurons, especially long projections, vary according to soma location and cell type. L4SSCs typically have only a local axon in the SSp but often form ipsi- and contralateral projections in VIS and AUD. L4TPCs and L4UPCs have projections to both neighboring and distal regions. (5) Like TPCs in other layers, ipsilateral L2TPCs typically have an apical dendrite, but bilateral L2TPCs commonly have 2 to 3 apical dendrites. (6) Clustering analyses based on dendrosomatic and axonal features with a large sample of L6bPCs, revealed multiple groups (i.e., objectively classified types) that were consistent with those simply grouped based on soma locations. Taken together, morphological features of fully reconstructed neurons suggest that axonal and dendritic morphologies, especially long axonal projections, vary according to soma locations, indicative of a topographic organizational principle in cortical network. These results demonstrate the potential of large-scale whole brain single neuron reconstructions for revealing general organizational rules of connectivity.

Abstract: There are a multitude of characteristics that define a cell type. Morphology is one of the most traditional and can be used in combination with other cellular properties, such as gene expression and electrophysiology, to identify robust cell types. One of the most distinct inhibitory cell types are Somatostatin (Sst) - expressing Martinotti cells, which are characterized by extensive layer 1 innervation. Other Sst-expressing cells lack extensive layer 1 innervation

and/or have unique inhibitory, long-range projection axons. Previously, we have described six morpho-electric (ME) types of the Sst subclass in mouse, primary visual cortex (Gouwens et al., 2018) that align, and further divide, the above-mentioned types. We now have a large dataset of reconstructed Sst neurons (>300 neurons) in mouse visual cortex that facilitates a more in-depth understanding of the diversity of this population. Here we describe the relationship between morphological types and ME-types and for a subset of cells we can directly relate morphological properties and types to transcriptomic cell types described in another recent paper (Tasic et al., 2018). With new advances in sparse genetic labeling and high-resolution whole brain fluorescence micro-optical sectioning tomography (fMOST) imaging, we extended this dataset to include some of the first whole brain reconstructed Sst neurons. We are further establishing the correspondence between the *in vitro*-labeled Sst neurons within and across transcriptomic types and the Sst neurons labeled *in vivo.*

Abstract: There is a major effort in the field of neuroscience to understand and describe the diversity of cell types in the brain. Recently, single cell transcriptomics has massively accelerated this effort, and transformed the way that we approach cell type classification. Instead of relying on cellular properties such as morphology, physiology and/or function to define cell types, transcriptomic studies rely largely on gene expression pattern. Much less work has been

done to understand the relationship between gene-defined cell types and these other important cellular properties.
The 'Patch-Seq' method is a modified patch clamp protocol that was developed to directly access gene expression, morphology, and electrophysiology from the same cell. We used this method on acute mouse brain slices to perform a systematic, multiple modality characterization of hundreds of inhibitory neurons across multiple molecular subclasses (e.g., Sst, Pvalb and Vip) in the adult primary visual cortex. Using transcriptomic data, we mapped each cell to a previously described transcriptome-based cell type taxonomy (Tasic et al., 2018), and reconstructed a representative set of neurons from multiple inhibitory transcriptomic types. From these data, we derived a quantitative morphological signature for each transcriptomic type. We also performed clustering analyses based on morphology alone, and described the relationship between morphological types and transcriptomic types. These analyses revealed a complex relationship between morphological properties and transcriptomic cell types. For some transcriptomic types, there is a clear consistency with morphological types, particularly within a layer. For other transcriptomic types, the morphology varies in terms of features such as axon extent, while other features, such as axon distribution around the soma are consistent within a type. To gain a better understanding of the genes that underlie morphological differences within an inhibitory subclass, we also investigated how gene expression differs as a function of anatomical location, laminar branch distribution and morphology. This work provides the basis for understanding the relationship between morphological and transcriptomic properties of cortical neurons.

Abstract: A critical component of the mouse neocortex is its rich variety of inhibitory interneuron populations, with well-described differences in transcriptomic, electrical, and morphological properties. Understanding how these properties relate within and across these subsets of neurons can provide the foundation for elucidating their ultimate function.
We provide a global approach to addressing how well electrical and transcriptional signatures of inhibitory interneurons correspond via standardized pipeline generation of 'Patch-Seq' data from thousands of neurons from the mouse visual cortex. The electrophysiological properties of single cells are derived from automated feature extraction of recordings collected with the whole cell patch clamp technique. At the end of a recording, the cell's nucleus is harvested for transcriptional profiling via RNA-seq; transcriptomic class is assigned by mapping the cell to the Allen Institute's previously defined transcriptomic tree. We see strong correspondence between the electrophysiological and transcriptional profiles in the 4 major classes of interneurons - Pvalb, Sst, Vip, and Lamp5. Within each class we observe cases in which individual transcriptomically defined subsets of cells have distinct and overlapping electrophysiological features. These data are a valuable tool in the interpretation of transcriptomic-based classification schemes.

Title: Correspondences between transcriptomic, electrophysiological, and morphological characteristics of interneurons in mouse visual cortex

Authors: *N. W. GOUWENS, F. BAFTIZADEH, A. BUDZILLO, R. DALLEY, J. MILLER, S. A. SORENSEN, B. TASIC, Z. YAO, A. ARKHIPOV, G. J. MURPHY, C. KOCH, H. ZENG; Allen Inst. for Brain Sci., Seattle, WA

Abstract: Addressing the complexity of neuronal circuits by classifying cellular components into meaningful types is an ongoing challenge. Recent single-cell transcriptomic studies have

provided high-dimensional, high-throughput classifications of neocortical neurons. While the broad subclasses identified by these studies have been shown to be consistent with types defined by electrophysiological and morphological properties, it is unclear if these properties remain consistent at the level of individual transcriptomic types, which would have implications for the roles of those types in cortical circuits. To investigate this, we made whole-cell Patch-Seq recordings from mouse visual cortical interneurons labeled by transgenic lines, primarily from the Sst and Pvalb subclasses. The neurons' intrinsic electrophysiological properties were characterized by a standardized stimulus protocol, and the neurons were filled with biocytin for morphological reconstruction. After recording, the nuclear contents of the cell were extracted to profile the transcriptome by RNA-seq. This data set, with electrophysiological, morphological, and transcriptomic all collected from the same cells, enabled us to assess directly the correspondences between transcriptomic types (or t-types, identified by mapping to a benchmark data set of FACS-collected cells) and their electrophysiological and morphological properties, which were characterized in a low-dimensional feature space. We also compared the t-types to a new set of types identified by unsupervised clustering based on combining transcriptomic data with electrophysiological and morphological features. We found that, in agreement with earlier studies, all three properties were consistent at the subclass level; for example, cells with Pvalb t-types exhibited joint electrophysiological and morphological characteristics that were largely distinct from those of cells with Sst t-types. We also identified additional consistency at the level of individual transcriptomic types; however, the strength of the correspondences varied across types and across interneuron subclasses. Our analyses here inform cell type classification by characterizing patterns of cell-by-cell co-variation in gene expression, local morphology, and electrophysiological properties, as well as by estimating the extent to which intrinsic electrophysiological and morphological properties can be inferred if the transcriptomic type of an interneuron is known.

Title: Distribution and strength of interlaminar synaptic connectivity in mouse primary visual cortex revealed by two-photon optogenetic stimulation

Authors: *T. A. HAGE, A. BOSMA-MOODY, C. A. BAKER, M. B. KRATZ, L. CAMPAGNOLA, S. C. SEEMAN, T. JARSKY, G. J. MURPHY;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: An initial step towards understanding how cortical neurons transform and process information is to thoroughly characterize the connectivity within and between classes and types of neurons. Our approach to do so employs targeted 2-photon optogenetic stimulation at cellular resolution to measure connectivity in the primary visual cortex of adult (>P40) mice. To restrict expression of the ChrimsonR opsin to cell classes of interest, we used both a Cre-dependent transgenic effector line (Ai167) and a combinatorial approach where an AAV-FLEX ChrimsonR (soma-targeted) was injected into selected Cre lines. The results described here utilized the excitatory Scnn1a-, Rorb-, Tlx3- and Ntsr1-Cre lines, and the inhibitory Sst-Cre line. We photostimulated putative presynaptic neurons by rapid galvo-based-spiral scanning of the soma. We measured synaptic inputs via simultaneous whole cell patch clamp of 1-4 postsynaptic cells. Initial data collection focused on L2/3 pyramidal neurons as a postsynaptic class. We characterized canonical feed-forward inputs from L4 excitatory neurons and feedback inputs from L5 and L6. Additionally, we explored within- and between- layer inhibitory connections from somatostatin neurons onto L2/3 pyramidal neurons. Across this study, we identified more than 250 connections from over 4500 probed. The highest rates of connectivity onto L2/3 pyramidal neurons were observed from L4 excitatory neurons and local Sst-neurons within L2/3. Furthermore, we found infrequent feedback connections from excitatory and Sst-neurons in L5 onto L2/3 pyramidal neurons, notably, with PSP amplitudes that were often larger than the more canonical feed-forward inputs. By combining simultaneous patch clamp recordings with photostimulation of dozens of individual putative presynaptic cells, we have measured >25 instances of divergence of a single presynaptic neuron to 2-4 postsynaptic cells. Similarly, we have observed >50 examples of convergence of 2-12 presynaptic neurons onto individual postsynaptic neurons. Future analyses will describe heterogeneity in the strength of afferent and efferent connections of single cells as well as variability in the spatial profiles of connection probability and strength measured within and between cell classes.

Abstract: The brain is composed of millions of diverse neurons that differ systematically in the genes that they express. Analyses of single cell gene expression data reveal clusters which correspond to different cell types that differ in their connectivity and function. Can neurons from within a single genetic cluster be further extracted based on connectional properties, and if so do they differ systematically in the genes that they express? For example, most recent studies of single cell transcriptome analyses suggest only two or three distinct genetic cell type clusters in layer 2/3 (L2/3) pyramidal neurons of mouse primary visual cortex (V1). In contrast, L2/3 neurons in V1 are known to project more than 10 different higher cortical areas, resulting in far more than two or three cell types with distinct connectivity. Here we address these questions by combining retrograde labeling, single cell gene expression, and rabies-based analyses of connectivity to assess cortical-cortical projection neurons in the mouse V1 projecting to higher visual areas called AL (anterolateral) or PM (posteromedial). We find that pyramidal neurons projecting to different cortical targets, AL or PM, and with known functional differences differ systematically in their gene expression despite forming only a single genetic cluster with continuous variability. In addition, these two different neuronal types receive preferential feedback inputs from the higher visual areas they project to, suggesting like-to-like circuit organization as feedback to feedforward connectivity mode. These observations demonstrate that single cell gene expression analysis in isolation is insufficient to distinguish all neuron types.

Title: Inter-areal coordination and dendritic integration in visual cortex

Authors: *D. HERRMANN, M. FISEK, A. EGEA-WEISS, M. CLOVES, M. HAUSSER; UCL, London, United Kingdom

Abstract: A striking feature of cortex is the morphologically elaborate and electrically excitable dendritic arbors of pyramidal neurons. Dendrites can sample inputs selectively and act as functional subunits, providing a powerful substrate for computation. However, principles governing the relationship between dendritic recruitment and information flow through long-range cortical networks remain unclear. To examine this relationship, we performed *in vivo* two-photon imaging experiments in two visual cortical areas in the mouse: primary visual cortex (V1) and the higher visual area LM. We investigated how dendritic recruitment and cortical coordination depend on sensory stimulation and behavioral state in awake head-fixed mice running spontaneously on wheels without reward, focusing specifically on cortico-cortically projecting layer 5 neurons. We measured dendritic activation patterns using simultaneous dual-color volume imaging in apical and basal dendritic domains by co-expressing the green neurotransmitter indicators SF-iGluSnFR for glutamate or iGABA-SnFR for GABA in combination with the red calcium indicator jRGECO1a. We examined stimulus and locomotion-evoked changes in input (glutamate or GABA) and output (calcium) signals recorded across large fields of view, providing cell-type specific population level input-output relationships. Next, we measured somatic and dendritic calcium signals in individual neurons. At both the population level and in individual neurons we find that dendritic recruitment depends on visual stimulation and locomotor state and predicts increased functional coupling between cortical areas during locomotion. To directly test this prediction, we used patterned two-photon optogenetics to activate small populations in V1 or LM while monitoring responses in the recipient area. We find feedforward and feedback influences are differentially organized topographically and differentially modulated by behavioral state. Separately, we measured correlated variability in activity across cortical areas to relate dendritic recruitment and functional connectivity to correlations in large cortical populations. In summary, our results suggest that there exists an intimate relationship between dendritic processing and cortico-cortical coordination.

Title: The feedback receptive field of neurons in the mammalian primary visual cortex

Authors: *A. KELLER[1], M. M. ROTH[1], M. SCANZIANI[2];
[1]UCSF, San Francisco, CA; [2]Univ. of California, San Francisco, San Francisco, CA

Abstract: We sense our environment through a chain of connections linking the sensory organs to neurons in the brain. In the visual system, this feedforward pathway defines the classical receptive field (cRF), the visual space where a stimulus excites the neuron. The response of neurons to stimuli inside the cRF can be inhibited by stimuli outside the cRF when the stimuli inside and outside share similar features. This inhibition implements an efficient coding strategy through which neurons compare the inside with the outside of the cRF to only report differences. Here we show that in mouse primary visual cortex those same inhibitory outside stimuli become strongly excitatory when the stimulus inside the cRF is absent. Excitation by outside stimuli is slower and delayed compared to excitation by inside stimuli and is preferentially reduced by anesthesia or by silencing higher visual areas, indicating that it originates from feedback projections. Furthermore, neurons excited by outside stimuli are selectively located in cortical layers receiving feedback projections. By responding to stimuli inside or outside the cRF but not to both together, these neurons compute an exclusive-or function (XOR). Thus, we have identified an excitatory feedback receptive field that, by complementing the feedforward cRF, enables neurons to capture differences between stimulus features across visual space independently if the excitatory stimulus is inside or outside the cRF. This generalization may contribute to efficient coding strategies like predictive processing.

Title: Eye movement information in V1 is carried through feedback projections

Authors: *S. K. MIURA[1], M. SCANZIANI[2];
[1]Univ. of California San Francisco, San Francisco, CA; [2]Univ. of California, San Francisco, San Francisco, CA

Abstract: Saccades have a profound impact on vision, both perceptually and physiologically. Using mouse primary visual cortex (V1) as a model system, we have begun to dissect the circuit that carries saccade information to cortex.
Similar to previous reports in cats and monkeys, we find that saccades modulate activity in mouse V1. This activity change is caused by input of extra-retinal origin that persists even under suppression of all neuronal activity in the eyes. Further, we show that it contains information about the direction of eye movement. Indeed, saccade direction can be predicted based on V1 activity, even before the onset of saccades.
In order to determine the source of the saccade information in V1, we took a candidate approach in which we silenced different brain regions while recording saccade-related activity in V1. Our first candidate was the dorsal lateral geniculate nucleus (dLGN) in thalamus, as the dLGN activity is also modulated by saccades. However, silencing the dLGN did not eliminate the modulation in V1. In contrast, silencing V1 eliminated saccade-related activity in the dLGN, suggesting that V1 is the source of saccade-information input in the dLGN and not vice-versa.
Upon further exploration, we identified the latero-posterior (LP) nucleus in the thalamus as the source of saccade information in V1. Consistent with studies in monkeys, neurons in mouse LP are also modulated by saccades. When LP was silenced pharmacologically, V1 was no longer modulated in response to saccades.
From our study, we suggest that saccade information flows from LP through V1 to the dLGN through the feedback pathway. The identification of the source of saccade information in V1 now enables us to explore the interaction of saccade information with visual information, and how this affects perception of the animals.

Title: Behavioral state and movement strongly modulate mesoscale pan-cortical neural activity

Authors: *E. D. VICKERS, S. JO, E. MCCARTHY, D. A. MCCORMICK;
Inst. of Neurosci., Univ. of Oregon, Eugene, OR

Abstract: Recent groundbreaking work has shown that nearly one-third of widespread brain activity during both spontaneous and task-driven behavioral epochs can be predicted by taking into account fluctuations of an assortment of externally observable arousal state measures such as walking, pupil diameter, whisker pad activity, and other small body movements. However, it is not clear that such a relationship exists for all brain areas to the same degree, or whether correlations between activity across widespread cortical subnetworks involved in sensory processing and decision making are also dependent on behavioral state. In order to address these outstanding questions, we developed in-vivo preparations in the mouse that allow us to perform both 1-photon widefield and 2-photon mesoscale calcium imaging, at different times in a single mouse, of either the entire dorsal cortical surface, including bilateral visual, somatosensory, motor, and premotor areas (upright), or a similarly large area of tempero-parietal cortex that also contains auditory cortical areas (left-rotated). Thus, we are able to simultaneously record the activity of large numbers of individual neurons across the entire cortical surface at up to 5 Hz (2-photon), and then, in the same mouse, to examine spatially down-sampled activity at up to 50 Hz (widefield). We examined behavioral state and movement-dependent patterns of widespread activity in large, overlapping subsets of excitatory neurons, as well as in parvalbumin- (PV), somatostatin- (SOM), and vasoactive intestinal peptide- (VIP) containing cortical interneurons. We focused either on differences in the state-dependence of spontaneous activity in bilateral visual, somatosensory, and premotor cortices (M2) in our upright preparation, or in unilateral auditory, somatosensory, visual, and premotor in our left-rotated preparation. Preliminary findings suggest that the bulk activity of both excitatory and inhibitory neurons across many brain areas correlates robustly to movement, pupil diameter fluctuations, and bilateral whisker motion energy. Despite these broad trends, we also observe considerable heterogeneity in degree of state and movement dependence, and in overall sparsity of activity, both across neighboring individual neurons and distant brain regions. Finally, we are developing a go / no-go audiovisual detection task that will allow us to examine changes in subnetwork activity and functional connectivity (both spontaneous and task-related) at both the widefield and single neuron level during task acquisition and learning in mice that are trained on auditory vs. visual target versions of the task.

Title: Orientation selectivity to synthetic natural patterns in a cortical-like model of the cat primary visual cortex

Authors: *H. LADRET[1], N. CORTES[2], L. PERRINET[3], C. F. CASANOVA[4];
[1]Ecole d'optometrie, Univ. de Montreal, Montreal, QC, Canada; [2]Ecole d'optometrie, Univ. De Montreal, Montreal, QC, Canada; [3]Inst. des Neurosciences de la Timone, Marseille, France; [4]Univ. Montreal, Montreal, QC, Canada

Abstract: A key property of the neurons in the primary visual cortex (V1) is their selectivity to oriented stimuli in the visual field. Orientation selectivity allows the segmentation of objects in natural visual scenes, which is the first step in building integrative representations from retinal inputs. As such, V1 has always been of central interest in creating artificial neural networks and the recent years have seen a growing interest in the creation of explainable yet robust and adaptive models of cortical visual processes, for fundamental or applied purposes. One notable challenge for those models is to behave reliably in generic natural environments, where information is usually hidden in noise, while most models are typically studied with oriented gratings. Here we show that a simple biologically inspired neural network accounts for orientation selectivity to natural-like textures in the cat's primary visual cortex. Our spiking neural network (SNN) is made of point neurons organized in recurrent and hierarchical layers based on the structure of cortical layers IV and II/III. We found that Spike-timing plasticity and synaptic recurrence allowed the SNN to self-organize its connections weights and reproduce the activity of neurons recorded with laminar probes in cortical areas 17 and 18 of cats, notably orientation tuning responses. After less than 5 seconds of stimulus presentation, the SNN displays narrow orientation selectivity (bandwidth = 10°) characteristic of sparse representations, removes noise from the input and learns the structure of natural pattern repetitions. Our results support the use of natural stimuli to study theoretical and experimental cortical dynamics. Furthermore, this model encourages using SNNs to reduce complexity in cortical networks as a method to understand the separate contribution of different components in the laminar organization of the cortex. From an applied perspective, the computations this network performs could also be used as an alternative to classical blackbox Deep Learning models used in artificial vision.

Title: Modeling the influence of surround suppression on size and contrast tuning in V1 and MT

Authors: *P. M. BAKER, W. BAIR;
Biol. Structure, Univ. of Washington, Seattle, WA

Abstract: The responses of many V1 neurons are suppressed by stimuli that extend beyond their classical receptive fields (RFs). This suppression has been proposed to contribute to pattern motion computation in MT neurons (Rust et al., 2006, Nat Neurosci; Majaj et al., 2007, J Neurosci; Tsui et al., 2010, J Neurophysiol). However these studies have not described how including iso-orientation surround suppression (IOSS) in V1 inputs shapes basic tuning for size and contrast in the recipient MT neurons. We have developed an image-computable modeling framework to build pattern-selective MT units (Baker and Bair, 2016, J Neurosci), and we extended this framework to include physiologically plausible V1 IOSS. We implemented commonly proposed phenomenological models of V1 IOSS that fit the range of suppression strengths found in macaque V1 (Sceniak et al., 2001, J Neurophysiol; Cavanaugh et al., 2002, J Neurosci). Our model MT units sum V1 inputs with RFs that are distributed across visual space to produce MT RFs ~5x the size of V1 RFs. We then tested tuning for stimulus size and contrast for both V1 and MT model units as we varied the strength of V1-level IOSS. We found that when IOSS was implemented as a V1 divisive normalization term, contrast response in both V1 and MT model units depended on stimulus size: the semi-saturation contrast (c50) obtained from fits to response vs. contrast curves decreased as size increased, both within and beyond the classical RF. We made a novel analysis of previously published data from 47 macaque V1 complex cells (Cavanaugh et al., 2002, J Neurosci) that supports this relationship between c50 and size. Our model shows that this effect may also contribute to a similar dependence of c50 on size that was previously described in macaque MT neurons (Sclar et al.,1990, Vision Res). As a consequence of this link between stimulus size and contrast tuning, the divisive form of V1 IOSS also offers a novel explanation for differences in c50 between V1 and MT, which in our model arises as a direct consequence of differences between V1 and MT units in spatial RF extent. We also found that a divisive form of V1 IOSS increased pattern index values obtained from responses to plaid stimuli in both component and pattern MT model units. Thus, V1 IOSS can be a physiologically plausible stand-in for the direction-tuned normalization that has been suggested to contribute to pattern sensitivity in MT. Beyond the dorsal pathway, this work also has broader significance in demonstrating how multiple normalization stages in filter-based, cascaded LN models may be instrumental for shaping response selectivities at higher levels of the circuit. We thank JA Movshon and J Cavanaugh for sharing data.

Title: Top-down modulations of bottom-up signal processing in a microcircuit model involving PV, SOM and VIP inhibitory interneurons

Authors: *N. WAGATSUMA[1,2], S. NOBUKAWA[3], T. FUKAI[4,2];
[1]Fac. of Sci., Toho Univ., Funabashi, Japan; [2]RIKEN, Wako, Japan; [3]Dept. of Computer Sci., Chiba Inst. of Technol., Narashino, Japan; [4]Neural Coding & Brain Computing, Onna-son, Japan

Abstract: Various types of inhibitory neurons contact each other for organizing a cortical network (Kawaguchi and Kubota, Cereb. Cortex, 1997; Markram et al., Nat. Rev. Neurosci., 2008). A majority of cortical inhibitory neurons expresses one of three genes, parvalbumin (PV), somatostatin (SOM) and vasoactive intestinal polypeptide (VIP) (Ruddy et al., Dev. Neurobiol., 2011), which play critical roles for regulating the activities of neuronal network. However, the detailed neuronal microcircuit consisting of these inhibitory neuron types and excitatory pyramidal (Pyr) neurons for processing external inputs such as feedforward sensory and feedback attentional signals remains largely unknown. Here, we developed a computational microcircuit model with biologically plausible structure and network of cortical visual layers 2 and 3 (Thomson et al., 2002; Binzegeer et al., 2004; Pfeffer et al., 2013). In our model, cooperation of Pyr neurons and three types of inhibitory interneurons determine the network activities. PV-positive inhibitory neurons are the largest inhibitory population in our model and mainly inhibited Pyr neurons and themselves. SOM-positive inhibitory neurons transmitted their signals to all other neuronal populations. VIP-positive inhibitory neurons suppressed the responses of SOM neurons and were activated by feedback signals. In addition, Pyr neurons were recurrently connected with a long-tailed, lognormal, distribution in their synaptic weights (Teramea et al., Sci. Rep., 2012). For testing the model responses, we carried out simulations of the model with various feedforward inputs representing the visual stimuli and feedback signals mediating selective attention. Interestingly, modulatory feedback signals to VIP neuronal populations more effectively activated our network via disinhibition of the Pyr neuron population compared to driving feedback inputs. Our proposed model might provide insights into the roles of inhibitory neuron types for regulating the activities of cortical microcircuit.

Title: Characterizing optogenetic rebound effects to parvalbumin expressing interneuron photostimulation in mouse primary visual cortex

Authors: J. T. SHAPIRO, J. L. KING, ***N. A. CROWDER**;
Psychology and Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: Mouse primary visual cortex (V1) has served as a model brain region for studying cortical circuitry due to the many genetic tools available in this species. Specifically, optogenetic tools have been used to map local GABAergic interneuron circuits and investigate unique roles for specific cell subtypes. Most of this past work has focused on how neural activity or behavior is modified when the contribution of specific cell types within local V1 circuits are artificially increased or decreased, but little attention has been paid to potential rebound effects that may be produced when photostimulation is terminated and inhibition and excitation in the circuit rebalance. To explore these potential optogenetic rebound effects we paired optogenetic activation of parvalbumin-expressing interneurons (PV+) with several visual stimulus types while collecting *in vivo* electrophysiological recordings from putative pyramidal (Pyr) and PV+ cells during and after PV+ photostimulation. Preliminary analyses indicate that when photostimulation was paired with flashed stimuli nonspecific rebound effects were produced, including following bars flashed inside or outside of the classical receptive field or sinusoidal gratings of preferred or non-preferred orientations. Generally, Pyr neurons that produced after-responses to flashed stimuli had larger rebound effects. Optogenetic rebound effects following drifting gratings tended to have smaller amplitudes. When photostimulation was terminated prior to the visual stimulus disappearing, Pyr cells showed prolonged suppression followed by delayed low amplitude excitatory rebounds. Increasing understanding of how and why optogenetic rebound effects occur may provide insights into how excitation and inhibition are balanced in cortex. Furthermore, this understanding may aid in the design or interpretation of behavioral studies that use optogenetic modulation because behavior may be altered not only from optogenetic stimulation itself, but from the optogenetic rebound as well.

Title: Inhibitory neuronal responses in the primary visual cortex of the aging mouse

Authors: *C. V. DIENI[1], M. SAVAGE[1], L. SINCICH[2], P. GAMLIN[1];
[1]Ophthalmology and Visual Sci., [2]Optometry & Vision Sci., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Deteriorating vision is a common condition associated with aging. With age, the central visual pathways and the retina both manifest anatomical and physiological changes that impair function. Overall neuronal activity in the central visual areas is reduced due to neuronal degeneration, which includes synaptic and dendritic spine loss, accompanied by a reduction in dendritic and axonal size. How age affects the relationship between the excitatory and inhibitory populations in the visual cortex has not been clarified. Since the synchronicity and cooperative activity of excitation and inhibition in cortical circuits is important for processing information, we have investigated whether aging alters the GABAergic inhibitory circuitry in healthy mice. We hypothesize that different classes of inhibitory neurons play distinct functional roles in the dynamic regulation of primary visual cortex (V1) over the life span. Here we focus on cells expressing parvalbumin (PV), which account for ~35% of inhibitory neurons in mouse neocortex and are densely connected to neighboring excitatory pyramidal neurons.To study inhibitory neuronal populations in V1 we used a combination of *in vitro* electrophysiological recordings combined with *in vivo* two-photon (2P) imaging using using a PVCre specific calcium indicator (jRCamp1b), comparing neural activity between young and old mice, comparing neural activity between young and old mice. We used *in vitro* cell-attached patch recordings in V1 cortical slices from transgenic reporter mice expressing PVCre Channelrhodopsin-2 (PVCre CHR2) to study the role of PV interneurons on V1 local circuitry. We found that spontaneous inhibitory currents (IPSCs) in pyramidal neurons in layer 2/3 were larger in magnitude and more numerous in aged mice. When we light-activated the PVCre CHR2 interneurons and measured the evoked IPSCs in pyramidal neurons we saw a reduction in current amplitude in older mice, but this was not significant compared to younger mice in the small sample tested to date. To examine if PV neural activity was altered *in vivo*, we recorded calcium transients with 2P imaging while the animals were visually stimulated with sinusoidal gratings of various orientations at a spatial

frequency of 0.05 cycle per degree. Preliminary data suggest that PV interneurons in layer 2/3 of young cortex exhibit little orientation tuning, whereas older mice had many neurons that appeared to be well tuned for stimulus orientation. These results suggest that the role of inhibitory circuitry in V1 changes with age and that PV interneurons may alter orientation tuning profiles in aged mouse cortex.

Title: Probing the role of cortical inhibitory neurons during visual spatial perception

Authors: *J. DEL ROSARIO[1,2], A. OTSUKI[1], B. WILLIAMS[1], L. BLANPAIN[2], B. HAIDER[1,2];
[1]Georgia Inst. of Technol., Atlanta, GA; [2]Emory Univ., Atlanta, GA

Abstract: Many studies of visual processing have established that inhibitory neurons shape the representation of visual information, particularly in primary visual cortex (V1). The use of transgenic mice has allowed detailed investigation of specific interneuron subtypes, and their roles in visual responses. Several studies show that inhibitory subtypes play distinct roles in spatial integration of visual stimuli (Adesnik et al., 2012; Dipoppa et al., 2018). However, there are few studies of the role of inhibitory subtypes on visual spatial perception. It is unclear if parvalbumin-expressing (PV+) and somatostatin expressing (SST+) inhibitory interneurons in V1 play overlapping or distinct roles for spatial perception of stimuli during behavior.
To investigate this question, we developed a behavioral task where head-fixed mice detected visual stimuli (Gabor gratings) localized in one of two discrete portions of visual space (binocular or monocular visual fields, ~70° apart; Speed et al., 2019). Mice indicated detection of visual stimuli by licking for water rewards. Mice were stationary, minimizing potential interactions of perception and locomotion. We trained mice expressing Channelrhodopsin-2 in PV+ or SST+ interneurons, and stimulated these interneurons in monocular or binocular V1 during stimulus presentation. Stimulation of either PV+ or SST+ neurons in localized regions of V1 significantly impaired perceptual report of small, low contrast stimuli that appeared in the retinotopically matched portion of the visual field (SST+: 84% impairment, 4 mice; PV+: 86% impairment, 3 mice). Perceptual impairments varied with light intensity, stimulus contrast, and stimulus location. Surprisingly, SST+ activation caused greater impairments than PV+ activation

for perceptual report of stimuli in retinotopically distant regions of visual space (>40° away from the site of stimulation).
We next investigated neural circuit activity by performing high-density silicon probe recordings during optogenetic stimulation in awake mice, and isolated spiking activity of SST+ (n=6), PV+ (n=31), and regular-spiking (RS) putative excitatory (n=83) neurons. Stimulation of either SST+ or PV+ interneurons rapidly inhibited RS neuron firing (50% suppression within 4 ms, n=77). Furthermore, SST+ neurons responded more (26% more than PV+ and 71% more than RS neurons) to visual stimuli in distal regions of the visual field (>30° away from the center of the receptive field). These results suggest that the broad spatial responsiveness of SST+ inhibitory interneurons may directly shape the perception of visual stimuli appearing across large regions of visual space.

Title: Long-range cortical connections for circuit optimization of hierarchical visual cortex

Authors: *S. BAEK[1], Y. PARK[1], W. CHOI[1,2], S.-B. PAIK[1,2];
[1]Dept. of Bio and Brain Engin., [2]Program of Brain and Cognitive Engin., Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Deep neural networks (DNN), inspired by the feedforward hierarchical structure of the brain, can perform image classification with human-level accuracy (He et al., 2015). However, DNNs with a number of layers as few as in the ventral stream of the human visual cortex (Krizhevsky et al 2012) cannot achieve human-level performance. Given this, what is the strategy of the brain to construct a network that performs more efficient visual information processing than DNNs can achieve? Here, we suggest that the long-range horizontal connectivity (LRC) observed in the early visual cortex of mammals (Bosking et al., 1997) might be a key factor for reducing structural costs in the visual system. We hypothesized that the LRC might reduce the average path length of a network so that visual perception is achieved with less wiring cost compared with feedforward (FF) networks. To validate our hypothesis, we designed a three-layer neural network model with convergent FF projections. Then, we designed a labeled-image set of various local- and global-correlations in the spatial organization. We compared the

classification performance of networks when LRCs were added to the model. We found that adding LRCs improved performance significantly more than just adding FFs with the same wiring cost. In addition, the enhanced performance with LRCs accompanied a noticeable reduction in the characteristic path length of the network. To confirm that the contribution of LRCs is selective for the global-correlation feature of images, we performed a pruning method that deleted unimportant connections for classification during training sessions. The remaining number of LRCs optimized for the images with global correlation was significantly larger than that optimized for images with local correlation only. Overall, our results suggest that LRCs can reduce the path length of the neural network and thereby enable more efficient visual information processing.

Title: A long timescale stimulus history effect in the primary visual cortex

Authors: *H. KIM, J. HOMANN, D. W. TANK, M. J. BERRY, II;
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Responses of neurons in the primary visual cortex (V1) are often understood as encoding the current visual stimulus. Yet, some studies indicate that temporal contingency effects exist in the responses of neurons in early sensory areas. We explored if the recent stimulus history would alter the response of V1 layer 2/3 pyramidal cells. We used two-photon calcium imaging in head-fixed awake mice during presentation of sequences of complex images. The activity of individual neurons was sparse, such that either one or none of the images in the sequence typically yielded a strong response. We then substituted an image preceding this primary image in order to determine if responses to the primary image were effected. We found that the amplitude of the neuron's response could be significantly altered by substitutions up to five images back from the primary image, even when the substituted image elicited virtually no response by itself. This stimulus history effect was heterogeneous across the population, with some cells showing facilitation and others suppression. For individual cells, the history effect was robust and reproducible across days. Our data show that responses of V1 neurons not only reflect the current stimulus but also encode, through their response amplitude, information about

multiple images previously presented as far as 1000 msec in the past. This might enable V1 to retain information about the extended trajectory of past stimuli and perform complex temporal computations that are as of yet not appreciated.

Title: Cellular mechanism of visually evoked theta oscillation in mouse primary visual cortex

Authors: *M. GAO, A. A. CHUBYKIN;
Biol. Sci., Purdue Univ., West Lafayette, IN

Abstract: The theta oscillation (4-8 Hz) of neural networks is a common phenomenon found throughout the mammalian central nervous system. It plays a critical role in information processing, communication of brain areas, learning and memory. Neuronal disorders, including autism spectrum disorder (ASD), Schizophrenia and Parkinson's disease among others, are often accompanied by abnormalities in theta oscillations. Understanding the mechanism of theta oscillation will provide us with insight into the computations in the brain and may help develop treatments for the related neuronal disorders. However, the physiological functions of theta oscillation in neocortex and the underlying mechanism remain unclear. Our group has recently discovered that familiar visual stimuli can robustly induce theta oscillations in the primary visual cortex (V1) of visually trained mice. To gain more mechanistic insight into this phenomenon, we utilized in vivo patch clamp recordings to dissect the activity of individual neurons during these oscillations. We recorded visual tuning of V1 neurons in untrained and trained mice to assess the effect of theta oscillation on the orientation (OS) and direction selectivity (DS). Using optogenetics, we measured the synaptic strength of specific projections in untrained and trained mice. Light-evoked excitatory postsynaptic currents (EPSCs) showed a significant increase in the strength of L5 projections to other layers of V1 in the trained mice. We have also discovered a decrease in the strength of the thalamocortical synapses following training. We found 4-8 Hz oscillations of membrane potential (Vm) and bursts of firing were evoked in single neurons in response to the familiar stimulus. Interestingly, the firing rate of visual responses was reduced after training. Although the firing rate of visual responses to all directions and orientations of sinusoidal drifting gratings was reduced, the direction selectivity index (DSI) was increased. This

increase was correlated with Vm theta power of the null direction. The results suggest that the theta oscillation can improve direction selectivity by modulating the stimulus-triggered spiking activity.

Title: Visual experience-dependent oscillations and underlying circuit connectivity changes are impaired in V1 of fragile X mice

Authors: *S. T. KISSINGER[1], Q. WU[1], C. J. QUINN[2], A. A. CHUBYKIN[1];
[1]Dept. of Biol. Sci., [2]Dept. of Industrial Engin., Purdue Univ., West Lafayette, IN

Abstract: Fragile X syndrome (FXS) is the most common inherited form of autism. Several neurophysiological impairments have been identified in individual neurons of the mouse model of FXS (*Fmr1* KO) thus far, including enhanced hippocampal long-term depression (LTD), increased excitatory to inhibitory (E/I) ratios, and impaired functional connectivity. However, little is known about how experience dependent changes in neural activity are disrupted in FXS at the scale of circuits or neural ensembles. Previously, we demonstrated that perceptual training to visual stimuli over several days promotes the emergence of visually evoked low-frequency oscillations in the primary visual cortex (V1) of awake mice, reflecting familiarity with a visual stimulus. We used this simple paradigm to assess perceptual learning in *Fmr1* KO mice with a multifaceted approach; including extracellular recordings across all layers of V1, computational analysis of functional connectivity (directed information) between layers, and channelrhodopsin-2 assisted circuit mapping (CRACM) in acute brain slices. Extracellular recordings revealed that the visually evoked oscillations are shorter in duration and lower in frequency in *Fmr1* KO mice (particularly in layers 2/3 and 4), reflecting differences in the intrinsic properties of the neurons driving these oscillations. Using directed information analysis, we found that perceptual training causes a net increase in information flow from cortical layers 2/3, 4 and 5 onto layer 4 fast spiking cells, connections which are attenuated in *Fmr1* KO mice compared to WT controls. Whole cell patch-clamp recordings using CRACM revealed that perceptual training significantly increased the synaptic strength of L5 pyramidal onto L4 fast spiking neurons, connections which are also significantly weaker in *Fmr1* KO mice compared to WT controls. This study has achieved two primary goals. First, we have demonstrated increases in the synaptic strength and

functional connectivity of specific connections that likely drive the experience dependent oscillations in V1. Second, we discovered that the oscillations are impaired in *Fmr1* KO mice, granting us insights into how an experienced sensory stimulus is differentially encoded in autism.

Title: Neuropilin-2/plexin-A3 receptors contributes to the proper wiring and function of the mouse primary visual cortex

Authors: *H. KHDOUR[1], T. S. TRAN[2], P.-O. POLACK[3];
[1]Ctr. of Mol. and Behavioral Neurosciences, Rutgers Univ. Newark, Newark, NJ; [2]Biol. Sci., Rutgers Univ., Newark, NJ; [3]Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ. - Newark, Newark, NJ

Abstract: Information processing in the mammalian neocortex is supported by the precise connectivity in the neural circuits underpinning the function. The establishment of the cortical circuits during development is under the control of multiple signaling systems. Several studies have shown the importance of the secreted Semaphorin 3F (Sema3F) in the establishment of cortical connectivity. Previously, we demonstrated that Sema3F signaling through its obligate receptor Neuropilin-2 (Nrp2) and signal transducing co-receptor Plexin A3 (PlxnA3) regulates spine number and morphologies on the proximal shaft of apical dendrites in layer 5 (L5) pyramidal neurons from the somatosensory cortex (S1). Another study showed Sema3F null mice exhibited increased spine density of layer 4 (L4) cortical neurons in primary visual cortex (V1). The identity of the inputs on these supernumerary spines in S1 and V1 are not known. Anatomical tracing showed that in the absence of the Sema3F signaling during development thalamocortical axons from the somatosensory and motor thalamic relay nuclei misproject their axons to the visual cortex at P7. However, since these previous studies were performed during developmental stages, it is not known whether the aberrant thalamocortical wiring still persists in the adult brain and contributes to the supernumerary spines found in L4 and L5 cortical neurons. Our hypothesis is that Sema3F signaling plays a key role in the maturation of a functional network in V1 and S1 by pruning ectopic thalamocortical synapses. To test this hypothesis, we conducted a survey for spine density in V1, S1, M1 and mPFC in L2/3, L4 and L5 using the Golgi staining method. We are currently performing retrograde tracing in adult and P14 Nrp2-/-

and PlxnA3-/- mice to identify the inputs on the supernumerary spines of L4 and L5 V1 neuron. We found that: [1] Npn2-/- and PlxnA3-/- brain sections exhibit supernumerary synapses in V1 L5 and L4; and [2] the ectopic projections from non-visual thalamic nuclei found at P7 are corrected in the adult Npn2 and PlxnA3 null mice. To assess the functionality of the cortical networks in V1, we are testing visual processing in the different V1 layers of wild type and Npn2 KO mice using calcium imaging. We find deficits in the maturation of the computational properties of L4 and L5, but not L2/3, neurons. Altogether, our results provide novel insights to previously unappreciated functions of Sema3F signaling in the refinement of the thalamocortical connectivity of V1, and it's role in the functional maturation of V1 circuit.

Title: Neural mechanisms for modulation of cortical variability

Authors: *L. NURMINEN[1], A. ANGELUCCI[2];
[1]Univ. of Utah, Salt Lake City, UT; [2]Ophthalmol, Moran Eye Inst., Univ. of Utah, Salt Lake Cty, UT

Abstract: Our goal was to provide a better understanding of the mechanisms underlying modulation of cortical variability. To achieve this, we recorded responses of single- and multiunits in primary visual cortex (V1) of sufentanil anesthetized marmoset monkeys, while optogenetically manipulating ArchT expressing axon terminals of V2-to-V1 feedback neurons. Injections of Cre-dependent and Cre-expressing AAV9 were made within 1 mm of the V1-V2 border, located *in vivo* using optical imaging, performed through a thinned skull. We (Nurminen et al. 2018) previously showed that this viral mixture results in near exclusive anterograde infection in primate cortex. We recorded responses of V1 neurons to high contrast grating stimuli of increasing size and computed fano-factor (FF) as a measure of variability. Our results replicate stimulus-induced decline in variability (Churchland et al. 2010) in marmoset V1. On average, baseline fano-factor was higher than the fano-factor measured while a grating stimulus

covered neurons' summation receptive field (sRF). However, in a significant proportion of neurons, presenting a small stimulus amplified variability. For stimulus sizes smaller than, and equal to the sRF, we found an inverse relationship between firing-rate (FR) and FF: as stimulus size increased up to the sRF diameter, firing-rate increase, and fano-factor decreased. The strength of the inverse relationship was the weakest in the granular (G) layer. When the stimulus covered the sRF, the most variable neurons were found in the G layer. When RF surround was stimulated, some neurons preserved the inverse relationship between FR and variability, while for others FR and variability became positively correlated. Our preliminary analyses revealed that neurons with weak network coupling showed the strongest positive relationship between FR and variability. To further investigate the mechanisms that modulate cortical variability, we optogenetically inactivated V2-to-V1 feedback connections. In all the neurons in which the optogenetic manipulation affected the FF vs. size functions, FFs were reduced when the stimulus size was small. In these neurons, the relationship between FF and FR became weaker when feedback connections were inactivated. Our results suggest that receptive field center and surround affect neural variability in different ways and that variability modulation in V1 depends on cortical layer and feedback connections.

Title: Three-photon imaging of neural and vascular responses in the visual cortex

Authors: *A. ROY, C. LIU, A. SIMONS, D. FARINELLA, P. KARA;
Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: The mammalian neocortex is divided into six distinct anatomical layers, with feedforward inputs arriving primarily into layer 4, local computations shaping response selectivity in layers 2/3, and top-down influences from other regions arriving via layers 1 and 6. In addition, in the primary visual cortex of non-rodent mammals, neurons with similar functional properties such as orientation and direction selectivity cluster together radially along the cortical surface, thereby forming functional maps in cortical layers 2/3. To date, structural and functional two-photon imaging of neurons in these layers have unraveled a wide array of principles that govern how these functional columns are organized and how neurons therein carry out various

computations. In recent years, two-photon imaging of vascular dynamics in layers 2/3 has also begun to reveal how local neural activity is coupled to changes in blood flow in the local vasculature. The precision of the mapping of neural and vascular features in layers 4–6 remains unknown, particularly because the visual cortex in non-rodent mammals is considerably thicker (~ 2 mm) compared to mice (~ 0.74 mm) and these deeper layers have been inaccessible with conventional two-photon imaging methods. However, three-photon imaging, by virtue of decreased scattering of longer wavelength excitation light and enhanced non-linear confinement of the excitation volume, provides suitable access to such depths. We have set up a three-photon microscope capable of imaging green and red fluorophores and label-free third-harmonic-generation signals from depths of > 1 mm in the neocortex. We mapped out the range of three-photon excitation wavelengths for an assortment of commonly used green and red fluorophores. Then, using these fluorophores we carried out three-photon imaging experiments of neural and vascular responses. We will present data regarding organization of the neural maps across various cortical layers and how single-vessel responses (dilation, blood velocity) in these cortical layers correlate with local neural activity.

Title: Four-dimensional mapping of stimulation-induced cortico-cortical spectral responses across the visual areas

Authors: *A. SUGIURA[1], N. MIMURA[1], K. TANAKA[1], Y. NAKAI[1], H. MOTOI[1], E. ASANO[1,2];

Abstract: We provided whole-brain level animations showing the dynamics of cortico-cortical spectral responses (CCSRs) elicited by single-pulse electrical stimulation to the lower- and higher-order visual areas. This study analyzed electrocorticography (ECoG) signals of 22 patients with focal epilepsy. As part of the pre-surgical evaluation, we delivered trains of electrical stimuli (pulse width: 0.3 ms; intensity: 5 mA; frequency: 1 Hz; train duration: 40 s) to a neighboring pair of subdural electrodes implanted at the vision-related areas (i.e., medical-

occipital, lateral-occipital, and fusiform gyri). We performed a time-frequency analysis at each electrode site to determine the stimulation-related modulations of gamma activity, as compared to the baseline period at 150 to 100 ms before the stimulus. On the three-dimensional FreeSurfer average surface image, we animated the dynamics of CCSRs at gamma band at all electrode sites showing significant amplitude modulations at 10-50 ms after the stimulation. Stimulation of the medical-occipital region elicited CCSRs at the lateral-occipital region. Stimulation of the lateral-occipital region elicited CCSRs at the fusiform, inferior-parietal, and inferior-temporal gyri, as well as at the frontal eye field. Stimulation of the fusiform region elicited CCSRs at the anterior part of the fusiform, parahippocampal, and entorhinal gyri. The present study demonstrated the capability of the aforementioned vision-related areas to deliver neural information directly via single axonal connectivity.

Title: Thalamic afferents to the precuneate cortex of the macaque monkey

Authors: *M. GAMBERINI[1], L. PASSARELLI[1], D. IMPIERI[1], P. FATTORI[1], C. GALLETTI[1], M. G. ROSA[2,3], S. BAKOLA[2,3];

Abstract: The precuneate cortex of macaque brain hosts different cortical areas. The aim of the present study was to characterize the thalamic afferents to the macaque precuneate cortex, based on a set of tracer injections in areas PGm, 31, and in nearby area PEci. Fluorescent retrograde neuronal tracers were injected in the precuneate cortex within and adjacent to area PGm of four

hemispheres of four male adult monkeys (*Macaca fascicularis*). Tracers were injected into the cortical thickness using a micro-syringe, or placed as crystals on the mesial cortex of the hemispheres based on visual inspection of the brain after a portion of the posterior parietal cortex of the contralateral hemisphere was retracted. Cyto- and myelo-architectural analysis of histological material established that in six cases tracers were delivered within the limits of area PGm, in one case within those of area 31 and one within area PEci. The three areas here analyzed present many similarities in the regional distribution of thalamic afferents but the specific nuclear origin of thalamic input varies across areas. The precuneate cortex receives strong input from the posterior thalamus, in particular, from the lateral posterior and the pulvinar complex, and moderate input from the medial, lateral, and intralaminar thalamic regions. Area PGm presents strong connectivity with the associative medial and visual lateral divisions of the pulvinar, whereas areas 31 and PEci receive exclusive afferents from the oral division of the pulvinar. All areas receive input from the 'motor' division of lateral thalamus, in particular from the ventral lateral (VL) nucleus, while area PEci receives input from both the 'sensory' (ventral posterior lateral, VPL) and 'motor' domains of the lateral thalamus. Consistent thalamic input to all three areas arrived from the medial dorsal (MD) nucleus, while the anterior lateral dorsal (LD) nucleus is uniquely connected with area PGm. Finally, areas 31 and PEci receive moderate afferents from the intralaminar region, in particular from the central lateral (CL) nucleus, whereas area PGm receives minor afferents from different intralaminar nuclei. The pattern of afferents indicate that macaque area PGm integrates information from a set of association, motor, and limbic regions of the thalamus, and emphasizes links with visual and multimodal thalamic regions. With respect to the adjacent superior parietal areas, where the thalamic afferents from VPL to areas PE, PEc, PEci, and from the oral pulvinar to area 31 describe a sensorimotor function, area PGm shows a role mainly focused in the processing of spatial and attentional information useful for navigation in a complex environment.

Title: Sensory and motor properties of physiologically identified neuronal classes in multiple areas of the parieto-frontal grasping network

Authors: *C. G. FERRONI[1], M. MARANESI[1], A. LIVI[2], M. LANZILOTTO[1], D. ALBERTINI[1], L. BONINI[1];

Abstract: The attribution of functional properties to specific neuronal classes (e.g. inhibitory interneurons, big or small pyramidal neurons, etc.) is crucial to better understand the neural machinery underlying sensory and motor processes. Indeed, several studies showed that cortical neurons can be identified by jointly considering a variety of features of their spike waveform and firing properties. However, the specific relation between physiologically-identified neuronal classes and their coding properties remains unclear. To address this issue, here we studied the features of extracellularly recorded spikes of 492 well-isolated single neurons. Neurons were sampled from 5 hemispheres of 3 macaque monkeys while they performed, or observed an experimenter performing, a reaching-grasping go/no-go task with three different objects as targets. Single neurons were recorded from anterior intraparietal area AIP (n=134), ventral premotor area F5 (n=135) and pre-supplementary motor area F6 (n=223). First, we performed an unsupervised clustering of spike waveforms that reliably dissociated 5 clusters across the investigated cortical regions. Then, we compared the response properties across cell class and found that visual responses to object presentation and action execution/observation differ across classes. Furthermore, we found functional specificities for cortical areas within each class. Interestingly, the number of neurons included in each cell class varied dramatically across areas, suggesting a possible link between physiologically identified classes and local cytoarchitectural specificities. Our findings shed light on the cellular mechanisms underlying local processing of sensorimotor information for planning and executing grasping actions and the observation of others' action.

Title: View-dependent processing of observed manipulative action in the monkey anterior intraparietal area (AIP)

Authors: *M. LANZILOTTO[1], M. MARANESI[1], A. LIVI[2], C. G. FERRONI[1], L. BONINI[1], G. A. ORBAN[1];

Abstract: The processing of observed manipulative actions (OMAs) is a fundamental prerequisite of social behavior in primates. Classical models assign a crucial role to temporal brain regions, which convey visual information to premotor cortex via inferior parietal areas. A recent our study (Lanzilotto et al. 2019) demonstrated that anterior intraparietal area (AIP) might be considered a crucial node of the monkey's action observation network, encoding the identity of a large variety of OMAs relative to those explored by previous studies. Nonetheless, whether and to what extent neuronal representation of OMAs is invariant to changes in the visual features of the stimuli, such as actor's body posture (standing or sitting) and visual perspective (frontal or side-view), is still unknown. To address this issue, we chronically recorded (multi- and single) unit activity with linear silicon probes from area AIP of two macaques (MK1 and MK2). During the recordings, the monkeys observed videos portraying 7 different manipulative action exemplars (drag, drop, grasp, push, roll, rotate and squeeze) performed on 2 objects of different colors (orange and magenta) by 2 actors (male and female) in 4 *formats* defined by combinations of two postures (sitting and standing) and two viewpoints (lateral and frontal). We recorded 297 units, of which 113 (38%) were action-selective in at least one format, as revealed by a 7x3 (actions x epochs) repeated measures ANOVA applied to each format ($p<0.05$), separately. Among action-selective units, more than half (n=63, 56%) exhibited OMAs selectivity only in one format (ranging from 10% for Standing-Frontal to 19% for Standing-Lateral format). Individual unit analysis, population and machine learning approaches confirmed that AIP neurons encode OMAs identity within each format, as recently demonstrated (Lanzilotto et al 2019), but also highlight that OMA representation depends on the visual features of each format, showing little evidence of visual invariance. These findings support the view that monkey's AIP constitutes an early node for the processing of OMA, representing their different instantiation by largely non-overlapping neuronal populations.

Title: Linkage of multiple sensory and motor properties in single neuron activity of the macaque anterior intraparietal area

Authors: *M. MARANESI[1], M. LANZILOTTO[1], A. LIVI[2], C. G. FERRONI[1], D. ALBERTINI[1], L. BONINI[1];
[1]Dept. of Med. and Surgery, Univ. of Parma, Parma, Italy; [2]Dept. of Neuroscience, Campus Box 8108, Camillo's Lab., Washington Univ. of St Louis, Saint Louis, MO

Abstract: The processing of sensory cues, observed objects, and self/others' actions is crucial for coordinating social interactions and relies on a network of interconnected frontal and parietal areas. Among these latter, the anterior intraparietal area (AIP) is considered a crucial node for many of these functions, such as the extraction of object affordances and the encoding and selection of hand postures for grasping, as well as the representation of observed manipulative actions. However, these properties have been demonstrated by different studies carried out with highly different tasks and methodologies, leaving unclear how AIP can underlie so many complex and heterogeneous processes. To address this issue, we recorded AIP single neuron activity from two macaques during 1) a visuomotor task in which they viewed and grasped (or refrained from grasping) objects of different size and shape (EXE), 2) an observation task in which a human performed the same task (OBS) in the monkey's peripersonal (OBSp) or extrapersonal (OBSe) space, 3) an observation task in which videos of grasping actions and static frames depicting objects or static images of grasping hands were presented (OBSv). Recordings were carried out with chronically-implanted linear multielectrode silicon probes. We isolated 134 single neurons with highly restrictive criteria. Then, we performed a hierarchical cluster analysis by computing the Mahalanobis distances among conditions of interest in all task contexts. These data show that AIP strongly encodes spatial information regarding the actual or expected position of objects relative to the monkey, as well as the type of target object, from target presentation epoch along the entire task unfolding period. Furthermore, AIP population activity also provides motor information as to whether and how the subject will act, and agent-related information about who is going to act in a specific context. Interestingly, AIP population activity differentiates the two extrapersonal contexts (OBSe and OBSv), but the type of object is not significantly represented in none of them. These results emphasized the role of AIP in the integration of sensory and motor properties for planning actions on reachable objects and agent-based representation of actions.

Title: Connectional gradients underlie functional transitions in monkey pre-supplementary motor area

Authors: *D. ALBERTINI[1], M. GERBELLA[2], M. LANZILOTTO[2], A. LIVI[4], M. MARANESI[2], C. G. FERRONI[3], L. BONINI[2];
[1]Univ. Di Parma, Parma, Italy; [3]Dept. of Med. and Surgery, [2]Univ. of Parma, Parma, Italy; [4]Dept. of Neuroscience, Campus Box 8108, Camillo's Lab., Washington Univ. of St Louis, Saint Louis, MO

Abstract: The pre-supplementary motor area F6 is involved in a variety of functions in multiple domains, from planning/withholding goal-directed actions in space to rule-based cognitive processes and social interactions. Yet, the neural machinery underlying this functional heterogeneity remains unclear. Here, we recorded a total of 291 units by means of chronic linear multielectrode silicon probes in different rostro-caudal sites of cytoarchitectonically verified area F6 in two monkeys. We measured local neural population dynamics while the monkeys performed a Go/No-Go reach-to-grasp task and observed the same task as performed by an experimenter in both the monkey's peripersonal and extrapersonal space. At the end of the recordings, the two probes implanted in each animal were removed and an antero-retrograde neural tracer was injected at the center of the spot previously occupied by each explanted probe, allowing us to investigate both the cortical and striatal connectivity of each recorded site. Finally, we correlated multimodal populations tuning with local connectivity patterns in all the four functionally characterized sites. We found stronger tuning of rostral area F6 to spatial position of objects and agents relative to the caudal one, which in turn exhibits stronger tuning to self and other's (observed) action. Functional specificities were associated with a rostro-caudal transition in connectivity strength from lateral prefrontal cortex, pregenual anterior cingulate cortex and associative striatum (rostrally), to dorso-ventral premotor areas and the motor putamen (caudally). These findings suggest that the functional heterogeneity of the pre-supplementary area F6 is accounted for by gradual transitions in functional properties grounded on local cortico-cortical and cortico-striatal connectional specificities.

Title: Common reference frames for spatial and non-spatial motor responses in parietal area V6A

Authors: K. HADJIDIMITRAKIS[1,2], M. GHODRATTI[1], R. BREVEGLIERI[2], M. G. ROSA[1], ***P. FATTORI**[2];
[1]Dept. of Physiol., Monash Univ., Clayton, Australia; [2]Biomed. and Neuromotor Sci., Univ. of Bologna, Bologna, Italy

Abstract: Goal-directed movements involve a series of neural computations that compare the sensory representations of goal location and effector position and transform them into motor commands. Neurons in posterior parietal cortex (PPC) control several effectors (e.g. eye, hand, foot) and encode goal location in a variety of spatial coordinate systems ranging from one relative to gaze (eye-centered reference frame) to coordinate systems centered on head, shoulder or hand. Despite many neurophysiological and imaging studies on effector specificity in PPC, there is little evidence on whether reference frames depend also on the selected effector and/or motor response. We addressed this issue in macaque PPC area V6A where we have previously reported that, during a fixate-to-reach task in 3D space with varied initial hand positions, most cells used mixed body- and hand-centered coordinates (Hadjidimitrakis et al. 2014). Here, we used singular value decomposition and gradient analyses to characterize the reference frames of V6A neurons (n=50) recorded from a monkey that fixated the same array of targets and after the Go cue, instead of reaching, performed a non-spatial motor response (button release). We found that most neurons used neither "pure" body-, nor hand-centered, but mixed body/hand coordinates. Interestingly, along the task progress, the effect of hand position on activity was stronger compared to that of target location, whereas activity more consistent with body-centered coding was present only in a subset of neurons active early in the task. Applying the same analyses to a larger population of V6A neurons recorded from the same monkey during reaches yielded similar results, indicating the use of consistent reference frames between spatial and non-spatial motor responses, thus highlighting V6A role in forming default movement plans. Moreover, our results suggest that single PPC neurons have stable reference frames across time and that the sensorimotor transformations most likely occur via the sequential recruitment of subpopulations with distinct reference frames.

Title: Functional and structural connectivity of the cingulate sulcus visual (CSv) area in macaque monkeys

Authors: V. DE CASTRO, C. LEGUEN, Y. HÉJJA-BRICHARD, P. AUDURIER, B. R. COTTEREAU, ***J.-B. DURAND**;
CNRS CERCO UMR 5549, Toulouse, France

Abstract: Recently, we described the cortical network involved in processing egomotion-compatible optic flow using functional MRI in 3 awake macaque monkeys (Cottereau et al, 2017). In all the animals, significant selectivity was observed in several areas previously associated with optic flow processing, and notably in MSTd, VIP, 7a/Opt, FEFsem and VPS. We also described a new region of the cingulate sulcus that may be a homologous of the cingulate sulcus visual (CSv) area evidenced in humans with the same protocol (Wall and Smith, 2008). To go further in the study of this potential homology, we aim at characterizing the connectivity of this monkey cingulate region, as recently achieved for the human CSv (Smith et al, 2017). Under slight anesthesia (Medetomidine: 10µg/kg, Ketamine: 10mg/kg), the same 3 monkeys underwent 3 sessions of resting-state fMRI (rs-fMRI) and 1 session of diffusion-tensor imaging (DTI) in order to assess the functional and structural connectivity of this cingulate region. In each of the 3 sessions of rs-fMRI, we recorded 2 runs of 20 minutes (GE-EPI sequences, 600 volumes/run, 32 axial slices, TR/TE: 2000/30ms, voxel size: 1.25x1.25x1.8 mm, SENSE factor: 2). For the DTI session, 3 repetitions were included in a sequence lasting 45 minutes (128 directions, b=1000s/mm2, 1 b0 volume with no diffusion weighting, TR/TE: 7132/61ms, voxel size: 0.89x0.89x1 mm, EPI factor: 55). Converging evidence from rs-fMRI and DTI indicates that the cingulate region previously documented in the same monkeys is connected to several visual (and vestibular) areas involved in optic flow processing, such as MSTd, VPS and 7a/Opt. Interestingly, we also observed connections with the foot and leg representations in the somatosensory and motor cortices. Altogether, this connectivity pattern echoes the one documented for human CSv, reinforcing the view of a strong functional homology. In both species, CSv may play an important role in linking sensory and motor systems for the online control of locomotion. Title: Activity of frontal network for performance of forced-choice manual response task in blindsight monkey

Authors: *Y. YAMAMOTO[1], R. YAMAGUCHI[2], T. TAKEI[3], Z. C. CHAO[3], T. ISA[4]; [1]Kyoto Univ., Kyoto, Japan; [2]Inst. for the Advanced Study of Human Biol. (WPI-ASHBi), Kyoto Univ., Kyoto-shi, Japan; [3]Grad Sch. of Med., [4]Dept. of Neuroscience, Grad. Sch. of Med. & Fac. of Med., Kyoto Univ., Kyoto, Japan

Abstract: Patients with the damage to the primary visual cortex (V1) report loss of visual awareness in their affected visual field but show considerable residual visuo-motor functions, the phenomenon termed blindsight. Most of previous studies in animal model of blindsight have employed oculomotor tasks to assess their residual visuo-motor functions. However, because of its nature, in the oculomotor behavior, it is sometimes difficult to differentiate reflexive orienting response and cognitive response. In addition, neural basis of visuo-motor response involving effectors other than eyes in blindsight condition is still unclear. To clarify points shown above, we applied a two alternative forced choice manual response task (2AFCMR) in the macaque monkey. In this task, eye positions were kept at a central fixation point. Then, push- or pull-responses of a lever was instructed by the location of visual cue presented in either upper or lower part of the visual hemifield. The monkey was trained to push or pull the lever in response to the Go signal presented 500-1000ms after the cue. Bilateral electrocorticogram (ECoG) was recorded before and after unilateral lesion of V1 with chronically implanted electrode arrays (48ch each) from dorsolateral prefrontal cortex, frontal eye field, dorsal and ventral premotor cortex and primary motor cortex. Before the V1 lesion, the luminance contract of the cue was 0.075 (near threshold), and the success rate was 86%. After the V1 lesion, the animal was trained at the maximum luminance contrast (0.95) from Day 16 after the lesion and the success ratio became above the chance level around Day 50 after the V1 lesion and reached 65 -79 % until

Day 55. Before and after the V1 lesion, we adjusted luminance contrast of visual cue to make the success rate is comparable between conditions. Before the V1 lesion, the time-frequency analysis showed that low frequency activity (5-8Hz: theta, 8-13Hz: alpha) in the premotor regions was increased in the trials where the monkey successfully detected the stimuli (i.e. Hit trials) compared to the trials where the monkey failed to detect the presented target (i.e. Miss trials). This increment was observed either before or after the Go signal. After the V1 lesion, the increment of the low frequency activity before the Go signal did not change from before the V1 lesion, whereas the low frequency activity after the Go signal was greater in the Miss trials than the Hit trials. These results suggest that neural processes of visual stimuli without oculomotor response in the premotor regions were preserved before and after the V1 lesion, whereas those before visuomotor response onset were affected by the V1 lesion.

Title: Constraints shape shared vs. separate dynamics in multitask networks

Authors: *L. N. DRISCOLL[1], G. R. YANG[3], F. WILLETT[2], K. V. SHENOY[4], D. SUSSILLO[5];
[1]Stanford Univ., Palo Alto, CA; [2]Neurosurg., Stanford Univ., Stanford, CA; [3]Columbia, New York, CA; [4]EE, BioE & Neurobio., Howard Hughes Med. Inst. - Stanford Univers, Stanford, CA; [5]Google AI, Mountain View, CA

Abstract: Human thought is inherently flexible. Preliminary work has identified how both artificial and biological networks perform context dependent operations within the framework of a single task[1,2]. However, it is unknown how computations for many tasks interact within a single network. To advance our understanding of the flexibility of biological networks, we are interested in how computations for multiple tasks are implemented within a single network of neurons. We use recurrently connected artificial neural networks as a model system to address this question, because the architecture is inspired by biological neural systems and because these model systems are capable of learning many tasks. We train each recurrent neural network (RNN) to perform a set of 20 standard cognitive tasks that includes variants of memory guided response, perceptual decision making, context-dependent decision-making, multi-sensory

integration, parametric working memory, inhibitory control, delayed match-to-sample, and delayed match-to-category tasks[3]. After training on all tasks, the network connections are fixed and the changes in activity patterns are computed solely from the initial condition, $x(0)$, and the input, $u(t)$.
We study network activity during the performance of each task as a dynamical system, governed by the initial state and the inputs to the system[4]. At the beginning of each trial, the network is cued on which task to perform. This 'rule' input produces a stable fixed point that neural trajectories move toward. Collectively, these task rule dependent fixed points are organized in neural activity space according to task similarity. Following stimulus onset, hidden unit activity evolves in mostly separate subspaces for each task. The organization of these subspaces depends on the constraints on the network. Under certain constraints, the subspaces are aligned such that the same decoder can readout the stimulus identity or the motor plan in the same way across tasks. Training on multiple tasks compared to training on a single task changes the dimensionality of working memory tasks, suggesting multi-task training could change the algorithms that perform memory computations. We will further characterize the effects of various constraints in order to develop hypotheses for testing in biological cortical networks during the performance of multiple tasks.

Title: Joint modeling of neural population dynamics and behavior in single-trial perceptual decision making

Authors: *M. D. GOLUB[1], C. CHANDRASEKARAN[3], W. T. NEWSOME[4,5], K. V. SHENOY[1,5,2,4], D. SUSSILLO[6,1];

Abstract: An emerging hypothesis in systems neuroscience is that neural population dynamics implement the computations that process sensory cues into behavioral responses. If computation is indeed performed through these dynamics, understanding the dynamical motifs expressed by a neural population could provide a rich description of how that population solves a task, flexibly generalizes across tasks, and learns to solve new tasks.

Existing approaches to identifying dynamical motifs typically employ either "task-models" or "neural data models." Task-models rely on training a recurrent neural network (RNN) to solve a task. After training, the RNN's activity can then be compared neural activity recorded in animals performing the same task. However, there may be many qualitatively different dynamical motifs that can solve a task, and the particular motif learned by an RNN can depend dramatically on model design and task representation. On the other hand, neural data-models seek dynamical latent variables that accurately summarize recorded population activity. While these models provide powerful single-trial estimates of neural state, their complexity can render them difficult to interpret. Further, neural data models lack an explicit link to the task, behavior and underlying computation.

Here we propose Goal-Oriented Learning of Dynamics (GOLD), a joint neural-behavioral model that overcomes the aforementioned limitations. GOLD uses RNNs to learn latent dynamics capable of generating single-trial behavior (i.e. task modeling), but constrains those dynamics to be consistent with single-trial population recordings (i.e. neural-data modeling). GOLD thus provides access to an interpretable, data-driven link between task goals, observed behavior, underlying neural computation, and observed neural population dynamics.

We demonstrate GOLD on population recordings from dorsal premotor cortex in rhesus macaques performing perceptual decision making. Using trials that were held out during model fitting, we found that GOLD solves the task via dynamical motifs that are substantially more consistent with the neural recordings compared to task models. GOLD-identified dynamics also predicted previously elusive single-trial behavioral effects, such as extreme reaction times. Finally, we demonstrate the interpretability of GOLD by reverse engineering its RNN, revealing a structure of condition-dependent fixed points that govern the dynamics and solve the task. Moving forward, GOLD may provide a comprehensive description of how a single neural population flexibly re-configures its dynamics across a multitude of tasks.

Title: Discrete population states in motor cortex during different arm movement tasks

Authors: *C. SPONHEIM[1], V. PAPADOURAKIS[2], N. KADMON HARPAZ[4], N. G. HATSOPOULOS[3];
[1]Computat. Neurosci., [2]Organismal Biol. and Anat., [3]Univ. of Chicago, Chicago, IL;
[4]Organismic and Evolutionary Biol., Harvard Univ., Cambridge, MA

Abstract: Despite being one of the longest-studied brain areas, we have yet to elucidate the role of primary motor cortex (M1) in the generation of movement. An essential part of understanding the role of M1 is the temporal structure of commands sent from its neural population to the spinal cord. Previous research indicates that although M1 activity continuously changes throughout a movement, there remains a latent structure with discrete states, corresponding to accelerative and decelerative kinematic components of movement (Kadmon Harpaz et al., 2018). Rhesus macaques performed either a random target pursuit task (RTP), or a standard eight direction center-out reaching task. We recorded from M1 and premotor cortex (PM) using chronically implanted, multi-electrode arrays while each monkey performed two alternating tasks, allowing us to evaluate activity from two tasks in the same population of neurons. We also recorded muscle activity during the tasks. We used a hidden Markov model to identify common latent states in M1 neural population activity. We then compared the timing and length of those latent states to the kinematics of arm movements. We were able to replicate previous findings, supporting the idea that latent states in M1 map to accelerative and decelerative components of motion. We are also in the process of identifying whether models trained on one task effectively identify consistent kinematic parameters in the other task. In addition, we compared the performance of models trained on one task (either RTP or center-out) with that trained on the other task. We also anticipate that the latent states observed in cortical activity will not be present during analysis of EMG activity. These results suggest that neural representations of arm movements may be constructed from elementary sets of building blocks. These elementary states, put together in different discrete combinations, create the vast array of movements of which animals are capable. This method can also be used to interrogate the differences in temporal structure between M1 and PM.

Title: Developing a motor task platform for freely-behaving common marmosets

Authors: ***M. SUNDIANG**, J. D. WALKER, D. D. MOORE, J. MACLEAN, N. HATSOPOULOS;
Univ. of Chicago, Chicago, IL

Abstract: Goal directed, skilled movements and their acquisition through learning have the potential to provide novel insights into motor control. Until recently, a common experimental paradigm for studying these behaviors has involved restrained subjects performing constrained reaching tasks. We have learned a lot from these tasks because it has allowed us to isolate specific movement patterns and perform trial averaging of neural activity. However this constrained approach to behavior may not capture the complexity of neural dynamics that accompany more naturalistic behaviors. Here, we present a novel motor task for studying skill acquisition in freely behaving marmosets. In their natural habitat, marmosets exhibit foraging behavior during which they stalk and pounce on prey which are usually insects such as beetles, crickets and locusts. We take advantage of the marmosets' natural tendency to forage for food and allow them to learn new prey hunting strategies. To do so, we use a correlated random walk to model the movement dynamics of a natural prey of the marmoset, specifically the *Tenebrio molitor* beetle. A moving target follows the generated beetle trajectory and is presented to the marmoset via a touch screen. Because the prey trajectories are created programmatically, the task is flexible: we can present the same trajectory multiple times to assess motor learning, and we can generate different prey dynamics to assess higher level learning, to name a few examples. The marmosets can demonstrate motor skill learning by increasing successful captures, decreasing their time to capture the prey, and performing captures using a more stereotyped and efficient arm trajectory. Using DeepLabCut, a pose estimation toolbox, we track upper limb kinematics without using markers that might interfere with the behavior. Previous work in our lab developed a platform for wirelessly recording from a multi-electrode array in marmoset M1 and neighboring cortical areas, allowing us to collect simultaneous neural and behavioral data from untethered, freely-behaving marmosets. Thus, our motor task platform opens an avenue for

studying complex motor behavior and a richer understanding of the neural dynamics that generate these behaviors.

Title: Comparing pose estimation performance using DeepLabCut and marker-based tracking

Authors: *D. D. MOORE[1], J. D. WALKER[1], J. N. MACLEAN[2], N. G. HATSOPOULOS[1]; [1]Dept. of Organismal Biol. and Anat., [2]Neurobio., Univ. of Chicago, Chicago, IL

Abstract: To reveal the neurophysiological underpinnings of natural voluntary movement, neural recordings must be paired with accurate tracking of limbs and postures. DeepLabCut (Mathis et al, 2018), a recent machine learning based advance in markerless tracking technology, has been demonstrated to efficiently track body parts across a broad range of species, behaviors, and settings with accuracy comparable to that of human labeling. To our knowledge, however, DeepLabCut has not yet been compared to simultaneous high resolution marker-based tracking. Such a comparison would indicate the extent to which DeepLabCut reliably characterizes kinematics with accuracy similar to existing marker-based systems that are far more prevalent in non-human primate motor control research. A 3D x-ray video fluoroscopy system that tracks markers placed under the skin (XROMM) provides a well-established baseline for comparison to pose estimation performed with DeepLabCut on video recordings of behavior. To this end, we collect simultaneously recorded behavioral data using both XROMM and high speed video (two Blackfly S cameras at 200 frames per second) as common marmosets engage in naturalistic foraging, then reconstruct three-dimensional kinematics of reaching events in a shared coordinate system. By doing so, we directly compare the Cartesian position and velocity of the hand, wrist, arm and torso computed by each tool to determine the accuracy of DeepLabCut relative to the XROMM. We then evaluate whether this accuracy is sufficient to reconstruct joint angles from marker positions. If DeepLabCut provides comparable pose estimation accuracy as expected, its impressive efficiency and flexibility will enable the study of more naturalistic, unconstrained behaviors in many fields including non-human primate motor control.

Title: Three dimensional dynamics of β oscillation phase in the monkey motor cortex during a reaching task

Authors: *H. WATANABE[1,2], K. TAKAHASHI[2,3], H. MUSHIAKE[1];
[1]Grad. Sch. of Med., Tohoku Univ., Sendai, Japan; [2]Dept. of Organismal Biol. and Anat., The Univ. of Chicago, Chicago, IL; [3]The Univ. of Chicago, Research Computing Center, IL

Abstract: *β* oscillations (15-30 Hz) are ubiquitous in the motor cortex of the mammals. There have been a few attempts to analyze 3D spatiotemporal dynamics of neuronal activities at *β* band in the motor cortex. Previously we characterized horizontal dynamics of *β* oscillations from electrocorticogram (ECoG) recording by looking timings of phase locking to the instruction cues and movement onsets. Here, we implanted 3D electrode arrays into the primary motor cortex (M1) and the premotor cortex (PM) of a monkey and analyzed how site-dependent phase locking of *β* oscillations can be characterized in 3D and how the locking is related to behavioral events. The monkey was trained to use a single arm to perform a reaching. The monkey kept the hand at the resting position for 2 seconds after a visual instruction target-cue randomly indicating one of the two positions, then reached to the target after an acoustic go-cue. Two 128-channel electrode arrays (Matrix Array™, NeuroNexus, MI, US) were implanted in M1 and PM contralateral to the arm. Each array consisted of an ECoG grid (32 channels), and a 3D intracortical part (96 channels) having 12 needle probes horizontally spaced by 0.4mm with eight electrodes 0.2mm apart along each needle. A prominent *β* peak was identified at 22 Hz. To extract the amplitude and phase of the *β* band, a signal from each contact was bidirectionally filtered (20-24Hz), then Hilbert transformed. The Percent of Phase Locking (PPL) of *β* oscillations over trials was computed in relation to the instruction and go cues respectively.
The PPL transiently increased among most channels around the reaching onsets, while the *β*

amplitude decreased. The PPL in many channels occurred after instruction-cue as previously reported. Most channels showed statistically significant PPL after the instruction-cues and around reaching onsets. There was a temporal sequence of peak timing of the PPL was characterized to start from M1 then PM around the instruction cue and to transient back to M1 before the movement onset. Furthermore, the peak PPL timing patterns along the depth were different for the two positions. These results indicate that the temporal dynamics of the phase of β oscillation carry task-relevant information contained in instruction cue signals and about reaching.

Title: Rapid visuomotor transformations and multiple gain field effects in primate ventral premotor (PMv) cortex during head-unrestrained reaches

Authors: *V. NACHER, H. K. ARORA, V. BHARMAURIA, X. YAN, S. SUN, H. WANG, J. D. CRAWFORD;
Ctr. for Vision Res., York Univ., Toronto, ON, Canada

Abstract: In natural conditions, reaching involves a coordinated sequence of gaze, head, and arm movements toward a visual stimulus. Several studies have examined eye-head-hand coordination in the human, but the underlying neural mechanisms, especially those controlling head motion, have not been studied. To this aim, two monkeys were trained in a reaching paradigm that allowed unencumbered head motion and reaching in depth. Gaze, head and motion were recorded using search coil and touch screen technology, respectively. Animals touched one of three central LEDs (different initial hand locations) at waist level while maintaining gaze on a central fixation dot (with a jitter of 7-10° from trial to trial) and were then rewarded if they touched a target appearing at one of 15 locations in a 40° x 20° (visual angle) array. Simultaneously, extracellular single unit activity was recorded from a prefrontal region that included ventral premotor cortex (PMv). Behavioral analysis showed the expected gaze-head-reach sequence, with enhanced gaze accuracy and increased head movement during and after gaze the gaze shift, compared to no-reach controls. Preliminary neurophysiological analysis

showed an assortment of target/stimulus, gaze, pre-reach and reach- related responses in PMv. We first tested for gaze, head and hand gain fields during the different neuronal responses, and found that 55% of target-aligned responses, 70% of gaze-aligned responses and all pre-reach-aligned responses were gain modulated by initial hand position. A small fraction of neurons showed a gain fields for both initial gaze and hand position during target-aligned responses (20%) and pre-hand-onset-aligned responses (10%). After removing the gain field effects, we fitted the residual data against various spatial models and found that the initial visual response best encoded the target relative to the eye (Te), whereas immediately afterwards, during gaze shifts until reach, neural responses preferentially coded displacement of the hand (dA). This Te-dA transformation occurred rapidly within a time window ranging from 150-200 ms. A more complete analysis will aim to describe the complete coding and distribution of gaze, head, and reach signals in this region.

Title: Early life blindsight: The pulvinar versus lateral geniculate nucleus

Authors: *D. M. FOX, I.-C. MUNDINANO, J. A. BOURNE;
Australian Regenerative Med. Inst., Clayton, Australia

Abstract: Extensive damage to the primary visual cortex (V1) typically results in cortical blindness, eliminating conscious visual perception. However, some patients elicit remarkable preservation of unconscious visual behaviour within their blind field, such as accurately reaching to grasp for objects. This phenomenon, which has garnered much interest, is known as ‘blindsight’. The neural substrate affording such visual capacity is still debated, with the majority of the focus on the visual thalamic nuclei. In this study, we aimed to delineate the relative influence of two thalamic nuclei proposed to be involved in providing auxiliary visual information; the lateral geniculate nucleus (LGN) and the medial subdivision of the inferior pulvinar (PIm) following early-life injury to V1. We used a multi-faceted approach; detailing the anatomy, connectivity and behaviour in the common marmoset (*Callithrix jacchus*, n = 10). Using our MRI-guided approach, animals received a left uni-lateral lesion to V1 and either the LGN (n=4) or PIm (n=4) at postnatal day 14. Early anatomical changes were identified by structural and diffusion MRI analysis, revealing differences in higher-order dorsal stream areas, compared to the intact hemisphere. Eighteen months following injury, we investigated their

visually-guided behaviours under naturalistic and psychophysical settings to explore the presence and extent of their blindsight capacity. We found that both lesion groups exhibited blindsight-like symptoms all presenting with a defined scotoma. However, each cohort possessed different capacities in which they could respond to contrast- and motion-sensitive stimuli within the scotoma. This dissociation revealed that PIm/V1 lesion animals showed decreased motion sensitivities while LGN/V1 lesions animals exhibited decreased contrast sensitivities. Prehensile kinematics remained similar amongst both lesion cohorts yet differed to intact controls in reaching velocity and end-point errors. Coinciding with the dorsal stream changes observed in the diffusion MRI, neural tracing and immunohistochemical techniques demonstrated similar changes in the density of anatomical projections to dorsal stream areas and their cellular profile. These results suggest an extensive role for visual thalamic nuclei in facilitating blindsight-like properties from an architectonic to an awake behaving level. However, PIm showed a greater influence following early-life lesion of V1 confirming its key role in the development of higher-order visual areas. These results also support the notion of blindsight as a modular phenomenon comprising multiple areas rather than a unitary model.

Title: Mesoscopic patterns in motor cortical excitability facilitate movement initiation

Authors: *K. BALASUBRAMANIAN[1], V. PAPADOURAKIS[1], W. LIANG[2], K. TAKAHASHI[1], M. BEST[1], A. J. SUMINSKI[3,4], N. G. HATSOPOULOS[1,2];

Abstract: Motor cortical neurons (M1) modulate prior to movement initiation but also during movement planning, action observation and motor imagery where movement does not occur. We hypothesize that for movement initiation to occur, two conditions must be met. First, local desynchronization of M1 occurs prior to movement initiation as revealed by attenuation in the local field potential oscillation amplitude in the beta frequency range, which is considered a signature of enhanced motor cortical excitability. Second, the onset of beta attenuation is not synchronous across different sites in M1 but rather takes place at different latencies in an orderly

spatial fashion reflecting planar propagating patterns of excitability along a spatially oriented axis. We show that both conditions are met in the non-human primate arm area of M1 for reaching initiation and in orofacial M1 for initiation of tongue protrusion. Moreover, we show that a preponderance of functional connections among units in M1 are oriented along the propagating axis during reaching initiation but not during planning and preparation. By decoding muscle activity using an artificial neural network from beta amplitude profiles across a set of electrodes, we also show that spatial perturbations that disrupt the natural propagating pattern of attenuation are more effective in disturbing decoding performance. Finally, to provide more direct causal evidence that this propagating pattern is necessary for movement initiation, we delivered spatio-temporal patterns of electrical stimulation that were either congruent or incongruent with the natural propagating patterns for reaching movements and showed that movement initiation was significantly delayed for incongruent electrical stimulation patterns.

Title: Shared and non shared neural subspaces between action execution and multi sensory action observation in the macaque primary motor cortex

Authors: *V. PAPADOURAKIS[1], A. J. SUMINSKI[2], K. TAKAHASHI[1], N. G. HATSOPOULOS[1];
[1]Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL; [2]Dept. of Neurolog. Surgery, Univ. of Wisconsin-Madison, Madison, WI

Abstract: Our ability to move and interact with our environment relies heavily on sensory information. Sensory input is used by the motor system to access information about important variables such as hand position or target location. Primary motor cortex (M1) is considered a major hub responsible for driving movement. M1 also responds in situations that don’t involve the generation of overt motor commands, such as passive movement of the limbs or action observation. The nature and significance of this activity is under investigation. These responses could simply reflect the feedback signals used during active movement, or they could serve a

non-movement related sensory process. Here, we compare the activity of populations of M1 neurons, recorded during the execution and multi- or uni-modal passive observation of upper limb movements. We take advantage of dimensionality reduction methods to explore the existence of and characterize shared and non-shared neural subspaces between these conditions. Two monkeys were trained to execute and observe a random target pursuit task. During execution, the animals moved a visual cursor aligned with their hand location using a two-link robotic exoskeleton. Immediately following a target hit, a new target appeared in a random location. During observation, the movements generated during execution were replayed to the monkey in three different observation variants. In the visual playback condition, cursor and targets were visible to the animal during playback while the animal maintained a static arm posture. In the proprioceptive playback condition, cursor and targets were invisible and the monkey's arm was moved by the robotic exoskeleton along the invisible cursor trajectory. In the visual + proprioceptive playback condition, cursor and targets were visible and the monkey's hand was moved by the exoskeleton. A 10x10 electrode array was used to record the spiking activity of single units in M1, while the monkeys performed the task. We were able to identify both shared and non-shared subspaces in almost all the across condition comparisons. Shared subspaces accounted for the majority of the population variance, indicating the existence of an underlying correlation structure of population activity that is preserved across conditions. In alignment with our single neuron results, population activity during action execution was more related to multimodal than to unimodal action observation. We also found condition-exclusive subspaces in all conditions. These unique population patterns could represent variables that differ between action execution and observation such as movement commands or feedforward sensory predictions.

Title: Cortical representation of bite force and gape in macaques

Authors: F. I. ARCE-MCSHANE[1], B. J. SESSLE[3], N. G. HATSOPOULOS[2], ***C. F. R. ROSS**[2]; [1]Dept. of Organismal Biol. and Anat., [2]Univ. of Chicago, Chicago, IL; [3]Univ. Toronto, Toronto, ON, Canada

Abstract: The precise control of bite force at varying degrees of mouth opening is vital for human mastication. Yet, the cortical control of bite force and gape is still poorly understood. To elucidate how neurons differentially encode bite force and gape, we examined neuronal spiking activity recorded with microelectrode arrays implanted chronically in the primary motor (MIo), primary somatosensory (SIo), and cortical masticatory (CMA) areas of the orofacial sensorimotor cortex in rhesus macaques. We used generalized linear models (GLM) to predict the time-varying spiking activity of each neuron as a function of bite force, gape, and spike history of a neuron. Across all areas and animals, bite force accounted for most of the information used to predict spiking: the performance of encoding models degraded significantly when bite force was removed but not when gape was removed. Encoding models in MIo performed better than in SIo but not any better in CMA. Across all cortical areas, the proportion of force-related neurons was higher than gape-related neurons and was highest in MIo. Lastly, the population of neurons in MIo, SIo, and CMA exhibited differences in preferred temporal lags of bite force in predicting spiking activity. Overall, the results suggest that while single-unit and population responses in all three areas play a role in encoding bite force and gape, the relative importance of these predictors are different across MIo, SIo and CMA.

Title: Sex differences in purkinje cell density in the cerebellar vermis of mice

Authors: *W. E. GRISHAM[1], **W. R. TOMITA**[2];
[1]Psychology, [2]Neurosci., UCLA, Los Angeles, CA

Abstract: Previously, MRI analyses of the cerebellar vermis revealed sex differences in mice (Corre et al. 2016). We examined these differences with a fine-grained, cellular approach, scrutinizing the vermis in cerebellar lobules 4 through 8 in XX female and XY^- -Sry male mice. Mice were gonadectomized at 73-77 days old and sacrificed at approximately 3 months. Brains were sectioned at 40-microns, mounted, and stained with thionin. Purkinje cell counts, area of granular and Purkinje cell layers, density of Purkinje cells, and mean thickness of the granular and Purkinje cell layers were measured at 10x in lobules 4 through 8.
Female mice showed greater Purkinje cell density than male mice across all lobules. No other measures, however, displayed a significant sex difference, though Purkinje cell counts showed a strong trend ($p = 0.059$). The differences in Purkinje cell density may reflect differences in

number because the cell layer areas did not show significant sex differences ($p = 0.719$). This sex difference in Purkinje cell density may be a result of organizational effects, changes at puberty, sex chromosome complement, or due to neurosteroids. Androgen receptors have been detected in Purkinje cells. Thus, androgens could affect change either in development or possibly at puberty. Sex chromosomes are another possible explanation; a difference in calbindin, which is only present in the cerebellum in Purkinje cells, is different due to sex chromosomes (XX > XY—regardless of gonad) (Abel et al. 2011). Neurosteroids may also play a role in these differences; the cerebellar Purkinje cells produce large amounts of neurosteroids (Tsutsui et al. 2011). These neurosteroids have different functions and are produced during neonatal life (Tsutsui et al. 2011). While allopregnanolone promotes Purkinje and granule cell survival, estradiol and progesterone promote Purkinje cell dendritic growth, spinogenesis, and synaptogenesis (Tsutsui et al. 2011). These neurosteroid effects could help explain the sex differences in Purkinje cell density.

Title: Impact of Purkinje cell simple spike synchrony on signal transmission from flocculus

Authors: *J. S. STAHL, A. KETTING-OLIVIER;
Neurol. Service, Cleveland Dept. of Veterans Affairs Med. Ctr., Cleveland, OH

Abstract: The degree to which Purkinje cells (PCs) ramifying on a single deep cerebellar nucleus (DCN) neuron fire in synchrony has been demonstrated to influence the DCN neuron's mean activity and response to excitation, prompting speculations that PCs carry a "synchrony code" in their simple spike (SS) activity. In this view, PCs exercise a gating function, with greater synchrony permitting greater transfer of excitatory signals through DCN neurons. However, PCs in the flocculus are not simply gates, as they are known to encode eye movement commands in their simple spike firing rates. It is unknown whether flocculus SS synchrony has any impact on the transfer of that rate-coded signal to the PCs' synaptic targets in the vestibular nuclei. An impact of SS synchrony on signal transfer might explain why disruptions in PC rhythmicity - if they also disrupt PC-PC synchrony - lead to cerebellar eye movement deficits in ataxic mice carrying mutations of genes for P/Q (CaV2.1) calcium channels. To determine if PC-PC synchrony impacts transfer of rate-coded signals, we exploited a property of optogenetics;

pulsed photostimuli engender stimulus-locked spiking that should synchronize PCs, whereas continuous stimulation engenders spikes temporally independent of the stimulus. We implanted a fiber optic cannula near the flocculus and recorded flocculus PCs in mice that express channelrhodopsin-2 specifically in PCs (F1 crosses of Ai32 and L7Cre-2 homozygotes). We stimulated the flocculus using either a fixed-amplitude, pulsed photostimulus whose 4ms pulses varied on a 0.4 Hz cycle between 14-73 pulse/s, or a photostimulus whose intensity varied continuously, also at 0.4 Hz. Both stimuli evoked sinusoidal variations of eye position with a diagonal trajectory. Tetrode recordings of 7 pairs of PCs proved that the pulsed stimulus evoked greater PC-PC synchrony, defined as the two PCs firing within 1.5 ms of each other. Single PC activity and the concomitant eye movements were processed by Fourier analysis to extract the amplitudes of firing rate modulation (|F|) and eye position (|E|), respectively. The |F|/|E| ratio was marginally higher during the pulsed than the continuous stimulus, indicating that the rate-coded signal associated with higher PC-PC synchrony was not transferred to downstream circuitry better than the signal associated with lower synchrony. The results cast doubt on whether PC synchrony plays any role in moment-to-moment regulation of eye movements driven by the flocculus (e.g., the optokinetic reflex), and whether alterations in synchrony provide a link between irregular firing in PCs of P/Q mutants and the mutants' vestibulocerebellar deficits.

Title: Purkinje cell firing rate changes in response to alternating current stimulation

Authors: H. CHI, S. CHERIAN, M.-E. FALDAS, *H. LU;
PCOM - Georgia Campus, Suwanee, GA

Abstract: Transcranial electric stimulation (tES) is an effective treatment method for cerebellar ataxia. The underlying mechanism is not fully understood. To understand the mechanism of tES to the cerebellar Purkinje cells (PCs), we have previously used the direct current stimulation (DCS) with whole-cell patch-clamp recordings. There was no significant increase in firing rate under either positive or negative DCS. In this project, in vitro experiments were conducted to quantitatively measure the effects of alternating current stimulation (ACS) on Purkinje cells as they are the sole output neurons of the cerebellar cortex. Spontaneous activity was examined first to detect the direct response to ACS with bias current (-0.45 nA to -0.25 nA, n=3). In general, the firing rate of the Purkinje cells increased (5 Hz to 15 Hz) during ACS. Basic property was tested using current injections (-0.5 nA to +0.5 nA) to compare three states: before, during, and after

ACS. Student's t-test was used to examine the frequency changes from ACS. No significant changes were observed between pre- and post- stimulations (p=0.87, n=9) or between pre- and during- stimulations (p=0.90, n=8). In consistence with this result, no significant change was found with input resistance between pre- and post- stimulations (p=0.79, n=9). To further our understanding of the frequency change in spontaneous activity, tests to include cell orientations and stimulation intensities will be considered.

Title: The hypergravity induced disruption of cerebellar motor coordination

Authors: *W. NOH[1], M. LEE[1], K.-S. KIM[3], H. KIM[3], S. YANG[2];
[2]Nano-Bioengineering, [1]Incheon Natl. Univ., Incheon, Korea, Republic of; [3]Inha Univ., Incheon, Korea, Republic of

Abstract: The cerebellum coordinates voluntary movements to gain smooth and balanced motor activity. It remains unknown how gravity is associated with cerebellum-dependent behaviors and Purkinje cell's activities. In order to investigate a causal relationship between the cerebellum physiology and gravity, we measured the AMPA-mediated fast currents and mGluR1-mediated slow currents, and cerebellum-dependent behaviors such as foot print and irregular ladder under a hypergravity condition(4G). We found abnormal foot print and irregular ladder in response to hypergravity which are correlated with decreased AMPA/mGluR1-mediated currents in Purkinje cells. These results indicate that hypergravity could severely disrupt the activity of Purkinje cells in Cerebellum.

Title: Enriched environment shortens the duration of action potentials in cerebellar granule cells

Authors: *A. ESHRA[1], P. HIRRLINGER[2], S. HALLERMANN[1];
[1]Univ. Leipzig, Leipzig, Germany; [2]Medizinisch-Experimentelles Zentrum, Med. Faculty, Univ. of Leipzig, Leipzig, Germany

Abstract: Environmental enrichment for rodents is known to enhance motor performance. Structural and molecular changes have been reported to be coupled with enriched environment, but functional alterations of single neurons remain elusive. Here, we compared mice grown up under control conditions and enriched environment. We tested the motor performance on a rotarod and subsequently preformed whole cell patch clamp recordings in cerebellar slices focusing on granule cells of lobule IX, which is known to receive extensive vestibular input. Mice grown up in an enriched environment stayed longer on an accelerating rotarod. Electrophysiological analyses revealed normal passive properties of granule cells and a functional adaptation to the enriched environment, manifested in faster action potentials with more depolarized voltage threshold and larger amplitude. Furthermore, the maximal firing frequency of action potentials was higher in mice grown up in an enriched environment. These data show that enriched environment causes specific alterations in the biophysical properties of neurons. Furthermore, we speculate that the ability of cerebellar granule cells to generate higher firing frequencies improves motor performance.

Title: Functional imaging of the monkey cerebellar cortex during action execution and observation

Authors: *H. SAVAKI[1], **V. RAOS**[1,2];
[1]IACM/FORTH, Heraklion, Greece; [2]Univ. of Crete Med. Sch., Heraklion, Greece

Abstract: We employed the ^{14}C-deoxyglucose quantitative autoradiographic method to obtain high-resolution functional maps of activity in the cerebellar cortex of six rhesus monkeys who

reached and grasped an object either in the light (EL) or in the dark (ED), of three monkeys who observed the same reaching-to-grasp movements executed by another subject (O), and of two monkeys who observed non-object-directed (purposeless) forelimb movements (BM). The extent and intensity of activations in the cerebellar cortical areas of the monkeys grasping in the light and of the monkeys observing either object-directed or purposeless forelimb movements were compared to those of the two fixation control monkeys (Cf). The activity pattern in two dark control monkeys (Cd) was used as reference for the measurement of effects in the animals grasping in the dark. Execution of reaching-to-grasp movements, both in the light and in the dark, activated the forelimb representation of the cerebellar hemispheric extensions of vermian lobules IV, V, VI and VIII, ipsilaterally to the moving forelimb. Moreover, crus II posterior in the ansiform lobule was activated bilaterally only by the execution of visually-guided movements. The activations induced by the observation of reaching-to-grasp movements were similar in extent and intensity with those induced by the observation of purposeless forelimb movements and therefore the O and BM monkeys were pooled together. Action observation activated the forelimb representation of the cerebellar hemispheric extensions of vermian lobules IV, V, VI, as well as the crus II posterior in the ansiform lobule, bilaterally. These results demonstrate that the cerebellar cortex, in addition to its involvement in the production of movement, plays an active role in the perception of observed movements.

Title: Dynamic interactions among the anterior cingulate, amygdala and cerebellum during acquisition of trace eyeblink conditioning in rats

Authors: *H. E. HALVERSON[1], J. KIM[2], J. H. FREEMAN[2];
[1]Iowa Neurosci. Inst., [2]Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: Eyeblink conditioning is a simple form of associative learning where a conditioned stimulus (CS), e.g., a tone) is repeatedly paired with an unconditioned stimulus (US, e.g., a periorbital shock) to yield a cerebellum-dependent conditioned response. Cerebellar learning during trace eyeblink conditioning, when there is a temporal gap between the CS and US, requires mossy input from the CS and persistent mossy fiber input from the forebrain. The

amygdala has also been shown to modulate cerebellar learning during eyeblink conditioning, through modulating mossy fiber inputs necessary for learning. The necessity of forebrain and cerebellum for acquisition and expression of trace eyeblink conditioned responses has been well-established, however, the dynamic interactions among these structures during learning has not been investigated. The current experiment used simultaneous tetrode recordings in anterior cingulate (right), amygdala (right) and anterior interpositus nucleus (left) during acquisition of trace eyeblink conditioning (250 ms tone/500 ms trace interval) to investigate the evolution of dynamic interactions among these necessary structures during forebrain dependent cerebellar learning. Single unit analysis revealed greater activity during the CS and trace interval in each area on trials when the rat showed a conditioned response relative to non-response trials, and alternatively more activity was found after the US on trials when the rat failed to show a conditioned response. Spectral power analyses showed that theta emerged in all three regions across learning. However, the theta emerged earlier in cerebellum than in the anterior cingulate or amygdala. Coherence was observed between each iteration of pairs and was greatest between cerebellum and anterior cingulate. The synchronous activity between areas became more organized in time during the sessions when the rats transitioned from an unlearned to a learned state. These results indicate that the cerebellum has dynamic interactions with the forebrain during acquisition of trace eyeblink conditioning and these interactions may be playing a larger role in the learning process than previously thought.

Title: Predictive processing by Purkinje cells in the vestibular cerebellum during active versus passive rotational and translational self-motion

Authors: *O. ZOBEIRI[1], K. E. CULLEN[2];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Dept. of Biomed. Engin., The Johns Hopkins Univ., Baltimore, MD

Abstract: The ability to distinguish between self-generated (reafference) vs. externally-applied (exafference) sensory signals is fundamental for ensuring accurate motor control as well as perceptual stability. This is particularly evident in the context of the vestibular system, in which the same central neurons that receive direct afferent input also project to motor neurons that

control vestibulo-spinal reflexes (VSR). Notably, while VSRs are essential for providing a postural response to unexpected perturbation, they are impeding during active head motion. Previous studies by our group have shown that central VSR neurons selectively code passive head movements. Although the cerebellum is hypothesized to play a crucial role in the cancellation of their responses to active motion, the exact underlying neural mechanism is unknown. Accordingly, here we recorded from Purkinje cells in the vestibular cerebellum (anterior vermis, lobules IV-V) in rhesus monkeys during comparable active & passive rotational and translational head movements. We first found that simple spike activity encodes passive head motion in a direction-dependent manner. Accordingly, for each Purkinje cell, we first developed a linear dynamic model of its neuronal response based on passive head movements kinematics in each direction. Then to compare each neuron's responses to active versus passive movements, we fit comparable models to neuronal responses during preferred and non-preferred active head movements. We found that neuronal sensitivities were markedly attenuated in the active condition (~70%, $p<0.01$). Next, we compared the patterning of climbing fiber inputs to the Purkinje cells for passive vs. active head movements and found that the probability of a complex spike firing increased (~60%, $p<0.01$) relative to baseline immediately following (20ms) the onset of head movement in the passive condition. In contrast, we found no increase in the probability of complex spike firing in the active condition, suggesting that complex spikes are preferentially elicited in response to externally-applied versus self-generated vestibular inputs. We speculate that the higher probability of complex spikes following the onset of a passive movement facilitates an increase in the sensitivity of the simple spike response to the vestibular stimulation. Taken together, these results provide new insights into the computations performed by Purkinje cells in anterior vermis that underlie the suppression of vestibular reafference.

Title: Differential axonal projections from substantia nigra and ventral tegmental area into cerebellum

Authors: *A. JUÁREZ-TELLO[1], J. A. MENDEZ[2];
[1]Inst. of Physics, Biophysics, Univ. Autónoma De San Luis Potosí, San Luis Potosí, Mexico;
[2]Inst. of Physics, Univ. Autonoma De San Luis Potosi, San Luis Potosi, Mexico

Abstract: Both the mesencephalic dopaminergic nucleus substantia nigra (A9) and the cerebellum play important roles in the control and integration of motor skills. The presence of the Dopaminergic markers tyrosine hydroxylase (TH) and Dopamine type 2 receptors (D2r) in the cerebellum, and the fact that there are no dopaminergic neurons in the cerebellum, suggests a possible direct interconnection between substantia nigra and the cerebellum.
In order to determine whether exists axonal projections from the substantia nigra *pars* compacta into cerebellum. We performed pressure injections of the anterograde tracer Dextran Alexa-Fluor 546 into the SNc as well as into VTA of adult p90 mice. 10 days later, the fluorescent signal was detected in different areas of the cerebellum. Conversely, injection of the retrograde tracer FluoroGold in the cerebellum produced the recovery of fluorescent signal within the substantia nigra and the VTA as well. We found that both the lateral part of substantia nigra and substantia nigra pars compacta project axons into lobules 4/5 and 3 of the cerebellum, whereas substantia nigra *pars* reticulata does project axon terminals mainly into lobule 6 and scarcely within lobules 4/5 and 3. We also found that VTA sends axonal projection into lobule 3. Moreover, when FluoroGold stained slices were counter-immunostained against TH, we found that the projection from VTA was predominately Dopaminergic whereas the nigral projections were mainly non-Dopaminergic. Our results reveals the presence of differential axonal projections from the ventral mesencephalon to the cerebellum. We speculate that this interconnection might be involved in fine motor integration.

Title: Sphingolipid levels in cerebellar compartments and its implications in Purkinje cell degeneration

Authors: *F. G. C. BLOT[1], M. KRIJNEN[1], S. M. DEN HOEDT[2], C. R. OSORIO[1], M. T. MULDER[2], M. SCHONEWILLE[1];
[1]Neurosci., [2]Erasmusmc, Rotterdam, Netherlands

Abstract: Lipid metabolism is known to be essential for Purkinje cell survival and degeneration. Knock-out mouse models for various enzymes in the sphingolipid metabolism pathway present a patterned degeneration throughout the cerebellar cortex, which is in line with the Zebrin II defined cerebellar modules. This non-homogeneous degeneration has also been observed in wide range of cerebellar pathologies, however, no mechanism has been so far identified to explain this Zebrin II-like patterned degeneration. To elucidate whether sphingolipid metabolism relates to

this phenotype we investigated the compartmentalization of sphingolipids and their relative enzymes. Here, we report differential sphingolipid levels in the cerebellar compartments, together with differential expression of the enzymes involved in this pathway. To assess whether sphingolipid metabolism is implicated in Purkinje cell degeneration, we crossbred mice that lack Sphk1 with mice carrying a mutated Atxn1 [82Q], a model for SCA1 that is featured by Purkinje cell degeneration. The Sphk1 deficiency in the Atxn1[82Q] results in an aggravated PC degeneration and appearance of a Zebrin II-like pattern of degeneration.

Title: Whisking related sensorimotor integration in the cerebellar corticonuclear circuit

Authors: *M. P. MEDINA, S. T. BROWN, I. M. RAMAN;
Neurobio., Northwestern Univ., Evanston, IL

Abstract: With extracellular recordings of crus I/II Purkinje cells (Pkj) and cerebellar nuclear cells (CbN) of the mouse lateral nucleus, we previously found that sensory input associated with air-puff evoked whisking drives well-timed suppressions of Pkj cell firing that correspond to elevations of CbN cell firing, suggesting that millisecond time-scale disinhibition increases CbN responses to mossy fiber input, augmenting motor output. Here, we investigated Pkj and CbN responses to contrasting, naturalistic sensory stimuli, namely, (1) passive contacts, in which a bar displaces previously stationary whiskers and (2) active contacts, in which mice actively protract their whiskers into the bar. With passive contacts, firing rates of Pkj cells first showed a well-timed transient decrease, and then increased for hundreds of ms, as they did in response to puffs. CbN cells showed transient increases in firing rate that peaked and decayed to baseline before the maximal Purkinje cell response. Passive contacts also reliably elicited Pkj complex spikes (CS). In contrast, with active contacts, well-timed Pkj cell inhibition and CbN cell disinhibition were greatly reduced or absent. Instead, increases in both CbN and Pkj cell firing rate began before contact, suggesting the activity of both cell types was primarily whisking-related. CS were not modulated with active contacts suggesting that self-initiated, likely predictable, sensory inputs are less effective than externally applied, unpredictable, stimuli at engaging the inferior

olive. We next compared Pkj and CbN responses by triggering the averaged responses to active movement onset rather than the sensory contact. Both Pkj and CbN cells showed activity that scaled with protraction amplitude. Changes in Pkj simple spike firing rate correlated well with changes in whisker position, outlasting the time of contact (which was about 50 ms after movement onset). In contrast, CbN cell responses, which preceded Pkj responses, were transient, peaking 8 ms after movement onset, well before contact. CbN firing rate changes correlated well with whisker velocity. These findings provide evidence that (1) externally applied but not self-initiated sensory inputs inhibit and synchronize Pkj cell simple spikes, briefly disinhibiting CbN cells, and elicit Pkj complex spikes; (2) with self-initiated contact, Pkj and CbN cell activity is more strongly related to whisker movements rather than sensory input; and (3) CbN cell responses during active whisking are well correlated to whisker velocity.

Title: The role of dystrophin on synaptic function in cerebellar nuclei

Authors: *T. KREKO-PIERCE[1], J. R. PUGH[2];
[1]UT Hlth. San Antonio, San Antonio, TX; [2]Physiol., UTHSCSA, San Antonio, TX

Abstract: Muscular dystrophy is an X-linked myopathy caused by mutations in dystrophin, the protein product of the DMD gene. In skeletal muscle dystrophin is a key component of the multiprotein dystroglycan complex acting as a linker between the intracellular cytoskeleton and the extracellular matrix, thus mediating the structural stability of the plasma membrane. In addition to high expression in the muscle tissue, dystrophin is also expressed in the central nervous system, particularly in neurons of the hippocampus and cerebellum; however, the role of this protein in the CNS remains largely unknown. Interestingly, many individuals with muscular dystrophy display severe cognitive deficits, suggesting the role of dystrophin in normal neuronal function. We hypothesize that dystrophin mutations disrupt normal cerebellar function which contributes to the loss of motor and cognitive function observed in muscular dystrophy patients. To test this hypothesis we use a combination of genetics (mouse model of muscular dystrophy-mdx), patch-clamp slice electrophysiology and immunohistochemistry and focus our analysis on the cells of the deep cerebellar nuclei, the sole output channel of the cerebellum. Using these

approaches we find significant morphological and functional synaptic impairments in the cells of the deep cerebellar nuclei of our mdx mouse.

Title: Reduced molecular layer interneuron inhibition to Purkinje cell in a mouse model of muscular dystrophy

Authors: *W.-C. WU, R. D. HOWELL, A. ZANOT, A. GINSBERG, J. R. PUGH;
Cell. and Integrative Physiol., Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Duchenne muscular dystrophy (DMD) being the most common form of childhood muscular dystrophy is caused by mutations in the gene encoding the protein dystrophin. In addition to muscle-related symptoms, about one third of patients display a range of cognitive deficits thought to result from loss of dystrophin expressed in the brain. While the function of dystrophin in muscle tissue has been researched in detail, its role in the central nervous system is poorly understood. It has been demonstrated that the highest expression of dystrophin in the brain is in cerebellar Purkinje cells, where it is colocalized with postsynaptic $GABA_A$ receptor clusters. We investigated changes in molecular layer interneuron (MLI)-Purkinje cell inhibitory synaptic transmission and Purkinje cell spontaneous firing using *mdx* mice, a mouse model of DMD lacking full-length dystrophin expression. In acute cerebellar slices we found that the amplitude and frequency of both spontaneous and miniature inhibitory postsynaptic currents of *mdx* Purkinje cells are reduced. This is accompanied by a decrease in the number of vesicles released at the basket cell (a type of MLI)-Purkinje cell synapse, suggesting dysfunctional synaptic transmission with possibly fewer release sites being present at MLI-Purkinje cell synapses. Purkinje cell firing activity has been demonstrated to play an integral role in computing behavioral output signals. We found that Purkinje cells from *mdx* mice fire more regularly and in paired basket-Purkinje cell recording we showed that basket cells from *mdx* mice are less capable of driving pauses in Purkinje cell firing. Current DMD treatments have targeted muscle tissue; however, our data shed light on involvement of dystrophin in the cerebellum which pave the way to future therapies targeting CNS-driven symptoms.

Title: Dissecting the organization and function of spinal projecting circuits from the interposed nucleus of the cerebellum

Authors: *A. R. THANAWALLA[1], A. K. K. YIP[2], N. ZAINOLABIDIN[2], J. M. CONNER[1], A. I. CHEN[2], E. AZIM[1];
[1]MNL-E, Salk Inst. for Biol. Studies, La Jolla, CA; [2]Sch. of Biol. Sci., Nanyang Technological Univ., Singapore, Singapore

Abstract: The cerebellum guides the coordination and precision of dexterous forelimb movements. These behaviors ultimately depend on output circuits that reside in the deep cerebellar nuclei (DCN). While most studies have explored DCN output to thalamic and brainstem structures, direct projections from the DCN to the spinal cord have primarily been described through classical tracing studies. The existence of these descending pathways suggests a means for the cerebellum to adjust the activity of spinal motor circuits directly and rapidly update motor output. However, the contributions of direct cerebello-spinal projections to forelimb movement and the specific classes of spinal motor circuits these projections recruit has not been defined.
Using molecular-genetic tools in mice, we describe subpopulations of neurons in the cerebellar interposed nucleus that directly target the cervical spinal cord. Using viral and genetic anterograde and retrograde mapping strategies to characterize their afferent and efferent connectivity, we find that interposed neurons target specific classes of premotor interneurons in the cervical spinal cord, and receive input from discrete supraspinal sensorimotor areas. Additionally, we observe that a distinct subset of spinal projecting interposed neurons also targets the thalamus, suggesting a role for this subpopulation in conveying both ascending and descending information during movement. To further define the diversity of interposed neurons, we performed single-cell gene expression analysis and uncovered putative molecular distinctions

between DCN neurons that reveal novel neuronal subtypes and guide the development of genetic tools for analysis of cerebellar output circuits. Finally, using molecular-genetic perturbation combined with high-resolution quantitative forelimb behavioral assays, we are exploring the role of spinal projecting interposed neurons in skilled forelimb movements. These findings define the organization of direct cerebellar output pathways to forelimb motor circuits in the spinal cord, revealing a potential neural substrate for rapid online correction of dexterous behaviors.

Title: Tottering mutation is not associated with breakdown of vermis Purkinje cell simple spike synchrony

Authors: *T. L. CONNOR[1], A. KETTING-OLIVIER[1], J. S. STAHL[2];
[1]Res. Svc., Cleveland Dept. Veterans Affairs Med. Ctr., Cleveland, OH; [2]Neurol., Case Western Reserve Univ., Cleveland, OH

Abstract: Mutations of Cacna1a, the gene coding for the ionophore component of P/Q (CaV2.1) calcium channels, cause cerebellar motor deficits including ataxia and deficient compensatory eye movements. Several lines of evidence that began with recordings of flocculus Purkinje cells (PCs) in the Cacna1a mouse mutant *tottering* (*tg*) support the hypothesis that disruptions in PC autorhythmicity ultimately negate the influence of cerebellar cortex over the PCs' synaptic targets in the deep cerebellar nuclei (DCN) and vestibular nuclei (VN). The mechanism of this interference remains unclear. Simple spike (SS) activity of adjacent PCs is known to exhibit partial synchrony, and this synchrony has been demonstrated to enhance the response of DCN neurons to their excitatory inputs. A possible explanation for cerebellar cortical dysfunction in Canca1a mutants is that the disruptions in PC autorhythmicity also disrupt the normal PC-PC synchrony. To test this idea, we assessed whether PCs of the anterior vermis of *tg* exhibit reductions in PC-PC synchrony. PC pairs (putative and definitively identified by documentation of SS pauses induced by complex spike (CS) activity) were recorded with tetrode electrodes in awake/restrained *tg* and C57BL/6 controls. PCs were located primarily in the depths of vermis folia 4-6. As in previous studies by us and others, *tg* PCs exhibited prominent irregularity in their SS discharge rates. From the cross-correlograms of the activity of each pair, we defined a

synchrony index (SI) as the area in the central ±1.5 ms of the correlogram that falls above the "baseline" cross-correlation (average value over the ±20-40 ms regions of the cross-correlogram), normalized to that baseline cross-correlation. Since the synchronized non-firing that occurs before and after each synchronized spike may be more relevant than the synchronized spikes themselves in controlling PC targets (because the release from inhibition during the non-firing allows PC targets to spike), we also defined an analogous complementary synchrony index (CSI) based on the area falling below the baseline cross-correlation within the central ±3 ms. In 51 *tg* and 51 C57BL/6 PC pairs, SI was non-significantly greater for *tg* vs. C57BL/6 controls (mean±SD were 0.98±0.51 vs. 0.83±0.51), and CSI were essentially equal (*tg*: 0.73±0.49; C57BL/6: 0.74±0.48). Thus, judging from observations in the anterior vermis, the prominent irregularity of PC firing in *tg* is not likely to be inducing cerebellar dysfunction through a deleterious effect on PC-PC synchrony.

Title: Purkinje cell specific $GABA_{A\alpha1}$ - knockout mice display a tremor phenotype

Authors: *A. K. NIETZ, C. KROOK-MAGNUSON, H. GUTIERREZ, J. KLEIN, C. SAUVE, S. MITCHELL, E. KROOK-MAGNUSON;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Essential tremor (ET) is the most prevalent movement disorder and can become disabling for patients. Previous research has shown aberrant activity in the cerebellum and other regions related to motor control coincide with tremor. The limited number of animal models of essential tremor have made it difficult to study the pathophysiology of tremor, the brain regions involved, and the mechanisms by which anti-tremor drugs exert their effects. Prior studies characterized a tremor model in which the α1 subunit of $GABA_A$ receptors is knocked out globally [1, 2]. Global knockout of the $GABA_{A\alpha1}$-subunit results in significantly reduced inhibitory transmission in the brain and tremor in homozygous knockout mice. Here we show that Purkinje cell specific deletion of the $GABA_{A\alpha1}$ subunit is sufficient to produce tremor,

supporting the idea that cerebellar dysfunction may be sufficient for tremor generation. We recorded spontaneous inhibitory currents (IPSCs) from Purkinje cells (PCs) and molecular layer interneurons (MLIs) in both global and Purkinje cell specific $GABA_{A\alpha1}$ subunit knockout mice. As expected, PCs from PC-specific homozygous knockout mice lacked IPSCs, whereas MLIs did not. Application of the α1 subunit specific agonist zolpidem prolonged synaptic decay in PC-specific knockout MLIs, suggesting the α1 subunit is still present in these cells and confirming the specificity of the knockout. Tremor measurements were performed by suspending animals by the tail from a force transducer. Data were analyzed using the power spectra of the force data. We found that while PC-specific $GABA_{A\alpha1}$ knockouts exhibited less severe tremor, the tremor exhibited had a similar frequency (20-30Hz) as in global knockouts, suggesting similar underlying mechanisms. We also found that ethanol administration (1.25g/kg) was able to ameliorate tremor in PC-specific knockout mice, consistent with previous findings in global knockout mice. PC-specific knockout mice therefore provide a useful tool for future experiments, including experiments aimed at understanding signaling changes giving rise to tremor in PC-specific $GABA_{A\alpha1}$-subunit knockout mice and how drug treatments work to provide symptomatic relief. Our findings in PC-specific $GABA_{A\alpha1}$ - subunit knockout mice reveal that impaired inhibition to cerebellar PCs can be sufficient to induce a tremor phenotype, and therefore highlight the potential significance of the cerebellum, and Purkinje cell inhibition in particular, in tremor.

Title: Cerebellar learning and Purkinje cell physiology abnormalities in the prickle2 knock-out mouse model of autism-like behavior

Authors: *P. ABBOTT, J. HARDIE, S. FARLEY, J. FREEMAN, A. BASSUK, K. PARKER; Univ. of Iowa, Iowa City, IA

Abstract: Autism spectrum disorders (ASD) involve abnormalities across brain systems, resulting in a constellation of symptoms including behavioral inflexibility, cognitive dysfunction, learning impairment, altered social interactions, and perceptive time difficulties. Recently, it was discovered that a common gene variant involved in non-canonical Wnt signaling, *prickle2*, was

present in individuals with ASD. Corroborated findings in *prickle2* knock-out and heterozygous mice suggest patterns of behavior similar to individuals with autism including altered social interaction on the three-chambered social task and behavioral inflexibility on the Barnes maze. Additionally, *prickle2* disruption results in hippocampal neuronal abnormalities including reduced dendritic branching, synapse number, and post-synaptic density size. Over the past several decades, there has become an increased focus on the cerebellum's involvement in ASD. Because *prickle2* is expressed in Purkinje cells, this animal model presents a unique opportunity to investigate cerebellar abnormalities that could exist alongside the previously reported autism-like phenotypes. We studied *prickle2*-disrupted mice on delay eyeblink conditioning, a reliable measure of cerebellar-dependent learning. Preliminary data suggest that *prickle2*-disrupted mice have altered learning of conditioned eyelid responses. Additional motor testing suggests no significant impairments in locomotion. We also explored structural and physiological abnormalities in animals with *prickle2* disruption using immunohistochemistry and whole-cell patch clamp recordings. Purkinje cells displayed an aberrant clustering in their respective layer. Recordings show that *prickle2*-null Purkinje cell action potentials have an attenuated afterhyperpolarization, while also displaying an unchanged firing frequency after stepwise current injection. Overall, these data suggest that *prickle2* knock-out mice have cerebellar abnormalities and could inspire future explorations into cerebellar mediated autism-like behavior.

Abstract: Parkinsonism is the combination of characteristic symptoms: tremor at rest, rigidity, bradykinesia-hypokinesia, flexed posture, loss of postural reflexes and the phenomenon of freezing. However, parkinsonism is diagnosed with at least one of the symptoms, i.e., shaking at rest or bradykinesia. As the cerebellum is highly involved in movement control, the aim of our study was to characterize the multiunit activity (MUA) at the cerebellum of male rats during exploration and grooming behavior in a model of parkinsonism. Resembling human parkinsonism, we induced mandibular tremor in male rats by an electrolytic lesion in the ventrolateral striatum (VLS) of the basal ganglia. Wistar male rats (250 to 350 g/bw) were randomly divided into three groups; an intact group that had only implanted the recording electrode (n=12); the sham group (n=12) where the lesion electrode was descended into the VLS but no current was applied; and the lesioned group (n=12) that had implanted the lesion electrode and a current was applied for a bilateral electrolytic lesion (3.5 mA/30s) of the VLS to induce the mandibular tremor. Recording electrodes were implanted to register the MUA of cerebellar neurons at Sim B (n=4), and Crus II (n=4) lobes in the granular layer, and in the deep dentate nuclei (n=4). MUA recordings were performed 48 h after stereotactic surgery and were computed by the Polyview system. Electrophysiological results were analyzed statistically considering the amplitude of traces during exploration and grooming behavior.Results showed statistical differences in Crus II lobe in sham and lesioned groups compared to the intact group, showing a decrease during grooming (P=0.0001), horizontal exploration (P=0.0014), and vertical exploration (P=0.0034). Our data suggested that Crus II lobe had a lower response because a direct interconnection with the VLS, indicating a possible role in parkinsonism of these cerebellar area.

Title: Purkinje cell encoding of limb position during skilled reach-to-grasp behavior in mice

Authors: *D. J. CALAME, A. L. PERSON;
Physiol. and Biophysics, Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: A leading hypothesis of cerebellar function is that the cerebellum generates an internal model to predict upcoming body kinematics allowing it to facilitate feedforward motor control, making movements smooth and accurate. Previous work in our lab has demonstrated that during

naturalistic reaching movements, the activity in the output of the cerebellum - the deep cerebellar nuclei - is graded in response to the initial velocity of outreach, acting to decelerate the limb to the endpoint on a reach-by-reach basis. Whether upstream elements of the cerebellar circuit learn to control this signaling to structure reach endpoint is unclear. In this study we recorded from Purkinje cells (PCs) while head-fixed mice performed a skilled reaching task in order to understand how simple spikes (SS) and complex spikes (CS) encode limb movements. By tracking paw position using both motion tracking and machine learning throughout the experimental session, we show that SSs are broadly modulated during reach, producing both bursting and pausing patterns. Using a variety of techniques, including multilinear regression of limb end effector kinematics and markerless tracking of limb postures, we show movement kinematics can explain up to 40% of the variance in individual PC firing rates. By adjusting the target position, we also demonstrate that PC SSs modulate their rates differentially during reaches to different distances, consistent with kinematic tuning, providing a possible mechanism by which the deep cerebellar nuclei are modulated during the decelerative phase of movement. We find that CS rate is consistently modulated during reach, and shows endpoint-related activity. Overall, CSs tend to be depressed during the outward phase of reach, consistent with observations in other species.

Title: A cerebellar neural mechanism of reach precision and its role in motor learning

Authors: *M. I. BECKER[1], A. L. PERSON[2];
[2]Physiol. and Biophysics, [1]Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Cerebellar dysfunction results in a unique constellation of behavioral deficits. During reaching movements, a characteristic oscillation of the limb occurs, especially noticeable in the over- and under-shooting of target endpoint, termed dysmetria. Nevertheless, the cerebellar neural mechanisms that impart endpoint precision to reaching movements remain unidentified. Here, we describe the relationship between activity in the anterior Interposed Nucleus (IntA) and

reach kinematics in order to understand how cerebellar output is utilized to actuate precise motor control. Using closed-loop optogenetic manipulations and single-unit recordings in mice, we found that IntA adaptively decelerates the limb to support reach endpoint precision and accuracy. More specifically, we observed that IntA activity is reciprocally scaled to match preceding reach velocity, such that both relatively slow and fast reaches decelerate with differing magnitudes to accurately obtain the target. We next asked whether this mechanism of enhancing reach precision via variable engagement of IntA activity is a product of motor learning. First, we tested whether reaches exhibit motor adaptation in response to a neural activity manipulation that produces hypometric reach endpoints. In preliminary experiments, analysis of trial-over-trial changes in reach kinematics in response to randomly-delivered optogenetic IntA excitation (which causes hypometria) revealed motor adaptation toward eumetric endpoints. In addition, we have established a motor adaptation paradigm in which optogenetic stimulation is applied in a block structure, enabling us to ask whether animals exhibit cumulative kinematic adaptation over trials, and whether this adaptation is accompanied by concomitant changes in IntA activity patterns. Future work will seek to identify how the causal relationship between IntA activity and reach kinematics is utilized and adjusted over the course of motor learning.

Title: Cerebellar expression and function of Cabin1

Authors: *K. M. DUNN, D. R. HAMMOND-WEINBERGER;
Biol. Sci., Murray State Univ., Murray, KY

Abstract: Unchecked overproduction of cerebellar cells can lead to medulloblastoma, the most common pediatric brain tumor. Cerebellar granule cells are normally overproduced and pruned into adulthood under the regulation of the transcription factors MADS/myocyte-enhancer-factor 2 (MEF2) and p53, both of which are regulated by Calcineurin-binding-protein 1 (Cabin1). MEF2 and p53 have opposing effects on healthy granule cell populations: MEF2 promotes cell survival and p53 promotes apoptosis. In medulloblastoma, the reverse appears: p53 is associated with tumor proliferation and MEF2 promotes apoptosis of tumor cells, while most other genetic determinants are unknown. A major obstacle in understanding the roles of Cabin1 in normal cerebellar development and tumorigenesis lies in reconciling the opposing roles that Cabin1

targets MEF2 and p53 play in normal versus diseased cells. Determining where and when Cabin1 is expressed during normal development and understanding its roles therein will provide clarification. Our central hypothesis is that Cabin1 functions in the cerebellum as a negative regulator of MEF2 and p53 to ensure appropriate numbers of granule cells are generated, maintained, and remodeled. To address these problems, we investigated Cabin1 expression in cerebellar development and function using double *in situ* hybridization in zebrafish. We also used Cabin1 loss-of-function to assess the effects on organismal behavior and target cell populations. Establishing roles for Cabin1 in the cerebellum will further our understanding of normal cerebellar development and of the molecular pathways that contribute to brain cancers.

Title: A computational model of neural connectivity dynamics in response to optogenetic stimulation of non-human primate sensorimotor cortex

Authors: *J. BLOCH[1], E. T. SHEA-BROWN[2,3,5], A. YAZDAN-SHAHMORAD[1,4]; [1]Bioengineering, [2]Applied Mathematics, [3]Physiol. and Biophysics, [4]Electrical and Computer Engin., Univ. of Washington, Seattle, WA; [5]Allen Inst. for Brain Sci., Seattle, WA

Abstract: Neural stimulation has been shown to result in the reorganization of neural connectivity. The details of this reorganization, however, are not well understood. According to the spike-timing dependent plasticity framework, paired stimulation of two cortical regions should increase the connectivity between the two stimulation sites. In-vivo experiments have been inconsistent in producing this targeted connectivity change, likely due to the complexity of network interactions mediating connectivity between a pair of sites. This underlying complexity of the network, in turn, necessitates the advent of more complex frameworks for targeted connectivity change.
In this study we analyze previously published data from Yazdan-Shahmorad et al. to develop a computational model of optogenetically induced network connectivity change. We then solve a controller which could allow us to change connectivity between two sites in a closed-loop, targeted manner. The dataset consists of neural signals recorded through micro-electrocorticography (uECoG) from the primary sensorimotor cortex of non-human primates,

and contains resting-state activity, activity in response to paired optogenetic stimulation protocols, and activity immediately after stimulation sessions.
To this end, we use a Kalman filter based approach to fit a linear state-space dynamical model composed of interactions between all electrodes, optogenetic stimulation, and gaussian noise. We then use this identified model to fit a controller of connectivity between two target electrodes. The state of the model is characterized by frequency band powers and the connectivity is characterized by frequency band coherence. Such a controller could optimize optogenetic stimulation in a closed-loop fashion to maximize the coherence between two neural sites. Future efforts can deploy this model to real-time for neurorehabilitation of aberrant brain connectivity.

Title: Calibration-less p300 speller system using massive data and convolutional neural network

Authors: ***J. LEE**[1], M. AHN[1], M. KWON[2], K. WON[2], S. JUN[2];
[1]Handong Global Univ., Pohang, Korea, Republic of; [2]Sch. of Electrical Engin. and Computer Sci., Gwangju Inst. of Sci. and Technol., Gwangju, Korea, Republic of

Abstract: Most BCI systems require calibration process where data is extracted from the user to construct a subject-specific classifier. This time-consuming process can be tedious for any user since there is no meaningful interaction. In this study, we introduce a novel way of achieving calibration-less BCI system in case of conventional 6 × 6 P300 speller paradigm. P300 speller uses P300 response for classification, and calibration process is essential because short inter-stimulus-interval is set to achieve high information transfer rate. Our idea is to feed large amount of other subjects' data into convolutional neural network (CNN). We first conducted offline analysis, using P300 speller data acquired from 55 subjects. For each subject, there were 2 training sessions of 5 letters each and 4 testing sessions of 7 letters each. As a whole, there were 99,000 trials acquired from all subjects' training session, of which target-nontarget ratio is 1:5. We used EEGNET as our CNN architecture and tested the network on the testing sessions [1]. Number of kernels per layer were increased compared to conventional architectures used for

P300 classification. This is so that CNN can store various forms of P300 signals. We compared our result to stepwise linear discriminant analysis (SWLDA). SWLDA was trained using conventional method and our method as well; to train with large dataset acquired from other subjects'. Our results show that calibration-less BCI system is achievable through simple usage of CNN and massive data acquired from other subjects. CNN, when trained using only the subject's data (conventional approach), achieved average letter accuracy of 93.63%, while CNN, when trained using other subjects' data achieved letter accuracy of 89.22%. As for SWLDA, it achieved 94.28% when using conventional method while achieving only 69.80% using our proposed method. Unlike conventional methods, CNN when combined with large dataset, achieves calibration-less BCI without any complicated methods. Our work goes further to improve this calibration-less, or zero-trained BCI system. Instead of using the output from the network as the system's output, we integrated a linear classifier (SWLDA). This linear classifier receives its label information from pre-trained CNN, and trains itself whenever new data comes in. Using this semi-supervised approach combined with zero-training approach, we were able to further increase the average letter accuracy up to 92.98% that is not statistically different from the performance of conventional method by SWLDA ($p > 0.05$).

Title: Optimizing decoding performance and power consumption for closed-loop implantable brain-machine interfaces

Authors: ***S. R. NASON**[1], A. K. VASKOV[2], P. G. PATIL[1,3,4,5], C. A. CHESTEK[1,2,5,6];
[1]Biomed. Engin., [2]Robotics, [3]Neurosurg., [4]Neurol., [5]Neurosci. Grad. Program, [6]Electrical Engin. and Computer Sci., Univ. of Michigan, Ann Arbor, MI

Abstract: Clinical translation of current brain-machine interfaces is limited by the need for patients to remain tethered to large processing computers to transmit the typical 96 channels of neural data from a Utah microelectrode array. Fully implantable brain-machine interfaces would mitigate that issue, but they have severe computational limitations compared to laboratory machines. Many groups have investigated algorithms in their laboratories ranging in complexity from linear regressions to deep neural networks, but there has been no systematic evaluation for

relevance to implantable devices. Thus, using the embedded device we previously presented (Bullard 2019), we compare linear regressions (LR), Kalman filters (KF), and shallow feedforward neural networks (NN) in terms of their suitability for implantable neural interfaces, focusing on computational complexity, execution time, and power consumption.
For this analysis, we assume a one-dimensional task and a 1 by 96 word (two byte) input feature vector containing the brain state estimate for a given 50ms time step. Since LR requires substantial neural history for adequate decoding performance, our implementation models a 10 bin Wiener filter (Chestek 2011). Our KF implementation follows the position-velocity steady-state KF approach (Malik 2011). The simple, preliminary NN is a dense, fully connected network of rectified linear units with two 24 unit hidden layers and a linear output unit. To test these algorithms on hardware, we implemented them on the 32-bit Atmel AT32UC3C2256C microcontroller we previously used and programmed it using embedded C. Each algorithm received randomized weight values between 0.1 and 1 and randomized inputs between 1 and 200. We estimated execution time by toggling voltage when the iteration began and ended, where the processor entered a standby sleep state during the remainder of each 50ms bin.
KF, LR, and NN had complexities of 300, 960, and 2,952 floating-point operations per iteration, respectively. The KF had the shortest execution time at 1.86ms, followed by LR at 3.84ms and the NN at 23.8ms. The KF had the lowest power consumption at 4.3mW, followed by LR at 6.6mW (due to the addition of history) and NN at 14mW for the microcontroller.
These results suggest that KFs have the quickest execution time and lowest power requirements to achieve the performance levels demonstrated in the literature. This implies KFs would work well in a closed-loop implantable brain-machine interface, but alternative NNs should be tested to best optimize performance and complexity. In our next steps, we aim to use our embedded device to validate these algorithms in closed-loop with nonhuman primates.

Title: Deep multi-state dynamic recurrent neural networks for robust brain machine interfaces

Authors: *B. HAGHI[1], S. KELLIS[2], M. ASHOK[1], S. SHAH[1], L. BASHFORD[2], D. KRAMER[3], B. LEE[3], C. LIU[3], R. ANDERSEN[2], A. EMAMI[1];
[1]Electrical Engin., [2]Biol. and Biol. Engin., Caltech, Pasadena, CA; [3]Neurorestoration Ctr. and Neurosurg., USC, Los Angeles, CA

Abstract: Brain-machine interfaces (BMIs) can help spinal cord injury (SCI) patients by decoding neural activity into useful control signals for guiding robotic limbs, computer cursors, or other assistive devices. BMI in its most basic form maps neural signals into kinematics, then closes the loop to enable direct neural control of kinematics. Such systems have shown promise in helping SCI patients; however, improving performance and robustness of these systems remains challenging. Even for simple movements, such as moving a computer cursor to a target on a computer screen, decoding performance can be highly variable over time.
Furthermore, most BMI systems currently run on high-power computer systems. Clinical translation of these systems will require decoders that can adapt to changing neural conditions, and which operate efficiently enough to run on mobile—even implantable—platforms. Recently, machine learning algorithms have shown promise in attaining high performance and robustness in BMIs. Therefore, to address a number of these challenges, we propose a deep multi-state Dynamic Recurrent Neural Network (DRNN) architecture. The DRNN is used for predicting Cartesian representation of kinematics from the open-loop neural data recorded from the posterior parietal cortex (PPC) of a human subject over 39 days in a BMI system. We design the algorithm to achieve a reasonable trade-off between performance, robustness, and to reduce the memory that is required to store the weights for hardware implementation. To achieve a better prediction performance and robustness, we generalize our model by feeding the predictions of the network back to the input. To solve the statistical distribution mismatch between the ground-truth and predictions, we apply a scheduled sampling approach to the model. By configuring the DRNN to operate without history, we reduce the number of memory accesses which has shown to consume the most significant power in neural network accelerators (Watmough et al., 2018). We compare our algorithm with the state-of-the-art methods in the literature to show that it performs favorably: DRNN achieves average correlation coefficients of (0.75, 0.88) for position (X, Y) and (0.74, 0.87) for velocity in X and Y directions. To the best of our knowledge, this is the first demonstration of applying deep learning-based decoders to human PPC data. The results show that multi-state DRNN has the potential to model the non-linear relationships between the neural data and the kinematics for robust BMIs.

Title: Source localization of Mu ERD in response to BCI intervention

Authors: K. GJINI, **A. REMSIK**, M. MAZROOYISEBDANI, L. WILLIAMS, *V. A. NAIR, V. PRABHAKARAN;
Radiology, Univ. of Wisconsin Madison, Madison, WI

Abstract: Objective: This research seeks to obtain source localization of neurophysiological changes associated with BCI intervention sessions for upper extremity motor recovery. We investigated whether Mu rhythm desynchronization of motor brain areas (ERD), compared to rest, changes between the beginning to the end (pre and post) of therapy in all sessions across all subjects (i.e. grandaveraged). **Methods**: N= 16 right hemisphere stroke survivors participated in 9-15 sessions with the BCI. Participants executed hand movements in response to visual cues displayed on a computer screen concordantly with the corresponding audio instructions (e.g., Left, Right, Rest). The 'screening' sessions (i.e. pre and post BCI intervention) contained two runs, each consisting of 15 trials for rest, left hand, and right hand movements (i.e., 5 trials for each of the three conditions, the order of trials in a run was random). All data from the pre and post conditions were then grandaveraged, respectively. eLORETA source estimates were calculated as follows: 1) Clean EEG data were segmented (LEFT hand attempted movements and REST) separately for PRE and POST conditions. 2) Cross-spectra for Mu[8-12 Hz] band were computed and then averaged (i.e. 1 average per each subject separately for Movement (left, right) and REST trials.3) eLORETA of Mu band power estimates at 6239 cortical locations/voxels were obtained, then normalized across all subjects. In the eLORETA implementation, computations are made in a realistic head model using the MNI152 template, with the three-dimensional solution space restricted to cortical gray matter, as determined by the probabilistic Talairach atlas. The specific frequency band cross-spectra (frequency-domain) obtained from the average-reference potential data, were the inputs for source localization. 4) eLORETA estimates between the two conditions [Movement - Rest] were then calculated in cortical space. 5) Statistical group comparison of POST vs PRE estimates were done using a one tailed t-test (ROI-based). **Results**: ERD increases were observed from pre-post ipsilesionally at primary motor cortex (Brodmann Area (BA) 4) and supplementary motor areas (BA 6), and contralesionally at BA 6. Additionally, ERD decrease was observed at contralesional BA 4. **Conclusion**: BCI intervention may help facilitate increased ERD in association with movement of the impaired upper extremity for the stroke-lesioned brain.

Title: Accurate prediction of large-scale LFP network dynamics in response to electrical stimulation

Authors: *Y. YANG[1], S. QIAO[3], O. G. SANI[1], B. PESARAN[3], M. M. SHANECHI[1,2];
[1]Ming Hsieh Dept. of Electrical and Computer Engin., [2]Neurosci. Grad. Program, USC, Los Angeles, CA; [3]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Modeling how neural activity recorded from large-scale distributed brain networks responds to electrical stimulation is critical for developing neurotechnology that aims to precisely modulate brain network activity. Here, we develop dynamic input-output (IO) models to describe the real-time LFP network response to continuously-changing stimulation patterns and test them in non-human primates (NHPs). To obtain informative data for learning the IO models, we apply a new stimulation pulse train to fully excite the LFP network. As the input in our models, we use the pulse train frequency and amplitude, which change in real time. As the output in our models, we use LFP power features. We fit and evaluate the IO models using cross-validation, where we use the trained IO models to feed-forward predict the evolution of LFP power features in response to stimulation in the test set. We compare the predicted evolution to the observed evolution. Further, we test if at-rest network connectivity can predict the variable strength of the stimulation effect across the network nodes. We calculate at-rest network connectivity using LFP power features that are recorded without stimulation. We find that our IO models accurately predict the dynamic LFP network response in cross-validation. Also, the dynamic structure of the IO models and modeling the changes in both stimulation amplitude and frequency are essential for this prediction. Moreover, the strength of the dynamic stimulation effect at different brain regions can be predicted from at-rest connectivity within the network. Our results have important implications for future design of closed-loop brain stimulation systems for treatment of neurological and neuropsychiatric disorders and for more precise modulation of brain functions.

Title: Dynamical characteristics of simultaneously-recorded spike and LFP activities underlying movement

Authors: *H. ABBASPOURAZAD[1], Y. WONG[2], B. PESARAN[3], M. M. SHANECHI[1]; [1]Electrical Engin., USC, Los Angeles, CA; [2]Monash Univ., Melbourne, Australia; [3]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Investigating low-dimensional neural dynamics underlying movements has so far focused on a single scale of brain activity, in particular neuronal spikes. However, movements are encoded across multiple spatial and temporal scales of neural activity, from spikes to local field potentials. Thus, examining the dynamical characteristics of spike-field network activity is important in understanding the neural mechanisms underlying movements. Here we developed multiscale dynamical models and a modal analysis to investigate the low-dimensional dynamical characteristics of simultaneously-recorded spike and LFP activities from non-human primates performing a 3D reach-to-grasp task. Our modal analysis allowed us to dissociate the different components of neural dynamics each with a distinct dynamical characteristic. We refer to these components as dynamical modes. We found that while spike and LFP networks had some distinct dynamical modes, they had a strongly present shared mode. This mode was the dominant mode in predicting the movement. In addition, these shared dynamical characteristics were preserved across different experimental sessions and monkeys. Further, these shared modes were not a replicate of the modes in the behavior. Finally, we used a novel multiscale algorithm to identify latent states and dynamics from mixed spike-LFP activity and found that the same shared unified mode was identified again from hybrid spike-LFP activities.

Title: Decoder for switching state space models with spike-field observations

Authors: *C. Y. SONG[1], H.-L. HSIEH[2], M. M. SHANECHI[1];
[1]Electrical Engin., [2]USC, Los Angeles, CA

Abstract: The dynamics of brain activity are inherently nonstationary and can change depending on context, for example based on the tasks performed, the stimuli received, or the attention focus maintained. Thus, to decode brain states in naturalistic scenarios, it is necessary to model and track such changes. Switching state space models can provide a basis for modeling a hidden neural state whose dynamics switch based on a discrete context. Previous works have used such a model for decoding behavioral states from a single neural recording modality. However, it is becoming increasingly common to measure the brain at multiple spatiotemporal scales by recording both spike and field activities simultaneously. Thus, tracking non-stationarity necessitates efficient decoders that can detect changes in spike-field neural dynamics and accurately estimate the underlying neural and behavioral states. Here, we develop a framework to address these challenges. We build a multiscale switching dynamical model that assumes an underlying hidden neural state can evolve with dynamics chosen arbitrarily from a finite set based on the value of a switch state. This switch state would also dictate how the neural state is represented in the recorded binary spike events and continuous field signals. Based on this model, we derive an efficient multiscale decoder that simultaneously estimates the underlying neural and switch states from an identified system using spike-field observations. As validation of these methods, we show with closed-loop numerical simulations that our new decoder is able to accurately estimate the switch state while decoding the neural and behavioral states.

Title: Decoding human confidence from neural signals

Authors: *R. N. MANMADHAN[1], O. G. SANI[1], N. SADRAS[1], C. Y. SONG[1], P. AHMADIPOURANARI[1], D. VALERIANI[2], C. CINEL[2], L. CITI[2], R. POLI[2], M. M. SHANECHI[1];
[1]Ming Hsieh Dept. of Electrical Engin., USC, Los Angeles, CA; [2]Sch. of Computer Sci. and Electronic Engin., Univ. of Essex, Colchester, United Kingdom

Abstract: Confidence is the perceived notion of correctness in our decisions. Understanding how confidence is encoded in neural signals can enhance our understanding of the underlying brain processes and enable decoding of confidence from neural signals. Neural decoders of confidence may enable brain machine interfaces (BMI) that can intelligently assist humans in decision making when they are not confident about their decisions and can pave the way for cooperation between humans and artificial intelligence. Here, we extend an experimental task designed to evoke confident and non-confident decision making in human subjects and use it to explore neural decoding of confidence. In each trial of this task, a character wearing either a hat or a helmet briefly appears on the screen and subjects attempt to dissociate between the two and report their level of confidence in their decision. We study neural signals recorded during the task to find neural correlates of confidence and explore their spatial and temporal characteristics. To rule out potential confounds, we design multiple control tasks to dissociate the neural correlates of confidence from those of visual stimuli processing and movement. Moreover, we build neural decoders that can classify whether the subject was confident in their decision or not. These decoders aggregate the spectral magnitude and phase information across recording channels to classify an individual subject's confidence at a single-trial level. Finally, we compare the confidence related information contained in different brain regions. These results have important implications for understanding brain processes involved in decision making and confidence, and may enable future human-machine collaboration systems.

Title: The topology and geometry of motor cortical dynamics underlying 3D movements

Authors: *H.-L. HSIEH[1], B. PESARAN[2], M. M. SHANECHI[1];
[1]Electrical Engin., USC, Los Angeles, CA; [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Due to their high dimensionality and complexity, precise modeling of neural population activity is challenging. To date, dynamical modeling and dimensionality reduction approaches have been largely linear. These approaches project the high-dimensional neural activity on a low-dimensional linear hyperplane for example using PCA. Thus, these approaches do not account for nonlinearity in neural dynamics. Here, we tackle the problem of dimensionality reduction for neural dynamics from another direction: identifying the underlying topology and geometry of the neural population activity. We develop tools using algebraic topology and differential geometry to explore the structure embedded in neuronal spiking activity recorded from a non-human primate (NHP) during a 3D movement. We also learn a dynamical model on this structure. We show that utilizing topology and geometry in modeling neural dynamics uncovers their nonlinear structure and sheds light on neural mechanisms of motor control.

Title: Multiscale spike-field network causality identification during a motor task

Authors: *C. WANG[1], B. PESARAN[2], M. M. SHANECHI[1];
[1]Electrical Engin., USC, Los Angeles, CA; [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Neural representations span various spatiotemporal scales from the spiking activity of single neurons to field activity measuring large-scale networks. To help understand neural mechanisms, simultaneous analyses of causal interactions within networks of spike and field activities are required. However, identifying these causal network interactions is challenging as spikes are binary-valued with a fast timescale while fields are continuous-valued with slower timescales. Traditional causality measures are not designed for these multiscale assessments. We build a novel multiscale causality measure in spike-field networks by constructing a combined likelihood function comprised of point process models for spikes and linear Gaussian models for

fields. We model the firing rates of neurons as a function of the history of both field signals and binary spike events. We model the fields as a function of the history of field signals and the history of the latent log-firing rates of neurons as predictors. We also develop a sequential maximum-likelihood parameter estimation procedure and statistical tests for evaluating significance. We evaluate this novel method by estimating multiscale causality graphs within spike-field network activity recorded from the motor cortex of a non-human primate performing a motor task. Once a causality graph is identified for the network, we measure its accuracy by constructing encoding models with the identified graph and assessing their prediction power for spikes and fields. We find that including the identified multiscale spike-to-field and field-to-spike connections improves prediction accuracy compared to when only single-scale spike-to-spike and field-to-field causal connections are modeled. Also, our method outperforms Granger causality in identifying multiscale causality graphs for both spikes and fields. These results validate the multiscale causality identification method, which can help build more accurate encoding models and study multiscale network interactions.

Title: A new preferential subspace identification (PSID) algorithm for learning dynamic neural encoding models with behavior-related latent states

Authors: *O. G. SANI[1], B. PESARAN[2], M. M. SHANECHI[1];
[1]USC, Los Angeles, CA; [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Learning a neural encoding model that describes the representation of a desired behavioral state (e.g., movement kinematics) in neural signals is critical in studying the neural mechanisms underlying behavior and in decoding it for brain-machine interfaces (BMIs). Two main approaches are traditionally used to build an encoding model for behavior: representational modeling and neural dynamics modeling. These approaches learn the dynamics of the encoding model either purely based on behavior (representational modeling) or purely based on neural signals (neural dynamics modeling) and as a result, may learn behavior dynamics that are not encoded in neural signals or behavior-unrelated neural dynamics, respectively. Thus new

approaches are needed that can specifically focus on learning behavior-related neural dynamics to help investigate the encoding of behavior. Here, we introduce a novel learning algorithm, termed preferential subspace identification (PSID), that takes the dynamics of both neural signals and behavior into account and learns a neural encoding model with a low-dimensional behavior-related latent state. Using both numerical simulations and local field potentials recorded from non-human primates during a naturalistic motor task, we demonstrate the advantage of the proposed algorithm in learning behavior-related neural dynamics. We also demonstrate how traditional representational modeling and neural dynamics modeling can be viewed as special cases of PSID. This new learning algorithm can help uncover low-dimensional neural dynamics that underlie behavior and can serve as a unifying framework that extends and relates traditional approaches for learning neural encoding models.

Title: Adaptive modeling of neural network dynamics with optimized learning rate

Authors: *P. AHMADIPOUR[1], Y. YANG[1], M. M. SHANECHI[1,2];
[1]Electrical Engin., [2]Neurosci. Grad. Program, USC, Los Angeles, CA

Abstract: Dynamic latent-state modeling has the ability to model large-scale neural network dynamics and perform dimensionality reduction, leading to its wide use in understanding neural mechanisms and decoding brain states. So far, these models have largely assumed that neural network activity is stationary in time. However, neural network dynamics could be non-stationary for example due to learning and plasticity or due to recording instability, especially over long periods of days or weeks. Therefore, developing adaptive latent-state modeling approaches is important to model non-stationary neural network dynamics but has not been achieved. Current adaptive approaches only focus on tracking representational neural encoding models, in which the state is not latent but rather is the behavior itself. Moreover, a key design parameter in any adaptive model is the learning rate, which controls the weighting of past observations in fitting the current model parameters and can significantly affect the accuracy of the fitted models. Thus a method is needed to optimize the learning in real time. To enable accurate tracking of neural network dynamics, we develop an adaptive latent-state modeling

approach and devise a method to automatically optimize its learning rate in real time. We use an adaptive linear state-space model structure. We develop a recursive adaptive learning algorithm to fit the model parameters in an efficient manner in real time. Finally, we devise an online learning rate optimization algorithm that optimizes the real-time tracking performance. We use comprehensive numerical simulations to validate our adaptive approach. We find that our adaptive algorithm can fit more accurate latent-state models than non-adaptive algorithms. We also find that the learning rate significantly affects the accuracy of the adaptively fitted models, and the optimal learning rate strongly varies as a function neural network properties. Finally, we find that our algorithm enables fast convergence to the optimal learning rate, leading to accurate tracking of non-stationary network dynamics. Together these results have significant implications for investigating non-stationary neural network dynamics, and for developing adaptive neuroethologies to decode and modulate brain states.

Title: Estimating event times from spike trains with a point process matched filter

Authors: *N. SADRAS[1], B. PESARAN[2], M. M. SHANECHI[1];
[1]Electrical Engin., USC, Los Angeles, CA; [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: The spatial response field (SRF) of a neuron describes the region of sensory or behavioral space that it is sensitive to. Further, some neurons exhibit temporal response fields (TRFs), which describe a transient temporal response to stimulus or behavioral event onset. The stimulus sensitivity of such neurons can be jointly characterized by a spatiotemporal response field (STRF). For neurons with purely spatial response fields, algorithms such as the point process filter (PPF) can be used to decode stimulus or behavioral states from spike trains in real time. When neurons exhibit TRFs, however, event times must be known ahead of time in order to perform decoding using existing methods. To solve this problem, an event detection method is necessary. To allow for decoding of neural states from spike trains when neurons exhibit STRFs, we develop the point-process matched filter (PPMF), an algorithm that can detect event times from spike trains. The PPMF can be used along with existing decoders to decode neural states

from neurons that exhibit STRFs when event times are unknown. We validate this method on spiking activity recorded from the prefrontal cortex (PFC) of a rhesus macaque monkey performing a delayed-saccade task. The task required the monkey to make saccades from a central fixation point to one of eight peripheral targets. We use the PPMF to detect task-related saccades, and use a maximum-likelihood point process classifier in order to classify detected saccades into one of eight directions. We evaluate our method via cross-validation across sessions for each day. Our results show that the PPMF can indeed detect events from neural activity, and can be used with classification algorithms to allow decoding from STRF-exhibiting neurons when event times are unknown.

Title: Neural signal emulation for closed-loop intracortical brain computer interface decoder design

Authors: ***J. BAE**[1], M. G. PERICH[2], L. E. MILLER[3], Z. C. DANZIGER[1];
[1]Biomed. Engin., Florida Intl. Univ., Miami, FL; [2]Dept of Fundamental Neurosciences, Fac. of Med., Univ. of Geneva, Geneve, Switzerland; [3]Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: Intracortical brain computer interfaces (iBCIs) are a promising avenue to restore the motor function of patients with neuromuscular disabilities. However, even with encouraging results from iBCIs for participants with tetraplegia, the extremely limited number of human participants available for development work remains as a crucial restriction limiting the widespread adaptation of iBCIs. A single participant is typical of most human iBCI studies. Even monkey studies generally have only 2 to 3 subjects. To overcome this limitation, we introduce a novel neural signal emulator which can simulate in real time, the intracortical neural activity of motor cortex associated with reaching tasks derived from human hand kinematics.
Easily accessible, high-dimensional kinematic signals from healthy human subjects (19D hand joint angles) are used as time-varying input to a recurrent artificial neural network (RNN) that emulates intracortical neural dynamics. The RNN (with 2 hidden layers) was trained on multiple sessions of intracortical recordings from arm area primary motor cortex (M1) of 2 monkeys who performed an 8-target center out reaching task. In the RNN, a common 1st hidden layer intended

to capture common underlying dynamics was shared across all sessions. A 2nd hidden layer and the output layer were individually trained in each session, allowing for variations in neural dynamics and in the number of outputs between sessions.
We first validated statistically if the output of the RNN is able to reproduce the intracortical neural dynamics associated with the reaching task. The emulated neural signals captured the actual neural signals' spatial and temporal characteristics, including the average firing rates of each unit. In addition, we had subjects drive the neural model in closed-loop experiments where a decoder translated the emulated neural firing into cursor position. Subjects performed the same target task and used the same decoder as a prior iBCI study in a paralyzed patient (Kim et al. 2008). Subjects using our model system showed comparable ability to control the cursor and acquire targets as the patient using the actual iBCI.
The neural spike emulator enables testing in closed-loop iBCI experiments without any invasive procedures, thereby allowing inclusion of a much larger pool of participants. In addition, the emulator provides a standard platform for decoder development and evaluation. The natural neural dynamics exhibited by the emulated signals and the comparable performance of actual and emulated signals in closed-loop experiments support the emulator's great potential to accelerate iBCI studies.

Title: System modeling of brain-neuromuscular functions for developing brain-computer interface

Authors: M. MENDOZA[1], S. CACERES[1], L.-L. PAN[2], W.-W. YANG[3], L.-W. CHOU[2], *V. C.-F. CHEN[1];
[1]Loyola Univ. Chicago, Chicago, IL; [2]Natl. Yang-Ming Univ., Taipei, Taiwan; [3]Univ. of Illinois at Urbana-Champaign, Champaign, IL

Abstract: Brain-computer interface (BCI) has been developed for the purpose of bypassing the spinal cord and peripheral nervous system to communicate or control a remote device. Prospective designs have claimed to be able to assist people with severe disabilities or apply to

the practice of neurorehabilitation. Nonetheless, due to the complicated and unpredictable nature of such systems, the feasibility and reliability of available BCIs remain to be fully explored. In this study, we applied system identification techniques for black-box modeling, attempting to find the most appropriate BCI system model. We utilized actual encephalography (EEG) and electromyography (EMG) signals acquired noninvasively from twelve human subjects. The EEG and EMG signals were collected simultaneously while the subjects performed thumb isometric flexion at 50% maximal voluntary contraction for 20 seconds. Based on 16-channel EEG signals and a 1-channel EMG signal collected from the surface of the thenar eminence, we generated model criteria for a state space model, an autoregressive with external input (ARX) model, an autoregressive moving average with external input (ARMAX) model, a nonlinear ARX model, and a nonlinear Hammerstein-Wiener estimation model. The models were calculated by using a 1-second epoch (2000 samples and bandpass filtered to focus on mu wave, 7.6 - 12.4 Hz) of the 16-EEG/1-EMG and validated by a successive 1-second epoch. The one-way ANOVA indicates that the Hammerstein-Wiener estimation model performed significantly better (best fits > 90%, $n = 19$, $p < 0.001$) than the other models, suggesting that the more common polynomial models (ARX and ARMAX) are unfit for BCI development. Despite that the Hammerstein-Wiener estimation model performed the best among all the models included in this study, the massive computation power and time required to properly function may affect the development of BCIs based on this model. The current results may be the basis for future designs of BCIs and can be integrated into brain stimulation models for routine neurorehabilitation sessions.

Title: Building neural decoders that meet user performance expectations using deep neural networks

Authors: ***D. FRIEDENBERG**[1], A. RICH[1], J. VASKO[1], M. A. SCHWEMMER[1], J. TING[2], N. SKOMROCK[1], M. A. BOCKBRADER[3], G. SHARMA[1];
[1]Battelle, Columbus, OH; [2]Univ. of Pittsburgh, Pittsburgh, PA; [3]Physical Med. & Rehabil., Ohio State Univ. Col. of Med., Columbus, OH

Abstract: Intracortical brain-computer interfaces (BCIs) have the potential to reduce disability associated with paralysis by translating neural activity into control of assistive devices. Surveys of potential end-users have identified key BCI system features, including high accuracy, rapid response times, multi-functionality, and minimal interruptions for daily set-up. We have developed novel BCI decoding algorithms that are specifically designed for quick, accurate and robust long-term performance in anticipation of BCI technologies transitioning from the lab to the home environment. Our approach is to build upon the deep neural network (DNN) frameworks developed for computer vision and natural language processing applications and adapt them to BCI decoding. We demonstrate that different components of these models can be adapted to solve complex problems that are specific to BCI applications. For instance, by changing the loss function of the model we can build decoders that sustain high performance for over a year without requiring the user to retrain. This is critical for users who have consistently expressed a desire for a system that requires minimal recalibration. Next, we examined architecture and pre-processing decisions and show that some of the pre-processing methods, like the boxcar filter, which are critical for other machine learning methods are not required for DNN models. By removing these filters, our DNN models improved their response time by about 200ms, another key BCI criterion identified by potential users. Additionally, we examine commonly used BCI features and show that they can be optimized simultaneously with the decoder, leading to more informative features and improved decoding performance. By doing so, we are able to extract more useful information from the array as well as to suggest a path forward

for building BCI decoding algorithms for new intracortical interfaces which may exhibit different and unknown signal characteristics that need to be learned.
Results are presented using a chronically-implanted intra-cortical microelectrode array in the motor cortex of a human study participant with C5/C6 quadriplegia from cervical spinal cord injury during an FDA and IRB-approved study.

Abstract: Severe neuromuscular impairments due to ALS, brainstem stroke and traumatic brain injuries may result in the loss of volitional muscle control, and in the inability of individuals to communicate. Brain computer interfaces (BCI) offer a unique channel for communication by circumventing the impaired motor pathways and controlling an external effector such as a computer cursor or robotic arm. The successful usage of such BCIs relies on the users' ability to

reliably utilize the feedback from the interface, which is predominantly visual in current BCIs. However patients with the most severe paralysis can have profound visual impairments making the reliable use of a visual-based BCI difficult or even unfeasible. Here we present a novel paradigm that enables iBCI control and communication in an auditory-reliant manner. Building on previous studies, we utilize spatial auditory signals to develop a multiclass auditory BCI for patients with severe motor impairments. Specifically, we propose to utilize head-response transfer functions (HRTF) to represent spatial auditory cues via headphones to the BCI user. To test the feasibility and reliability of HRTF-based feedback signals, we performed a target acquisition task in healthy subjects using manual cursor control. Subjects were instructed to rely on the auditory cues to navigate the cursor to the cued targets. Preliminary psychophysics testing suggests that manual cursor navigation is possible in an auditory-reliant manner using the HRTF filters updated in realtime. In addition to experimental development, detailed benchmark studies were performed to develop custom low latency architecture capable of presenting audio cues in real-time. Our results reveal that factors that influence audio latencies include: 1) the programming language, 2) the audio driver, and 3) the operating system (OS). Specifically, latencies of 320 ± 0.029ms (mean ± std) were recorded from a Windows OS with default audio drivers. This latency was dramatically reduced to 46 ±46ms with a specialized MATLAB realtime audio library and updating to use the ASIO audio driver. The lowest latencies were consistently observed in the Linux OS with the ASIO driver (11 ± 0.001ms). We present an optimized software and hardware architecture necessary to create a reliable low latency auditory interface that is capable of presenting auditory-reliant BCI communication. In sum, the results of this study demonstrate the development and implementation of a novel auditory-reliant intracortical BCI that provides real-time auditory feedback for communication in individuals with severe motor paralysis and sustained visual impairments.

Title: A new protein to improve motor performance with a limited hypertrophic effect in young and old mice

Authors: *M. BOIDO[1], R. SCHELLINO[1], O. BUTENKO[1], J. W. VRIJBLOED[2], R. G. FARIELLO[2], A. VERCELLI[1];

[1]Dept. Neuroscience, Neurosci. Inst. Cavalieri Ottolenghi, Univ. of Turin, Orbassano (TO), Italy; [2]PharmaFox AG, Möhlin, Aargau, Switzerland

Abstract: Several diseases (e.g. neuromuscular diseases and sarcopenia) determine skeletal muscle atrophy and weakness, representing an important clinical problem. Current efforts to improve muscle performance are focused on muscle trophism via inhibition of the myostatin pathway. The activin receptor (ActR-Fc), a myostatin inhibitor, can induce a remarkable gain in body weight: however such muscular hypertrophy per se is not sufficient to ensure a prolonged muscle performance. We speculate that increasing muscle mass without providing adequate incremental innervation could be counterproductive for sustaining long term efforts. We synthetized a novel protein (ActR-Fc-nLG3) by combining the C-terminal agrin nLG3 fragment (a key molecule in development/maintenance of NMJs) to the soluble activin receptor, to support both the myogenic and neurogenic component of muscle performance. Nine-week-old (young) and 22-month-old (aged) C57BL/6j male mice received subcutaneously 10 mg/kg ActR-Fc-nLG3; other age-matched animals received ActR-Fc or vehicle (control). Body weight and motor performances were monitored by rotarod or treadmill. After sacrifice, gastrocnemius, quadriceps and triceps muscles were collected and histologically analyzed. ActR-Fc-nLG3 administration determined a moderate but significant body and muscle weight increase compared to control (although inferior to ActR-Fc). In the young animals, ActR-Fc-nLG3 ensured a remarkable increased performance in the rotarod test. Moreover, concerning the old mice undergone treadmill exercise, during weeks, control and ActR-Fc groups started decreasing the distance run which at study end was significantly shorter (18.2% and 14.4% less, respectively) than at the beginning, whereas ActR-Fc-nLG3 group showed an increase of 2.8% from baseline. Finally, histology demonstrated that, in both treated groups, ActR-Fc-nLG3 administration increased the enfolding of junctional folds of the motor endplates, amplifying the surface area for acetylcholine receptors. Our results support the hypothesis that improving nerve-muscle interaction is an important factor for sustaining long term muscle activity: our work raises the hope that a possible therapy may be developed not only for sarcopenia, but also for many other neuromuscular disorders.

Abstract: At the lumbosacral level (L6-S2) somato-visceral reflexes are integrated to regulate functions of the lower urinary tract and pelvic-perineal floor muscles. Together, they are a continuous target of plasticity processes due to different factors, such as reproductive experience or mechanical damage, mainly, spinal cord injuries (SC). One of the processes that generates its remodeling is the rupture of nerves from the pelvic-perineal floor to the SC, such as the rupture or ventral nerve roots avulsion (VRA), mainly those of the lumbosacral plexus. Previous studies propose that the VRA of the lumbosacral plexus affects functions that depend on structural interactions between the SC, sympathetic / parasympathetic ganglia and nerves, altering the communication between these pathways. Also, it could affect the activation of the perineal muscles, such as the bulbspongiosus and the survival of their motor neurons (MN). The objective of this study was to determine the effect of the ventral roots avulsion at L6-S2 level on the activation of the bulbospongiosus muscle and the survival of their MN in the female rabbit. For this purpose, we used female rabbits (8 ± 2 months) divided into: 1) Sham (n = 5) and 2) L6-S2VRA (n = 5), which were anesthetized with 2 ml of sodium pentobarbital, were dissected. in the perineal region and bilaterally injected Fluroro ruby tracer (5µl bilateral) into the bulbospongiosus. After 15 days, all animals are anesthetized with 2 ml of sodium pentobarbital; Sham simulates the avulsion and L6-S2 VRA broke the ventral roots of L6-S2. After 15 days, the animals were anesthetized with 20% urethane (i.p.). A cystometrograms, urethral pressure and electromyograms of the bulbospongiosus muscle was recorded. After obtaining 4 micturition reflexes, intracardiac perfusion was performed with paraformaldehyde and 9% saline and spinal segments L6-S2 were obtained to place them 48 hrs in paraformaldehyde and then cryoprotected with 10, 20 and 30% sucrose solutions. Subsequently, transversal slices of 30 µ in cryostat were made. L6-S2 VRA affected bladder and urethral function; produced urinary retention; as well as decrease in the duration of activation frequency and MN number of the bulbospongiosus muscle. This would cause alterations in the activation of the bulbospongiosus during micturition, as well as changes in the frequency of activation and some alterations in the voiding.

Title: Muscle derived BMP4 regulates morphology and function of the neuromuscular junction in mice

Authors: J. HARRISON, B. PODOR, ***V. F. RAFUSE**;
Med. Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: Growth factors are well known to regulate morphological and electrophysiological properties of synapses including the neuromuscular junction (NMJ). For example, in *Drosophila*, mutants lacking proteins in the Bone Morphogenic Protein 4 (BMP4) signaling pathway have abnormally small muscle fibers, smaller NMJs with ultrastructure synaptic defects, smaller evoked excitatory junctional potentials, reduced frequency of spontaneous neurotransmitter release and an ~ 4-fold decrease in quantal content. Whether BMP4 signaling has a similar role at vertebrate NMJs is currently unknown. To examine this question, we generated doxycycline inducible, muscle-specific BMP4 null mice by crossing HSA-rtTA/TRE-Cre mice with mutant mice where exon 4 of the BMP4 gene is flanked by *loxP* sites (referred to here as BMP4 flox mice). Doxycycline induced knock-down of BMP4 expression in muscle was initiated at three months of age. Motor behavior tasks were examined pre- and post-doxycycline administration while electrophysiological and morphological characteristics of the NMJ were recorded 1-3 months after BMP4 knock-down. We found that BMP4 flox mice had a greater latency to fall on the rotarod turning at 40 rpm compared to wildtype littermates 14 days after doxycycline administration. Morphologically, Type I, but not Type IIa muscle fiber cross-sectional areas in soleus muscles were significantly smaller in BMP4 flox mice 3 months after doxycycline administration. Interestingly, NMJs were larger in BMP4 mice compared to the controls due to a significant increase in acetylcholine receptor cluster number and distribution. Electrophysiological studies showed that the amplitude and frequency of miniature endplate potentials (mEPPs) were significantly smaller in BMP4 flox mice compared to their wild-type littermates. Similarly, evoked EPP amplitude and quantal content were also significantly smaller in BMP4 floxed mice while the number of neurotransmission failures at high stimulus frequencies was significantly higher in muscles lacking BMP4. Finally, ex vivo contractile force recordings indicated that soleus muscles in BMP4 flox mice were significantly weaker that their

wild-type counterparts. Consequently, as observed in *Drosophila*, these results indicate that muscle derived BMP4 regulates morphological and electrophysiological attributes of the NMJ in mice. We are currently exploring the possibility that abnormalities caused by the loss of muscle derived BMP4 are associated with an accelerated, premature ageing phenotype.

Title: The chromatin remodeling enzyme, kismet, negatively regulates BMP signaling at the *Drosophila* neuromuscular junction

Authors: *J. A. PRESTON, B. HARSIN, F. L. W. LIEBL;
Southern Illinois Univ. Edwardsville, Edwardsville, IL

Abstract: Retrograde bone morphogenic protein (BMP) signaling at the *Drosophila* neuromuscular junction (NMJ) is critical for developing and mature motor neurons. It is involved in proper growth and localization of developing neurons and continued functionality in mature neurons. We have found that BMP signaling is increased in motor neurons of larvae with mutations in the gene coding for a chromodomain helicase DNA binding protein, Kismet (Kis). We also showed that BMP signaling is significantly reduced in *Enhancer of zeste [E(z)]* mutants. E(z) is a methyltransferase in the Polycomb Repressive Complex 2 (PRC2). Thus, Kis and PRC2 act in opposition to regulate BMP signaling. Both *kis* and *E(z)* mutants, however, exhibit similar deficits in neurotransmission characterized by significant reductions in evoked endplate junctional currents and quantal content. To determine how Kis may regulate BMP signaling, we examined BMP signaling after tissue specific knockdown of Kis. Knockdown of Kis in postsynaptic muscle but not presynaptic motor neurons or glial cells mimics the *kis* mutant increase in intersynaptic BMP signaling. Next, we will examine transcript levels of Glass Bottom Boat (Gbb), Mad, and BMP receptors in *kis* mutants and determine if E(z) may oppose Kis at these loci. Mutations in the human orthologs to *kis*, *CHD7* and *CHD8*, are correlated with neurodevelopmental diseases CHARGE and a subtype of autism spectrum disorder (ASD), respectively. A better characterization of the interaction between Kismet and BMP signaling at the mature *Drosophila* NMJ could lead to a better understanding of the pathology of CHARGE and ASD.

Title: GRP78 is essential for NMJ formation and maintenance

Authors: *H. JING[1], L. LI[2], G. XING[1], H. ZHANG[1], Z. DONG[1], W. CUI[1], Z. YU[1], N. GAO[1], W. XIONG[1], L. MEI[1];

Abstract: The neuromuscular junction (NMJ) is a peripheral synapse between motor nerves and skeletal muscle fibers. It is critical to muscle contraction. NMJ formation is controlled by agrin, a factor released from motor neurons that binds to LRP4 (a LDLR family member) to activate the receptor tyrosine kinase MuSK in muscle cells and thus promotes the aggregation of acetylcholine receptors (AChRs). Recent data suggest that the agrin-LRP4-MuSK signaling is also important for NMJ maintenance. However, mechanisms controlling the signaling pathway are not well understood. To this end, we attempted to identified proteins that interact with LRP4 with an idea that they may regulates its stability or function. We purified the LRP4 complex from HSA-Flag-LRP4 transgenic mice where Flag-LRP4 is specifically expressed in skeletal muscles and identified GRP78 by mass spectrometry. GRP78 is a molecular chaperone critical for protein transport. We show that GRP78 was concentrated at the NMJ, and at postsynaptic sarcoplasmic reticulum. Muscle-specific knockout of GRP78 reduced LRP4 in muscles and leads NMJ deficits including excessive axon arborization and reduced AChR clusters. To characterize the roles of GRP78 in adult, we generated HSA-Cre^{ER};GRP78$^{F/F}$ mice, in which Cre could be induced by tamoxifen. We found that NMJs became fragmented and denervated in adult mice where GRP78 was inducibly knocked out. These results demonstrate a critical role of GRP78 in NMJ formation and maintenance, identify a novel play in regulating the agrin signaling pathway.

Title: Nonlinear properties of song bird vocal muscles change over postnatal development

Authors: *I. ADAM, C. P. H. ELEMANS;
Univ. of Southern Denmark, Odense M, Denmark

Abstract: Motor skill learning typically occurs in a period when the brain is navigating a body that is still growing and developing. How the changing body, neural circuit formation and motor coding influence each other remains largely unknown. Over the course of song learning in songbirds the behavioral output, namely song, dramatically decreases in variability, which has mostly been attributed to changes in neural circuitry. However, the contraction speed of vocal muscles also changes and nearly doubles over the course of sensory guided motor learning. Because muscle force sets acoustic parameters such as pitch, amplitude and entropy, we investigate how nonlinear properties of force production change depending on muscle contraction speed. First, we focused on the effect of firing frequency on nonlinear force summation in syringeal muscles over song learning in male zebra finches. By comparing recorded data to twitch summation models, we find that identical stimulation patterns yield strikingly dissimilar force profiles depending on the isometric twitch speed of the muscle. The magnitude of nonlinear force summation depends on the stimulation frequency as well as muscle speed and sex of the animal.
Furthermore, we investigated to what extent spike timing at sub millisecond precision can penetrate into force profiles depending on isometric muscle speed. We find that sub millisecond spike timing has effects on maximal tension, timing of maximal tension as well as the shape of force profiles at physiologically relevant stimulation frequencies. In conclusion, we find that force profiles elicited by stimulation patterns within the physiological range of the songbird vocal system change dramatically depending on muscle speed. To achieve a stable acoustic target thus requires adaptation of the motor code to the changing muscle properties over development.

Title: Fine-resolution motor control of birdsong

Authors: *A. MAXWELL, I. ADAM, H. RÖSSLER, E. BØGH HANSEN, C. P. ELEMANS; Univ. of Southern Denmark, Odense M, Denmark

Abstract: The degree of fine control in any complex behaviour is limited by the minimal force step available, i.e. the resolution, when activating muscles. Control resolution is set by the number and size distribution of motor units (MUs). While locomotor muscles have MUs of thousands of muscle fibers, extraocular muscles contain MUs as small as 5-10 muscle fibers allowing fine eye motion control. Songbirds have fine control over acoustic parameters of their song, but very little is known how the motor pool is organized. Here we combine estimates of MU size, *in vitro* muscle force measurements and *in vitro* sound production to predict the control resolution of a key acoustic parameter, fundamental frequency (f_o), in zebra finches.
Superfast syringeal muscles are innervated by motor neurons in the tracheosyringeal part of the hypoglossal motor nucleus (nXIIts). To measure the number of syringeal MUs in male zebra finches, we quantified the number of motor neurons in left and right nXIIts root and major dorsal/ventral branches with laminin/neurofilament stained cross sections of the trachea and the syrinx, respectively. Because nXIIts also contains a small portion of efferent fibers, our data slightly overestimates the number of MUs. As a proxy for MU size, we measured the innervation ratio of syringeal musculature, and quantified the number of muscle fibers in a syringeal cross section. We found that each side of the syrinx consist of 3,000-4,500 muscle fibers innervated by 750-800 myelinated motor neurons. The mean innervation ratios are among the lowest known at only 3-5 muscle fibers/motor neuron.
To estimate the detailed level of control over acoustic parameters such small MUs provide we focused on the effect of recruitment on f_o. We first measured force kinetics and maximal isometric tension generated by *musculus syringealis ventralis* (VS) fibers *in vitro*. To measure how VS force generation increases f_o, we induced sound production using an *in vitro* syrinx preparation and dynamically actuated the VS insertion site while measuring VS shortening as a function of force. Our results suggest that full activation of the VS provides a f_o range of about 500-800 Hz, which is consistent with *in vivo* recordings. Combined, our data suggests that zebra finches have extremely precise control over f_o in the order of 1-2 Hz/MU.

Title: Inter individual variability and reliability of cortico spinal excitability modulation across intermittent, continuous and sham theta burst stimulation in humans

Authors: *P. O. B. BOUCHER, R. A. OZDEMIR, S. TADAYON, E. SANTARNECCHI, A. PASCUAL-LEONE, M. SHAFI;
Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: Highly variable inter and intra individual results across transcranial theta burst stimulation (TBS) studies challenge the contention that TBS is more effective and reliable in modulating cortico-spinal excitability as other longer, less tolerated repetitive transcranial magnetic stimulation (TMS) protocols as initially proposed in preliminary studies. We compared two classically defined TBS protocols, continuous TBS (cTBS) and intermittent TBS (iTBS), to their sham equivalents with 24 participants in repeat neuronavigated visits (at least 48h between visits; test-retest performed 1 month apart). Inter and intra individual variability in modulation of corticospinal excitability was measured by motor evoked potentials (MEPs). Averaged MEPs collected before and after each TBS protocol at timed intervals were compared within a visit, to other TBS-modulated MEPs in separate visits, and across repeat visits of the same protocol to assess the relative suppression/facilitation of each TBS protocol and its reliability. cTBS suppresses MEPs as compared to sham stimulation and iTBS facilitates MEPs as compared to baseline MEPs in participants' initial visits. However, none of the protocols modulate cortico-spinal excitability in repeat visits. As well, sham stimulation demonstrated a faciliatory effect above baseline MEPs and even above iTBS at some time points in the initial visit but had no modulatory effect in the repeat visit. In the first within-subject study to test both iTBS and cTBS against sham stimulation across repeat visits, the effectiveness and most tellingly the reliability of both TBS protocols is challenged. Covariates such as genetics, geodesic distance between repeat visit hotspots, and cortical thickness are modelled with MEPs to determine the effect, if any, these variables play in the modulation of cortico-spinal excitability by TBS protocols. Finally, the neurophysiological substrate of sham TBS effects, as well as the need to account for placebo-like effects when assessing TMS efficacy, are also discussed.

Title: Interfacing motor neurons and skeletal muscle cells with thousands of bi-directional microelectrodes

Authors: *M. RADIVOJEVIC, M. LEWANDOWSKA, E. BOGATIKOV, A. R. PUNGA; Neurosci., Uppsala Univ., Uppsala, Sweden

Abstract: Impaired signal transmission between motor neurons and muscle fibers causes neuromuscular disorders such as amyotrophic lateral sclerosis, myasthenia gravis and muscular dystrophies. Despite efforts dedicated for developing new drugs for these diseases, there are still no curative treatments, and new therapeutic strategies are needed. Formulation of new therapies can be aided through advancing the knowledge about the functional interplay between subcellular elements of the neuromuscular system. Such insights, however, require experimental ability to noninvasively access and control electrical signals arising across different compartments of motor neurons and myotubes. To provide such access, we cultured primary rodent motor neurons and skeletal muscle cells directly on high-density microelectrode arrays. These arrays comprise 26,400 planar microelectrodes packed within an area of ~8.1 mm^2, providing a density of 3,264 electrodes per mm^2. Each of the electrodes can serve as recording and stimulation source, enabling bi-directional communication with any cell interfacing the array. Here we firstly present a method for electrical imaging of individual motor neurons and myotubes across hundreds of microelectrodes. Secondly, we present a method for extracellular electrical stimulation of targeted motor neurons. Finally, we present experimental approach to investigate excitability of myotubes in response to extracellular stimulation. We used spike-sorting algorithms to electrically identify individual cells in the cultures and to track action-potential (AP) propagation across subcellular compartments. We were able to monitor the AP initiation, axonal propagation and dendritic backpropagation in motor neurons. Likewise, the method enabled us to detect the AP initiation and to track bi-directional AP propagation across the sarcolemma of individual myotubes. We used extracellular voltage stimulation to activate individual cells in neuronal and myotube cultures. Stimulation directed at the axon initial

segment provided activation of targeted motor neurons. The presented methods could aid the development of a platform for preclinical studies of neuromuscular disorders.

Title: Exploring novel treatments for disorders that feature defects of the neuromuscular junction structure

Authors: *M. PANEA, J. COSSINS, R. WEBSTER, D. BEESON;
Nuffield Dept. of Clin. Neurosciences, Univ. of Oxford, Oxford, United Kingdom

Abstract: Congenital myasthenic syndromes (CMS) are a group of inherited disorders that affect the signal transmission at the neuromuscular junction (NMJ) and share the clinical feature of fatigable muscle weakness. In *DOK7*-CMS compromised neurotransmission is due to small and destabilised NMJs. DOK7 is a cytoplasmic-adaptor protein which amplifies the signalling from muscle-specific receptor tyrosine kinase (MuSK) that is responsible for the formation and stabilisation of the NMJ. It has recently been shown that large amounts of DOK7 protein in muscles generate enlarged NMJs in mice which are very efficient in signal transmission, have no reported detrimental effects and can ultimately lead to a complete recovery for disease model mice.
In this study we aim to identify small molecules that can specifically upregulate the amount of DOK7 in muscles as a potential therapy for CMS. By using an AAV system we generated enlarged NMJs in wild-type mice to further investigate the morphology of these synapses and show that their electrophysiology is similar to the normal-sized NMJs. Use of this system to infect wild-type C2C12 cells combined with titration of the levels of DOK7 showed that an approximate 2-3 fold increase in DOK7 protein levels is sufficient to generate AChR clusters. 5431 small molecules from a library of muscle-specific compounds were used in screening experiments. Initial screening was performed in triplicates on a C2C12 reporter cell line designed to contain a 1-Kb sequence of the DOK7 promoter fused to firefly Luciferase. Confirmatory results were performed for potential candidate upregulating compounds using a similar EGFP reporter cell line. Five potential hits that show significant upregulation after being tested on both reporter cell lines are being further investigated. They will provide the basis for a more detailed

analysis of the effects of DOK7-upregulation in cell culture biological assays and ultimately for *in vivo* testing.

Abstract: Several changes occur during normal aging contributing to a loss of skeletal muscle mass and function leading to higher rates of morbidity and mortality, hospitalizations and poor quality of life. Among important factors contributing to muscle changes are alterations of the neuromuscular junction (NMJ). Works using rodents revealed that the NMJ is a tripartite synapse composed of the presynaptic motor nerve terminal, the postsynaptic fiber and perisynaptic Schwann cells (PSCs), glial cells at the NMJ, each component being involved in the functional and structural properties of the synapse. However, the human NMJ remains widely understudied in part due to poor recovery of NMJ material from muscle biopsies. We therefore developed an approach using electrostimulation to identify the best location to perform a muscle biopsy of the vastus lateralis to enhance NMJ sampling (BeeNMJ). We obtained neuromuscular material from a cohort of 9 young (18-30 years) and 16 older adults (over 55 years) to study the alterations of the NMJs throughout aging process. An array of physiological characteristics of the participants (physical activity level, muscle strength, EMG, etc.) was assessed in a separate visit prior to the biopsies. Muscle samples were stained by immunohistochemistry for the nerve terminal (NF-

M/SV2), postsynaptic nAChRs (α-btx), PSCs (s100β) and muscle fiber type (MHC I) and imaged using a FV-1000 or a LSM880 confocal microscope. NMJs were characterised for each of their components and compared between age groups. The data showed that human NMJs were significantly different from their rodent counterparts, especially regarding postsynaptic and PSCs morphology. Comparative analyses also revealed that NMJ structure remained relatively stable throughout aging. However, a higher proportion of denervated NMJ and lower glial coverage of the NMJ were observed in older individuals. These data will be correlated with participants' physiological data to identify the critical NMJ parameters that best reflect the physiological state of each individual. Our results should enable a better understanding of the underlying mechanisms leading to neuromuscular aging and develop better therapeutic approaches to limit muscle weakening in aging.

Title: A role of lamin A/C in preventing neuromuscular junction decline in aged mice

Authors: *N. GAO[1], K. ZHAO[2], G. XING[1], H. JING[1], L. XIONG[1], H. GUO[1], W.-C. XIONG[1], L. MEI[1];

Abstract: During aging, skeletal muscles become atrophic and lose contractile force. This affects a large population of elderly regardless of ethnicity, gender, and wealth and is the most common cause of age-related loss of independence, frailty, and mortality. As the elderly proportion in the population continues to increase, the potential social and economic burden of muscle aging is becoming enormous. The neuromuscular junction (NMJ) is a synapse between motor neuron terminals and skeletal muscle fibers that transmit signals from motor neurons to muscle fibers. The neuromuscular transmission is critical for the control of muscle contraction and is thus essential for our physical mobility and daily life. Extensive research has revealed insight into the pathophysiological mechanisms of muscle aging. However, although NMJ structures and functions are disrupted in aged animals, little is known about underlying mechanisms. In contrast to NMJ formation, which has been studied extensively, much less is understood about mechanisms of NMJ maintenance, in particular in aged animals. To this end,

we screened for proteins that are reduced in aged muscles and identified lamin A/C, intermediate filament proteins that determine the interphase nuclear architecture. The lmna gene is mutated in Hutchinson-Gilford progeria syndrome (HGPS), a disease of accelerated aging and premature osteoporosis. We found muscle-specific lamin A/C mutant mice had no problem in forming NMJs, but displayed age-related NMJ deficits including reduced AChR cluster size, increased cluster fragments, diminished innervation, and impairment neuromuscular transmission. These deficits were not observed in mice lacking lamin A/C in motor neurons. These results suggest a role of lamin A/C in maintaining proper NMJ structure and function. Experiments are under way to investigate underlying mechanisms.
Key words: aging, neuromuscular junction, Lamin A/C

Title: Optimus parameters of electrical stimulation for ischiocavernosus and bulbospongiosus nerves in nulliparous female rabbit

Authors: *D. A. ZACAPA[1], C. HERNÁNDEZ-BONILLA[2], D. L. CORONA-QUINTANILLA[2], R. ZEMPOALTECA[2], F. CASTELÁN[3], M. ROMERO-ORTEGA[4], M. MARTÍNEZ-GÓMEZ[3];

Abstract: Neuromodulation by electrical stimulation of sacral spinal roots and peripheral nerves have been a therapeutic option to treat pelvic floor disorders. Clinical studies have been demonstrated that electrical stimulation of the pudendal nerve is a viable alternative for neuromodulation, since it innervates the urethral sphincter and some pelvic floor muscles (ischiocavernosus (Iscm) and bulbospongiosus (Bsm) muscles). However, it has not been evaluated the electrical stimulation benefits on specific perineal nerves to develop an effective

treatment. In this study, optimal electrical stimulation parameters were determined for ischiocavernosus (Iscn) and bulbospongiosus (Bsn) nerves. Electromyograms (EMG) (Iscn and Bsn) during electrical nerve stimulation were record in nulliparous anesthetized female rabbits (urethane 1.5 g/Kg body weight, intraperitoneal)11.7 ± 0.3 months age and 4.39 ± 0.13 Kg weight. In a first stage, we applied a single square pulse (1 ms), until find the current to evoke the minimum electromyographic activity in perineal muscles. That was defined as electrical current threshold value (CThV), specifically to Iscm or Bsm.
Results obtained show that the CThV for Isc was 1.42 ± 0.24 μA and for Bs 0.41 ± 0.19 μA. To 6 CThV were observed three components in the EMG records of Iscm, amplitude was 5.26 V ± 0.59, 6.46 V ± 1.5 and 5.9 V ± 0.9 respectively. For Bsm (4 CThV) the amplitude was 8.49 V ± 4.1, 7.98 V ± 2.99 and 2.36 V ± 1.8. The intensity of current applied at 6 CThV on Iscn was 6.31 ± 1.15 μA and at 4 CThV on Bsn was 1.15 ± 0.27 μA.
Our results suggest that the Iscn need more CThV to activate the Iscm. Meanwhile, the Bsn required minor CThV. These results showed that to treatment effective is necessary applying electrical stimulation differential in specific nerves.

Title: Effect of multiparity on the force generated by the obturator internus and bulboglandularis muscles in the vagina and urethra of the female rabbit

Authors: *C. HERNÁNDEZ BONILLA[1], R. ZEMPOALTECA[2], D. L. CORONA QUINTANILLA[2], F. CASTELÁN[3], M. MARTÍNEZ GÓMEZ[3];

Abstract: The parturition is a mechanical and hormonal event, which has been linked to alterations in the pelvic floor muscles and its innervation. Studies in female rabbits (*Oryctolagus cuniculus*) have showed that the multiparity modifies fiber type composition and the contractile

properties of pelvic floor muscles, affecting the genesis of vaginal pressure. However, there are other striated muscles anatomically related to the pelvic vagina and urethra as the obturator internus (OI) and bulboglandularis (Bg) muscles that could be damaged by the effect of multiparity. The aim of this study was to evaluate in young nulliparous and young multiparous rabbits, the contractile force in isometric conditions and the pressure generated on the pelvic vagina and urethra by OI and Bg muscles. Twenty-four Chinchilla-breed female rabbits (11-12 months old) were used in this study. Animals were divided in two groups: young virgin nulliparous (n=12) and young multiparous (n=12). Each condition (nulliparous and multiparous) was randomly distributed into two experimental groups. In the first group, was evaluated the pelvic intravaginal pressure (IVP) and intraurethral pressure (IUP) generated by the contraction of the OI and Bg muscles (n=6 per group). The second group was evaluated contractile force developed by OI muscle (n=6 per group). We observed contraction of the OI muscle at 100 Hz, this contraction generated a high IVP in nulliparous females and low in multiparous. The IUP generated by the contraction of OI muscle did not show significant differences between groups. During the contraction of Bg muscle at 100 Hz, the IVP generated was greater in female nulliparous respect to multiparous. The IUP generated by the contraction of the Bg muscle in nulliparous females was greater in comparison to multiparous. The contractile force generated by OI muscle did not show significant differences between groups and the Bg was not possible registered. The results showed that the OI and Bg muscles contribute in a differential way to the generation of IVP and IUP. Likewise, the multiparity affects muscles differently because the contractile properties of the OI muscle were unchanged. This in turn, could modify reproductive and non-reproductive processes.

Title: Identification and expression of glutamate receptors genes in innervated and uninnervated regions of the ventral diaphragm muscle of the moth Manduca sexta

Authors: A. MORALES BENITEZ, K. M. YATSKO, R. J. BAYLINE;
Washington & Jefferson Col., Washington, PA

Abstract: Modulation of rhythmic patterns of myogenic muscles by motor neurons occurs in many organisms. The ventral diaphragm muscle (VDM) of the tobacco hornworm *Manduca sexta* is myogenic and controls the movement of hemolymph. The VDM shares many similarities

with the dorsal heart muscle. The VDM receives innervation in the most posterior (abdominal segment 6—A6) and anterior (A2-A3) segments. Segments A4 and A5 are uninnervated. While the heart exhibits both anterograde and retrograde cardiac activity, only the fast anterograde contractions are initiated by neural control of the anterograde pacemakers via glutamatergic innervation. Similarly, the VDM experiences an increase in contraction rate following bath application of glutamate. However when the uninnervated A4-A5 segments of the muscle are isolated, glutamate induces a decreased contraction rate. We hypothesized that a difference in expression of glutamate receptor genes accounted for these contrasting responses in the muscle. Specifically, abdominal segments A4 and A5 were expected to present inhibitory chloride channels while segments A6 and A3 were expected to show excitatory GluRIIA receptors. BLAST searches of the *M. sexta* genome revealed potential peptide sequence matches for ionotropic and metabotropic glutamate receptors. We extracted and purified RNA from the adult VDM to generate regional cDNA. We used PCR to amplify sequences of interest using primers for the putative *M. sexta* GluRIIA and GluRCl receptors. Purified PCR products were ligated into the TOPO plasmid to transform bacteria. After successfully growing our colonies and running PCR, we gathered enough evidence to suggest the VDM might present both excitatory GluRIIA and inhibitory GluRCl receptor channels. Initial results suggest that GluRIIA channels are absent from the uninnervated regions of the muscle, while GluRCl channels are present throughout the muscle. This suggests a mechanism by which glutamate could decrease contraction rate in the uninnervated sections via specific activation of the GluRCl channels.

Title: The synaptic associated microRNA, miR-133b, plays an important role in the progression of Duchenne muscular dystrophy

Authors: T. TAETZSCH[1], ***D. SHAPIRO**[1,2], G. VALDEZ[3,1];
[1]Fralin Biomed. Res. Inst., Roanoke, VA; [2]The Grad. Program in Mol. Biology, Cell Biol. and Biochem., [3]Dept. of Mol. Biology, Cell Biology, and Biochem., Brown Univ., Providence, RI

Abstract: The muscle and synaptically enriched microRNA, miR-133b, has been implicated in the biogenesis and maturation of muscle fibers. While mir-133b is increased in Duchenne muscular dystrophy (DMD), it remains unknown whether the induction of miR-133b is required to mitigate muscle fiberdegeneration in this disease. To assess the role of miR-133b in DMD-affected skeletal muscles, we genetically ablated miR-133b from the mdx mouse model for DMD. We have found that loss of miR-133b exacerbates muscle degeneration in the tibialis anterior (TA) muscle. In the absence of miR-133b, the TA becomes populated with muscle fibers exhibiting a rather small cross-sectional area (CSA) and containing centralized myonuclei. Additionally, loss of miR-133b increases both the size of the interstitial space around muscle fibers and the number of mononucleated cells contained within it. To determine if miR-133b directly impacts muscle fiber regeneration following acute injury, we performed cardiotoxin (CTX) injury of the TA muscle of healthy miR-133b null mice and their littermate controls. We did not observe differences in the size of regenerating muscle fibers following CTX-injury in miR-133b null TA, suggesting that the impact of miR-133b on muscle fibersize in mdx muscle is related to a chronic aspect of the disease. Along these lines, RNA seq analysis revealed that while the impact on the transcriptome of healthy miR-133b null muscle is limited, a wide range of genes are impacted by miR-133b deletion in mdx muscle, including a number of previously identified miR-133b targets as well as several members of the TGF-β pathway including LTBP4, a gene associated with increased severity of DMD. Combined, our data suggest that miR-133b functions to slow muscle degeneration in DMD.

Title: Argonaute 2 plays a local role in maintaining and repairing injured and ALS-afflicted NMJs

Authors: *T. TAETZSCH[1], D. SHAPIRO[2], G. VALDEZ[2];
[1]FBRI, Virginia Tech., Roanoke, VA; [2]Brown Univ., Providence, RI

Abstract: The ability of microRNAs to mediate stress-responses in skeletal muscles, including neuromuscular junctions (NMJs), depends on the function of a variety of proteins. Here, we

examined levels and distribution of genes involved in microRNA biogenesis, transport and translational repression in skeletal muscles and their synapses. We found that expression of genes for miRNA biogenesis (DGCR8, Exportin), components of the RNA induced silencing complex (Argonaute2, Dicer, TARBP2, TNRC6a) and RISC-interactors (HSP90a, PCBP1) decreases as muscles mature. Corroborating these findings, we found reduced protein levels of Argonaute 2 (Ago2), the catalytic core of the RNA induced silencing complex (RISC), in muscles from juvenile and young adult compared to newborn mice. Interestingly, Ago2 concentrates at NMJs as animals mature, suggesting that Ago2 levels and distribution are linked to the innervation status of the NMJ. To examine this possibility, we assessed Ago2 in skeletal muscles following severing of innervating motor axons. Immunostaining revealed that Ago2 vacates denervated NMJs, and then gradually returns as motor axons re-innervate postsynaptic sites. We next asked whether Ago2 expression and distribution are affected in Amyotrophic Lateral Sclerosis (ALS), a disease that causes progressive degeneration of NMJs. Surprisingly, Ago2 is largely missing from intact NMJs in presymptomatic and remains absent during the symptomatic stage of the disease in $SOD1^{G93A}$ mice, a mouse model for ALS. Together, these findings suggest that Ago2 plays a local role in repairing NMJs, and its absence may contribute to NMJ degeneration in ALS.

Title: Dynamics of nicotinic acetylcholine receptor subpopulations at the normal and injured neuromuscular synapse *in vivo*

Authors: *D. ZELADA, F. BERMEDO-GARCÍA, J. P. HENRÍQUEZ;
Cell Biol., Univ. De Concepción, Concepcion, Chile

Abstract: Introduction: The vertebrate neuromuscular junction (NMJ) is a cholinergic peripheral synapse where the post-synaptic muscle membrane specialization interacts with a pre-synaptic motor neuron terminal. NMJ injury leads to the denervation of post-synaptic apparatuses with morphological and functional impairment of the nicotinic acetylcholine receptor (nAChR) aggregates. Our aim is to explore the dynamics of nAChRs subpopulations at the injured NMJ.

Materials and Methods: *Levator auris longus* (LAL) muscles were denervated by facial nerve crush or resection. To analyze nAChR dynamics, we initially labelled surface nAChRs by *in vivo* injection of Alexa-488-Bungarotoxin (BTX). After different times, newly incorporated AChRs at the muscle surface were labelled with Alexa-555-BTX and then, intracellular AChRs were labelled with Alexa-647-BTX. Injured and control non-denervated NMJs were analyzed by confocal microscopy.
Results: Despite an initial preservation of post-synaptic structures, long-term facial nerve resection leads to a remarkable loss in their pretzel-like morphology. Pre-existing surface (S) nAChR stability decreases as NMJ degeneration proceeds, evidenced by a remarkable increase in the 555/488-BTX staining ratio within each post-synapse. Interestingly, new (N) nAChRs were peripherally incorporated into the remaining postsynaptic domains. Also, denervation-induced ectopic (E) nAChR clusters exhibited reduced stability, which displayed both plaque and O-shape morphologies. Remarkably, we found that altered nAChRs turnover precedes the morphological dismantlement of the post-synaptic domain.
Discussion: Our results indicate that NMJ injury leads to an increase of nAChR turnover, suggesting that early morphological preservation of the post-synapse after injury does not correlate with its stability.

Title: Effect of posture on transdiaphragmatic pressure

Authors: C. WHITNEY[1], M. PAREJA-CAJIAO[2], H. M. GRANSEE[2], G. C. SIECK[3], C. B. MANTILLA[4];
[1]Biomed. Engin., Mayo Clin. Grad. Sch. of Biomed. Sci., Rochester, MN; [3]Physiol. & Biomed. Engin., [4]Anesthesiol., [2]Mayo Clin., Rochester, MN

Abstract: Transdiaphragmatic pressure (Pdi) is commonly used as a surrogate for diaphragm muscle force generation during ventilatory (eupnea, sigh, hypercapnia/hypoxia, airway occlusion) and expulsive (cough, sneeze) behaviors. Most studies have measured Pdi while animals are in a supine position, and have thus far failed to address how position and postural adjustments can affect Pdi. Accordingly, in the present study we focused on the effect of position

on Pdi measurements in rats. Adult Sprague Dawley rats (4 female, 4 male) were anesthetized with ketamine/xylazine. On the first day, animals were placed in supine, prone, right curled and left curled positions within a BUXCO FinePointe whole body plethysmography system to record respiratory rate and tidal volumes during eupnea and hypoxia-hypercapnia. The following day, Millar mikro tip pressure transducers were placed in the stomach (gastric pressure - Pgas) and esophagus (esophageal pressure - Peso), and Pdi was measured as the difference between Pgas and Peso. In each animal, Pdi generated during eupnea and hypoxia-hypercapnia was measured while the animals were placed in the supine, prone, right curled and left curled positions. Tukey-Kramer post-hoc test was used to compare the effect of posture and behavior (eupnea/hypercapnia-hypoxia) on Pdi amplitude, breathing frequency, and duty cycle. From these results, we concluded no differences were found across postures in the bound (isometric) or unbound state of the diaphragm muscle. The postural invariance of Pdi measurements across ventilatory behaviors supports the use of Pdi for diaphragm muscle force.

Title: Deletion of Lynx1 promotes compensatory reinnervation of NMJs and delays ALS onset

Authors: S. K. VAUGHAN[1,2,3], ***K. T. REGA**[1], T. D. MYERS[1], G. VALDEZ[1,3];
[1]Fralin Biomed. Res. Inst., Roanoke, VA; [2]Grad. Program in Translational Biology, Medicine, and Hlth., Virginia Tech., Blacksburg, VA; [3]Mol. Biology, Cell Biology, and Biochem., Brown Univ., Providence, RI

Abstract: Dysregulated cholinergic transmission at the neuromuscular junction (NMJ) has been shown to directly contribute to neuromuscular degeneration. Cholinergic dysregulation has also been implicated in amyotrophic lateral sclerosis (ALS) pathology, and thus may contribute to disease progression. Specifically, ALS-afflicted animals have increased spontaneous activity due to elevated ACh at the synaptic cleft, and heightened expression of immature nicotinic acetylcholine receptors (nAChRs) in muscle fibers. Thus, modifying the sensitivity of nAChRs to ACh may reduce deleterious effects of cholinergic dysfunction on NMJs and muscle fibers. In

unpublished findings, we have gathered significant data showing that Lynx1 desensitizes nAChRs at the NMJ to ACh, which contributes to NMJ maintenance and stability. In this study, we asked if Lynx1 also functions to preserve and repair NMJs during the progression of ALS. We found that Lynx1 levels decrease in skeletal muscles before NMJs degenerate in $SOD1^{G93A}$ mice. To determine if this decrease contributes to ALS-pathogenesis, we examined $SOD1^{G93A}$ mice lacking Lynx1 ($SOD1^{G93A}$;$Lynx1^{-/-}$). Interestingly, deletion of Lynx1 significantly delays the onset of ALS symptoms without altering the lifespan of male $SOD1^{G93A}$ mice. Since NMJs undergo bouts of degeneration and regeneration, a process called compensatory reinnervation, during the initial onset of symptoms, these findings suggested that loss of Lynx1 promotes compensatory reinnervation. To test this possibility, we used a fibular nerve crush model to examine NMJ reinnervation in $Lynx1^{-/-}$ and control mice. In $Lynx1^{-/-}$ mice, NMJs are reinnervated at a faster rate compared to control mice, supporting the hypothesis that skeletal muscles in $SOD1^{G93A}$ mice reduce endogenous Lynx1 levels to promote compensatory reinnervation. However, we also found that complete loss of Lynx1 delays cellular changes necessary for NMJs to fully repair following denervation. These include the elimination of redundant axons innervating the same muscle fiber, and the shedding of extensions that go beyond the postsynaptic region. Deletion of Lynx1 also exacerbates denervation-induced fragmentation of postsynaptic sites, and the appearance of extra-synaptic clusters of nAChRs. Not surprisingly, these morphological changes at NMJs have downstream effects on muscle fibers, and the expression of genes involved in NMJs stability, myogenesis, and muscle atrophy. Altogether, these data shed light on the therapeutic potential of Lynx1 for promoting repair of NMJs, and delaying ALS disease progression.

Abstract: Cholinergic transmission is essential for voluntary movement and plays a central role in sculpting and maintaining neuromuscular junctions (NMJs) and muscle fibers. Unfortunately, cholinergic transmission becomes dysregulated with advancing age and recent discoveries show that such changes contribute to age-related neuromuscular degeneration. Thus, finding ways to mitigate the effects of dysregulated cholinergic activity may prevent NMJ degeneration. Here, we asked if Lynx1, a GPI-anchored protein shown to modulate cholinergic transmission in the brain, plays a similar role at NMJs. We first show that Lynx1 mRNA is expressed by skeletal muscles and C2C12 myotubes. Furthermore, the expression of Lynx1 in muscle fibers is developmentally regulated and has a direct correlation with cholinergic activity. We show that Lynx1 localizes to the NMJ in young adult mice and interacts with NMJ-associated nAChRs. Importantly, electrophysiological analysis revealed that Lynx1 functions to desensitize nAChRs to ACh at the NMJ. We then examined the role of Lynx1 in the development and maintenance of NMJs and muscle fibers. Using $Lynx1^{-/-}$ animals, we determined that Lynx1 has no significant impact on NMJ development. However, deletion of Lynx1 significantly increases the incidence of NMJs with age-related morphological features in young adult and middle-aged mice. Deletion of Lynx1 also accelerates nAChR turnover and alters expression of genes that function to stabilize the postsynaptic region of the NMJ. Together, these findings demonstrate that Lynx1 is a promising candidate molecule for mitigating the deleterious effects of aberrant cholinergic transmission on aging NMJs and skeletal muscles.

Title: Development of the murine vasopressin system

Authors: E. J. SOMMER, E. A. AULINO, ***H. K. CALDWELL**;
Biol. Sciences, Biomed. Sciences, Brain Hlth. Res. Inst., Kent State Univ., Kent, OH

Abstract: While there has been extensive study of the arginine vasopressin (Avp) system in adults, much less is known, or understood, about the early development of this system. In most

adult mammals, Avp is primarily produced in parvocellular neurons of the supraoptic and paraventricular nucleus of the hypothalamus and to a lesser extent in a handful of other brain nuclei. Avp has also been identified in cells other than neurons, including astrocytes. Given the mounting evidence that Avp's sister neuropeptide, oxytocin, is important for brain development in the perinatal period, it seems appropriate to examine the developing Avp system as well, since both are important modulators of social behavior. Previous work from our lab has found Avp mRNA in the mouse brain as early as embryonic day (E) 12.5. However, as mRNA expression is not necessarily indicative of ligand expression, we decided use immunohistochemistry to identify Avp-immunoreactive cells. Mouse brains of both sexes were collected at E14.5, E16.5, E18.5, and postnatal day (P) 2, and stained for Avp. Preliminary data suggest that there are Avp-immunoreactive cells throughout the brain in both males and females as early as E16.5. However, further work is needed to determine the specific cell types in which Avp is expressed, as well as the precise neuroanatomical localization of Avp-immunoreactivity.

Title: Peripheral vasopressin 1A receptors in neonatal mice

Authors: *K. R. DAY, M. A. GREENWOOD, E. A. D. HAMMOCK;
Psychology, Florida State Univ., Tallahassee, FL

Abstract: The process of parturition leads to an infant experiencing a dramatic spike in circulating vasopressin (AVP) that is unique to neonates exposed to vaginal delivery. Massive neuroendocrine activation of the HPA axis is believed to provide protection from the stresses of hypoxia and hypercapnia that are naturally associated with labor. Prior research suggests AVP may provide analgesic effects via vasopressin receptor 1a (AVPR1A), providing additional need for investigation as to which tissues the massive amounts of AVP may be acting on at birth. Utilizing 0.050nM I^{125} radioligand with high binding specificity for AVPR1A (Vasopressin (Linear), V-1A Antagonist (Phenylacetyl1, 0-Me-D-Tyr2, [^{125}I-Arg6]-)) we performed autoradiography to investigate which organs and tissues may be sensitive to the surge of AVP associated with vaginal delivery. Whole post-natal day 0 (P0) male (n=3) and female (n=3) C57/BL6j wildtype mice were cryosectioned in the sagittal plane in 20 micron sections. We

determined specificity of binding by comparing receptor binding observed in wildtype mice to *Avpr1a* KO male (n=3) and female (n=3) mice. To identify potential nonspecific binding, adjacent tissue sections for each specimen were competed with 1000nM of unlabeled vasopressin. For unbiased region of interest measurements of AVPR1A, post processing Cresyl Violet staining was completed. Image stacking, analysis and quantification were performed with ImageJ software and the TurboReg plugin. We confirmed that AVPR1A is present in the periphery of neonatal male and female C57/BL6j wildtype mice. Our results identify the robust presence of AVPR1A in the oronasal cavity, anogenital region, bone, spinal cord, and bladder of P0 male and female wildtype mice. Additional nonspecific binding can be seen in brown adipose tissue, liver, and fecal matter. Sex-specific variations in the presence of AVPR1A in anogenital regions can be observed, with greater binding in the female anogenital area. Identification of perinatal tissues and organs with AVPR1A will lead to a better understanding if the role of AVP at birth in the transition to postnatal life.

Title: Behavioral traits associated with neurodevelopmental disorders in the mice lacking both vasopressin 1a and 1b receptors

Authors: *F. MAEKAWA[1,2], E. KIMURA[1,3], K. SANO[1,4], T. ENDO[5], K. NAKAMURA[6,2]; [1]Natl. Inst. for Envrn. Studies, Tsukuba, Japan; [2]Saitama Univ., Saitama, Japan; [3]Japan Society for the Promotion of Sci., Tokyo, Japan; [4]Univ. of Tsukuba, Tsukuba, Japan; [5]Phenovance Research & Technol., Kashiwa, Japan; [6]Natl. Res. Inst. Child Hlth. & Develop., Setagaya, Japan

Abstract: Background: Vasopressin is a hormone synthesized in hypothalamic nuclei and is secreted not only as a hormone from posterior pituitary but also as a neuropeptide within brain. Vasopressin regulates the execution of communicative and adaptive behaviors, and the effect of vasopressin on these behaviors is thought to be mediated by vasopressin 1a and 1b receptors (V1aR and V1bR, respectively), predominant receptors in mouse brain. Although it has been reported that genetic deletion of either receptors causes different types of behavioral impairments in mice, it has remained unclear whether genetic deletion of both receptors causes either additive,

synergistic, or different actions. **Aim**: In this study, we examined the effects of gene deletion of both V1aR and V1bR on neonatal ultrasonic vocalization (USV), an index of communicative behavior, and adaptive behavior under new environment in group-housed condition.**Methods:**The USV of postnatal pups was measured for 1 min in sound-attenuate chamber, and the USV frequencies of 60-100 kHz were analyzed. After maturation, the various aspects of mouse behavior were recorded using the apparatus named IntelliCage. The visit number to corners, small rooms for drinking water, during 24 hours after the first entry into IntelliCage was used as an index of adaptive behavior.**Results:** We could detect significant alternation of frequency and duration of USV in the mice lacking both V1aR and V1bR. The adaptation to IntelliCage was also significantly decreased in the mice lacking both V1aR and V1bR. Such changes were not detected in the mice deficient in either receptor.**Discussion**: These results suggest the possibility that, as far as the USV and the adaptation to new environment are concerned, V1aR and V1bR compensate each other and severe impairments occur only if both receptors are deficient.

Title: Molecular signatures for co-transmission within vasopressinergic neurons of mouse and rat central nervous system

Authors: L. ZHANG[1], V. S. HERNANDEZ[1], *L. E. EIDEN[2];
[1]Physiology/Medicine, Natl. Autonomous Univ. of Mexico, Mexico City, Mexico; [2]Section on Mol. Neurosci., NIH, NIMH-IRP, Bethesda, MD

Abstract: Using high-resolution ISH methods, radio-ribonucleotide and RNAscope® 2.5 HD duplex assay, with VGLUT1, VGLUT2 and VGAT probes as well as AVP probes, we investigated the co-transmission signatures of vasopressinergic neurons throughout the central nervous system of the rat and mouse. The mainly glutamatergic AVP cell groups include: hypothalamic paraventricular (PVN, both media and lateral division and all antero-posterior span) and supraoptic (SON) nuclei, accessory nuclei (which include nucleus circularis and the

posterior fornical nucleus, as well as the tufted cells of the olfactory bulb). We remark here on a newly-identified vasopressinergic cell group, comprising layer V glutamatergic pyramidal neurons of the lateral entorhinal cortex, which also are glutamatergic. The mainly GABAergic AVP cell groups include those of the suprachiasmatic nucleus (SCN), the bed nucleus of the stria terminalis, medial posterior internal division (BSTmpi), the intra-amygdala division of BST (BSTIA), and the central amygdala. These data suggest that the traditional parsing of vasopressinergic cell groups into magno- and parvocellular should include also an additional neurochemical classification based on co-transmitter phenotype.

Title: Behavioral and neural investigations in the Brattleboro rat reveal a role for central vasopressin projections in behavioral arousal during adolescence

Authors: *K. SCHATZ[1], L. M. BROWN[1], A. R. BARRETT[1], L. C. ROTH[2], V. GRINEVICH[3], M. J. PAUL[4];
[1]Univ. at Buffalo, Buffalo, NY; [2]Univ. of Oslo, Oslo, Norway; [3]Dept. of Neuropeptide Res. for Psychiatry, Central Inst. of Mental Hlth. (CIMH-ZI), Med. Fac. Mannheim, Heidelberg Univ., Heidelberg, Germany; [4]Psychology, Univ. at Buffalo, SUNY, Buffalo, NY

Abstract: The neuropeptide, arginine vasopressin (AVP), has been implicated in a number of neurodevelopmental disorders that impact social and emotional development (e.g., autism and ADHD). Nevertheless, we do not understand how AVP modulates behavioral development or how its altered function contributes to neurodevelopmental disorders. The Brattleboro rat, which lacks AVP due to a mutation in the *Avp* gene, is an ideal model to study the impact of life-long AVP disruption. Brattleboro rats suffer from diabetes insipidus, excessive drinking and urination, due to the loss of AVP action on the kidney. Recently, we found that male and female adolescent homozygous Brattleboro rats (Homs) engage in less social play than their Het littermates, and amount of play behavior was correlated with the amount of behavioral arousal in an open field. This suggests that AVP may modulate levels of social play through its regulation of arousal. To further investigate the link between arousal and social behavior, our first experiment tested whether adolescent Hom rats exhibit decreased behavioral arousal in an open field test compared

to wild type (WT) littermates. Consistent with previous findings, Homs traveled less distance, spent more time inactive, and entered the center of the arena fewer times than WT littermates. We then asked which pathway(s) mediate AVP's actions on arousal. In experiment 2, we infused a recombinant adeno-associated virus containing an AVP promoter driving expression of a functional AVP gene (rAAV-AVP) or a Venus fluorescent marker (rAAV-Venus) into the paraventricular nucleus of the hypothalamus (PVN) of male and female adolescent Hom rats. The rAAV-AVP selectively rescued AVP production in magnocellular cells and fibers of the PVN, including projections to limbic areas such as the lateral habenula, hippocampus, medial amygdala, and lateral septum. These findings support previous reports indicating extraneurohypophysial projections of PVN AVP magnocellular cells. Hom rAAV-AVP infused rats showed a marked decrease in water intake, but behavioral arousal in the open field was unaffected. These data implicate a role for AVP in the regulation of arousal during adolescence. Furthermore, the present findings indicate that the hypoaroused phenotype of adolescent Hom rats is not due to the loss of AVP function in magnocellular cells or a side effect of diabetes insipidus, but favors the hypothesis that central, parvocellular AVP mechanisms underlie the regulation of arousal during adolescence. Ongoing studies are testing the role of hindbrain AVP projections in the regulation of arousal and social behavior during adolescence.

Title: Effect of sex and autism diagnosis on oxytocin and vasopressin 1a receptors in the substantia nigra, hippocampus, and primary visual cortex of the human brain

Authors: *M. C. PALUMBO[1], T. C. SIMMONS[1], A. L. SMITH[2], M. M. GOODMAN[2], K. L. BALES[1], S. M. FREEMAN[1,3];
[1]California Natl. Primate Res. Ctr., Univ. of California Davis, Davis, CA; [2]Ctr. for Translational Social Neurosci., Emory Univ., Atlanta, GA; [3]Dept. of Biol., Utah State Univ., Logan, UT

Abstract: Oxytocin (OT) and vasopressin (AVP) influence complex social behaviors across mammals. In humans, clinical trials have begun using OT to treat Autism Spectrum Disorder (ASD), a condition characterized in part by deficits in sociality. However, our knowledge of the OT and AVP systems in the human brain is limited. This study used competitive binding

receptor autoradiography to quantify putative oxytocin receptor (OXTR) and vasopressin receptor 1a (AVPR1a) densities in postmortem human brain tissue from individuals with ASD and neurotypical (NT) specimens. We examined three regions previously shown to contain dense OXTR or AVPR1a receptor binding in the human brain: the substantia nigra (SN), hippocampus, and primary visual cortex (V1). The NIH NeuroBioBank provided us with the following specimens: 8-9 ASD males, 6-8 ASD females, 7-8 NT males, and 6-7 NT females. In the SN, OXTR density was lower in ASD females compared to ASD males (p=0.0293), although neither group was significantly different from NT. Previous reports have postulated sex differences in ASD severity, and our results in the SN provide neuroanatomical support for this idea. Additionally, among ASD specimens, we found a significant negative association between OXTR density in the SN and the patient's Autism Diagnostic Interview-Revised (ADI-R) scores for quantitative abnormalities in reciprocal social interaction (p=0.0479; r=-0.6709) and for abnormality of development (p=0.0144; r=-0.7738). The higher the ADI-R score, the more severe the symptoms, so our results show that lower OXTR densities in the SN correlate with more severe social symptoms. We did not find any effect of ASD or sex on AVPR1a density in the hippocampus or V1, nor were there significant associations between age and either OXTR or AVPR1a density in any region of interest. We did find significant positive associations in ASD between AVPR1a density in the dentate gyrus and ADI-R scores for abnormality of development (p=0.0273; r=0.7641), as well as between OXTR density and social interaction ADI-R scores in all subregions of V1. Correlations between ADI-R scores and receptor binding in multiple brain regions associated with sensory processing provide some of the first neuroanatomical evidence underlying ASD symptom severity.

Title: Useful tools for oxytocin studies: A new reporter and a new cre recombinase driver to precisely recapitulate oxytocin receptor expression profiles in mouse brains

Authors: *Y. U. INOUE[1], R. KANEKO[2], Y. MORIMOTO[1], T. INOUE[1];
[1]Dept. of Biochem. and Cell. Biol., Natl. Inst. of Neuroscience, NCNP, Kodaira, Tokyo, Japan;
[2]Bioresource Ctr., Gunma Univ. Grad. Sch. of Med., Maebashi, Gunma, Japan

Abstract: Oxytocin (Oxt), a natural brain peptide produced within the hypothalamus, plays an important role in regulating social behaviors. It is also expected as a potential therapeutic for social deficits in autism spectrum disorders. Oxytocin receptor (Oxtr) is abundantly expressed in the brain and its relationship with social behaviors have also been extensively studied in mouse brains. However, multiple independent tools have been used to visualize Oxtr expressions and the resulted expression patterns are not fully consistent with each other. First, commercially available antibodies don't have enough specificities to Oxtr protein, and detection of *Oxtr* mRNA by *in situ* hybridization has been reported to be difficult. Secondly, several reporter lines and Cre recombinase driver lines have been generated by BAC transgenesis or ES cell-based gene targeting, yet they have somewhat different expression profiles probably because of the different integrity and context for their reporter/driver expressions in each line. Here, we employ CRISPR/Cas9 genome editing technology to generate novel knock-in mouse lines to precisely recapitulate the endogenous Oxtr expression profiles. We establish *Oxtr-PAtag-T2A-tdTomato* reporter line and *Oxtr-PAtag-T2A-iCre* driver line, in which fluorescent reporter or codon-improved Cre recombinase is bicistronically expressed within the Oxtr-expressing cells depending on T2A peptide cleavage. Furthermore, in order to directly determine the endogenous Oxtr localizations, PA-tag is fused to C-terminus of the receptor protein. By using these knock-in lines, we carefully analyze the co-localization of tdTomato/iCre with PA-tag in the brain tissues to obtain a precise Oxtr expression atlas. As the results, in addition to the previously reported brain regions where Oxtr expressions have been detected, we confirmed the receptor expressions in the other regions such as the nucleus accumbens. It is noteworthy that *Oxtr-PAtag-T2A-tdTomato* reporter line can be maintained in the homozygous state without the laborious genotyping procedure and the tdTomato fluorescence can immediately illuminate brain tissues without immunostaining. Our knock-in mouse lines could thus serve useful tools to investigate roles of Oxt-Oxtr system in the social brain.

Title: Disruption of oxytocin signaling during mouse fetal development results in sex-specific deficits in adult social behaviors

Authors: *E. A. AULINO[1,2], H. K. CALDWELL[1,2];
[1]Dept. of Biol. Sci., [2]Brain Hlth. Res. Inst., Kent State Univ., Kent, OH

Abstract: In adults, the neuropeptide oxytocin (Oxt) is known to be important to the neuromodulation of social behaviors in both males and females. However, there is also evidence to suggest that the Oxt system plays an important role in the neurochemical 'shaping' of the social brain during early development. For instance, mice whose Oxt signaling is impaired during fetal life have heighted inter-male aggression and impaired social-recognition in adulthood; these same deficits are not observed when the Oxt receptor (Oxtr) is genetically disrupted two weeks after birth. Even in a non-traditional model species, such as prairie voles, disruption of the Oxt system in neonates results in sex-specific behavioral changes in adulthood. Taken together, these studies point to Oxt having an important role in early brain development – specifically being involved in the development of neural circuitry integral to sex-specific behavior. Based in part on the aforementioned studies, as well as data from our lab that has found that there are significant sex-differences in the development of the Oxt system in the embryonic mouse brain, we sought to perform functional studies linking the fetal Oxt system to changes in adult social behaviors. We hypothesized that transient disruption of Oxtr signaling during fetal life would result in sex-specific behavioral differences in adulthood. To test this hypothesis, we performed transuterine microinjections of either saline or an Oxtr antagonist into the lateral ventricles of embryonic day (E) 16.5 in C57BL/6J mice and observed their behavior in adulthood. We found that transient disruption of Oxtr signaling at E16.5 resulted in increased aggressive behavior in adult males and impaired social recognition memory in adult females. While additional study is still needed to determine the mechanism by which these behavioral alterations have occurred, these results suggest that the Oxt system is important to sex-specific brain organization.

Title: Mice prefer oxytocin-containing social stimuli

Authors: *M. TABBAA, E. A. D. HAMMOCK;
Psychology, Florida State Univ., Tallahassee, FL

Abstract: Oxytocin (OXT) regulates species typical social behaviors and interacts with early life experience to shape adult responses. Recent data from our lab characterizing oxytocin receptor (OXTR) ligand binding in the mouth and nasal cavity as well as the brain and behavioral response of orally-applied OXT in pre-weanling mice suggest that socially-acquired OXT may affect sensory processing and subsequent brain development through peripheral OXTR. Peripheral OXTRs may be activated in social contexts to drive social interactions throughout life. If OXT is exchanged between individuals and this influences social behavior, then mice should be able to distinguish between a conspecific with and without OXT as indicated by behavioral preference in a two-choice assay. To begin to address this hypothesis, we tested the social preference of adult C57 male (N=13) and female (N=12) mice for OXT containing wild-type (WT) versus OXT knock-out (KO) same-sex stimulus mice in a 30-minute three-chambered choice test. Next, we asked if mice would show a preference for same-sex mouse bedding with and without OXT. Bedding was collected from cages containing only OXT KO mice and was then contaminated with either synthetic OXT or saline. One week later, this test was repeated to evaluate the responses to opposite-sex bedding with and without OXT. Behaviors were video recorded and later scored by a researcher blind to stimulus mice genotype and bedding condition. During the social preference test for OXT WT versus KO same sex stimulus mice, both males and females spent more time sniffing the face of OXT WT mice compared to OXT KO mice. In the soiled bedding test, there were no differences in investigation of same sex OXT KO bedding containing OXT compared to saline. However, males spent more time investigating female bedding containing OXT compared to saline. In contrast, females did not show a preference for male OXT KO bedding containing OXT over saline. Combined, these data indicate the possibility for socially-acquired OXT to modulate species-typical social interactions, with potential for sex-specific effects. Next, we will attempt to replicate and extend these findings using mice with a deletion of *Oxtr* from peripheral sensory ganglia.

Title: Oxytocin modulation in social pair-induced fear behavior

Authors: *M. JANG, T. JUNG, J. NOH;
Dankook Univ., Yongin, Korea, Republic of

Abstract: We previously reported that the pair exposure with conspecific during fear conditioning in adolescent rats helped to cope with both freezing response and fear memory and those effects were correlated with cellular activity in the medial prefrontal cortex (mPFC). Oxytocin can be proposed as a candidate substance for pair exposure effect due to reporting that oxytocin controls social behavior and its receptors are widely expressed in the mPFC but its role for social pair remains unclear. To determine this issue, we performed a passive avoidance test (0.7 mA, 5 s) in pair-exposed adolescent rats treated by oxytocin receptor antagonist atosiban peripherally (via i.p injection) and centrally (injected in mPFC). Peripheral administration of atosiban before learning session significantly increased the freezing behavior and decreased the black room preference in pair exposed rats compared with saline-injected pair rats. Atosiban-injection via stereotaxically implanted guide cannula into the mPFC in pair rats significantly increased the freezing behavior and the step-through latency into the black room compared with ACSF-injected pair rats. Our finding indicates endogenous oxytocin released in paired condition play an important role in the modulation of fear-related behavior and fear memory in adolescent rats.

Title: Modulation of pupillary behavior by oxytocin in mice

Authors: *M. A. GREENWOOD[1], E. A. HAMMOCK[2];
[1]Psychology,Program in Neurosci., [2]Psychology, Florida State Univ., Tallahassee, FL

Abstract: Oxytocin (OXT) is a peptide with important regulatory roles in both physiological and behavioral contexts. OXT binds to the OXT receptor (OXTR) in the central and peripheral nervous systems, with diverse patterns of expression dependent on many variables including but

not limited to species, sex, and stage of development. OXTR have previously been identified in the eye across rodent species. However, the functionality of these receptors has not been thoroughly explored. The aim of this project was to investigate the role of OXTR on pupillary changes under constant luminance. Adult transgenic male and female *Oxt* and *Oxtr* wild-type and knockout mice were used to assess differences in pupillary responsiveness to the topical application of OXT directly to the eye. These assessments in adult mice demonstrated, relative to wild-type mice (n=20), a significantly dilated pupil in OXTR knockout mice (n=9) and a constricted baseline pupil diameter in *Oxt* knockout mice (n=10), which was rescued by the topical application of OXT (n=8). These data support a potential developmental role for OXTR and an activational role for OXT on autonomic regulation in the visual system.

Title: Behavioral effects of an oxytocin receptor antagonist on a mouse modeling the complete deletion of the Williams Syndrome critical region

Authors: *K. R. NYGAARD[1], N. D. KOPP[2], E. MINAKOVA[3], S. E. MALONEY[4], J. D. DOUGHERTY[1];
[1]Genet. and Psychiatry, [2]Genet., [3]Pediatrics, [4]Psychiatry, Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Atypical behaviors, including increased sociability and a propensity for non-social phobias, are hallmarks of Williams Syndrome (WS). Caused by a relatively small genetic deletion, WS thus offers a unique view of the genetic contributions of behavioral phenotypes. While some genes have easily been mapped to the cardiac phenotypes of WS, the neurogenetics underlying the behavioral phenotypes are unknown. Dysregulation of the oxytocin system has been observed in people with WS but the mechanisms behind it and behavioral consequences of it are not well understood. Our objective is to elucidate the mechanisms and consequences of dysregulated oxytocin in WS by examining the effects of an oxytocin receptor antagonist on a mouse model with a hemizygous deletion of the entire syntenic WS critical region. Prior studies in the lab have shown increased oxytocin in the hypothalamus of these Complete Deletion (CD)

mice. As the hypothalamus is critical in fear memory, we chose to examine the behavior of our CD mice in the Conditioned Fear task. In this task, associative learning is examined by measuring freezing behavior in response to pairing both contextual and auditory cues with an adverse stimulus. Blinded to genotypes, I examined the freezing behavior of adult CD and wild-type (WT) mice of both sexes on a C57BL/6J background. The CD mice demonstrated increased freezing to the stimulus during acquisition but showed decreased freezing relative to WT littermates in response to the auditory cue 48 hours later. These data suggest deficits in amygdalar-dependent conditioning in mice hemizygous for the WS critical region. We hypothesized the abnormal freezing response in CD mice was influenced by the dysregulated oxytocin system. To test this hypothesis, CD and WT mice were split into two groups. Both groups were fitted with a cannula to facilitate drug delivery directly to the left lateral ventricle. Half of each group was given an oxytocin receptor antagonist, while the others received a normal saline vehicle solution. We are currently collecting and analyzing the freezing behavior measured in the Conditioned Fear task. In the future, we hope to expand this design to other phenotypes of the CD mice in order to best understand the impact of oxytocin on the various behaviors. These results will help to inform the mechanisms and consequences of oxytocin dysregulation in WS. The knowledge can also help inform other social or anxiety disorders, and mechanisms of oxytocin in general.

Title: Molecular anatomy of oxytocin receptors in peripheral sensory ganglia of neonatal mice

Authors: *R. VAIDYANATHAN, E. A. HAMMOCK;
Psychology, Program in Neurosci., Florida State Univ., Tallahassee, FL

Abstract: Neonatal mice abundantly express oxytocin receptors (OXTRs) in a range of peripheral tissues where circulating oxytocin (OXT) can mediate tissue-specific effects via peripheral OXTR. OXTR-containing regions in the face such as the mandibular and maxillary periodontium, eye, and whisker pads are innervated by sensory afferents of the trigeminal ganglion. Similarly, other OXTR-containing regions in the body such as the anogenital region

and adrenal glands are innervated by the dorsal root ganglia. We have previously identified *Oxtr* mRNA in the trigeminal sensory ganglia (TG) and dorsal root ganglia (DRG) of neonatal mice. In this study we aim to A) refine the anatomy of *Oxtr* in the TG, and B) to determine if peripheral OXTR are synthesized in the peripheral sensory ganglia. Previously, we identified by in-situ hybridization that *Oxtr* mRNA colocalize with different types of sensory neurons in the TG. Mechanosensory neurons (TrkB positive) show the highest co-expression of *Oxtr*, but nociceptive neurons (TrkA positive) and proprioceptive neurons (TrkC positive) show low and moderate levels of co-expression with *Oxtr* in the TG, respectively. In our current study, we use markers for thermoreceptive neurons to identify if *Oxtr* in the TG colocalize with warm or cold-sensitive neural populations. Preliminary data suggest that *Oxtr* co-localizes with thermoreceptive neurons. To address aim B, we selectively eliminate *Oxtr* from sensory ganglia (TG and DRG) using a Cre-lox P approach and quantify peripheral OXTR ligand-binding in the whole body of neonatal C57BL/6J mice. Our preliminary findings suggest that OXTR are not fully eliminated in the periphery due to the deletion of *Oxtr* from sensory ganglia. We predict that some of these peripheral regions will show a decrease in OXTR-ligand binding compared to their WT controls.

Title: Brain wide input output mapping of hypothalamic oxytocin neurons

Authors: *S. SON, Y. KIM;
Dept. of Neural and Behavioral Sci., Col. of Medicine, Penn State Univ., Hershey, PA

Abstract: Oxytocin (OXT) is the evolutionarily conserved neuropeptide in mammals, which is produced by neurons of the paraventricular hypothalamic (PVH) and the supraoptic (SO) nucleus. Many studies have been conducted to show that OXT neurons projected to broad brain regions and the spinal cord, and revealed underlying mechanisms of OXT to the circuit-specific behaviors. However, it is unclear how OXT neurons within the hypothalamic nuclei are topographically organized with regard to input and output throughout the whole-brain. Here, we employed viral vector-based techniques, which combined with adeno-associated virus (AAV) and monosynaptic rabies tracing techniques, to label axonal output and pre-synaptic input of OXT neurons in mice. We imaged the whole mouse brains at cellular resolution using serial two-

photon tomography and used whole-brain data processing pipeline to achieve quantitative input-output mapping of hypothalamic OXT neurons. The OXT neurons of PVH projected dorsally to the lateral zone of hypothalamic and continued into the medulla through the midbrain and the pons. This pathway provides dense input to the substantia nigra, the ventral tegmental area, the periaqueductal gray (PAG), and the parabrachial nucleus. The OXT neurons also projected to the forebrain regions; the nucleus accumbens (ACB), the lateral septal nucleus (LS), and olfactory cortex areas. Both of the OXT neurons in PVH and SO were ventrally projected into the tuberal nucleus (TU), then reached to the median eminence. Rabies-virus-based input mapping indicated that OXT neurons of the PVH received synaptic input from the hypothalamus, the thalamus, and the striatum, while inputs in the SO were mainly from the hypothalamic area. Interestingly, the brain regions previously associated with social behavior, learning, and memory were reciprocally connected, including the ventromedial hypothalamic nucleus, the parasubthalamic nucleus, the lateral hypothalamic area, the central amygdalar nucleus, the bed nuclei of the stria terminalis, the PAG, the LS, and the ACB. In summary, our data established the anatomical organization of OXT neurons in order to understand the neural circuit mechanisms of OXT neurons in regulating different circuit specific behaviors.

Title: Decreased GRIN1 receptor subunit protein expression in the basolateral amygdala of phencyclidine-treated oxytocin knockout mice

Authors: *K. M. RODRIGUEZ[1,3], H. K. CALDWELL[2,3];
[1]Sch. of Biomed. Sci., [2]Dept. of Biol. Sci., Kent State Univ., Kent, OH; [3]Kent State Univ., Brain Hlth. Res. Inst., Kent, OH

Abstract: It is hypothesized that the oxytocin (Oxt) system, known for its neural modulation of social behaviors, may contribute to the social impairments observed in many neuropsychiatric disorders, including schizophrenia. Support for this hypothesis comes from some studies demonstrating that some patients diagnosed with schizophrenia that have higher plasma Oxt levels also have less severe positive symptoms and exhibit fewer social deficits. There is also evidence that genetic polymorphisms of the *Oxt* and *Oxt* receptor (*Oxtr*) genes may also contribute to symptom severity and treatment efficacy in some individuals diagnosed with schizophrenia. Interestingly, Oxt is known to interact with many of the neurotransmitters disrupted in schizophrenia, including dopamine and glutamate; both of which are also important

for the modulation of social behavior. However, how Oxt and these neurotransmitters interact is unclear. The glutamate hypothesis of schizophrenia supposes that the hypo-functioning of N-methyl-D-aspartate (NMDA) receptors are involved in the negative and cognitive impairments of schizophrenia. Work in our lab has found that Oxt knockout (-/-) mice treated acutely or subchronically with phencyclidine (PCP), an NMDA receptor antagonist, have greater impairments in prepulse inhibition of the startle reflex and sociability, respectively, compared to controls. Thus, here we sought to investigate how a PCP model of schizophrenia and genetic disruption of Oxt, i.e. Oxt -/- mice, affected expression of NMDA receptor subunits. Specifically, we focused on GRIN1, GRIN2a and GRIN2b, as genetic polymorphisms in these receptor subunits are correlated with schizophrenia. We found differential expression patterns in brain areas involved in social behavior. Specifically, as compared to controls, PCP-treated Oxt -/- mice had increased *GRIN1* and *GRIN2a* mRNA expression in the basolateral amygdala (BLA). However, protein expression of GRIN1 was decreased in the BLA. Using this mouse model, future work will explore how Oxt and glutamate may interact in the BLA to affect social behavior.

Title: Synapsin Ia regulates the oxytocin release in the hypothalamic-neurohypophysial system of adult male rats

Authors: *C.-T. HUANG[1], E.-C. CHEN[1], C.-T. WANG[1,2,3,4];
[1]Inst. of Mol. and Cell. Biol., [2]Dept. of Life Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan; [4]Genome and Systems Biol. Program, Natl. Taiwan Univ. and Academia Sinica, Taipei, Taiwan

Abstract: Oxytocin (OT), a hormone that regulates delivery and lactation, is synthesized from the magnocellular neurons (MCNs) of paraventricular nucleus (PVN) and supraoptic nucleus (SON) in the hypothalamic-neurohypophysis system (HNS). With the deepening of research, many studies indicated that OT neurons can project their axon terminals into different brain regions, including amygdala, nucleus accumbens (NAc), ventromedial nucleus (VMN), and dorsal vagal complex (DVC), thus regulating emotion, motivation, glucose homeostasis, gastric

motility, and social behavior. However, the molecular mechanism underlying the regulation of OT release remains unclear. In the HNS, the axon terminals of OT neurons contain two types of vesicles, i.e., OT-laden large dense-core vesicles (LDCVs) and microvesicles (MVs) similar to synaptic vesicles (SVs). Although the release from both types of vesicles can be mediated by Ca^{2+}-dependent exocytosis, a specific protein Syn Ia is exclusively expressed in MVs/SVs and regulates the exocytosis through phosphorylation. In this study, we aimed to determine the role of Syn Ia in regulating the OT release from the HNS. First, we designed a series of the OT neuron-specific constructs expressing the exocytosis reporter and Syn Ia (or the Syn Ia mutant). Next, we transfected the SON-OT neurons with these constructs in adult male SD rats by using *in vivo* electroporation. To further detect the expression of these constructs, we performed immunostaining by labeling the exocytosis reporter. As the results, we found that the immunoreactivity of the LDCV-specific reporter (Neurophysin-pHVenus) was relatively localized to the OT immunoreactivity compared to that of the general vesicle reporter (Synaptobrevin II-pHVenus). Furthermore, by using ELISA, we detected the changes in OT level in the plasma of transfected rats before and after *in vivo* electroporation. We found that overexpressing Syn Ia in the SON-OT neurons can increase the OT release to peripheral plasma compared to the control, but overexpressing the Syn Ia mutant cannot. Thus, our results suggest that Syn Ia may regulate the OT release from the HNS.

Title: Water deprivation influences predator-triggered fear response: Finding a causal role for the hypothalamic vasopressin system ascending innervations to limbic regions

Authors: *E. C. GUERRA[1], T. G. PADILLA[1], V. S. HERNÁNDEZ[1], M. C. CÁRDENAS-AGUAYO[1], O. R. HERNÁNDEZ-PÉREZ[1], F. JÁUREGUI[2], S. LUQUÍN[2], L. E. EIDEN[3], L. ZHANG[1];

Abstract: We have previously reported that the hypothalamic vasopressinergic magnocellular neurosecretory neuron (AVPMNN) system possesses ascending projections to the lateral habenula, amygdala, hippocampus and locus coeruleus which may have synapse organizing functions when it is persistently up-regulated. Here, we devised a predator odor + cat exposure test to assess purposeful movement, freezing behavior and Fos expression, comparing C57BL6 mice deprived of water for 24 hours (WD24) with control mice. Inside a hood, mice were housed individually in small wire cages (15cm x 15 cm x 45cm) modified from standard wire cage mice traps. Cat urine material was collected from domestic cat litter boxes and was inserted into 50 mL Falcon tubes. During the experiment, the opened Falcon tubes were introduced individually into each cage while recording mice behavior. After five minutes, a young male cat was introduced to the hood. This procedure lasted 5 min. Perfusion and fixation were performed 90 min later for Fos expression assessment. Predator odor triggered purposeful movements such as approaching and withdrawal from the Falcon tube, but this behavior decreased during the 5 min observation period. The WD group had significantly higher counts of both purposeful movement and immobility during cat presentation. Moreover, Fos expression assessment showed that most of the olfactory pathway, as well as limbic regions such as the dentate gyrus, hippocampal CA3, MPO, BNST, PVN, LS, claustrum, MeA, and CeA, were active with significantly higher level of Fos expression in the WD24 group. Caudate-putamen was unexpectedly active in the WD group. To further elucidate the causal involvement of AVPMNN system, GluR1 and PSD95, two major postsynaptic density proteins expression levels were assayed in the lateral habenula, central amygdala and ventral hippocampus, with semiquantitative immunoblotting in basal, WD24, water deprived for 48 h (WD48) and WD48 + 24 h and 48 h of hydration restoration groups. A statistically significant increase was observed between the basal and WD48 groups in PSD95 expression of the amygdala, lateral habenula, and ventral hippocampus as well as GluR1 expression in the ventral hippocampus. Additionally, using 10 nm AVP, 30 min incubation of ventral hippocampus acute slices, significant pERK expression was observed with Western blot. This data suggests that thirst, an internal water-electrolytes imbalance due to water deprivation, which potently up-regulated the AVPMNN system as one of the main homeostatic mechanisms, could modify neuronal activation patterns in both sensorial and limbic systems to determine a behavioral response to facilitate survival.

Title: OXTR and AVPR1A polymorphisms are associated with religious experience in a functional neuroimaging genetic study

Authors: *L. DAI[1], J. KING[2], M. FERGUSON[2], J. NIELSON[2], H. NAZARLOO[5], C. CARTER[6], J. S. ANDERSON[3], J. R. KORENBERG[4];
[1]Brain Istitute, Dept. of Pediatrics, [2]Dept. of Radiology, Univ. of Utah, Salt Lake City, UT; [3]Neuroradiology, [4]Brain Institute, Dept. of Pediatrics, Univ. of Utah, Salt Lake Cty, UT; [5]The Kinsey Inst., Bloomington, IL; [6]Kinsey Inst., Bloomington, IN

Abstract: The origins of religious experience remain controversial. The relationship between self and other, whether beings or dieties, is a concept common to social science and religious philosophy. Therefore, the brain systems mediating these may overlap, suggesting the social neuropeptides oxytocin (OT), arginine vasopressin (AVP) and their receptors, the OXTR and the V1a, respectively, may also be involved in the brain networks of religious experience. In our prior studies, we have shown that endogenous OT, but not AVP, was associated with BOLD imaging in anterior and posterior cingulate cortex, ventromedial prefrontal cortex and anterior insula, the hubs of default mode and paralimbic networks that are involved in self-awareness and self-other, when individuals felt the Spirit. In this report, we explored the hypothesis that the genetic variance of the receptors, OXTR and AVPR1A, might be independently associated with specific brain substrates in response to three religiously evocative tasks, and combined with self-experience reports, in a cohort of individuals trained to report spiritual responses. Our results showed that DNA polymorphisms of OXTR (rs2254298, rs2268498) were associated with left dorsolateral prefrontal cortex, right inferior parietal and left posterior cingulate cortex. The AVPR1A promoter-region microsatellite repeat length of RS3 was associated with right ventrolateral orbitofrontal cortex. These brain substrates were also involved in default mode network, self-other and high cortical processes, suggesting the genetic variance, present for birth, possibly acting throughout development, and the other, reflecting the variable interaction and results of a spectrum of developmental and experiential events. Putting together with our prior studies, these results indicate that both the original state of the receptors, and the endogenous peptide, are involved in religious experience, most strongly in regions involved in early developing brain systems but also with the later appearing brain systems for the more complex aspects of self involving others.

Title: Sexually dimorphic control of parenting behavior by the medial amygdala

Authors: *R. K. HU, P. B. CHEN, Y. E. WU, L. PAN, S. HUANG, P. MICEVYCH, W. HONG;
UCLA, Los Angeles, CA

Abstract: Social behaviors encompass a broad set of behaviors critical for the survival and well-being of an individual. The diverse catalog and contextual display of social behaviors can greatly vary between the sexes, and disruption of social behaviors, which is a prominent feature in psychiatric disorders, often appears in a sexually dimorphic manner. A major challenge in neuroscience lies in understanding how sex differences, from molecules to circuits, synergistically contribute to sex differences in behavioral displays. Parenting and infanticidal behaviors are opposing pup-directed behaviors that are sexually dimorphic. Although studies have implicated the medial preoptic area as a key region for regulating parental behaviors, little is known about the contribution of other brain regions beyond the medial preoptic area in parenting, and even less is known about brain regions regulating infanticidal behavior and its relationship to parenting.
The medial amygdala (MeA) is a sexually dimorphic brain region involved in adult-directed social behaviors. A longstanding view is that the MeA is not part of the main circuitry that promotes parenting behavior towards pups, but may be involved in suppressing parental behaviors. In this study, we establish a sexually dimorphic role for the MeA in regulating pup-directed behaviors. Contrary to traditional views, activation of GABAergic neurons in the posterodorsal region of the MeA (MeApd) actually promotes parenting in females, whereas GABAergic neurons in males regulate both parenting and infanticidal behavior in an activity level-dependent manner. In contrast, glutamatergic neurons in the MeApd exert the same effect on both males and females in promoting self-grooming behavior. Using single-cell RNA

sequencing, we comprehensively characterize cell type heterogeneity and transcription profiles in the MeA between males and females, and find that sex differences are specifically represented in GABAergic neurons. This supports a sex-specific role for GABAergic neurons, but not glutamatergic neurons, in behavioral and circuit functions. Collectively, these findings demonstrate that GABAergic neurons in the MeApd control parental and infanticidal behaviors in an activity level-dependent, sexually dimorphic manner, and provide important insight into the connection between sex differences at the levels of molecules, cells, and circuits in regulating sexually dimorphic behaviors.

Title: Effects of corticosterone and estrogen on HPA axis activity and telomeres length in brain areas of female rats

Authors: P. C. G. BARCELLOS[1], L. C. ZANELATTO[2], B. A. A. S. LEMOS[3], R. T. C. SALOMA-RODRIGUES[3], *C. R. FRANCI[1];
[1]Physiol., Ribeirao Preto Med. School, USP, Ribeirão Preto, Brazil; [2]Intrnl. Med., Ribeirão Preto Med. School, USP, Ribeirão Preto, Brazil; [3]Intrnl. Med., Ribeirão Preto Med. Sch. , USP, Ribeirão Preto, Brazil

Abstract: The telomeres are structures present at the endings of chromosomes and act to stabilize the DNA during cell division. Throughout the aging telomere shortening undergoes a process, but other factors can enhance this process, such as chronic stress. Chronic stress induces changes in the functioning of an organism, including increased glucocorticoid levels, which may affect physical and psychological state, such as anxiety and depression. Recent work correlates chronic psychosocial stress to the reduction of the telomere length of certain cells and estrogen may also influence telomere repair. However, it is unclear whether increased glucocorticoid concentrations influence telomere length in brain tissue cells. The objective of this study was to verify whether chronic exposure to glucocorticoids promotes changes in telomere length of encephalic areas involved in the control of hypothalamic-hypophysis-adrenal (HPA) axis activity

and whether estrogen modulates these changes. Methods: Wistar female rats were ovariectomized and daily treated with estrogen cypionate, at doses of 50 and 100 ug/kg. The animals were subdivided into treated with corticosterone or its respective vehicle for 28 days. On the day following the end of corticosterone injections, the animals were sacrificed by decapitation to the withdrawal of blood samples, brain, and pituitary. Plasma corticosterone, progesterone, luteinizing hormone, follicle stimulating hormone, and estradiol were determined by radioimmunoassay. Results: Treatment with estrogen increased the secretion of corticosterone (326.03±32.99 / 361.20±34.87 ng/mL) and progesterone (5.53±0.85 / 5.47±1.26 ng/mL), compared to their respective control group treated with oil and saline (134.70±6.12 ng/mL /1.05±0.15 ng/mL) The combined treatment maintained of estrogen and corticosterone maintained plasma corticosterone and progesterone similar to the control treated with oil. mRNA levels for CRH, AVP, and POMC were reduced by estrogen. The telomeres length in the paraventricular nucleus was not altered by corticosterone and estrogen, but in the central amygdala and dorsal hippocampus, estradiol cypionate shortened telomeres of the cells in the brain nuclei. Thus, the treatment with corticosterone did not alter the length of telomeres, and estrogen doesn't have a protective factor in the brain tissue of the central amygdala and the dorsal hippocampus. Financial support: CAPES, CNPq and FAPESP agencies from Brazil.

Title: Early life stress induces changes on specific brain areas for cognitive and motivational functions: Inside the multimodal effects of maternal separation in C57BL6J mice

Authors: *G. TALANI[1], D. COLOMBO[2], E. SAOLINI[2], G. M. CALANDRA[2], F. BIGGIO[2], G. BIGGIO[2,1], E. SANNA[2,1];
[1]Natl. Res. Council, Cagliari, Italy; [2]Univ. of Cagliari, Cagliari, Italy

Abstract: Stress occurring early in life may be predictive for the development of neuropsychiatric disorders as well as increased vulnerability to drug use disorders in adulthood. Repeated maternal separation (RMS) in rodents is a powerful model to investigate the consequences of neonatal stress on brain plasticity and vulnerability to ethanol (EtOH) abuse. Here we extended our recent findings about the potential mechanisms involved in the long-term

effects of RMS in C57BL/6J adult mice by evaluating the changes in neuronal plasticity at both GABAergic and glutamatergic synapses in the hippocampus (hip) and nucleus accumbens (NAcc), areas involved in learning and memory function and drug reward, respectively. Patch-clamp experiments performed in the hip revealed that RMS causes a significant enhancement in the tonic component of the GABAergic inhibition in dentate gyrus granule cells from male, but not females, mice. RMS is also accompanied in males by a marked increase in the frequency of GABAergic IPSCs recorded in the same neurons. Interestingly, all these changes induced by RMS were paralleled by an impairment in LTD formation in the CA1 subregion in male but not in female mice, an effect that may involve an increased function of the endocannabinoid system and which was accompanied by an impaired cognitive performance in the Barnes maze test. RMS is also associated in males with a marked increase of EtOH intake and preference in the two-bottle free choice paradigm, while in females this result is not statistically relevant. We observed a significant RMS-induced changes in synaptic plasticity with a reduction of LTD formation in the NAcc MSNs, an effect that is accompanied with an impairment of the AMPA/NMDA ratio. Interestingly, these functional and behavioral changes were no longer appreciable in RMS male mice when treated with a single injection of beta-ethinylestradiol at PND3, suggesting that alteration in the hormonal asset may strongly influences the neuronal and behavioral impairments induced by RMS. Taken together, these findings demonstrate that RMS is associated with long-lasting effects on synaptic plasticity in both hip and NAcc of C57BL/6J male mice, alteration of learning and memory as well as goal directed behavior. In line with previous findings, our data may support a gender-dependent effect of RMS. Supported by CNR-DISVA-Sardegna Ricerche

Title: Effects of maternal separation paired with juvenile social isolation on adult anxiety-like behavior and perineuronal net-ensheathed parvalbumin interneurons in male and female rats

Authors: *K. R. GILDAWIE, J. A. HONEYCUTT, H. C. BRENHOUSE;
Psychology, Northeastern Univ., Boston, MA

Abstract: Exposure to early life adversity leads to behavioral and neurological dysfunction, and increased vulnerability to a multitude of neuropsychiatric and inflammatory disorders, such as depression, anxiety, and schizophrenia. Notably, clinical studies demonstrate an additive effect of adversity, where repeated stressful life events throughout childhood results in more severe neuropsychiatric symptoms. It is not understood, however, whether differential timing of later stressors alters the neurobiological consequences of early life adversity in a sex-dependent manner. Research demonstrates that the formation of perineuronal nets (PNNs) - which preferentially enwrap fast-spiking parvalbumin (PV)-expressing interneurons - is essential for proper neurodevelopment. PNNs exhibit delayed and protracted formation throughout the brain, gradually maturing from the postnatal time period through early adulthood. We have previously observed that adversity during developmental periods where PNNs are not yet fully formed could disrupt the formation of PNNs surrounding PV+ cells in the prefrontal cortex (PFC). To further investigate the later-life behavioral and cellular implications of multiple developmental stressors, male and female rat pups underwent maternal separation (MS) for 4 hours per day from postnatal day (P) 2-20 (or control rearing), followed by juvenile social isolation (SI) from P21-35 (or standard pair-housing). SI rats were then pair-housed with cage mates matched for sex, age, and experimental group until early adulthood (P70), when anxiety-like behavior was measured using the open field test and elevated zero maze. At P85, rats were perfused and brains were collected, cryoprotected, and sliced on a freezing microtome to 40 µm slices. Tissue sections containing the prelimbic (PL) and infralimbic (IL) PFC were stained using *Wisteria floribunda* agglutinin, anti-PV antibody, and NeuroTrace (for layer specificity analyses). Z-stacks were obtained (6 stacks per section) using fluorescent microscopy in 3 consecutive sections of the PFC and the FIJI macro plugin PIPSQUEAK was used to quantify the number and intensity of PNNs, PV cells, and PNNs ensheathing PV cells. We present findings elucidating the association between adult PFC PNN dysfunction and enhanced anxiety-like behavior following multiple instances of adversity throughout development. These data provide critical information regarding the differential windows of vulnerability to chronic stress exposure in males and females, which have the potential to aid in the development and application of interventions for children who have experienced early life adversity.

Title: Early life stress in mice causes a change in the excitation-inhibition balance in prefrontal cortex neurons during development

Authors: *H. KARST[1], L. I. VAN MOURIK[1], M. JOELS[2];
[1]Univ. Med. Ctr. Utrecht, Utrecht, Netherlands; [2]Univ. Med. Ctr. Groningen, Groningen, Netherlands

Abstract: The excitation-inhibition (EI) balance plays an important role during maturation of the brain. A disturbance of the balance is thought to predispose to the development of psychiatric disorders. Early life stress (ELS) can cause impairments in cognitive and a variety of behavioral functions later in life. It is hypothesized that a disturbance of the EI balance may contribute to these abnormalities. In this study we followed the EI balance during maturation by recording the glutamatergic and GABAergic transmission from neurons of the mouse infralimbic medial prefrontal cortex (imPFC) layer 2/3. Mice were exposed from postnatal day (P)2 until P9 to the limited nesting and bedding model. At P9, P15, P21 (weaning), at 6 weeks (adolescent) and at 10-12 weeks (adult) male mice were used for in vitro electrophysiology. We recorded miniature excitatory (mEPSCs) and inhibitory currents (mIPSCs) in the same neurons. This was done by recording the mEPSCs at -65 mV, the reversal potential for GABA (chloride) currents and by recording the mIPSCs at +10mV, the reversal potential for glutamate currents. Compared to the control mice, the mEPSC frequency in imPFC neurons of ELS mice was remarkably decreased at P9 and P21. The frequency of the mIPSCs, however, was not affected after ELS. When calculating the EI balance by dividing the frequency of the mEPSCs by the frequency of the mIPSCs, the balance was considerably lower in ELS mice. Later in development, from adolescence onwards, the effect of ELS on the EI balance was not detected anymore. An important property of the GABAergic transmission during development is the GABA-switch, the moment when GABA switches from being excitatory to inhibitory, caused by a shift in the reversal potential (Erev) of chloride. We recorded the GABA-switch in slices of ELS and control mice with the perforated patch clamp technique by measuring the Erev for chloride. In control mice, the switch takes place around P14 in the imPFC neurons. In ELS mice the switch takes place earlier, already at P9, but perhaps even sooner, during the ELS period from P2 until P9. Most likely a change in the expression or phosphorylation of the Chloride co-transporters, NKCC1 and KCC2 is responsible for this effect, which we are currently investigating. We conclude that the EI balance in ELS mice is changed early in life, by 1) a decrease in the glutamate transmission and 2) by a shift of the GABA-switch towards an earlier moment in life, both effects probably resulting in a suppression of the excitability.

Title: Maternal presence/absence during early-life immune challenge: Effects in pups and dams

Authors: *S. CASTANY[1], J. ZAJDEL[1], A. ZAGER[2], A. BLOMQVIST[2], K. SHIONOYA[2], D. ENGBLOM[1];

Abstract: Maternal-infant interactions profoundly affect the ability of the pups to respond to different kinds of stressors. Stressors such as maternal separation and early-life sickness may have an impact on the hypothalamic-pituitary-adrenal (HPA) axis and brain function of both pups and dams. We examined how maternal separation affected inflammatory gene expression and corticosterone response in mouse pups (8-9 days old) after an acute immune challenge induced by lipopolysaccharide (LPS; 40 μg/kg ip). Maternal separation robustly potentiated the hypothalamic expression of IL1β, IL6, TNFα, COX2, CCL2 and CxCL10, as well as the corticosterone response, seen 3 hours after immune challenge. Such separation-induced potentiation of the inflammatory response and the resulting HPA-axis activation may have detrimental effects if the separation is prolonged or repeated. Little is known about how having sick pups affects the mothers/dams. To address this question, we examined if LPS-induced inflammation in pups elicited hypothalamic inflammatory signaling also in their dams. Surprisingly, systemic inflammation in pups led to an induction of inflammatory gene expression in the hypothalamus of their dams. This was accompanied by HPA axis activation. The induction of inflammatory signaling in dams did not require physical contact with the LPS-injected pups. Collectively, our results highlight how bidirectional mother-infant interaction can modulate the inflammatory response.

Abstract: Maternal stress during pregnancy and during early parenting may program physiological responses and lifetime trajectories of the infant, interact with genetic liabilities and early-life challenges and determine ultimate health status. Seeking a prenatal measure with a preventive clinical significance, we hypothesized that the coordinated roles of the autonomic nervous system (ANS) and the hypothalamic-pituitary-adrenal axis (HPA) in the integrated stress response may be monitored by measuring several maternal and fetal molecular and biophysical biomarkers. We performed a prospective study in stressed mothers with controls matched 1:1 for parity, maternal age and gestational age at study entry. Pregnant women were administered the Cohen Perceived Stress Scale questionnaire (PSS-10), which categorized them as Stressed Group (SG) for PSS-10 score ≥19. The extent of coupling between maternal and fetal heart rate (mHR, fHR) derived from maternal abdominal ECG was quantified. Assessment by the bivariate phase-rectified signal averaging algorithm (BPRSA) yielded fetal stress index (FSI) values. On the day of parturition, maternal blood and hair strands from the posterior vertex region on the head were collected for cortisol measurements. Cord blood samples and saliva/buccal samples from the newborns were also collected. Maternal and newborn serum was used to measure acetylthiocholine hydrolytic activity of acetyl- and butyrylcholinesterases (AChE, BChE). Infants' cognitive development was assessed by Bayley Scale III of Infant Development (BSID) at 24 months of age when a new saliva sample was taken to be processed for epigenetic biomarkers. Preliminary results show that prenatal maternal stress identified in the third trimester by PSS-10 has an impact on the coordination of fetal and maternal heart rate (captured by FSI) and on fetal oxygenation at birth. Machine learning approaches (with internal validation) indicated that the fetal AChE/BChE ratio is predicted best by joint fetal-maternal stress biomarker FSI, but not by maternal stress levels alone. In conclusion, the maternal and fetal stress status may be shaped by both maternal cortisol and the maternal and fetal AChE/BChE balance, validating our hypothesis that PS-induced programming is reflected in mHR and fHR biomarkers of ANS activity.

Title: Neonatal pain has lasting effects on fear, anxiety, and somatosensory function through changes in amygdala CRF signaling

Authors: ***S. M. DAVIS**[1], J. ZUKE[1], E. RUSSO[1], D. PADMANABHAN[1], M. A. BURMAN[2]; [2]Psychology, [1]Univ. of New England, Biddeford, ME

Abstract: Human infants in the neonatal intensive care unit (NICU) are exposed to a variety of stressful and painful events and are more likely to suffer from conditions such as chronic pain, anxiety and depression. Our lab has adapted rodent models to investigate the behavioral and neurobiological mechanisms underlying these changes. In particular, rats received either 4 left hindpaw pricks per day for postnatal days (PNDs) 1-7 or 2% lambda-carrageenan injections on PND 1 and 4. Contextual and auditory fear conditioning, elevated plus maze behavior, and somatosensory function were assessed in late childhood (PND 24), adolescence (PND 45), and adulthood (PND 66) in male and female rats. Contrary to our initial hypothesis, we found reductions in auditory fear conditioning across the lifespan in rats exposed to neonatal pain. In addition, we observed reduced anxiety, but enhanced stress-induced tactile hypersensitivity in PND 24 rats exposed to neonatal pain. The stress-induced tactile hypersensitivity was reduced by administration of a CRFR1 antagonist either systemically during neonatal stress on PND 1-7 or intra-amygdala during the activating stressor on PND 24. In addition, a subset of subject's brains were collected on PND 6 and underwent florescent *in situ* hybridization (RNAScope®) for corticotropin releasing factor (CRF) and c-Fos to examine the acute effects of neonatal pain. Expression was examined using automated thresholding and quantification, which revealed that neonatal pain significantly enhanced CRF signaling in the amygdala, but not hypothalamus in male, but not female, rats. All together, these experiments provide evidence that amygdala CRF signalizing is at least one mechanism by which neonatal pain and stress have lasting effects of affective and sensory function.

Title: Developmental-stage dependent behavioural and neurochemical deficits produced by embryonic ethanol exposure in zebrafish: A model for FASD

Authors: *A. FACCIOL[1], C. BAILLEUL[2], S. NGUYEN[2], R. T. GERLAI[3];
[1]Cell and Systems Biol., [2]Biol., [3]Psychology, Univ. of Toronto Mississauga, Mississauga, ON, Canada

Abstract: Fetal Alcohol Spectrum Disorder (FASD) is a disease category that encompasses a large number of deficits resulting from the consumption of alcohol by pregnant women. Symptoms of FASD include morphological, behavioural and cognitive deficits, however, the expression and severity of these deficits is highly variable. One hypothesis for this variability is the varying developmental stage at which alcohol was administered. Although ethanol induced developmental stage-dependent deficits have been investigated in zebrafish, these studies focused on the use of high doses of and/or prolonged exposure to ethanol. While such exposure regimens do produce robust alterations, short exposure to low doses of ethanol will more accurately mimic the mild and more prevalent forms of FASD. To investigate the developmental stage-dependent effects of mild ethanol exposure, we exposed zebrafish embryos to 1% ethanol for 2 hours at one of six key developmental stages: 5 hours post fertilization (hpf), 10hpf, 16hpf, 24hpf, 36hpf and 48hpf. A “No exposure” group was also included to control for the procedure of exposure itself. Following exposure to alcohol or freshwater, zebrafish were raised normally to 1 month of age, at which they were behaviourally tested in an open tank to analyze ethanol-induced alteration in locomotor and anxiety-related behaviours. Following behavioural analysis, brains were dissected and analyzed for neurotransmitter levels, specifically dopamine, serotonin and their metabolites, via HPLC. Although results show no significant effect of ethanol exposure on behaviour in 1 month old fish, neurochemical analysis revealed a developmental stage-dependent decrease in all neurotransmitters analyzed. Specifically, dopamine, serotonin and their metabolites were all lower in ethanol exposed zebrafish compared to control fish but only with exposure at 10, 16 and 24hpf. This study, together with previous studies modeling FASD in zebrafish, suggest that although 1 month of age may be too young for detection of behavioural deficits, the deficits manifest at the neurochemical level. Additionally, the deficits found here in 1 month old fish are concordant with embryonic ethanol-induced neurochemical deficits reported

in adulthood. This study is the first to investigate the developmental stage-dependent effects of short, low dose ethanol on both behavioural and neurochemical phenotypes.

Title: Maternal separation and monosodium glutamate intake don't affect spatial memory, but increase weight gain and water intake in male Wistar rats

Authors: C. SIERRA[1], *Z. DUENAS[2];
[1]Univ. Nacional, Bogota, Colombia; [2]Univ. Nacional De Colombia, Bogota, Colombia

Abstract: Humans and rodents, like most mammals, share in the early stages of life a bond given by the mother-child relationship, where it has been shown that disruption generates negative effects on the later life of the offspring in the short, medium and long term, altering the neuroendocrine and behavioral response. Monosodium glutamate (GMS) is a food additive widely used to enhance and improve food acceptance, in addition, it has been related to neurotoxicity and long-term consequences in animal models. The objective of this study was to determine if maternal separation during breastfeeding (MSDB) influences the consumption of MSG and whether these two factors produce changes in learning, spatial memory, weight and water intake of separate male rats; compared to their control group. The MSDB protocol was performed from day 1 to 21 of life for a period of 360 minutes daily: 180 in the morning and 180 in the afternoon, during the dark phase. The control group was the animals that did not undergo the maternal separation protocol, nor did them receive GMS. On the postnatal day 30 the animals previously assigned started treatment with MSG. Four work groups were managed: Control group: males without GMS and without maternal separation (n = 7): males with MSDB and GMS (n = 12), males without MSDB and with MSG (n = 11), and finally males with MSDB and without MSG (n = 10). During one month, the GMS groups were awarded two bottles with the same amount of water, one containing the GMS and the other just water, which was changed every 2 days. GMS every 24 hours, body weight every 3 days, and finally day 60 rats were exposed to the widely valid Barnes maze. It was found that animals subjected to the MSDB paradigm, an increase in the consumption of MSG, possibly related to an increase in weight found in the same experimental group. Additionally, in the learning and retrieval tests, significant differences were not found for individuals who were exposed to the MSDB paradigm, but them tending to perform worse in spatial memory tests when compared to their respective controls. The results indicate that early stress may be associated with changes in eating patterns

as well as some cognitive impairments, considering that MSG may possibly be associated with the cognitive performances shown in this study.
Key words: Maternal separation, monosodium glutamate, early stress, spatial memory, Barnes Maze

Title: Effects of social subordination and consumption of an obesogenic diet on total brain size and structural development of cortico-limbic regions: A longitudinal study in infant and juvenile macaques

Authors: *M. H. KYLE[1,2], A. KALDAS[1,2], M. PINCUS[1,2], J. GODFREY[1,2], Z. KOVACS-BALINT[2], E. L. MORIN[1,2], D. DE LEON[2], L. LI[1], B. R. HOWELL[3], M. A. STYNER[4], C. PAYNE[1], K. ETHUN[2], M. E. WILSON[1,2], M. SANCHEZ[1,2];

Abstract: Although child obesity rates in the United States continue to rise, our understanding of the neurodevelopmental impact of obesogenic diets remains limited. Obesity in children is commonly comorbid with chronic psychosocial stress, which is associated with neurobehavioral alterations and is itself a cumulative risk factor for obesity. It remains poorly-understood, however, how psychosocial stress interacts with consumption of obesogenic diets to affect brain development, and which biological mechanisms underlie these effects. This study longitudinally investigated the potential synergistic impact of postnatal exposure to psychosocial stress and consumption of an obesogenic diet on brain development in female rhesus macaques, while examining underlying biological signals. We used a translational macaque model of social

subordination stress, and followed 41 female rhesus monkeys (n=21 dominant, n=20 subordinate) with access to a low-calorie diet (LCD) only, or to both a LCD and an obesogenic, calorically dense diet (HCD; Choice condition) from birth. Food intake was recorded continuously using automated feeders. Brain structural MRI data was collected during infancy (at 2 weeks, 6 months) and in the juvenile, pre-pubertal period (16 months). Physiological measures of chronic stress activation (hair cortisol accumulation), inflammation (C-reactive protein; CRP), body weight, and kilocalories (Kcals) consumed from each diet were collected in parallel. Subordinate animals had higher CRP levels, and subjects with access to a HCD consumed more Kcals than LCD subjects, but there were no group differences in body weight at any age. Subjects who consumed a HCD had larger overall brain size (intracranial volume; ICV), prefrontal cortex (PFC), insula (INS), and amygdala (AMYG) volumes than those on the LCD. Subordinate animals had larger AMYG, PFC, and hippocampus (HIPP) volumes than dominants, and the overall AMYG growth rate was predicted by cumulative exposure to CRP. Cumulative HCD Kcal consumption predicted PFC and INS growth rates. Our findings suggest that postnatal consumption of an obesogenic diet has robust effects on global brain growth during early development, and that diet and social subordination have region-specific, non-synergistic effects on primate neural development that first appear during infancy and are predicted by inflammation and HCD Kcal consumption.
We are currently analyzing effects of diet and subordination on the development of PFC subregions and the nucleus accumbens, and will also probe maternal Kcal consumption and dosed relative rank as predictors of structural brain alterations.

Title: Disrupted development: An investigation of post-natal restricted resources on neurobiological, behavioral and morphological outcomes

Authors: *M. H. KENT[1], K. LAMBERT[1], G. BOWEN[1], S. DESINOR[1], D. VAVRA[1], K. SCIANDRA[1], K. GILLENWATER[1], C. GLORY[1], E. MEISEL[1], R. OLIVARES-NAVARRETE[2], J. PIETZER[2];
[1]Univ. of Richmond, Richmond, VA; [2]Virginia Commonwealth Univ., Richmond, VA

Abstract: The quality of maternal care depends on the availability and quality of necessary resources. Accordingly, limited environmental resources may result in atypical maternal care, disrupting various developmental outcomes of her pups. On postnatal day (PND) 1, maternal Long-Evans rats in the current study were randomly assigned to either a standard resource (SR) group, provided with 4 cups of bedding and 2 paper towels for nesting material, or a limited resource (LR) group, provided with a quarter of the bedding/ nesting materials given to the SR group. Offspring were observed daily and handled weekly to record developmental measurements such as weight, timing of eye-opening, and various morphological measures. After weaning (PND 21), pups were standard housed in same-sex dyads for continued observations. Subsequent behavioral tests revealed a sex by resource interaction in play behavior on PND 28; specifically, SR reduced play attacks in males while it increased play attacks in females. A sex x resource interaction was also observed in anxiety responses in the open field task with SR resulting in more exploratory rear responses in males and, in contrast, fewer rear responses in the females. No effects were observed in a spatial learning task. Focusing on morphological variables, tail and foot length measurements of LR males and females were shorter on PND 7, 14, 21, and 28 but was no longer present after PND 35. Following the behavioral assessments, animals were perfused at 56 days of age so that the brains could be prepared for immunohistochemical assays for the presence of glucocorticoid receptors, microglia, and oxytocin. Interestingly, the same sex x resource interactions were observed as trends in levels of oxytocin and microglia immunoreactivity. Specifically, in the medial forebrain bundle and supraoptic nucleus, LR increased oxytocin-ir in males while decreasing it in females. Further, tail vertebrae were assessed by micro CT. Vertebrae from LR showed an increase in trabecular separation and decrease in bone volume and bone connectivity resulting in lower bone density. Tail tendons showed a decrease in hydroxyproline suggesting a decrease in collagen content in the LR animals. Thus, although the restricted resources only persisted for a brief duration, the effects appear to be far-reaching and pervasive. Considering that 45% of children across the world are raised in impoverished conditions characterized by restricted resources, it is important to explore long-term effects in human experiencing early life stress.

Title: Effects of neonatal procedural pain and reduced maternal care on brain development and cell proliferation in male and female rat pups

Authors: B. M. TIMMERMAN[1], S. M. MOONEY-LEBER[2], *S. BRUMMELTE[1];
[1]Psychology, Wayne State Univ., Detroit, MI; [2]Penn State Univ., University Park, PA

Abstract: Preterm birth accounted for almost 10% of all U.S. live births in 2016. Children born preterm often display impaired cognitive, behavioral, motor, and neural development compared to full-term peers. Prior studies have found a relationship between these alterations and the number of neonatal stressors that preterm infants experience. Utilizing a rodent model, our study investigated how stressors that preterm infants commonly experience in the Neonatal Intensive Care Unit, particularly procedural pain and reduced maternal care, may alter brain development. Male and female rat pups were bred in-house and culled on the day after birth (postnatal day one (PD 1)) so litters had equal numbers of male and female pups. Pups received either repeated needle insertions into their paws (pain group) or stimulation with a paintbrush (touch control). Afterwards, pups were placed back in their home cages either within a tea-ball infuser for 30 minutes to reduce maternal care (isolation) or on the nest with littermates (no isolation). This resulted in the following four groups within each litter (n=8): pain, pain + isolation, touch, touch + isolation. This stress exposure was performed in 4 sessions per day from PD 1 - 4. Animals were sacrificed at PD 8 and brain sections were processed via immunohistochemistry for Ki67, a marker of cell proliferation. Preliminary results suggest that pups that received pain plus isolation had significantly lower cell proliferation in the dentate gyrus compared to pups in the touch plus isolation group. Our findings may indicate that neonatal pain and isolation have a synergistic effect on cell proliferation in the dentate gyrus of 8-day-old rat pups. Future research will investigate additional markers of brain maturation as well as explore the consequences of these early life stressors once animals reach adulthood.

Title: Effect of enriched early environments and lipopolysaccharide treatment on retrotransposon expression in stress-sensitive brain regions

Authors: *A. A. AIKEN[1], A. C. KENTNER[2], R. G. HUNTER[1];
[1]Psychology, Univ. of Massachusetts Boston, Boston, MA; [2]Sch. of Arts and Sci., Massachusetts Col. of Pharm. & Hlth. Sci., Boston, MA

Abstract: Environmental enrichment has been observed to both protect the brain and attenuate responses to varied stressors. In the present study, an animal model of maternal immune activation (MIA), which has been associated with a variety of neurodevelopmental defects, was utilized as a stressor. Further, the potential involvement of epigenetic mechanisms was analyzed as they may serve as a means to induce lasting physiological and behavioral changes following stress exposure. Previous work in our lab found that short interspersed elements (SINEs) are repressed epigenetically after acute stress, giving rise to the concept that the mammalian genome may be regulating retrotransposon RNA expression in response to environmental challenges. Thus, SINE RNA expression may be adaptive, an idea supported by observations demonstrating regulated B2 SINE expression in response to restraint stress and heat shock. Once thought of as "junk", transposons have now been linked to multiple nervous system disorders including post-traumatic stress disorder and schizophrenia. As a disorder that is characterized by developmental neuroinflammation and high retrotransposon activity, schizophrenia may, in fact, result from environmental stressors (e.g. MIA) that alter retrotransposon activity in the developing brain. To test for potential effects of housing environment on neural responses to a developmental inflammatory insult, Sprague-Dawley rats were housed and bred in either standard animal care control, social control, or enriched environment housing. On gestational day 11 dams were administered either saline or lipopolysaccharide (LPS) to provide an inflammatory challenge and brains were obtained from male and female offspring on postnatal day 21. Preliminary results revealed dysregulation of B2 in the medial prefrontal cortex, medial preoptic area, and hippocampus indicating B2 involvement in response to the gestational LPS stressor in these regions compared to saline-treated controls. We anticipate that EE housing will ameliorate the observed effects of LPS on B2 expression in order to further regulate the stress response.

Title: Maternal-fetal reactions to acute emotional stress in prenatal depressed mothers: Correlations with fetal biomagnetometry measures

Authors: *P. CHANDRA[1], A. OYETUNJI[2], K. GUSTAFSON[3];
[1]Univ. of Missouri Kansas City, Kansas City, MO; [2]Truman Med. Ctr., Kansas City, MO; [3]Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Introduction: Perinatal maternal stress is now known to have negative programming effects on fetal neurodevelopment, which may be the origins or precursors of neuropsychiatric problems, as postulated by the 'fetal programming hypotheses'. But the underlying mechanisms are not well understood. The autonomic nervous system (ANS) regulates maternal physiologic reactions to unpleasant conditions or perceived threat by altering sympathetic and parasympathetic input but there is limited evidence that the fetus responds to maternal emotional or autonomic state in real-time. The aim of the study is to determine if maternal autonomic reactivity induces a similar response in the fetus. If confirmed, the results would support a model of *in utero* programming; suggest underlying mechanisms by which maternal stress affects fetal outcomes. **Methods:** Fifteen pregnant women between 30-32 weeks gestation, with history of perinatal depression and fifteen control subjects are participating in the study. Simultaneous maternal-fetal magnetocardiograms (MCG) were recorded while women viewed a series of photos with validated emotional valence that ranged from neutral, pleasant, unpleasant and threatening. Simultaneous maternal-fetal biomagnetometry was recorded and subjected to independent component analysis (ICA) to extract and separate maternal and fetal MCGs and other fetal signals. Time-frequency plots were used to assess maternal and fetal autonomic reactivity. **Results:** Our findings noted a typical maternal ANS response with increased vagal input during neutral and pleasant pictures and increased sympathetic input during unpleasant and threatening pictures. Some subjects showed an atypical maternal ANS response with chronic hyper-sympathetic response, low ANS reactivity, high stress index, and reduced sympatho-vagal interaction. We noted that depressed maternal and fetal pairs had a maternal HR and sympathetic drive increased with negative valence of pictures. Fetal HR mirrored maternal HR. Also, fetal breathing movements resulting in increased vagal drive occurred at initiation of unpleasant pictures, and lower HR during threatening pictures. **Conclusions:** These data establish a link between maternal and fetal ANS reactivity that occurs while women view pictures designed to evoke emotional responses. These data support our hypothesis and suggest that maternal emotion and physiologic reactions related to stress may have a direct effect on the autonomic reactivity and neurodevelopment of the fetus. The information gained from the study would help to identify at -risk fetuses and support early intervention during pregnancy.

Title: The impact of early developmental stress on anxiety, cognition, and inflammation in adulthood

Authors: *C. HAGEN, J. FIGG, K. BRICE, J. PETERMAN, G. BOEHM, M. CHUMLEY; Texas Christian Univ., Fort Worth, TX

Abstract: It has been widely established that psychological stress has the potential to negatively impact brain health through a variety of mechanisms. Both chronic and acute stress have been shown to alter the inflammatory response which has implications for the progression of neurodegenerative diseases like Alzheimer's disease. This study aims to investigate the effects of stress during early development, specifically maternal stress during pregnancy and its impact on anxiety, learning, and neuroinflammation in the adult offspring. Development while *in utero* is particularly susceptible to stress and can have lasting effects well into adulthood. Here, we measured anxiety behaviors in elevated zero, performance in contextual fear conditioning, and the production of pro-inflammatory cytokines in the hippocampus of adult mice exposed to different early life stress timelines. These timelines were designed to investigate the long-term effects of early postnatal stress as well as how prenatal stress can either attenuate, exacerbate, or supersede these effects. Mice were assigned to one of three conditions: (1) mice undergoing stress during the entire prenatal period in combination with the early postnatal period, (2) mice undergoing stress just during the early postnatal period, (3) and mice undergoing no additional stress at any point. Ultimately, mice in the combination stress paradigm showed cognitive deficits in contextual fear conditioning with no change in anxiety behaviors in elevated zero. Mice in this condition also showed downregulated hippocampal TNF-αand IL-6 while mice that underwent only postnatal stress showed no change in cytokine levels. This suggests an immunosuppressive effect of prenatal stress in combination with postnatal stress.

Title: The effects of early life adversity on instrumental reward learning

Authors: *M. GALLO[1], A. A. HAMID[2], D. OFRAY[1], D. SHLEIFER[1], G. MANZANO-NIEVES[2], C. LOPEZ[1], E. HRABARCHUK[1], K. G. BATH[1];

Abstract: Exposure to early life adversity (ELA) alters the risk for later development of pathology. Here, we use a mouse model of ELA, limited bedding and nesting (LBN) stress, to determine its effects on development of key brain centers associated with reward processing and instrumental reward learning. LBN alters early experience of pups, leading to unpredictable, fragmented care, impacting the reliability and predictability of the early environment. These experiences likely have profound effects on the development of reward systems, possibly contributing to behavioral symptoms associated with risk for major depressive disorder, hedonic responding, addiction, and risk taking behavior. To assess sex and developmental differences between groups, we used adolescent and adult male and female mice for all experiments. Our results showed that LBN rearing was associated with altered development and expression of dopamine receptors in the striatum of mice. Additionally, we note that females exhibiting differences in striatal dopamine receptor expression compared to males. Using variations of a lever press / reward task, we assessed learning rates, willingness to expend effort to receive a reward, and break point for reward responding. Current findings provide a critical starting point to more fully probe the effects of ELA on reward processing, effort allocation, and possible neural substrates underlying disruption in these behaviors following ELA.

Title: Type of early life adversity confers differential risk for altered timing of development

Authors: *C. DEMAESTRI, M. CRITZ, T. PAN, K. BATH;
Dept. of Cognitive, Linguistic, and Psychological Sci., Brown Univ., Providence, RI

Abstract: Early life adversity (ELA) dramatically increases the risk for developing psychiatric disorders, including anxiety and depression, and is associated with poorer health outcomes. Females have elevated risk for ELA-associated pathology and are twice as likely than males to

develop depression and post-traumatic stress disorder. A significant gap in the literature remains with regard to how the specific type and severity of ELA may influences outcomes and contribute to sex-specific risk. ELA can come in many forms, including extreme poverty, hypervigilant parenting, physical abuse, or parental neglect, to name a few. Importantly, these disparate experiences may provide unique signals to the developing organism about the quality of their environment and drive different effects on brain and behavioral development. Understanding the unique consequences of different forms of ELA on neurobehavioral development will be critical for identifying sex-specific risk factors.
Here, we compare two mouse models of ELA reflecting different forms of adversity with relevance for humans. Specifically, we test the effects of limiting maternal resources or repeated maternal separation on genetic markers of neuronal maturation, somatic and sensory development, and anxiety- like phenotypes during development.
We have identified sex-specific effects of ELA, where mice who are subjected to adversity fail to meet typical developmental milestones. We find that the domain of functioning impacted, and the severity of these effects depend upon both up on the form of stress and sex of the developing animal.
The current work advances our understanding of what developmental mechanisms are impacted in response to ELA, sex-specific vulnerabilities, and the contribution of each to health outcomes. Such findings may reveal targets for earlier interventions or identification of genetic biomarkers of risk/resilience and provide critical groundwork for individualized medicine.

Title: Early life adversity increases addiction-like behavior for opioid drugs

Authors: *S. C. LEVIS[1,2], J. L. BOLTON[2], B. S. BENTZLEY[3], C. R. PERRONE[1], T. Z. BARAM[2], S. V. MAHLER[1];

Abstract: Maternal attachment and quality of maternal care is critical for the neurodevelopmental outcome of offspring across species, including rodents and humans. Fragmented maternal care has been shown to have deleterious effects on the developing brain, and may predispose individuals to develop neuropsychiatric conditions such as anxiety, depression, and addiction. We previously demonstrated that providing limited bedding and nesting (LBN) to early postpartum rodents, a naturalistic rodent model for poverty and early life adversity, causes fragmented maternal care. This leads to anhedonia-like behavior for natural rewards and the abused drug cocaine in adult offspring reared under these conditions. Here we test whether LBN impacts addiction-like behaviors for the opioid drugs of abuse heroin and remifentanil in male and female rats. We examined self-administration, extinction, reinstatement, and economic demand measures of opioid addiction. We also examined heroin-induced neural activity (c-Fos) in LBN and control rats, including in neurons that project to nucleus accumbens (labeled via intra-accumbens injections of the retrograde tracer cholera toxin beta subunit; CTb). Taken together, our data suggest that early-life adversity causes long-lasting neurobiological changes in brain reward and stress circuits that markedly increase risk for addiction to opioid drugs in particular.

Title: Exploring mild stress to induce stress inoculation in early life prairie voles

Authors: *O. AKINBO[1], A. J. GRIPPO[2], L. MATUSZEWICH[3];
[1]Dept. of Psychology Northern Illinois Univ., Dekalb, IL; [2]Dept of Psychology, Northern Illinois Univ. Dept. of Psychology, Dekalb, IL; [3]Dept. of Psychology, Northern Illinois Univ., Dekalb, IL

Abstract: The experience of brief mild stress during early life may have an inoculating effect to more severe stress in adulthood. Mild stress exposure may increase resiliency by reducing anxiety, emotional distress and cardiovascular dysfunction. Stress inoculation elicits protective effects in humans, other primates, mice and rats. The socially monogamous prairie vole may be an ideal model to investigate whether mild stress has an inoculating effect on later social stress, given their social structure of pair bonding and living in family groups. In an exploratory study, we investigated the feasibility of studying stress inoculation as a function of mild stress applied to prairie voles early in life. Female prairie voles were assigned to a mild stress (n = 32) or

control condition (n = 8), at post-natal day (PND) 21 or PND 29. Mild stress was operationalized by handling the animal with a garden glove or placing in a cup covered with a garden-gloved hand for 30 seconds, either for 1 day or 3 days. These manipulations resulted in the following 10 groups: PND 21 control, PND 21 glove handled for 1 day, PND 21 glove handled for 3 days, PND 21 cup handled for 1 day, PND 21 cup handled for 3 days, PND 29 control, PND 29 glove handled for 1 day, PND 29 glove handled for 3 days, PND 29 cup handled for 1 day, and PND 29 cup handled for 3 days. On the last day of the mild stress protocol, blood was collected in anesthetized animals 10 minutes after the handling and assayed for corticosterone concentrations. Age matched control animals remained undisturbed until anesthetized for blood collection. Corticosterone was slightly higher in the mild stress groups relative to controls. Glove handling yielded higher corticosterone concentrations than cup handling in both age groups. PND 29 control animals exhibited higher basal corticosterone concentrations than PND 21 animals. Finally, when compared to control adult (PND 60-90) female prairie voles from a previous study, both PND 21 and 29 control animals exhibited higher basal corticosterone concentrations. These results indicate that early life prairie voles are a viable model to study stress inoculation. The clinical implications of the results may inform early life intervention strategies to build resiliency in humans.

Title: Modulating behavioral effects of early life adversity by targeting prefrontal cortex NMDA NR2A subunits in adolescent rats: Impact on infant-caretaker communication, cognition, and anxiety

Authors: *L. E. GRANATA, J. A. HONEYCUTT, H. C. BRENHOUSE;
Psychology, Northeastern Univ., Boston, MA

Abstract: Early adverse experiences are linked to social dysfunction and increased vulnerability to psychiatric disorders. An ethologically relevant model of adversity in rodents is the maternal separation (MS) paradigm. MS during development leads to behavioral deficits in adolescence, with concurrent aberrant development of the prefrontal cortex (PFC). Specifically, the NMDA receptor NR2A subunit and the post-synaptic density protein PSD-95 show increased expression, along with a decrease in parvalbumin (PV)-positive interneurons in rats. PSD-95 is an anchoring

protein, localizing NR2A-containing NMDA receptors to the post-synaptic membrane to facilitate calcium influx/synaptic depolarization. Increased NR2A and PSD-95 following MS likely enhances PFC activity, with possible consequences of PV loss and behavioral deficits. We have shown that after MS, intracranial treatment with TAT2A, a cell-permeable peptide that uncouples NR2A from PSD-95, returned PV expression and measures of anxiety to control levels. We have also reported sex differences in the developmental trajectories of rats exposed to MS, with females showing PV loss and behavioral deficits earlier than males. Here, we aim to elucidate the effects of disrupting NR2A/PSD-95 associations after MS at two developmental timepoints: juvenility or adolescence. To determine the effects of MS and TAT2A treatment, male and female rat pups were separated from dams for 4 hours daily from postnatal day (P)2 - P20. A cannula was surgically implanted in the PFC at P25 (juvenility) or P35 (adolescence) for repeated intracranial injections of TAT2A or vehicle in rats that were then tested in PFC-dependent assessments of anxiety and cognition at P42. Anxiety-like behavior was tested in the open field and elevated zero maze, and cognition was tested via spontaneous alternation in the Y-Maze. To assess the impact of MS on mother-infant communication, juvenile ultrasonic vocalizations (USVs) were collected at weaning and analyzed to determine whether early variations in USV emission can predict later behavior. While USVs are understood as behavioral markers of a rat's affective state, our work shows that juvenile USVs may also reflect a learned response to early experiences, reflected by MS-induced changes in emitted USV number/type. By correlating juvenile USV properties with adolescent behavior, we can determine whether individual differences in response to an aversive experience underlies vulnerability to behavioral dysfunction. Our results demonstrate that specific juvenile USV types predict the degree of anxiety-like behavior in adolescence dependent on rearing condition and TAT2A treatment.

Abstract: High levels of environmental and psychological stressors at key developmental stages such as early life and adolescence have been related to the onset of depression and posttraumatic stress disorder (PTSD) in adults. Depression and PTSD also seem to involve increased peripheral inflammation. Since some children are repeatedly exposed to stressors during both infancy and adolescence, we examined the effects of combining early life stress, modeled by maternal separation (MS), and repeated restraint stress during adolescence on depressive-like and PTSD-related behaviors in an animal model. We also explored whether the combined developmental stressors induced neuroinflammation by measuring the activity of microglia. We hypothesized that the combined developmental stressors would impair fear extinction and increase depressive-like behaviors by enhancing microglia activity in the brain. Male and female rat pups were separated from the dam for 3 hours daily from P1-14, exposed to 3 hours of restraint stress during adolescence (P29-43), and exposed to fear conditioning and extinction and forced swim test as adults. Interestingly, exposure to the combined stressors during key developmental stages did not affect acquisition or extinction of cued fear in either sex. However, the stressed rats showed increased depressive-like behavior. In addition, exposure to the combined stressors increased the microglial activity (Iba-1 immunostaining) in the ventral hippocampus (vHPC) suggesting neuroinflammation. Our follow-up study found that MS alone caused the same depressive-like behavior as the combined stressors in both sexes, suggesting that the early life stress is critical to the development of the depressive-like behavior. Currently, we are evaluating if there is an increase in pro-inflammatory cytokines in the vHPC. Our findings suggest that early life stress may activate hippocampal microglia to produce depressive-like behaviors in adults of both sexes.

Title: The impact of a Western-pattern diet on the interaction of prenatal stress, maternal behavior, and offspring phenotype

Authors: *N. CLAUSS[1], J. BYRD-CRAVEN[1], P. CAMPBELL[2];
[1]Oklahoma State Univ., Stillwater, OK; [2]Univ. of California- Riverside, Riverside, CA

Abstract: A Western-pattern diet (WPD) during lactation has been found to lead to anxiety reduction in rodent offspring. However, a WPD can also impact maternal behavior during lactation, and previous investigations have yet to disentangle the relative impact of potential nutrition-induced epigenetic changes from diet-induced changes in maternal behavior. To address this gap in the literature, experimentally and sexually naïve female *Mus musculus* (*n* = 32) and their offspring (*n* = 192) were maintained on a chow or WPD and experienced prenatal stress or no stress (8 dams per group). After weaning at PND 21, offspring were housed with same-sex siblings and further divided into groups fed either chow or WPD (12 mice per group; see Fig. 1).

Figure 1. **Maternal experimental groups, lactation diet experimental groups, and weaning diet experimental groups.**

Maternal behavior was assessed at PND 1 and revealed that stressed dams fed a WPD engaged in greater maternal behaviors than stressed dams fed chow. Anxiety-related behavior and exploration in the offspring were tested in the Open Field at PND 23 and PND 70; and reverse transcription followed by quantitative real-time PCR was used to assess mRNA levels of the following genes were examined: ER, DRD1, DRD2, GCR, and OXTR. Results revealed that the relationship between early stress and juvenile anxiety was mediated by gene expression and moderated by lactation diet, indicating that juvenile offspring of non-stressed dams and the stressed dams fed a WPD displayed significantly less anxious behavior than the chow-fed offspring of stressed dams. In adulthood, there was a three-way interaction between early stress, adult diet, and offspring sex to impact adult phenotype, with females driving this interaction. This preliminary data suggests that the lasting effects of developmental stress could be mitigated by a diet that stimulates the same neuroendocrine systems depleted by early stress. If replicated in humans, these results could provide insight into developmental correlates of pathological stress-induced eating and inform intervention development.

Title: Investigation of serotonin-related gene expression and socioemotional behaviors as a result of early-life exposure to clomipramine in Sprague-Dawley mother rats

Authors: *B. N. REGULA[1], C. M. RAGAN[2], N. SHAH[3];
[1]Psychology, Purdue Univ. Northwest, Hammond, IN; [2]Psychology, Purdue Univ. Northwest, Westville, IN; [3]Sch. of Med., St. George's Univ., True Blue, Grenada

Abstract: Early exposure to antidepressants can alter brain mechanisms during development. Previous animal models show that administering the tricyclic antidepressant, clomipramine, to rats during a sensitive period in development causes alterations to the serotonergic system and induces obsessive-compulsive disorder (OCD)-like behaviors in adulthood. Similarly, rats that display anxiety-like behaviors show increased gene expression of 5-HT2C in the orbitofrontal cortex (OFC) due to the deficiency of serotonin. However, previous studies have not examined long-term effects of early clomipramine exposure on mothers during the postpartum period. Therefore, our laboratory has used a model of early-life clomipramine exposure to observe its molecular and behavioral effects on Sprague-Dawley dams. During postnatal days 9-16, male and female pups from 8 litters were intraperitoneally-injected with either clomipramine or saline (control) to induce OCD-like behaviors in adulthood. To continue this study, OFC tissue from the mother brains and male brains from the same litter were examined to explore the effects that early clomipramine exposure has on the serotonin receptor, 5-HT2C. RNA from the OFC was isolated and quantitative real-time PCR was used to measure 5-HT2C mRNA expression normalized to the housekeeping gene CYPA. Results showed no significant differences in 5-HT2C gene expression in the OFC in saline vs. clomipramine-treated dams, however the clomipramine-exposed dams made more total hole pokes and engaged in more passive nursing than saline-treated dams. Conversely, clomipramine-exposed males had higher 5-HT2C gene expression in the OFC. The difference in 5-HT2C expression in the OFC between the males and females may be linked to pregnancy/lactation-related stress as the serotonergic system is rather dynamic during the reproduction period. Therefore, to further analyze the differences in gene expression between the males and females, expression of the serotonin transporter, SERT, which is responsible for serotonin reuptake, will be examined in both populations as well as in the offspring.

Title: Effects of early life stress on social group dynamics in mice

Authors: *G. BATISTA[1], N. W. HODGSON[2], J. SCHNEIDER[3], S. EL-SHAWA[3], J. LEVINE[3], T. K. HENSCH[1,2];
[1]Harvard Univ., Cambridge, MA; [2]Boston Children's Hosp., Boston, MA; [3]Univ. of Toronto Mississauga, Mississauga, ON, Canada

Abstract: Abnormal maturational trajectories following early life stress (ELS) lead to cognitive and social deficits associated with several psychiatric disorders. A comprehensive assessment of the impact of ELS on different social traits in mice is needed to uncover the underlying mechanisms. Here, we employed social network analysis to characterize the interactions of individual young adult (P60-P70) mice housed in more naturalistic groups. We were able to extract network parameters that are modified when animals exposed to control care (CC) or fragmented care (FC) in early life (P2-P9) interact with each other in adulthood. These results were compared to their performance on various standard laboratory tests commonly used to assess social behaviors (dominance, sociability, novelty seeking and empathy). Tracking body and head/tail position information of individuals identified by machine learning algorithm revealed interactions in four categories. This information was then used to compare the organization of social networks comprised of balanced CC and FC cohorts. Several aspects of the networks were notably altered when FC mice were included in the social group. Average clustering, global efficiency and betweenness centrality were increased in CC/FC groups as compared with purely CC/CC interactions. In contrast, average assortativity was reduced in mixed CC/FC networks. These effects were mainly observed in male interactions; however, some changes were also noted in female networks. Sociability over an inanimate object, as measured in a standard three-chamber assay, was not affected in either sex, while social novelty seeking was selectively impaired in males after ELS. Likewise, FC males in the tube test were more likely to be victorious over CC challengers, indicating increased dominance (consistent with their broader territorial urine marking). Elevated observational fear learning, commonly used as a proxy of empathy in mice, was primarily driven by FC females. Taken together, ELS affects distinct aspects of social behavior in mice, not only individually but at an ecological

group level. These findings will guide future research into molecular and circuit mechanisms mediating ELS-induced social impairments.

Title: Light at night during development increases susceptibility to an immune challenge in adulthood in female mice

Authors: *R. CHEN, L. K. FONKEN;
Div. of Pharmacol. and Toxicology, Univ. of Texas at Austin, Austin, TX

Abstract: The increase of light at night (LAN) in the past few decades accompanies the increased prevalence rate of mood disorders in young populations. Chronic dim light (~5 lux) at night can alter the circadian system leading to changes in mood as well as neuroimmune changes such as microglia activation. Neuroimmune activation is closely linked to mood disorders: activation of the immune system leads to mood disturbances and elevated expression of both pro- and anti-inflammatory cytokines can accompany mood disorders. However, the effects of dim light at night (LAN) during development remains unclear. Here we aimed to evaluate the effect of dim LAN during critical developmental windows on neuroimmune function and affective behaviors in adulthood. Male and female C57/BL6 mice were exposed to chronic dim LAN [12:12 light (150 lux) /dim (10 lux) cycle] during early life (PND 10 - 24) or adolescence (PND 30 - 44) or a standard light-dark cycle [12: 12 light (150 lux)/dark (0 lux)]. In both sexes, dim LAN exposure during development did not lead to a difference in growth patterns compared to mice housed in the standard light-dark cycle. No spontaneous anxiety- or depressive-like effects were observed in the open field test and the sucrose preference test. Post-LPS (10 ug/kg) pro-inflammatory cytokine levels in the hippocampus (HPC) and medial prefrontal cortex (mPFC) were measured when the animals reached adulthood. In HPC, LPS induced a significant increase in inflammatory markers IL-β and IL-6 in LAN but not control animals. This difference was only shown in female but not male mice. These data may indicate a greater vulnerability to developmental LAN exposure in female mice. Ongoing experiments will examine behavioral outcomes, such as whether anxiety- and depressive-like responses are exacerbated following an immune challenge in mice exposed to LAN during development.

Title: Mast cells as potential mediators of early life adversity effects on adult physiology and behavior

Authors: ***N. DUQUE-WILCKENS**[1], N. MARADIAGA[2], F. STOELTING[3], E. MACKEY[2], E. SARNO[3], K. THELEN[3], A. MCCAULIFF[3], A. ROBISON[4], A. MOESER[2];
[1]Physiol., [2]Large Animal Clin. Sci., [4]Neurosci., [3]Michigan State Univ., East Lansing, MI

Abstract: Early life adversity (ELA) is linked to an increased susceptibility to adulthood major depressive disorder (MDD), one of the most common and debilitating psychiatric diseases and for which available treatments are largely ineffective. Inflammation in the brain is a key mechanism underlying the pathophysiology of MDD, and studies across species suggest that ELA increases vulnerability to depression by priming the immune system for an amplified and more persistent inflammatory response to environmental stressors. However, the cellular and molecular mechanisms of this long-lasting effect are not fully understood. Mast cells (MCs) are uniquely positioned to drive ELA-mediated inflammatory responses that lead to MDD. First, they are distributed throughout the body, including the brain and meninges, and are highly activated in response to psychological stress. Second, they can release a variety of mediators responsible for initiating, amplifying, and prolonging inflammation; and third, they can disrupt blood-brain barrier integrity, allowing peripheral proinflammatory substances to enter the brain. Surprisingly, to our knowledge, no studies of MC effects on the brain in models of MDD have been performed to date. Using a mouse model of ELA consisting of neonatal maternal separation combined with early weaning (NMSEW), we first found that, compared to normal handling (NH), NMSEW mice exhibit heightened MCs hyperactivity demonstrated by higher basal and restraint stress-induced serum histamine levels. Additionally, analysis of bone marrow-derived MCs (BMMCs) showed that BMMCs derived from adult NMSEW mice had increased proinflammatory cytokine release after allergen stimulation (including TNFalfa and IL-6), together with persistent histone methylation modifications, suggesting that MCs are permanently, epigenetically programmed by NMSEW. Further, preliminary data suggest that meningeal MCs show increased hyperactivity in NMSEW vs NH females. Here we found that exposure to a 2nd hit stress during adulthood reduced social interaction in NMSEW but not NH males, and sucrose preference in NMSEW compared to NH females. Currently, we are using a combination of novel

mouse genetic tools, in vivo imaging technology, and behavioral and immunological studies to fully characterize ELA-driven functional changes in MCs, and establish the extent to which MCs are necessary and/or sufficient for stress-induced phenotypes in ELA exposed mice.

Title: Methylene blue rescues mitochondrial respiration impairments in developing iron-deficient hippocampal neurons

Authors: ***T. W. BASTIAN**, L. M. LANIER, M. K. GEORGIEFF;
Univ. of Minnesota, Minneapolis, MN

Abstract: Iron deficiency (ID) affects an estimated 2 billion people worldwide, including 30-40% of pregnant women and children. ID is particularly deleterious during fetal/neonatal brain development, leading to neurological impairments, including deficits in hippocampal-mediated learning and memory. These deficits often persist into adolescence and adulthood despite early-life iron repletion. Unfortunately, in some iron-deficient populations nutritional iron supplementation is either not realistic or can even be dangerous (e.g., with coexisting malarial infection). Because iron therapy is not always possible or effective, it is necessary to develop alternative treatment strategies targeting the underlying neurodevelopmental deficits of early-life ID.

Iron is necessary for mitochondrial enzymes involved in cellular energy production, supporting metabolically demanding developmental processes such as dendrite growth/branching. Early-life ID impairs mitochondrial respiration, ATP production, and dendritic complexity in the developing brain, with its most pronounced effect on hippocampal neurons. Methylene blue (MB) accumulates in mitochondria, and at low doses, acts as an alternative electron transport shuttle, enhancing mitochondrial energy production. We hypothesized that MB treatment would improve mitochondrial respiration and ATP production in a dose-dependent manner in developing iron-deficient neurons.

Mouse embryonic hippocampal neuronal cultures were treated with deferoxamine (DFO, an iron

chelator) beginning at 3 days in vitro (DIV). At 11 or 14DIV, iron-deficient cultures were treated with varying doses of MB, with and without concomitant iron repletion, or left untreated. Mitochondrial oxygen consumption rate (OCR) and ATP levels were assessed after 7 days (i.e., at 18 or 21DIV).
Consistent with our previous findings, DFO treatment significantly reduced neuronal OCR and ATP levels. When given from 11 to 18DIV, 17nM or 50nM MB partially rescued OCR, while 150nM MB increased cell death in iron-deficient neurons. When given from 14 to 21DIV, iron and 17nM and 50nM MB treatments all partially restored neuronal ATP levels. ATP levels were fully rescued when MB and iron treatments were combined.
Our findings show that MB can improve mitochondrial energy production following early-life ID. Importantly, energy metabolism deficits that persist even after iron treatment can be recovered with combined iron/MB treatment. Thus, stimulating mitochondrial energy production, in addition to or instead of iron repletion, has potential as a therapeutic target for the neurological deficits of early-life ID.

Title: Effect of methylphenidate on cell proliferation and memory in adult female rats exposed to chronic stress during the gestation stage

Authors: S. CASTELLANOS DE ALBA, A. FREGOSO-GONZÁLEZ, A. GARCÍA-ZAMUDIO, T. MORALES-SALCEDO, A. AGUILAR-DELGADILLO, J. GARCÍA-ESTRADA, D. FERNANDEZ-QUEZADA, F. JAUREGUI-HUERTA, S. LUQUIN, *Y. RUVALCABA-DELGADILLO;
Univ. de Guadalajara, Guadalajara, Mexico

Abstract: Methylphenidate (MPH) is a drug prescribed for the treatment of some pathologies such as attention deficit hyperactivity disorder (ADHD) in children and adolescents. This disorder is related to the hypo-functionality of the prefrontal cortex (PFC). The PFC and the hippocampus are regions of great relevance in cognitive processes such as memory. They also participate in the regulation of neuroendocrine processes as the stress response. The function of the medial PFC and the hippocampus can be altered due to stressful events. OBJECTIVE:

Evaluate whether chronic treatment with MPH improves cognitive ability (working memory) and modifies cell proliferation in mPFC and hippocampus of adult rats exposed to a model of chronic variable stress (CVS) during pregnancy. METHODS: Female Wistar rats were exposed to CVS during days 13-19 of gestation. After birth, the female offspring of stressed mothers and controls remained in laboratory conditions until four months of age. In this age we evaluate the work memory (tasks alternance / discrimination) with T maze task. After evaluation, we administered chronic treatment with MPH (40 days). In addition, BrdU was administered (days 28, 29 and 30 of the treatment with MPH). After the treatment with MPH, they were exposed again to the working memory test and cell proliferation and astrocyte response were analyzed in the mPFC and hippocampus of the CVS and control groups with and without MPH. RESULTS: We found a decreased number of BrdU + cells in mCPF of the CVS groups with and without MPH treatment compared to the control groups. In this region the control group with MPH treatment showed significantly more BrdU positive cells than the control group without MPH. In the hippocampus, an increase was observed in BrdU + cells in the CVS group treated with MPH compared to the other groups. Regarding the cognitive evaluation, the MPH did not have any beneficial effect in the execution of the work memory task in all the groups.

Title: Maternal insulin resistance transgenerationally impairs memory via germline histone modifications via germline histone modifications

Authors: *S. FUSCO, M. SPINELLI, S. COCCO, C. RIPOLI, A. MASTRODONATO, G. LIVRIZZI, F. NATALE, M. RINAUDO, C. GRASSI;
Inst. of Human Physiol., Univ. Cattolica Del Sacro Cuore, Rome, Italy

Abstract: Metabolic diseases harm brain health and cognitive functions, but whether maternal metabolic unbalance may affect brain plasticity of next generations is still unclear. To address this question, C57 adult female mice (F0) were fed with either standard or high fat diet (SD or HFD, respectively) from 4 weeks before mating until the 3rd week of suckling. The first

generation of HFD-fed mice, hereinafter referred as F1-HFD, and their descendants (F2-HFD and F3-HFD, respectively) were all fed with SD and were tested by behavioral, electrophysiological and molecular analyses. All HFD-descendant mice showed a lower discrimination index than the SD mice in a standard novel object recognition paradigm (F1-HFD = 56.5 ± 0.8%, F2-HFD = 54.6 ± 0.6%, F3-HFD = 55.8 ± 0.9% vs SD = 68.7 ± 1.0%; n=8-10 per group, $p<0.01$ for each comparison). These effects were associated with a significant impairment of spatial learning and memory in the Morris water maze. Time spent to reach the platform at the 3rd and the 4th training days was increased by +106.2% and +130.1%, respectively in F1-HFD; +78.9% and +91.6% in F2-HFD; +70.3% and +161.1% in F3-HFD, when compared to SD mice (n=8-10 per group, $p<0.05$ for each comparison). Accordingly, electrophysiological analyses on hippocampal brain slices of F1-, F2- and F3-HFD mice revealed severe deficits of long-term potentiation at CA3-CA1 synapses (ranging from -37% in F1-HFD to -52% in F3-HFD; n=11-15 slices from 4-5 mice per group, $p<0.05$ for each comparison). We demonstrated that maternal HFD-dependent insulin resistance induces multigenerational impairment of synaptic plasticity, learning and memory by epigenetically inhibiting Bdnf expression in both germline and hippocampus of progeny. These effects were triggered by downregulation of both TrkB and insulin receptor signaling in maternal ovaries, whose changes affected the recruitment of histone remodelers on BDNF regulatory sequences. Notably, either intraperitoneal administration of BDNF to the mothers or exposure of the offspring to novel enriched environment counteracted the transmission of HFD detrimental effects to the next generations by restoring the BDNF levels via opposite epigenetic changes on the same loci. More importantly, preserved insulin sensitivity in HFD-fed p66Shc KO mice also prevented the cognitive impairment of progeny. Collectively, our data suggest that maternal diet transgenerationally impacts on descendants' brain health via epigenetic modifications susceptible to lifestyle.

Abstract: Behavioral factors (e.g., artificial breeding of the offspring) produce negative effects in the propagation of evoked compound action potentials (eCAP) and in the myelination process of peripheral nerve axons (Segura et al, 2014). In the present study we analyze whether the presence or absence of littermates modify the chaotic fluctuations in area of the eCAPs in sural nerves (SU) from Wistar rats (60 days of age) reared with their mothers. We worked with litters of 9 male rats (littermates were tagged by their weight (±1SD) in light, intermediate, and heavy) and with only one pup. eCAPs were recorded in nerves by means of conventional electrophysiological techniques. Scalar time series were formed by using the area values of the sequentially generated eCAPs (N=1000; 1Hz freq., 2xU) in SU nerves from each group of rats. If each time series corresponds to measurements of one degree of freedom in a dynamical system that evolves near an attractor, it is then possible to reconstruct phase space orbits using methods from chaos theory which we implemented in Python. In the reconstruction of phase space orbits it is necessary to determine the time interval (τ) for observation, and the embedding dimension. Our results show changes in the dynamics of the reconstructed orbits of sural nerves from lightweigth rats and without littermates as compared with those of the control group, the latter being more symmetrical. In the case of heavyweight rats the reconstruction of orbits showed much more background noise, even though eCAP records from all groups are overall quite similar. τ was obtained using the mutual information function which measures the interdependence between two variables, the idea being that $x(t + \tau)$ brings new information, thus a large τ value would mean that there is a good amount of redundancy in the time series of eCAPs. In this sense, control time series has the most redundancy, whereas a loss of redundancy was observed in the other times series, remaining at 8% in the lightweight group, 29% in the heavyweight group, and 14% in the group with no littermates. Therefore, eCAP time series from the lightweight and without littermates groups had the most redundant information loss. Our results indicate that lightweigth and without siblings rats present alterations in the transmission of sensory information from the periphery to the central nervous system.

Title: A cross-talk between the molecular clock and the metabolic/redox oscillator operates in glioblastoma cancer cells displaying a differential temporal susceptibility to chemotherapy

Authors: *M. E. GUIDO, P. M. WAGNER;
Ciquibic Conicet Univ. Nacional de Cordoba, Cordoba, Argentina

Abstract: Biological clocks ticking on a near 24 h period (circadian) are constituted by a molecular clock core displaying transcriptional/translational negative feedback loops of clock and clock-controlled genes, and proteins. They are even present in immortalized cell lines driving transcriptional and metabolic rhythms regulating physiological processes. In addition, redox oscillations evolutionally conserved from humans to Archae were found to persist without transcription. Circadian desynchrony as a consequence of modern life (shiftwork, jetlag, etc.) may promote higher cancer risk and metabolic disorders. Nevertheless, little is known about the biological clock on proliferating tumor cells. Here we investigated metabolic/redox rhythms in human glioblastoma T98G cells and whether these cells displayed differential time responses to chemotherapy after treatment with bortezomib (BOR) or SR9009, a Rev- erb agonist. In synchronized cells, rhythms of redox and lipid metabolism were observed while cell viability significantly changed over time after BOR or SR9009 treatment. For BOR, the temporal changes in susceptibility together with the redox cycles were further altered after *Bmal1* knock-down, indicating a significant cross-talk between the molecular clock and the metabolic oscillator. In addition, SR9009 used to affect the molecular clockwork, exhibited significant anti proliferative effects in T98G cells and altered metabolic pathways involving reactive oxygen species and lipid droplets. Our results suggest that an intrinsic metabolic clock works in proliferating cells and the metabolic rhythms generated could be taken into account for a more efficient chronotherapy to determine time of day when glioblastoma cells are more susceptible to treatment.

Title: A circadian output center controlling feeding:fasting rhythms in *Drosophila*

Authors: *D. J. CAVANAUGH, A. P. DREYER, M. M. MARTIN, C. V. FULGHAM, D. A. JABR, J. BESHEL;
Biol., Loyola Univ. Chicago, Chicago, IL

Abstract: The circadian system produces ~24-hr rhythms in physiology and behavior and can be divided into three major components: a core molecular clock in the brain, input pathways that synchronize the molecular clock to environmental cycles, and output pathways that couple the clock to overt physiological and behavioral outputs. Most circadian studies in *Drosophila* have been conducted with respect to locomotor behavior, and little is known about circadian control of other outputs such as feeding behavior. We used a recently developed feeding monitor to characterize the contribution to circadian feeding rhythms of two key neuronal populations in the *Drosophila* pars intercerebralis (PI), which is functionally homologous to the mammalian hypothalamus. We demonstrate that thermogenetic manipulations of PI neurons expressing the neuropeptide SIFamide (SIFa) as well as mutations of the *SIFa* gene degrade feeding:fasting rhythms. In contrast, manipulations of a nearby population of PI neurons that express the Drosophila insulin-like peptides (DILPs) affect total food consumption but leave feeding rhythms intact. The distinct contribution of these two PI cell populations to feeding is accompanied by vastly different neuronal connectivity as determined by trans-Tango synaptic mapping. These results for the first time identify a non-clock cell neuronal population in *Drosophila* that regulates feeding: fasting rhythms and furthermore demonstrate dissociable control of circadian and homeostatic aspects of feeding regulation by molecularly-defined neurons in a putative circadian output hub.

Title: The poly(C) motif in the proximal promoter region of the D-box binding protein (DBP) drives its high-amplitude oscillation

Authors: *S. KIM[1], P. KWON[1], K.-T. KIM[1], T.-Y. ROH[1], H.-M. KIM[1], H. YI[2], H.-O. KU[2]; [1]POSTECH, Pohang, Korea, Republic of; [2]Vet Drugs and Biologics Division, Animal and Plant Quarantine Agency, Gimcheon, Korea, Republic of

Abstract: DBP, also known as D-site albumin promoter binding protein, is a transcription activator that binds to the D-box of its target gene. It has been known that there are more than 2000 D-boxes that govern about 10% of the clock-controlled gene. DBP supports the rhythmic transcription of the D-box containing clock-genes, in part by displaying high-amplitude cycling of its own transcripts compared to other circadian clock genes. However, the underlying mechanism of its high-amplitude cycling remains elusive. Here, we demonstrated that the poly(C) motif within the DBP proximal promoter provoked the transcriptional activation, in addition to a well-known E-box element. Furthermore, we generated poly(C) deleted cell line to demonstrate the endogenous effect of the poly(C) motif within the DBP promoter. We investigated that RNA polymerase 2 (Pol2) recruitment on the DBP promoter was decreased in poly(C) deleted cell line. Next, Assay for Transposase Accessible Chromatin (ATAC)-qPCR showed that the poly(C) motif induced higher chromatin accessibility within the region of DBP promoter. Finally, we identified that the oscillation amplitude of endogenous *DBP* mRNA of the poly(C) deleted cell line was decreased, which also affected the oscillation of other clock genes that are controlled by DBP. Taken together, our results provide new insights into the function of the poly(C) motif as a novel enhancer of DBP, along with its significance in the regulation of circadian rhythms.

Title: The circadian gene Bmal1 in the striatum regulates alcohol intake and preference in male and female mice

Authors: ***N. DE ZAVALIA**, P. SOLIS, G. PARENT, S. FERRARO, K. SHÖTTNER, S. AMIR;
Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Perturbations in the function of core circadian clock components such as *BMAL1*, *Per1* and *Per2*, or to the circadian environment, can affect alcohol intake and are associated with alcohol use disorder. The neuronal pathways that mediate this disorder are not well understood. The striatum is of special interest because it is involved in ethanol drinking and it is the site of ethanol neuroadaptations. However, the molecular and cellular mechanisms that mediate alcohol-induced striatal neuroplasticity and neuroadaptation remain to be defined. The aim of this work was to study ethanol intake in mice containing a functional mutation in *Bmal1* gene in the striatum. We created a conditional *Bmal1* knock-out mouse using the Cre-loxP system. *Bmal1*$^{lox/lox}$ mice were crossed to *Gpr88-cre* mice to specifically knock out *Bmal1* in Gpr88 expressing striatal medium spiny neurons. 12-18 week old WT, Knock-out (KO) and Heterozygote (HET) male and female mice were tested in: (A) 24 h intermittent ethanol (15% v/v) access protocol; (B) 24 h intermittent ethanol access protocol with ascending concentrations

of ethanol (5-45% v/v); (C) sucrose (0.25 or 2% m/v) access protocol. Blood alcohol concentration (BAC) levels after an alcohol injection (3.6 g/kg, 20% v/v) were measure at different times. Selective depletion of *Bmal1* mRNA and protein was observed in the striatum of KO mice compared with WT mice. No significant differences in the expression levels of *Bmal1* was observed in the suprachiasmatic nuclei (the master circadian clock) or hippocampus of KO compared with WT mice. No significant differences in alcohol consumption were observed between $Gpr88^{cre/+}$ and $Gpr88^{+/+}$ mice. *Bmal1* KO male mice drink significantly more alcohol and have a higher alcohol preference than WT mice (n=10/group, $P < 0.05$). Bmal1 KO female mice drink less alcohol and have a lower alcohol preference than WT mice (n=10/group, $P < 0.05$). No significant differences in alcohol intake and alcohol preference between HET and WT male and female mice were observed. No significant differences in sucrose intake and sucrose preference were observed between any of the genotypes studied. These preliminary results suggest a sex based difference in alcohol-related *Bmal1* function in the striatum. A protective role of *Bmal1* against alcohol intake was observed only in male and not in female mice. Further studies are being carried out to determine the mechanisms that explain how *Bmal1* exerts its protective function and to understand the sex differences observed in this study.

Title: Genetic dissection of the circadian rhythm of body temperature

Authors: *I.-M. LIAO[1], M. IZUMO[1], B. JEONG[1], J. S. TAKAHASHI[2];
[1]Dept. of Neurosci., Univ. of Texas Southwestern Med. Ctr., Dallas, TX; [2]Chair, Dept. of Neurosci., Univ. of Texas Southwestern Med. Center, Howard Hughes Med. Inst., Dallas, TX

Abstract: Mammals possess endogenous clocks that drive the near 24-hour circadian rhythms of many important physiological processes. These internal clocks are encoded genetically and are crucial for anticipating environmental changes. Disrupted body temperature (Tb) homeostasis can be life-threatening, thus it is critical for mammals to maintain Tb in a stable physiological range. Tb fluctuates with the circadian cycle, and the daily rhythms of Tb may serve as entraining cues for synchronizing peripheral clocks. The suprachiasmatic nucleus (SCN) and the

medial preoptic area (MPOA) of the hypothalamus play roles in regulating Tb rhythm and thermal sensing, respectively; however, the neural mechanisms underlying Tb rhythmicity remain poorly understood. We hypothesize that the SCN drives the rhythmicity of Tb, while the MPOA provides temporal modulation to shape distinct features of Tb rhythm. To search for critical clocks responsible for generating Tb rhythmicity, we used *Cre/LoxP* recombination to selectively delete *Bmal1,* an essential transcription factor for generating molecular circadian rhythms, from the SCN and/or MPOA. In addition, we used a retrograde neural tracer to investigate the anatomical connections between the SCN and the MPOA seeking direct neuronal interactions between the two regions. We found that disruption of forebrain clocks abolishes the circadian rhythm of Tb in mice. In contrast, disrupting SCN clocks led to the gradual dissociation of Tb rhythm. Finally, our initial neural tracing results indicate that the SCN projects directly to the MPOA. In sum, our data suggest that forebrain clocks are indispensable for, while SCN clocks play a partial role in the generation of Tb rhythms. Further study of forebrain clocks outside of the SCN and functional analyses of the SCN-MPOA neurocircuit are required to understand how individual components work together in a neural network to generate Tb rhythmicity.

Title: MYBBP1a - ZFHX3 complex acts a repressor on core circadian gene expression

Authors: *M. YIN[1], S. MILITI[2], H. HILTON[1], G. BANKS[1], C. ESAPA[1], P. NOLAN[1]; [1]Medicail Res. Council Harwell Inst. UK, Didcot, United Kingdom; [2]Ludwig Inst. for Cancer Res., Oxford, United Kingdom

Abstract: Abstract
The transcription factor, ZFHX3 has been identified as a regulator of circadian rhythms in the suprachiasmatic nucleus (SCN) - the site of the master clock of the body. The Short-Circuit missense mutation in ZFHX3 (*Sci*) displays a short circadian period phenotype. Although evidence shows that reducing the transcriptional regulation of ZFHX3 disturbs the expression of neuropeptides which are essential to SCN signalling, the role of ZFHX3 in SCN circadian function and the molecular mechanism underlying ZFHX3-dependent networks in circadian regulation is unclear.

Through immunoprecipitation studies we have identified a potential cofactor of ZFHX3, Myb-binding protein 1a (MYBBP1a). This nuclear protein predominantly localizes in the nucleolus and functions as a shutting protein for both nuclear import and export. Although it does not contain obvious DNA-RNA binding motifs, previous studies showed that MYBBP1a associates with a number of transcription factors to regulate gene transcription. Evidence suggests that it may regulate the molecular circadian clock by acting with CRY1 as a co-repressor of *Per2*. Our results show that ZFHX3 is localized in the nucleus and is co-localized with MYBBP1a at the nucleolus. The protein-protein interaction between ZFHX3 and MYBPP1a has also been demonstrated by pull down. Hence, we propose MYBBP1a may interact with ZFHX3 to regulate circadian gene expression. To test our hypothesis, we employed luciferase reporter assays to characterize the role of MYBPP1a/ZFHX3 complex in circadian gene expression. Through such experiments, the results imply that the MYBBP1a may bind to ZFHX3 to repress its activity as a TF. Moreover, I am currently developing a method to further dissect how this complex effect the transactional regulation to provide insight to the mechanisms underpinning the circadian regulation of transcription.

Title: Central circadian clock regulates cognitive function and insulin sensitivity

Authors: ***X. LI**[1], W. ZHOU[1], Y. HE[2], T. YANG[1], Y. GONG[1], G. DING[1], S. LEE[1], J. QIAN[1], Y. XU[2], Z. SUN[1];
[1]Dept. of Med., [2]Children's Nutr. Res. Ctr., Baylor Col. of Med., Houston, TX

Abstract: Glucose metabolism and neurocognitive functions is regulated by the central circadian clock in the brain. Elevated basal glucose levels at the onset of the active cycle is associated with elevated sensitivity to insulin in normal conditions. Here we show that the suprachiasmatic nuclei (SCN) of the brain drives the timing of the glucose counter-regulation. Nuclear receptors Nr1d1/2 are key components of the molecular clock machinery. We found in mice that Nr1d1/2

in the SCN GABAergic neurons controls diurnal variation of insulin sensitivity, likely through indirectly regulating the sympathetic nervous system, in a manner that is independent of the circadian consummatory or locomotor behaviors. In addition to glucose metabolism, Nr1d1/2 also regulate learning and memory. These findings provide molecular and cellular insights into the circadian rhythms and chronodisruption in insulin sensitivity and cognitive dysfunction.

Abstract: Circadian rhythms are the outward manifestation of an internal timing system that measures time in 24-hr increments. The mammalian circadian system is hierarchical, with a pacemaker in the suprachiasmatic nucleus synchronizing cell-autonomous oscillators in peripheral tissues. Much of what we know about rhythmicity in peripheral tissues comes from studies monitoring bioluminescence rhythms in animal models in which luciferase reporter expression is controlled by a clock gene, e.g., PERIOD2::LUCIFERASE (PER2::LUC) knock-in mice. A limitation with these models is that rhythmicity cannot be monitored in specific cell types due to widespread reporter expression. To address this shortcoming, we generated a mouse that expresses luciferase from the *Dbp* locus only after *Cre*-mediated recombination. Crossing the conditional reporter mice with mice expressing *Cre* recombinase in various cell types allowed detection of rhythmic bioluminescence in the expected tissues, *in vivo* and *ex vivo*, as well as in slice cultures containing the SCN. These results were expected given the widespread, highly rhythmic expression of *Dbp* and the specificity of the Cre lines used. Our *Cre*-conditional

knock-in construct also contains sequence encoding a destabilized GFP, flanked by loxP sites, upstream of the *luciferase* gene; current studies are assessing GFP rhythmicity. The phase of bioluminescence rhythms from explants of mouse peripheral tissues indicated that Dbp^{Luc} bioluminescence rhythms have an earlier phase than PER2::LUC rhythms, as expected from gene expression rhythms. Importantly, we confirmed that editing of the *Dbp* locus did not alter the period of circadian locomotor activity rhythms. Thus, this mouse line is useful for studying circadian rhythms in a cell-type specific manner.

Title: Clock gene per1 and per2 is involved in the mechanism underlying the rapid antidepressant action of adenosine A1 receptor agonist

Authors: *S.-X. LI;
Natl. Inst. On Drug Dependence,Peking Univ., Beijing, China

Abstract: Objective
To explore the anti-depressant effect and mechanism of adenosine A1 receptor agonist CCPA
Method
We performed behavioral tests at 6h, 12h, 24h, 36h, 48h, and 72h after intraperitoneal injection of adenosine A1 receptor agonist CCPA (0.2mg/kg) in a 28-day chronic unpredictability stress (CUS) rat model of depression, to explore CCPA's rapid anti-depressive effect and its onset and maintenance time. In order to explore the molecular mechanism underlying CCPA rapid anti-depressant avtion, we used western blot to detect the expression of adenosine A1 receptor and it’s downstream molecules in mPFC and hippocampus CA1 in rats. To further verify the role of

per1 gene in rapid anti-depressant action, microinjection of adenosine related virus to knock down per1 gene expression in target brain region, and then conduct behavioral tests.

Result

Compared to the control, the CUS rats exhibited significant depression-like behaviors. Compared with the CUS group, the preference value of sugar water was significantly increased 12 hours after intraperitoneal injection of CCPA 0.2mg/kg ($p<0.05$), and the immobility time in forced swim test was significantly shortened ($p<0.01$).The antidepressant action of CCPA lasted up to 36 hours.

CUS led to a significant decrease in theexpression of *p*-CREB and PER1 protein levels in the hippocampal CA1 brain region ($p<0.05$), and CCPA (0.2mg/kg) reversed the decrease in *p*-CREB and PER1 levels in the hippocampal CA1 brain region. No significant changes in these protein levels were observed in mPFC brain region. AAV-*shper*1 was injected into the CA1 brain region of normal rats, and behavioral test was conducted 21 days later. It was found that the preference value of sugar water was significantly reduced in the AAV-*shper*1 group ($p<0.05$), and the immobility time in the forced swim test was prolonged ($p<0.05$). After intraperitoneal injection of CCPA (0.2mg/kg) at 12h, 24h and 36h, the preference value of sugar water increased significantly ($p<0.05$).

Conclusion

Adenosine A1 receptor agonist CCPA has a rapid antidepressant effect;*Per1* in the hippocampal CA1 is involved in the occurrence of depression-like behaviors and mediates the rapid antidepressant effect of CCPA.

Title: Molecular and behavioural consequences of circadian clock gene deletion within the mouse striatum

Authors: *P. SOLIS, K. SCHÖTTNER, M. A. BUTTON, N. DE ZAVALIA, S. AMIR;
Ctr. for Studies in Behavioral Neurobio. (CSBN), Concordia Univ., Montreal, QC, Canada

Abstract: Circadian clocks generate rhythms ranging from the molecular to behavioral level which are believed to be essential for optimal function of the biological system in a daily changing environment. Indeed, organism-wide or tissue specific disruption of circadian clocks is

associated with a wide range of chronic health problems in humans including mental disorders, emphasizing their clinical relevance. The circadian clock in medium spiny neurons (MSNs) of the striatum is of great interest given the fact that this brain region is associated with mood- and anxiety-related conditions, raising the question if a disruption of the circadian clock may alter these processes and contribute to the incidence of neuropsychiatric disorders. To investigate the role of circadian clock genes in the striatum, conditional Bmal1 or Per2 knockout mice were generated by crossing C57BJ/6 mice homozygous for floxed alleles of the Bmal1 or Per2 locus with C57BJ/6 mice expressing Cre under the control of the Gpr88 promoter. The knockout is confirmed by mRNA expression analysis of the Bmal1 or Per2 floxed locus in homo- and heterozygote mice compared to homozygote wild type (WT) littermates. Further examination by immunohistochemical staining and Western blotting demonstrates that expression of Bmal1 and Per2 is abolished in striatal MSNs of knockout mice. Strikingly, mRNA expression of circadian clock and clock-controlled genes is altered in clock gene knockouts compared to control animals at various time points throughout the 24h day. Subsequently, knockout mice and WT littermate controls were tested to assess the impact of the Bmal1 and Per2 knockout in striatal MSNs on behaviour with focus on circadian as well as mood- and anxiety-related phenotypes. Various parameters of daily locomotor activity rhythms are similar in Bmal1 or Per2 knockouts compared to control mice. Neither Bmal1 nor Per2 knockout male and female mice kept in groups display differences regarding the time spend in the central area of an open field, or immobility time in a tail suspension test compared to WT controls when tested during the light portion of the light/dark cycle. However, female Bmal1 knockout mice show significantly higher levels of locomotor activity in the open field compared to WT control mice. These preliminary results indicate that loss of the circadian clock genes Bmal1 or Per2 in the striatum doesn't affect anxiety- and depressive-like behavior when tested during the light portion of the 24h day. Future studies need to be conducted in order to elaborate if these outcomes are consistent throughout the entire 24h light/dark cycle and under challenging conditions such as stress.

Title: A neuronal circuit that modulates rhythmic activity under warm temperature in the fruit fly, *Drosophila melanogaster*

Authors: *A. IYENGAR, V. SHEEBA;
Neurosci. Unit, Jawaharlal Nehru Ctr. For Advanced Scientific Res., Bangalore, India

Abstract: Organisms modulate their behaviour in response to extreme environmental conditions to mitigate their harsh effects. Under stressful conditions like prolonged durations of warmth, organisms may counter excessive heating or desiccation by shifting their activity from the day into the night, when the conditions are likely to be less harsh. Modulation of a rhythmic behaviour such as locomotor activity in response to the environment would require an interaction between at least two neuronal systems: (1) a sensory system to receive input from the environment, and (2) the internal clock to correctly time rhythmic activity in response to this input. Our lab focuses on understanding the neuronal circuit underlying the behavioural modulation under warm ambient condition, using the genetically amenable model system, the fruit fly, *Drosophila melanogaster*. Previous work in the lab identified a thermosensory mutant of the ion channel *Drosophila* Transient Receptor Potential-A1 (dTRPA1) that fails to sense warm temperature and, unlike a wildtype fly, does not shift its activity into the night under warm ambient condition. To identify the neuronal basis for this behaviour, I investigated the role of a specific cluster of the *dTRPA1*-expressing neurons in the fly brain. Since these *dTRPA1*$^{+}$ neurons were known to include some core clock neurons, I further categorised these neurons into clock and non-clock subgroups and evaluated their relative contributions during modulation of rhythmic activity under warm ambient condition. I also explored how information from the *dTRPA1*-expressing neurons is communicated downstream and identified two neurotransmitters as potential communication factors for this circuit.

Title: The role of SOX2 in circadian timekeeping

Authors: *A. H. CHENG[1,3], P. BOUCHARD-CANNON[1,3], S. W. FUNG[3], S. HEGAZI[1,3], C. LOWDEN[1,3], R. W. NESS[3,2], H.-Y. M. CHENG[1,3];

Abstract: Most aspects of behaviour and physiology exhibit circadian (~24-hour long) rhythms that align with the day-night cycle. In mammals, these overt rhythms are controlled and coordinated by a central circadian pacemaker in the hypothalamus known as the suprachiasmatic nucleus (SCN). Here we report that SRY (sex determining region Y)-box 2 (SOX2), a transcription factor that have been shown to play critical roles throughout central nervous system development, promotes robust and coherent circadian behavior in mice.
We specifically ablated SOX2 in SCN neurons by crossing mice expressing Cre recombinase in GABAergic neurons (*Vgat*-IRES-Cre) with mice carrying the loxP-flanked alleles of *Sox2* (*Sox2*$^{fl/fl}$). This conditional knockout mouse strain (cKO) demonstrated weaker, poorly consolidated rhythms, unstable activity onsets, and greater variability in the phase angle of entrainment under 12-hr light:12-h dark schedule and skeleton photoperiod. Sox2 cKOs also showed significant wheel-running activity in the first 3 hours after light onset, leading to a prolonged active phase (alpha). In reaction to experimental jetlag, most of the Sox2 cKOs exhibited erratic and impaired re-entrainment to the shifted external light cycles. Upon release into constant darkness conditions, Sox2 cKOs exhibited a significantly longer period, in addition to reduced amplitude and prolonged active phase compared to controls. Under constant light conditions of gradually increasing light intensity, a majority of the Sox2 cKOs became arrhythmic under mid- to high light intensity. Collectively, these findings suggest that Sox2 cKOs may have impaired light-induced entrainment and are highly susceptible to constant light-induced arrhythmicity.
In an effort to understand the origins for the profound circadian behavioral phenotypes arising from *Sox2* ablation within the SCN, we analyzed the SCN transcriptomes of Sox2 cKOs and controls at 4 circadian times (CT 0, 6, 12, and 18) using RNA-sequencing. We identified 233 differentially expressed genes (DEGs) in the SCN of Sox2 cKOs with DESeq2. Amongst the 233 DEGs are known regulators of neuropeptide signaling and rhythmic process in the SCN. Further analysis conducted with MetaCycle confirmed that the rhythmic transcriptome of the SCN is perturbed in Sox2 cKOs. Finally, we selected 7 genes from the set of DEGs and used ChIP-qPCR and confirmed the binding of SOX2 near predicted region in SCN tissues.

Title: Measuring circadian bioluminescence from mice lacking a functional central clock

Authors: *B. MARTIN-BURGOS[1], P. MOLYNEUX[1], V. VAN DER VINNE[2], T. LEISE[3], D. R. WEAVER[4], M. E. HARRINGTON[1];
[1]Neurosci Prog, Smith Col., Northampton, MA; [2]Univ. of Oxford, Oxford, United Kingdom; [3]Amherst Col., Amherst, MA; [4]Neurobio., UMass Med. Sch., Worcester, MA

Abstract: Circadian (approximately 24 h) rhythms arise from intracellular clocks that must be phase coordinated. The suprachiasmatic nucleus (SCN) is the pacemaker or central clock which receives direct input from the eyes and maintains peripheral phase alignment through systemic rhythmicity. Circadian disruption, as experienced in shift work, nocturnal light exposure and aging, impacts health by affecting interactions between peripheral and central clocks. To better understand this process, we used a method developed by our lab that measures PER2::LUC bioluminescence from freely moving mice. We applied this *in vivo* technique to study peripheral rhythmicity of mice lacking a functional central clock (Vgat-Cre^{+} Bmal1$^{fl/fl}$) in the absence of environmental rhythmicity (DD). Locomotor activity data in LD were collected prior to the experiment and during the 7-day *in vivo* bioluminescence experiment (in DD). Three days prior to recording, each mouse received a subcutaneous implant of an osmotic mini-pump delivering a synthetic luciferin, CycLuc1. Records were analyzed using discrete wavelet transforms (DWT). Results were compared to control and to arrhythmic Bmal1$^{-/-}$ mice to determine whether the absence of a central brain clock results in rapid loss of peripheral rhythm amplitude. The locomotor activity of Vgat-Cre^{+} Bmal1$^{fl/fl}$ mice becomes arrhythmic upon placement in DD, yet here we demonstrate that these mice can show rhythmic PER2::LUC bioluminescence arising from peripheral tissues. The circadian component of this rhythm was weaker than that seen in control (Vgat-Cre^{-} Bmal1$^{fl/fl}$) mice but was significantly different from arrhythmic Bmal1$^{-/-}$ mice. Our results suggest that a functional central clock is not required to maintain synchronization of cellular clocks in peripheral tissues. Circadian oscillators in peripheral tissues may be synchronized by prior housing under LD or by our brief anesthesia (circa 15 min) and pump implantation. Discrete wavelet transforms allowed quantification of persistence of rhythmicity in noisy records. Our technique for *in vivo* bioluminescence measures of circadian gene expression in freely-moving mice allows definite demonstration of rhythms in gene expression without invasive surgery or prolonged anesthesia.

Title: Time restricted feeding rescues hippocampal disruption after chronic high fat diet feeding

Authors: *J. DAVIS[1], S. YATES[1], J. POLLOCK[2], D. POLLOCK[2], M. YOUNG[2], S. BAILEY[2], K. L. GAMBLE[3];

Abstract: Chronic circadian disruption (i.e. shift work, jet lag) is associated with increased risk for developing obesity, diabetes, and cardiovascular dysfunction. Obesity itself increases the risk of numerous additional diseases including diabetes, cardiovascular disease, and cognitive impairment. Given recent establishment of links between the circadian clock and metabolism, and that both sleep-wake status and obesity can have a profound impact on cognitive performance, we hypothesized that calorically dense diets alter the molecular clock and day-night differences in synaptic plasticity and spatial memory. Secondarily, we predict that these effects are due to altered food intake patterns, and could be rescued by restricting food access to an animal's active period. Wild-type C57BL/6J mice were fed HFD or control diet for 18 weeks followed by 2 weeks of time restricted feeding (TRF, with food access only at night). Following TRF, hippocampal extracts were collected to analyze clock gene expression (PER2, BMAL1) via western blot analysis. An additional cohort of Per2-Luciferase mice were fed following the same protocol and upon competition of the TRF, multiple tissues were extracted and cultured to determine the phase of PER2 expression across various tissues. Spatial working memory was assessed using spontaneous alternation performance in a T-maze during the inactive and active periods. Slice electrophysiology was performed on hippocampal slices at CA3-CA1 synapses to assess differences in long-term potentiation (LTP) during both the active and inactive phases. Results indicate that hippocampal cultures from PER2 luciferase HFD fed mice have a slightly shorter period than control animals and that PER2 protein expression revealed a loss of rhythmicity in the hippocampus of HFD fed mice compared to controls (cosinor analysis, $p < 0.05$ for CD and $p > 0.05$ for HFD). Additionally, we found that 2 weeks of TRF rescues day/night differences in HFD animals in spontaneous alternation as well as restores LTP to levels similar to those of control fed animals. In conclusion, it appears that HFD disrupts hippocampal

clock gene rhythms and spatial working memory. Moreover, restricting food access to the night can rescue synaptic plasticity as well as day-night differences in spatial working memory.

Title: A single factor dominates the behavior of rhythmic genes in mouse organs

Authors: Y. CHENG[1], L. ZHANG[2], ***G.-Z. WANG**[1];
[1]CAS-MPG Partner Inst. for Computat. Biol., Shanghai, China; [2]Huazhong Univ. of Sci. and Technol., Wuhan, China

Abstract: Circadian rhythms, regulated by both the internal and external environment of the body, are multi-scale biological phenomena with great complexity. At the molecular level, thousands of genes have been shown to exhibit rhythmic transcription, which are both organ-specific and species-specific, but what determines their rhythmicity remains unclear. Here we show that, for circadian rhythmic genes in mouse organs, there is a strong positive correlation between transcription level and rhythmic amplitude, and transcription level can explain more than 70% of the variation in amplitude. Our results further demonstrate that functionality and tissue specificity are not strong predictors of amplitude, and expression levels of rhythmic genes are linked to the energy consumed. This single determinant led us to assess the significance of rhythmic expression itself on the design of the transcriptional system. The rhythmical regulation of highly expressed genes can effectively reduce the energetic cost in transcription, facilitating the long-term adaptive evolution of the whole genetic system.

Title: Circadian variation of neurometabolic activity in the prefrontal cortex: Effects of light and aging

Authors: *N. K. WALLACE, I. N. KARATSOREOS, M. SAVENKOVA, F. POLLARD; Integrative Physiol. and Neurosci., Washington State Univ., Pullman, WA

Abstract: Neural activity is energetically expensive, but neurons do not keep large reserves of energetic substrates. Thus, the support of neural activity requires that energy needs be met by dynamic interactions between neurons, glia, and blood vessels. One essential metabolic substrate in the brain is lactate, which is produced in astrocytes in response to increased neuronal activity and transported into the extracellular space for neuronal uptake. The goals of this study were twofold; the first goal was determine whether lactate metabolism in the prefrontal cortex (PFC) shows a circadian pattern, and to explore how environmental circadian desynchronization in young adults might affect it. The second goal was to probe how lactate metabolism was affected by normal aging, which is accompanied by blunted and destabilized circadian rhythms. Environmental circadian desynchronization was induced by exposure to a 20h light-dark (T20) cycle for 6 weeks. In all cases, Male, C57BL6/N mice were used. Adults in Control and T20 groups were 6-7 months old, while Aged mice were obtained from the NIA Aging colonies at 15-17 months old and tested at 19-20 months old. Mice were implanted with EEG, EMG (to monitor sleep), and a PFC cannula through which a lactate biosensor was inserted. Our results demonstrate that in Control mice, extracellular lactate in the PFC is rhythmic under both light-dark (LD) and constant dark (DD) conditions. In Aged mice, lactate rhythms in LD were similar to Controls, but significantly blunted in DD. In the T20 group, the PFC lactate rhythm was significantly reduced in amplitude and phase shifted with respect to the LD cycle. Further exploration revealed that the relationship between sleep state and lactate were modified under these conditions. In healthy mice, extracellular lactate increases during wake and REM sleep, when firing rates are high, and decreases during NREM sleep, when neural firing becomes less frequent. This relationship was blunted by T20. To probe underlying mechanisms, we examined expression of lactate-related transcripts in PFC using RT-qPCR. We found that T20 changed the pattern of expression of several genes related to metabolism and plasticity. Aging also changed expression of the enzymes that convert between lactate and pyruvate. While Control mice

showed a daily rhythm in the ratio of LDHA to LDHB expression, this rhythm was abolished in Aged mice. Our findings provide new information on the circadian control of neurometabolism under both normal and circadian desynchronized conditions. These findings point to a potential mechanism by which disrupted circadian clocks can affect neural function, and perhaps cognitive behaviors.

Title: The role of innexin genes in Lymnaea stagnalis

Authors: *B. MERSMAN, S. JOLLY, Z. LIN, F. XU;
Biol., St. Louis Univ., Saint Louis, MO

Abstract: Proper synapse formation is required for all brain functions, from simple reflexes to high cognitive tasks including learning and memory. However, most synaptic studies focus on the regulation and formation of chemical synapses, with advances in gap junction-mediated electrical synapse research lagging far behind. Even more, very little information is known about which genes contribute to proper electrical synapse formation throughout nervous system development. The objective of this study was to help shed light into the role of the *innexin* family, the genes coding for gap junction proteins, in the development of an invertebrate nervous system. To study genetic information at a single cellular level, we opted to utilize the mollusc *Lymnaea stagnalis* (*L. stagnalis*), whose physically large, well-defined neuronal networks and published genome allows for a unique opportunity to examine cell-specific expression of genes throughout electrical synapse formation in the developing *Lymnaea* brain. To begin characterizing *innexin*, eight isoforms of the gene, named *Inx1 - Inx8*, were cloned and sequenced. To do this, degenerate primers were created via homology studies of innexin in other invertebrates and utilized in RT-PCR. 3’ and 5’ rapid amplification of cDNA ends (RACE) was used to obtain a full reading frame of *Inx1*. The *Inx1* sequence was then entered in a whole

genome BLAST search to obtain seven other *innexin* isoforms. To study the localization of *innexin* at the cellular level, *in situ* hybridization experiments were completed with DIG-labeled probes targeting the *Inx1* transcript; these results revealed cell-specific localization to the plasma membrane in some known electrical synapse-forming cells while absent in others, implying genetic differences between functionally identical cells. To further confirm cellular differences in *innexin* expression, intron-spanning primers specific to each *innexin* isoform were designed for single cell qPCR. Throughout the central nervous system, electrical synapse-forming cells expressed various levels of each isoform, indicating the genetic specificity involved in proper synapse formation and validating the *in situ* hybridization results. A similar single cell qPCR experiment was then completed on *L. stagnalis* during a wide range of developmental time points; expression patterns of *innexin* isoforms changed with the development of the invertebrate. Taken together, our results indicate an evolving genetic makeup at the cellular level that contributes to proper electrical synapse formation over developmental time.

Title: Examination of oligodendrocyte connexin32 interactions with wild-type connexin47 and PMLD/SPG44 connexin47 mutants

Authors: G. DUNGAN, *M. FREIDIN, C. K. ABRAMS;
Neurol., Univ. of Illinois at Chicago, Chicago, IL

Abstract: Connexins (Cx) are a family of homologous integral membrane proteins which form gap junctions. Homotypic cell-cell channels are composed of two identical connexon hemichannels, while in heterotypic channels the two hemichannels differ. Oligodendrocytes (Oligos) express Cx29, Cx32, Cx47. Recent functional and EM studies have shown O/O coupling via either Cx32/Cx32 or Cx47/Cx47 homotypic channels. Based on the lack of heterotypic coupling between Cx32 and Cx47 between transfected cells expressing either Cx32 or Cx47, heterotypic coupling in Oligos is unlikely. However, given the substantial overlap in Oligo expression patterns of Cx32 and Cx47, the possibility of functional interactions between these two remains. Astrocytes (As) express both Cx30 and Cx43. Using transfected cells, we and others have shown coupling between As and Oligos (A/O) is likely composed of Cx30/Cx32 and

Cx43/Cx47 heterotypic channels.
Mutations in the genes for human Cx47 (GJC12) and Cx32 (GJB1) lead to neurologic diseases. Mutations in GJC12 cause a severe early onset central nervous system dysmyelinating disorder, Pelizaeus-Merzbacher-Like disease (PMLD1 or HLD2 and the milder, later onset disorder, Hereditary Spastic Paraplegia (SPG44). Mutations in GJB1 are associated the demyelinating peripheral neuropathy, CMT1X. In these disorders, interactions between mutant forms of Cx47 and wild-type Cx32 may contribute to the disease phenotypes. Mice lacking either Cx32 or Cx47 show minimal CNS abnormalities while mice lacking both connexins show a florid and severe CNS phenotype. Thus, it is unlikely that simple loss of function in patients with mutations in Cx32 or Cx47 is sufficient to explain CNS phenotypes. Some or all of the CNS manifestations may arise as a result of pathological interactions between Cx32 WT and mutant forms of Cx47 or between mutant forms of Cx32 and Cx47 WT. We used dual whole cell recordings, immunofluorescence colocalization, and co-immunoprecipitation to evaluate evidence for heteromeric interactions between WT Cx32 and WT Cx47. We use the same techniques to further evaluate whether four mutant forms of Cx47 associated with PMLD1 and SPG44 show interactions with Cx32 which differ from those between WT Cx47 and WT Cx32.

Title: Electrical coupling and NMDA dependent strengthening of electrical synapses in the mouse inferior olive depend on CaMKIIa

Authors: *H. E. SPEED[1], Z. ZHU[1], A. SHARDARBEKOVA[1], S. COULTRAP[2], K. BAYER[2], J. WELSH[1,3];
[1]Ctr. for Integrative Brain Res., Seattle Children's Res. Inst., Seattle, WA; [2]Pharmacol., Univ. of Colorado - Denver, Denver, CO; [3]Pediatrics, Univ. of Washington, Seattle, WA

Abstract: Subthreshold membrane oscillations in the inferior olive (IO) drive climbing fiber input to the cerebellum and are critical for the timing of coordinated movement. Connexin36 (Cx36) proteins form gap junctions that allow for electrical coupling between IO neurons and synchronous changes in membrane potential. We have previously shown that NMDA receptors (NMDARs) are bidirectional modulators of electrical coupling and that the NMDAR subunit,

GluN1, collocates with Cx36 at gap junctions. Although a shunting effect of NMDAR activation, due to increased input conductance (Gin) and decreased junctional conductance (Gj), may contribute to reductions in electrical coupling, the potentiating effect of NMDAR activation on electrical transmission is mediated by CaMKII-dependent mechanisms. Supporting this hypothesis, we show that the strength of electrical coupling among IO neurons, as measured by the coupling coefficient (CC), is decreased in a floxed CaMKIIα knockout (KO) transgenic mouse as compared to WT (C57BL/6J). We crossed CaMKIIα KO mice with a second mouse line expressing cre under the ptf1a promoter, resulting in a tissue-specific genetic rescue of CaMKIIα activity in the IO. This restored CC to within WT levels (WT: 0.59 ± 0.16%, N = 28; KO: 0.13 ± 0.04%, N = 22; Rescue: 0.83 ± 0.39%, N = 6, mean ± SEM). Likewise, Gj was decreased between connected pairs from KO mice and was restored to WT levels in the IO-specific rescue (WT: 58.38 ± 12.89 pS; KO: 24.66 ± 10.02 pS, Rescue: 51.53 ± 15.69 pS). IO neurons from KO mice depolarized in response to bath application of 5 µm NMDA, indicating the NMDA receptors were present and active. However, CC was largely unaffected by NMDA in neurons from KO mice (Strengthened: N = 2/17, Weakened: N = 2/17). WT neurons showed mixed responses to NMDA (Strengthened: N = 4/20; Weakened: N = 12/20), and neurons from Rescue mice exhibited robust potentiation of CC (Strengthened: N = 3/3). Subthreshold oscillations in membrane potential were less prevalent in KO mice (WT: 87.9%, KO: 23.8%, Rescue: 61.5%), but the amplitude (WT: 2.55 ± 0.21 mV, N = 45; KO: 2.07 ± 0.38 mV, N = 16; Rescue: 7.65 ± 2.13 mV, N = 15) and frequency (WT: 4.95 ± 0.36 Hz; KO: 4.92 ± 0.34 Hz; Rescue: 6.25 ± 0.90 Hz) of those neurons that did oscillate were typical. We conclude that the basal level of electrical coupling among IO neurons and its strengthening by NMDA receptor activation are dependent on CaMKIIα.

Abstract: Connexins (cxs) belong to a family of transmembrane homologous proteins that form intercellular channels. Each intercellular channel is formed by two hemichannels or connexons. Depending on the connexin subtype hemichannels may be functional. The superior cervical ganglia (SCG) is the only ganglion in the sympathetic nervous system that innervates the head and neck, where it innervates many organs, glands and parts of the carotid system. SCG are formed by neuronal units surrounded by satellite glial cells and nerve fibers. Electrical coupling among satellite glial cells in SGG. In addition, incidence of coupling was enhanced by Ach. Moreover, electrical coupling between SCG cultured neurons from neonatal rats has been described. However, the molecular substrate for these cell-cell interactions are unknown. Recently, we found that both satellite glial cells and neurons express connexin 36 in dorsal root ganglia. Here we asked whether cervical superior ganglia also express this gap junction protein. For this, cervical superior ganglia rat sections were stained with a previously characterized anti-Cx36 antibody and analyzed by immunohistochemistry. We found that all neurons in SGCs express Cx36. Their levels of expression were similar. Cx36 was also found at membranes of nerve fibers. Satellite glia cells also express Cx36. SGC sections incubated only with secondary antibody were not stained with anti-Cx36. The subcellular distribution of this protein is presently analyzed by inmunolabeling techniques as well as the expression of Cx36 mRNA using qRTPC. In summary, we provide evidence that Cx36 channels may intercommunicate SCG cells.

Title: Loss of synchronous activity across gap junctions results in a phase-dependent change in coupling conductance magnitude

Authors: *D. R. KICK[1], D. J. SCHULZ[2];
[1]Div. of Biol. Sci., Univ. of Missouri, Columbia, MO; [2]Div. of Biol. Sci., Univ. of Missouri-Columbia, Columbia, MO

Abstract: Many rhythms necessary for survival (e.g. chewing, breathing) require precise coordination between the neurons which generate them. In the Cancer borealis cardiac ganglion (CG) motor neuron coordination is facilitated by gap junction mediated electrical coupling. Altered coupling has been shown to be a component of homeostatic compensation, and a product of tetanic nerve stimulation or evoked spiking. However, the salient electrophysiological signal driving gap junction modification has not been determined.
Here, we use two electrode voltage clamp to alter the synchrony and total depolarization of two CG motor neurons which are entirely synchronous at baseline. We separate the effect of desynchronization between neurons from that of depolarization by introducing a phase shift or aberrantly depolarizing the two clamped neurons. We tested phase angles of 0°, 22.5°, 45°, 90°, (0, 1/16th, 1/8th, or 1/4th the period) and increased the amplitude and duration of depolarization, with and without a 22.5° delay.
Using a resampled linear model we find coupling resistance changes due to an interaction of phase and time (empirical p (ep) &lt 0.001). Furthermore, the time course and directionality of the effect appears to change with phase, 22.5° resulting in a decrease of the median delta of -0.6 megaohms (MΩ) by 20 minutes whereas 90° manifested increase in the median delta of +0.5 MΩ by 60 minutes. Our results suggest there may be a cost to network output that is non-linear with respect to phase angle - minimized by increasing coupling when the difference between activity is slight and decreasing when it passes a threshold.
To confirm that the effects seen are due to desynchronization, we compared the effect of two phase angles (0° and 22.5°) with and without elevated depolarization. We find elevated depolarization has no effect on coupling resistance (ep &gt 0.9), whereas phase does (ep &lt 0.01). Taken in conjunction with the above, we conclude that desynchronization rather than depolarization per se induces modulation of coupling strength. While the gap junctions are unaffected, depolarization amplitude appears to alter coupling indirectly by altering membrane resistance over time (ep &lt 0.01).
We extend these findings by using dynamic clamp to assess the consequences of coupling strength and desynchronization to motor neuron output. We achieve this by artificially coupling motor neurons of two active CGs, permitting full control over coupling conductance and a wide range of phase angles. Taken together our work suggests a specific signal which drives coupling change and suggests why non-linear regulation with respect to desynchronization may occur.

Abstract: Memory for cues associated with threat is critical for survival, and a leading model for elucidating how sensory information is linked to adaptive behavior by learning. While the brain-wide circuits mediating auditory threat memory have been intensely investigated, it remains unclear whether auditory cortex is critically involved. Here, we address the role of auditory cortex and the adjacent temporal association area (TeA) in auditory threat memory using a combination of optogenetic activity manipulations in defined cortical areas and output pathways, viral tracing, pathway-specific *in vivo* 2-photon calcium imaging, and computational analyses of population plasticity. Intriguingly, our results reveal that for both acquisition and retrieval of threat memory, auditory cortex is selectively required for memory to complex stimuli, while stimulus processing in TeA is vital for all forms of cued threat memory. Additionally, we found that inhibition of ventral auditory cortex and TeA resulted in much stronger memory retrieval deficits than inhibition of primary auditory cortex. Retrograde tracing revealed that this medio-temporal impact gradient is paralleled by the organization of projections to the lateral amygdala (LA), an area known to be crucial for threat memory, with the majority of amygdala-projecting neurons in temporal neocortex located in TeA. Consistent with a critical role for information transfer from temporal neocortex to the amygdala in memory retrieval, inhibition of temporal neocortex axon terminals in the amygdala produced a robust retrieval deficit. Finally, *in vivo* 2-photon calcium imaging specifically of amygdala-projecting neurons in auditory cortex before and after threat conditioning revealed that this projection pathway governs threat memory expression through a balanced form of population plasticity selectively supporting the discrimination of salient sensory stimuli. In summary, our results demonstrate a striking impact of CS complexity on the role of auditory cortex, and identify temporal neocortex and its projection to the LA as critical substrates for acquisition and expression of auditory threat memory. Information transfer from temporal neocortex to the LA thus plays a critical role in cued threat memory.

Title: Cell assemblies representing contextual emotional memory in the basolateral amygdala

Authors: K. WATANABE[1], G. GIRARDEAU[2], G. BUZSAKI[3], J. P. JOHANSEN[4], ***T. FUKAI**[5];
[1]Ascent Robotics, Inc, Tokyo, Japan; [2]Inst. du Fer-à-Moulin, Inserm/Sorbonne Univ., Paris, France; [3]New York University, Sch. of Med., New York, NY; [4]RIKEN Ctr. for Brain Sci., Saitama, Japan; [5]Okinawa Inst. of Sci. and Technol., Onna-son, Japan

Abstract: The basolateral amygdala (BLA) is required for the expression of fear learning and memory, but it is not clear how contextual emotional memories are represented in BLA neurons. Recent recordings of neural ensembles in rats learning the location of an aversive air puff in a linear track have revealed coordinated reactivations of hippocampal-BLA cell pairs during sleep following learning [1]. Sequential firing of neuronal ensembles plays an active role in hippocampal memory processing, but it is not known whether sequential firing of cell assemblies exists in the BLA and, if so, whether this represents any aspect of contextual emotional memory. By using edit distance [2], a metric in computer science to measure similarity between two strings, we have recently developed a machine learning method to detect the recurring firing patterns of neuronal ensembles. With this method, we identified subgroups of BLA neurons that are repeatedly activated in fixed sequential firing patterns near the location of air puff. The recurring activation was stronger for the run direction involving the air puff than for the "safe" direction where no air puff was presented. Moreover, when the location of the air puff was changed and animals learned the new location, the reactivation of the previous subgroup of BLA neurons largely decreased, while a different subgroup became activated over the course of training at the new air puff location. These results suggest that contextual emotional memory is encoded as sequential firing of cell assemblies in the BLA.

Title: TBI increases gamma in amygdala-prefrontal cortex circuitry and impairs extinction of fear memories

Authors: *M. D. SERGISON[1,2], C. D. ADAM[1,2], C. COTTONE[1], N. MAHESHWARI[1], A. V. ULYANOVA[1,2], H.-C. I. CHEN[1,2], V. E. JOHNSON[1,2], J. A. WOLF[1,2];

Abstract: Traumatic Brain Injury (TBI) has been implicated in memory deficits and anxiety disorders such as Post-Traumatic Stress Disorder (PTSD), and is commonly seen in Veterans returning from combat. To investigate the effect of TBI on substrates of fear memory, we subjected rats to a lateral fluid percussion injury (FPI) and chronically implanted high-density silicon electrodes in the basolateral amygdala (BLA) as well as bipolar electrodes in medial prefrontal cortex (mPFC) and ventral hippocampus (vHC). We recorded during an anxiety and fear behavior paradigm 2 weeks post injury using elevated plus maze (PM), open field (OF), and fear conditioning (FC). The FC paradigm consisted of acquisition, where rats learned to associate white noise (CS+) with a mild footshock, followed by two days of extinction, where rats were presented the white noise and a novel tone (CS-) without the footshock. Although we found no difference in anxiety behaviors and fear acquisition between FPI and sham surgery rats, FPI animals extinguished fear at a slower rate and showed a higher fear response on day 2 of extinction. We tested an additional cohort of rats 6 months post injury. Sham and FPI rats at 6 months showed no difference in the rate of fear acquisition, but both groups were faster compared to rats tested at 2 weeks. FPI animals at 6 months also had slower fear extinction than the 6 month sham animals, and both groups extinguished fear slower than 2 week FPI rats, suggesting an aging effect. In the 2 week animals, we found that FPI led to an increase in the power of baseline gamma oscillations (45-110Hz) in BLA, which further increased following FC in comparison with sham animals. During extinction, this increased local BLA gamma began to return to baseline levels. BLA gamma is thought to arise from interactions of interneurons with pyramidal cells, so this increase may result from a compensatory interneuronal response to increased pyramidal cell activity. Additionally, FPI led to an increased mPFC-BLA gamma

coherence post FC, which also lowered during extinction, and an increase in phase-amplitude coupling of BLA gamma to low frequencies in mPFC, which shifted to theta after acquisition. These changes to the amygdala-prefrontal interactions could represent dysfunction in top-down extinction pathways, leading to impaired extinction. We also have mirrored our paradigm in a pig model, using heart rate as an indicator of fear state. We found that heart rate changes during extinction follows the traditional extinction curve during and between trials. Combined with future recordings from these animals, this paradigm will help present a thorough elucidation of the limbic circuitry affected by TBI and PTSD.

Title: A projection from ventral hippocampus to basolateral amygdala is involved in the destabilization of remote fear memory

Authors: *Y. HAN[1], J. SHI[2], L. LU[3];
[1]Peking Univ., Beijing, China; [2]Natl. Inst. On Drug Dependence of Peking Un, Beijing, China; [3]Inst. Mental Health,Peking Univ. Sixth Hospita, Beijing City, China

Abstract: Background: Fear response often occurs after reactivation of fear memories by exposure to unconditioned stimulus (UCS) or fear-associated conditioned stimuli (CSs). Fear memories that were reactivated by fear-associated CSs undergo reconsolidation and interfering with this reconsolidation inhibit subsequent fear response. Our previous study demonstrated the efficacy of a novel UCS-based memory reconsolidation interference procedure for inhibiting nicotine craving induced by exposure to diverse nicotine-associated CSs and nicotine itself. In present study we intend to investigate the neural circuits underlying the destabilization after UCS-based retrieval. **Methods**: Brain activity was assessed by c-fos immunofluorescence after CS or UCS retrieval 1 d or 14 d after fear conditioning. Designer receptors exclusively activated by designer drugs (DREADDs), anisomycin or propranolol were used to explore the involvement of ventral hippocampus (vHipp) and basolateral amygdala (BLA) in the reconsolidation of recent and remote fear memory. **Results**: We found that CS and UCS retrieval induce different patterns of brain region activation and this pattern change with time. Both CS and UCS retrieval 1 d after learning induced the activation of prelimbic cortex (PrL), dorsal hippocampus and BLA.

Fourteen days after conditioning, CS retrieval activated PrL and infralimbic cortex, while UCS retrieval activated PrL, vHipp, BLA and central amygdala. Propranolol microinjections into the BLA or anisomycin microinjections into the vHipp disrupted the UCS retrieval-mediated reconsolidation of remote fear memory, and this memory impairment effects persisted for at least two weeks with no recovery after reminder shock. Moreover, inactivation of vHipp, but not PrL projections to BLA by DREADDs after UCS retrieval impaired remote fear memory.
Conclusion: Our results suggest that a projection from ventral hippocampus to basolateral amygdala may be involved in UCS retrieval-induced reconsolidation of remote fear memory.

Title: Fear induced synaptic reorganization in the BLA-mPFC connectivity

Authors: *J. SONG, J. KIM;
Ctr. for Functional Connectomics, KIST Korea Inst. of Sci. & Tech., Seoul, Korea, Republic of

Abstract: The neural connection between the basolateral amygdala (BLA) and the medial prefrontal cortex (mPFC) is important for the acquisition and extinction of fear. Previously, it is demonstrated that fear conditioning results in synaptic changes of mPFC neurons, such as the elimination of individual spines and alterations in the synaptic efficacy (1,2). However, detailed descriptions of input- and cell type-specific changes in single neurons remains elusive.
In this study, taking advantage of our newly developed mGRASP as a synapse detector, we sought to delineate the fear-induced cell-type-specific changes in the BLA→mPFC synaptic connectivity. We found that fear conditioning induces layer- and cell type-specific decreases in the anatomical measures of the BLA→mPFC synaptic connectivity.Our observation suggests that the cell-type- and location-dependent differences in synaptic decreases in the BLA→mPFC connectivity may result in the changes of net E/I balance in the mPFC microcircuits. We further investigated the changes in the synaptic connectivity in the reciprocal projection (i.e. mPFC→BLA) and discuss its implication in fear-induced responses.

Title: Functional disconnection between ventral hippocampus and prelimbic cortex impairs the acquisition of contextual fear conditioning with temporal discontinuity

Authors: *T. B. DOS SANTOS, A. E. WALLAU, J. C. K. SOARES, M. M. DE OLIVEIRA; Psychobiology, Univ. Federal de São Paulo, Sao Paulo, Brazil

Abstract: A previously experienced context can be associated separated by a time interval of 5s from a posterior aversive stimulus. This task was called contextual fear conditioning with temporal discontinuity (CFC-5s) and differentially required prelimbic cortex (PL) activity. However, it is unclear the effect of this time factor in the interplay among brain regions to form the memory trace. Because there are ascending ipsilateral connections from ventral CA1 hippocampus (CA1v) to PL; PL is related to the maintenance of stimuli over time and CA1v to contextual fear conditioning (CFC), their functional interaction could be necessary for the acquisition of CFC-5s, and so, in a distinctive manner compared to delay associations, as standard CFC. We investigated the effect of pharmacological functional disconnection of CA1v and PL in CFC-5s and CFC tasks. Male Wistar rats of 11-week-old were submitted to ipsi or contralateral cannula implantation in CA1v and PL, counterbalanced by side. After 1-week recovery, rats were infused with muscimol (IPSI or CONT groups) or PBS (PBS group, counterbalanced) 30min before training. In CFC-5s task, rats were exposed for 5min to the context and then allocated in transition boxes for 5s. Next, they were placed in the context receiving one footshock immediately (0.8mA, 1s). In CFC task, rats received a footshock after 5min in the context. Test was performed 48h later and freezing responses were measured during 5min. Rats were submitted 7d later to re-training and 48h later to re-test, similarly to the described, but without any infusions. Data were analyzed by Generalized Estimating Equations adjusted for Gamma distribution followed by Bonferroni pairwise contrast. In CFC-5s, PBS and

IPSI groups had significantly higher freezing responses in test compared to their values in training and higher freezing responses compared to CONT group in test. In CFC task, all groups had significantly higher freezing responses compared to their values in training and none differed in the test. There was no difference between groups in re-training or in re-test in both tasks, indicating that the impairment observed was due the disconnection. Time affects the neurobiology of CFC. The functional connection between CA1v-PL is necessary for acquisition of CFC-5s, but not CFC.

Title: Distinct roles of the anterior and posterior retrosplenial cortices in encoding, but not retrieval, of trace fear memory

Authors: *S. TRASK[1], S. E. PULLINS[2], F. J. HELMSTETTER[3];
[1]The Univ. of Wisconsin - Milwaukee, Milwaukee, WI; [2]Psychology, Univ. of Wisconsin - Milwaukee, Milwaukee, WI; [3]Deptartment of Psychology, Univ. of Wisconsin Milwaukee Dept. of Psychology, Milwaukee, WI

Abstract: The retrosplenial cortex (RSC) has a prominent role in memory and has dense reciprocal connections with other brain regions important for memory formation and retrieval including the hippocampus and prefrontal cortex. Trace fear conditioning, in which a neutral conditional stimulus (CS) is followed by a brief stimulus-free interval before a footshock (the unconditional stimulus or UCS), is a powerful method used to study memory in rats and can be separated into encoding (e.g., original learning) and retrieval (later performance to the CS) phases. Importantly, this type of learning incorporates information about the environment in which learning takes place ("where" information) with information about the CS ("what" information). While most research on encoding and retrieval of trace fear memory has focused on the hippocampus and prefrontal cortex, recent data has begun to suggest a critical role for the RSC in trace memory encoding. In two experiments, we tested the hypothesis that the posterior region of the retrosplenial cortex (pRSC, which is closely interconnected with the hippocampus) would have a selective role in both encoding and retrieval of context-related information while the anterior portion (aRSC) would be important for processing event-related (e.g., CS-UCS)

information. Using optogenetics, either the aRSC or pRSC was silenced precisely during the CS-UCS period on training trials during memory encoding (Experiment 1) or during the CS period of retrieval testing (Experiment 2). In Experiment 1, we found that silencing the aRSC during acquisition resulted in a selective impairment in responding to the CS during retention testing, whereas silencing the pRSC during acquisition resulted in impaired responding to the training context. However, in Experiment 2 silencing of either region resulted in impaired CS freezing. Preliminary data quantifying immediate early gene (e.g., zif268) expression in RSC support effective and anatomically selective inhibition of neural activity. Together, these results suggest that while encoding of trace fear conditioning relies on distinct "where" and "what" circuits, both regions are needed later expression of that memory. While the role of the retrosplenial cortex has been demonstrated in other paradigms examining contextually-bound learning, these results suggest distinct roles for the anterior and posterior regions of the retrosplenial cortex in the encoding, but not retrieval, of trace fear memory.

Title: Ventral hippocampus dynamically regulates encoding of shock-related information in the basolateral amygdala during trace fear conditioning

Authors: *M. R. HERBST[1], R. C. TWINING[1], M. R. GILMARTIN[2];
[2]Biomed. Sci., [1]Marquette Univ., Milwaukee, WI

Abstract: The association of a neutral conditional stimulus (CS) and aversive footshock unconditional stimulus (UCS) in fear conditioning critically depends on the amygdala. However, if the CS and UCS are separated in time, additional brain areas are needed, including the prelimbic cortex (PL) and the ventral hippocampus (VH). We have identified a putative role for the PL in providing sustained firing during the CS-UCS interval (Gilmartin & McEchron, 2005; Gilmartin et al., 2013); however, the contribution of the VH to memory formation and learning-related neuronal firing remains unclear. Here, we first characterized neuronal responses in the VH during trace fear conditioning (TFC) using *in vivo* electrophysiological recordings of area CA1 of the VH. The majority of recorded VH neurons (90%) encoded the shock UCS, with the predominate response being a sustained increase in neuronal spiking (72%). Since the VH sends

direct monosynaptic connections to multiple targets required for trace fear memory, these results suggest that the VH may provide shock-related information to these structures, perhaps in parallel. We have shown previously that input from the VH to the PL during trace fear conditioning is needed for contextual, but not cued, fear memory. In the current study we silenced VH terminals in the basolateral amygdala (BLA) in rats using projection targeting optogenetics (AAV-ArchT) while simultaneously recording BLA neurons during TFC. Silencing occurred briefly during each CS-UCS pairing, beginning 20-sec prior to CS onset and terminating 20-sec after UCS offset. In controls, the shock caused predominantly sustained increases in BLA neuronal spiking (35.4% excitatory; 6.3% inhibitory). However, silencing VH input to BLA during these trials not only reduced shock-related excitatory encoding (8.3%) but, in some cases, inverted it (47.2% inhibitory). The loss of VH input to BLA led to deficits in contextual fear and increased fear to the cue in a shifted context. These initial findings suggest that VH modulates the encoding of shock information in the BLA during training to differentially affect cued and contextual fear.

Title: Prefrontal neuronal encoding of threat-predictive cues across the estrous cycle

Authors: M. LAVIOLA, M. HERBST, R. C. TWINING, ***M. R. GILMARTIN**;
Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: The association of a neutral conditional stimulus (CS) and aversive footshock unconditional stimulus (UCS) that are separated in time, as in trace fear conditioning, requires activity in the prelimbic area (PL) of the medial prefrontal cortex. We have previously shown that a subset of PL cells shows sustained firing in response to the CS and that optogenetic silencing of prefrontal activity during the trace interval between the cue and shock prevents learning (Gilmartin & McEchron, 2005; Gilmartin et al., 2013). Recently, we have uncovered sex differences in the prefrontal cortical contribution to trace conditioning (Kirry et al., 2018; 2019). In one study, the estrous cycle gated the memory-impairing effects of a muscarinic antagonist in the PL (Kirry et al., 2019), which suggested that circulating ovarian hormones may

modulate prefrontal encoding during aversive learning. Here we recorded neuronal activity in the medial prefrontal cortex during the acquisition and extinction of trace fear conditioning. The estrous cycle of female Long-Evans rats was tracked for two cycles and then half of the rats started training on the day of proestrus and the other half started training on the day of metestrus. Training occurred over two days and testing in a shifted context occurred when the rats returned to their initial training cycle stage. Initial results (n = 3/group) revealed similar sustained activation to the CS but divergent encoding of the UCS during day 1 of training. Proestrus females exhibited a robust increase in firing in response to the UCS, and metestrus females exhibited a modest response and even a decrease in firing. Neuronal encoding on day 2 of training and subsequent conditional fear to the cue and context at test was similar between groups. Follow-up experiments will determine whether these divergent patterns of PL encoding of the UCS mediate cycle differences in cued fear retention after only one day of training, that can be overcome with additional training. These findings will reveal how prefrontal encoding of threat-related stimuli does and does not change across the estrous cycle, shedding light on how neuromodulation of prefrontal activity differentially affects the formation of fear memories between sexes and across the estrous cycle.

Title: Silencing afferent input to prefrontal cortex during trace fear conditioning

Authors: *R. C. TWINING, A. J. KIRRY, K. LEPAK, M. R. GILMARTIN;
Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: The prelimbic medial prefrontal cortex (PL) receives afferent input from the amygdala, insula, mediodorsal thalamus (MD), and the ventral hippocampus (VH). It is an integral component of a neural system that mediates cognitive and emotional processes and regulates a wide range of adaptive behaviors (Hiser and Koenigs, 2018). In humans, dysfunction of the mPFC and its functional connections is associated with anxiety disorders and post-traumatic stress disorder. In animal models, the mPFC is critical for cognitive and emotional aspects of conditional fear expression, extinction, and renewal, the encoding of aversive

locations, prospective or temporal encoding, and spatial working memory (Ramanathan et al., 2018; Marek et al., 2018; Sharpe and Killcross, 2015, Spellman, 2015; Sotrez-Bayon, 2012); however, it is not required during acquisition of standard fear conditioning when an auditory conditional stimulus (CS) co-terminates with a shock unconditional stimulus (UCS). The PL is required for the acquisition of cued fear only when a temporal gap or trace interval is imposed between the CS and UCS. Indeed, approximately 30% of PL neurons exhibit sustained increases in learning-related neuronal spiking that bridges the trace interval (Gilmartin & McEchron, 2005) and optogenetic silencing of this activity blocks the formation of a trace fear memory (Gilmartin, 2013). While the PL mediates cued and contextual fear during TFC, it is unknown which afferent inputs support learning or learning-related neuronal spiking. Given the similar density of monosynaptic input to PL from the VH and MD and their demonstrated importance for spatial working memory, we hypothesized that either or both inputs would be required for trace fear memory and might regulate learning-related PL activity. Here we injected AAV9/CAG-ArchT-GFP into the VH or MD (750 or 500 nl/side) and implanted optic fibers 0.5 mm above the terminals in PL or cell bodies in the MD. We silenced during a 2-trial TFC protocol and repeated for 3 days. Cued and contextual fear was tested without silencing after each 2-trial block. So far, we have shown that silencing VH-PL impaired context fear but could be restored if the VH-PL was silenced again during retrieval. Interestingly, monosynaptic VH input to PL is not required for cued fear. Therefore, despite the dependence of cued fear on both the PL and VH, either indirect or parallel afferents mediate trace fear memory formation. Since the MD inputs sustain PL neuronal activation across temporal delays during spatial working memory tasks (Bolkan, 2017), the ongoing study will determine the extent to which trace fear memory depends on MD neuronal activity and its inputs to PL.

Title: Atlas-based mapping of Fos-immunoreactive neurons in the medial prefrontal cortex and ventral hippocampus in association with context fear in the juvenile and adult male rat

Authors: *A. PINEDA SANCHEZ[1], A. ENRIQUEZ[1], K. NEGISHI[1], A. J. SANTARELLI[2], A. M. KHAN[1], A. M. POULOS[2];
[1]Biol. Sci., Univ. of Texas at El Paso, El Paso, TX; [2]Psychology, State Univ. of New York, Univ. At Albany, Albany, NY

Abstract: The hippocampus and the medial prefrontal cortex (mPFC) are important brain regions for contextual fear retrieval in rats. We have reported (Santarelli *et al*., 2018; *Neurobiol Learn Mem*) greater numbers of Fos-immunoreactive (Fos-ir) neurons in the juvenile mPFC and adult ventral hippocampus (vH) for rats that acquired a contextual fear response, which was not evident in infants (P19). Here, we focused on atlas-based mapping for the precise spatial distributions of these Fos-ir patterns. Two-channel immunofluorescence images of Nissl-stained tissue immunolabeled for Fos-ir were examined in juvenile and adult rats for one of three different behavioral conditions: home cage and non-shock controls; or a delayed shock experimental group. Nissl cytoarchitecture was parcellated, assigned locations within a rat brain atlas (L. W. Swanson (2018) *Brain Maps 4.0*, *J Comp Neurol*) to plot mPFC and vH Fos-ir patterns, and the boundaries established from the Nissl channel overlaid onto the second channel showing Fos-ir. Each Fos-ir neuron was then annotated onto a data layer and the final drawings transferred to the corresponding atlas templates. For Fos-ir neuronal distributions in the vicinity of the mPFC, we identified Swanson atlas level 8 gray matter structures as harboring significant numbers of neurons, especially along medially located subregions of the mPFC (dorsal part of the anterior cingulate area, and prelimbic and infralimbic areas), as well as olfactory-associated regions, orbitofrontal subregions, tenia tecta, and claustrum. For the ventral hippocampus, robust Fos-ir neurons were identified across groups at atlas level 39, specifically within dorsal and ventral aspects of the subiculum, CA1, and CA3 regions; and within the dentate gyrus. The careful delineation of the Fos-ir neuronal distributions in these animals is a critical step for our ongoing analysis of neuronal activation associated with context fear across developmental ages and will facilitate detailed quantitative analyses across behavioral conditions in the near future. These data can then, in turn, be contextualized in relation to other datasets that have also been mapped within the same spatial reference.

Abstract: In adult rodents the ventral hippocampus (vH) and medial prefrontal cortex (mPFC) contribute to the retrieval of contextual fear memories. However, in juvenile rats it remains to be known about the relative contributions of these regions in contextual fear conditioning. In the current study, we sought to determine the necessity of the vH and mPFC in the retrieval contextual fear memories in juvenile and adult Long-Evans male rats by temporary inactivation of these regions. During surgery, bilateral cannulae were stereotaxically positioned within vH or mPFC. Following recovery, juvenile and adult rats underwent standard contextual fear conditioning procedures. Prior to testing of context fear, GABA-A agonist, muscimol or saline were infused within vH or mPFC. Our preliminary results indicate a differential effect of infusion upon age and site of infusion on observed freezing during context fear testing. These results may suggest that there may be age-dependent differences in the functional contribution of vH and mPFC in contextual fear conditioning.

Title: Neuronal tract tracing of developmental fear-related neural circuitry in male and female rats

Authors: *N. ODYNOCKI, L. M. COLON, A. M. POULOS;
Univ. at Albany State Univ. of New York, Albany, NY

Abstract: Much of our current understanding of the neural circuits in context fear conditioning has been established in the adult male rat. The basolateral amygdala complex (BLA) and the

major sources of its afferents - the medial prefrontal cortex (mPFC) and CA1 region of the ventral hippocampus (vCA1) - represent a major portion of the neural circuit underlying the processing, storage and retrieval of conditional fear responses. We and others have previously demonstrated in developing male rats that the connectional and functional status of many of these afferents undergoes a protracted development. In contrast, little is known regarding the neuroanatomical status of the BLA afferents and efferents in the developing female rat. Here we use both the anterograde and retrograde tracers, *Phaseolus vulgaris*-leucoagglutinin (PHA-L) and Fluorogold (FG), respectively, to elaborate the distributions, densities and inter-connectivity of the BLA, mPFC and vCA1 in juvenile and adult male and female Long-Evans rats. We have begun initial injection site mapping as part of a larger project to map developing BLA afferents and vCA1 and mPFC efferents. In experiment 1, FG iontophoretic injections were targeted within the basolateral amygdalar nuclei of female rats. In experiment 2, PHA-L iontophoretic injections were targeted within vCA1 and mPFC regions of male and female rats. After four days, animals were perfused, brains were extracted, sectioned and Nissl-stained. The cytoarchitecture of specific coronal sections was parcellated and aligned to a rat brain atlas (L.W. Swanson, 2018 *Brain Maps 4.0, J Comp Neurol*). These parcellations were used to inform the bounded limits within which PHA-L and FG injection deposits were confined. The BLA injection sites were confirmed within the rostral BLA and resulted in FG labeling within the ventral hippocampus CA1 and medial prefrontal cortical regions. A similar approach as that used to map the injection sites is being used as part of our ongoing analyses to map the distribution and/or density of FG-labelled neurons and PHA-L-labelled terminals within prelimbic and infralimbic areas, ventral CA1 and anterior and posterior portions of the BLA. Collectively, these studies will provide high-spatial resolution maps of key neural projection patterns that likely contribute to conditional fear responses.

Title: The bed nucleus of the stria terminalis regulates context-dependent flight behavior in rats

Authors: *M. TOTTY[1,2], N. WARREN[1], K. R. RAMANATHAN[1,2], R. RESSLER[1,2], S. MAREN[1,2];

Abstract: Fadok and colleagues (2017) have developed a modified Pavlovian fear conditioning procedure in which a serial conditioned stimulus (SCS) consisting of serial presentations of pure tone (7 kHz) and white noise (1-20 kHz), followed by a footshock unconditioned stimulus (US). After conditioning, mice exhibit freezing to the tone, but transition to flight (e.g. escape jumps and increased movement speed) during the noise. The transition from freezing to flight behavior is gated by the central nucleus of the amygdala (CeA), and flight responses are only elicited within the conditioning context (Fadok et al., 2017). Here, we replicate these behavioral findings in male and female Long-Evans rats and further investigate how flight responses are contextually regulated. After SCS conditioning, rats either received unsignaled footshocks in a novel context (Shock) or were exposed to the same novel context for an equal amount of time (No-Shock). The next day, Shock animals displayed flight responses to SCS-alone presentations within the unsignaled footshock context, whereas No-Shock animals did not. We therefore conclude that flight responses are dependent upon contextual fear, irrespective of where SCS conditioning occurs. The bed nucleus of the stria terminalis (BNST), central amygdala (CeA), and the ventral hippocampus (VH) have been implicated in contextual fear. In the second experiment, we show that muscimol inactivation of either the BNST or the CeA, but not the VH, diminishes flight responses in the conditioning context. These findings advance our understanding of the neural circuitry underlying the contextual regulation of active defensive behavior by demonstrating that flight responses are dependent upon contextual fear and that this effect is mediated by the BNST.

Title: Overexpression of microRNA-33 in the bed nucleus of the stria terminalis blocks state-dependent learning of contextual fear in rats

Authors: *R. S. BLAIR[1], G. M. ACCA[2], S. MAREN[1,2], N. NAGAYA[1,2];
[1]Psychological and Brain Sci., [2]Inst. for Neurosci., Texas A&M Univ., College Station, TX

Abstract: Sex steroids can modulate emotional behavior in both rodents and humans. We have previously shown that allopregnanolone (ALLO), a progesterone metabolite, can induce state-dependent contextual fear when infused into the bed nucleus of the stria terminalis (BNST) of male rats. Because ALLO is a strong potentiator of $GABA_A$ receptors, the state dependence it

confers may involve regulation of GABAergic tone. In mice, intra-hippocampal infusion of gaboxadol induces state-dependent contextual fear by suppressing miR-33, a microRNA that regulates GABA-related proteins. To determine if miR-33 contributes to ALLO-induced state-dependent learning, we bilaterally injected a virus designed for overexpression (GFP rno-mir-33 AAV) into the BNST of adult males; blank virus (AAV-mir-GFP-Blank) was injected into the control group. Two weeks post-injection, animals received intra-BNST infusions of either ALLO (8 μg/μl) or vehicle (VEH; 30% β-cyclodextrin). Within 10 min, they were subjected to Pavlovian fear conditioning consisting of 5 tone (2kHz, 10 s, 80 dB)-footshock (2 s, 1 mA) pairings. On subsequent days, retention tests for context (10 min) and tone (4 CS-alone trials in a novel context) followed infusions of ALLO only. VEH-trained, ALLO-tested controls displayed low levels of contextual freezing compared to ALLO-ALLO controls, consistent with state-dependent learning. In contrast, VEH-ALLO rats from the miR-33-injected group displayed contextual freezing similar to ALLO-ALLO rats of both groups, consistent with a lack of state-dependent learning. Cue-induced freezing was not affected by viral transduction or hormone treatment. These findings suggest that overexpression of miR-33 in the BNST can block induction of state-dependent contextual fear. Thus, ALLO-induced state-dependent fear learning may involve miR-33-regulated, GABA-mediated molecular pathways within the BNST.

Title: Nucleus reuniens influences medial prefrontal cortex and hippocampal neuronal activity during retrieval of extinguished fear memories

Authors: *K. R. RAMANATHAN[1], J. JIN[1], K. DEISSEROTH[2], S. MAREN[1];
[1]Dept of Psychological and Brain Sci. & Inst. for Neurosciences, Texas A&M Univ., College Station, TX; [2]Bioengin & Psych, Stanford Univ. Dept. of Psychology, Stanford, CA

Abstract: Coordinated activity between the medial prefrontal cortex (mPFC) and hippocampus (HPC) is essential for encoding and retrieving spatial, working and contextual memories. The nucleus reuniens (RE) is a ventral midline thalamic nucleus that has a role in synchronizing activity in the HPC and mPFC. In Pavlovian fear conditioning, we have recently showed that RE

inactivation impairs both the acquisition of hippocampal-dependent contextual fear memories as well as the extinction of fear to an auditory conditioned stimulus (CS). We hypothesized that the extinction deficit may be due to RE inactivation impairing behaviorally relevant neural activity in the mPFC and HPC. To test this idea, we examined the influence of RE inactivation on the induction of c-fos in mPFC and HPC by an extinguished conditional stimulus (CS). Consistent with our hypotheses, we found that inactivation of RE impaired the expression of extinction and this was associated with decreased c-fos expression in both the mPFC and HPC. We are currently exploring the functional role for RE projections to mPFC or HPC (or both) in extinction retrieval using an intersectional optogenetic strategy. Taken together, these data show that RE has a crucial role regulating neuronal activity in the mPFC and HPC that promotes successful retrieval of extinguished fear memories.

Title: Locus coeruleus norepinephrine drives stress-induced increases in basolateral amygdala firing and impairs extinction learning

Authors: *O. W. MILES[1], T. F. GIUSTINO[2], K. R. RAMANATHAN[2], M. S. TOTTY[1], S. MAREN[1];
[1]Psychological and Brain Sci., [2]Texas A&M Univ., College Station, TX

Abstract: Stress impairs extinction learning and these deficits depend, in part, on stress-induced norepinephrine release in the basolateral amygdala (BLA). For example, systemic or intra-BLA administration of propranolol reduces the immediate extinction deficit (IED), an impairment in extinction learning that occurs when extinction trials are administered soon after fear conditioning. Here, we explored whether locus coreuleus norepinephrine (LC-NE) regulates stress-induced changes in spike firing in the BLA and consequent extinction learning impairments. Rats were implanted with recording arrays in the BLA and, after recovery from

surgery, underwent a standard auditory fear conditioning procedure. Fear conditioning produced an immediate and dramatic increase in the spontaneous firing of BLA neurons that persisted (and in some units increased further) up to an hour after conditioning. This stress-induced increase in BLA firing was prevented by systemic administration of propranolol. Conditioning with a weaker footshock caused smaller increases in BLA firing rate, but this could be augmented by chemogenetic activation of the LC. Conditioned freezing to a tone paired with a weak footshock was immune to the IED, but chemogenetic activation of the LC prior to the weak conditioning protocol increased conditioned freezing behavior and induced an IED. These data suggest that stress-induced activation of the LC increases BLA spike firing and causes impairments in extinction learning. Stress-induced increases in BLA activity mediated by LC-NE may be a viable therapeutic target for individuals suffering from stress- and trauma-related disorders.

Title: Dorsal hippocampus mediates covert retrieval of a contextual fear memory

Authors: *R. RESSLER[1,2], T. D. GOODE[3], C. EVEMY[1], A. MARTINEZ[1], S. KIM[1], S. MAREN[1,2];
[1]Psychological and Brain Sci., Texas A&M Univ., College Station, TX; [2]Inst. for Neurosci., College Station, TX; [3]Massachusetts Gen. Hosp., Boston, MA

Abstract: Memories enter a liable state after retrieval, and administration of protein synthesis inhibitors interferes with the reconsolidation of reactivated memories. Although inhibition of protein synthesis within the amygdala interferes with the reconsolidation of fear to a first-order auditory conditioned stimulus (CS), indirectly reactivated fear memories are not sensitive to protein synthesis within the amygdala. Given that higher order S-S associations are thought to depend on the hippocampus, we conducted a series of experiments to examine the role of the dorsal hippocampus (DH) in the reconsolidation of indirectly retrieved fear memory. Previous reports suggest backward (BW) conditioning, a procedure in which the unconditioned stimulus directly precedes the CS is mediated by contextual fear. To confirm this, we tested whether

extinction of the conditioning context selectively reduced fear to a BW CS. Accordingly, animals were fear conditioned using either forward (FW) or BW trials (context A). Next, animals underwent context extinction (A) or novel context exposure (B). Finally, animals were tested for fear to the CS in a third novel context (C). Results revealed that CS-elicited fear was attenuated in BW-conditioned but not FW-conditioned animals. In a separate cohort, we also examined whether the opposite was true. That is, does extinction of an auditory CS in a novel context (B) reduce fear to the conditioning context (A) selectively in BW-conditioned animals. Similar Exp. 1, impairments in contextual fear retrieval following CS extinction were selective to animals that had received BW conditioning. In the final experiment, animals were implanted with bilateral cannulae aimed at DH and after recovery were conditioned to a FW or BW CS as in Exp.1 and 2. 24 hours later rats received a single CS presentation in a familiar context (B), which we hypothesized would reactivate the memory of the conditioning context (A) in BW but not FW-conditioned animals. To target the reconsolidation of this reactivated context memory we infused a protein synthesis inhibitor (rapamycin) or vehicle into the DH immediately following the retrieval session. Lastly, we assessed fear in the conditioning context (A). Consistent with our hypothesis, intra-DH infusion reduced fear selectively in animals that were conditioned to a BW CS. These results provide evidence that the BW, but not FW, CS reactivated a hippocampal representation of the original conditioning context, and that reconsolidation of this memory required hippocampal protein synthesis. This has important implications for novel therapeutic approaches to target and selectively erase traumatic memories.

Title: Signaled active avoidance performance is context-dependent

Authors: *C. R. OLEKSIAK, J. M. MOSCARELLO, S. MAREN;
Psychological and Brain Sci. and Inst. for Neurosci., Texas A&M Univ., College Station, TX

Abstract: After Pavlovian fear conditioning, the expression of conditioned fear is context-independent: rats that learn an association between a conditioned stimulus (CS) and an aversive unconditioned stimulus (US) in one context will show robust fear responses, such as freezing, to

the CS in a different context. It is unclear whether other learned defensive responses, such as active avoidance behavior, are context-independent. Here we examined whether two-way signaled active avoidance behavior in rats is affected by a context shift. Sprague-Dawley rats received four days of signaled avoidance conditioning which consisted of thirty tone warning signals (2 kHz, 80 dB, 15 s) paired with footshock (0.7 mA, 0.5 s) per day. Rats could avoid the footshock US and terminate the warning signal by shuttling from one side of the apparatus to the other prior to US onset. After conditioning, the rats had two counterbalanced tests in either the conditioning context or in a shifted context. In both tests, 10 tones were presented absent shock and avoidance responses did not terminate the tone (i.e. both tests were 'reinforcement-free'). The rats performed significantly fewer avoidance responses in the shifted context compared to the original context. This was accompanied by an increase in freezing to the warning signal in the shifted context. Hence, unlike Pavlovian fear conditioning, active avoidance conditioning is context-dependent. Future work will examine the neural circuits mediating the context-dependence of avoidance responses.

Title: The role of hippocampus to amygdala projection in two way active avoidance

Authors: *K. SUNG[1], J. YU[2], J. PYO[2], J.-H. KIM[2];
[1]Div. of Integrative Biosci. & Biotech., [2]Dept. of Life Sci., POSTECH, Pohang, Korea, Republic of

Abstract: Fear and defensive behavior triggered by fear are critical for survival of animal. For a decade, studies about neural circuit of fear are based on pavlovian fear conditioning paradigm whereas avoidance related fear circuit is overlooked.In prior studies, it is revealed that amygdala, medial prefrontal cortex, and nucleus accumbens are involved in avoidance learning & performance. But it is not well known about hippocampus in active avoidance. There were some reports that hippocampus involve in active avoidance performance. But it is not known how hippocampus contribute in avoidance learning and performanceIn our study, we found that hippocampal neurons are activated during active avoidance training & test by c-fos staining. And we found that hippocampal amygdala projection is necessary for active avoidance learning by optogenetically inhibiting hippocampal amygdala projection during avoidance learning.

Title: Reduced renewal of conditioned suppression following lesions of the dorsal hippocampus

Authors: *A. TAVAKKOLI, D. I. FOURNIER, D. J. BUCCI, T. P. TODD;
Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Extinction of fear to a conditioned stimulus (CS) is a context-dependent; removal from the extinction context results in renewal of conditioned fear to the CS (Bouton & Bolles, 1979). Prior experiments have demonstrated a critical role for the dorsal hippocampus (DH) in fear renewal. However, the majority of these studies examined renewal in conditioned freezing procedures. The role of the DH in renewal is less clear in other procedures, such as conditioned suppression. For example, pre-training fornix lesions or pre-training neurotoxic lesions of the entire hippocampus have no impact on ABA renewal of conditioned suppression (Frohardt et al., 2000; Wilson et al., 1995). Likewise, post-extinction lesions of the DH do not weaken ABA renewal of conditioned suppression (Todd et al., 2017). Since all prior conditioned suppression experiments examined ABA renewal, which involves a return to the original conditioning context, the current study examined the impact of pre-training DH lesions on ABC renewal. ABC renewal isolates the contextual retrieval of extinction because it does not involve a return to the original conditioning context. All rats received light-shock pairings in Context A, followed by the extinction of the light CS in Context B. In experiment 1, rats received DH lesions prior to conditioning, while in experiment 2 they were lesioned after extinction. In both experiments, sham lesioned rats showed reduced fear to the CS presentation in Context B, followed by a renewal of fear when the CS was presented in an equally familiar Context C. Although Sham lesioned rats demonstrated ABC renewal, DH lesioned rats did not. Summation testing revealed that the extinction context was not a conditioned inhibitor, and likely controlled extinction responding by modulating the light-shock association. Overall, these experiments suggest that the DH is necessary for renewal when it occurs in a relatively neutral context.

Title: MDMA and memory: A dose-effect analysis on Pavlovian fear conditioning

Authors: *M. M. PANTONI, S. G. ANAGNOSTARAS;
Dept. of Psychology, UC San Diego, La Jolla, CA

Abstract: ±3,4-methylenedioxymethamphetamine (MDMA) is a recreational drug that is also being pursued as a therapeutic for PTSD and other mood and anxiety disorders. Despite strong evidence of its therapeutic potential, these pursuits are hindered by evidence that MDMA produces robust neurotoxicity and cognitive deficits at high doses. These findings, however, may not generalize to typical recreational or therapeutic use of low-dose MDMA. To date, there is little research on the cognitive effects of low/moderate doses of MDMA (less than 3 mg/kg) - the doses that users typically take. In the present study, we examined the effects of MDMA on learning and memory across a range of doses using a Pavlovian fear conditioning paradigm. Hybrid C57BL/6Jx129S1/SvImJ mice were randomly assigned to groups by MDMA dose. Mice were trained on-drug with a single tone-shock pairing and then tested off-drug one week later for long-term context and tone fear memory. We assessed the effects of doses of 0.1 to 8 mg/kg MDMA relative to vehicle control on immediate memory and long-term contextual and cued memory. With increasing interest in therapeutic uses of MDMA, this research will help determine if low doses are therapeutically viable in terms of adverse effects on learning and memory.

Title: Dopamine and the hunger hormone ghrelin: Novel targets to rescue impaired fear extinction?

Authors: *E. M. FRITZ[1], A. PIERRE[2], M. KHARITONOVA[1], A. SAH[1], O. BUKALO[3], D. DE BUNDEL[2], A. HOLMES[3], N. SINGEWALD[1];

Abstract: A considerable number of patients suffering from anxiety disorders and PTSD do not show long-term benefit from currently available treatments such as exposure-based behavioral therapy (EBT). It has been proposed that in those patients fear extinction, the central mechanism underlying EBT is impaired, leaving them with refractory symptoms and a high risk of relapse. This insufficient treatment response is well-modeled in the 129S1/SvImJ (S1) mouse strain, which exhibits impaired fear extinction following Pavlovian fear conditioning. We have previously shown that enhancing dopaminergic (DA) signaling by L-DOPA treatment rescues the deficient extinction phenotype of S1 mice.
In order to elucidate the underlying neurocircuitry we are now employing optogenetics and viral tracing techniques to target the midbrain DA system. Our preliminary findings suggest a major role for mesocortical projections from the ventral tegmental area (VTA) to the infralimbic cortex (IL), as selective inhibition of these projections decelerates extinction learning in usually extinction-competent DAT-Cre (C57BL/6J) mice. To forge new therapeutic paths, we are also exploring non-pharmacological measures to enhance endogenous DA signaling. The hunger hormone ghrelin is known to promote mesocorticolimbic DA release, so we utilized an overnight fasting paradigm to activate the ghrelin-DA axis. Using ELISA, we assessed whether ghrelin release is intact in extinction-impaired S1 mice and found total ghrelin plasma levels comparable to those of C57BL/6J mice. Active ghrelin levels, however, were higher in S1 mice under fasted as well as non-fasted conditions. qPCR revealed that ghrelin receptor (GHSR) mRNA expression in arcuate nucleus and VTA is influenced differently by fasting in both mouse strains. Fear extinction in GHSR-KO mice was not altered, suggesting that intact ghrelin signaling is no requisite to extinguish fear. Nevertheless, in S1 mice overnight fasting before fear extinction supported the formation of long-lasting extinction memories. Protection from fear reinstatement was accompanied by higher expression of Zif268, a marker for neuronal activity, specifically in layer 5/6 of the IL, which receives a majority of VTA DA projections.
Overall, our data further strengthens the notion of the IL as a critical player in mediating dopamine's extinction-promoting effects. What role alterations of the ghrelin/GHSR system play in impaired fear extinction, however, remains to be elucidated. We propose enhancing DA signaling (pharmacologically or non-pharmacologically) as a powerful tool to augment EBT in patients with treatment-resistant anxiety disorders.

Title: Role of μ-opioid and CB1 receptors of the dorsal periaqueductal gray matter in the modulation of aversive and antinociceptive responses induced by fear

Authors: *J. M. ZANOVELI, M. M. GODOI, J. M. CUNHA;
Federal Univ. of Parana, Curitiba, Brazil

Abstract: A wealth of evidence indicates that the activation of CB1 and μ-opioid receptors (MOR) in the dorsal periaqueductal gray matter (dPAG) inhibits more intense fear-like responses. Given that the aversive dPAG stimulation also induces an antinociceptive effect, we propose to investigate the role of cannabinoid and opioid system in dPAG on antiaversive and antinociceptive effects mediated by the dPAG chemical stimulation. For that, the basal thermal threshold was evaluated using the tail-flick test. In the next day, the animals received intra-dPAG injection of CB1 receptor-selective agonist ACEA (0.5 pmol/0,2 μL), CB1 receptor antagonist AM251 (100 pmol/0,2 μL), MOR agonist DAMGO (0.5 pmol/0,2 μL), MOR antagonist CTOP (0,1 nmol/0,2 μL) or its vehicle (0,2 μL) followed by the intra-dPAG injection of N-methyl-D-aspartate (NMDA, 1 nmol/0,2 μL) to evaluate aversive responses - freezing and crossing behaviors - in free-moving animals. Immediately after, the thermal threshold was evaluated again. All procedures were approved by the Research Ethics Committee for the Use of Animals of the Biological Sciences Sector of the Federal University of Paraná (#1188). The CB1 receptor agonist and MOR agonist, but not its respective antagonists, prevented the NMDA-induced aversive responses. While the CB1 agonist did not alter the antinociceptive effect induced by aversive chemical stimulation in the dPAG with NMDA, the MOR agonist induced a more marked antinocicpertive effect when compared to vehicle-treated animals chemically stimulated with NMDA. Our findings indicate a beneficial effect of the activation of CB1 receptor and MOR into dPAG on aversive behavioral consequences of chemical stimulation of dPAG, highlighting that the activation of MOR in the dPAG enhances the fear-induced antinociception.

Title: Nucleus reuniens in Pavlovian trace fear conditioning

Authors: *Y.-J. LIN, C.-H. CHANG;
Inst. of Systems Neuroscience, NTHU, Hsinchu, Taiwan

Abstract: The Nucleus Reuniens (RE) of the midline thalamus interconnects the hippocampus (HPC) and the medial prefrontal cortex (mPFC). A considerable amount of studies has suggested that the RE plays a critical role in emotion, memory, and various cognitive tasks. However, much less is known about RE contribution in different learning phases of Pavlovian fear conditioning. In Pavlovian fear conditioning, an initially neutral conditioned stimulus (CS), such as tone, is associated with an aversive unconditioned stimulus (US), such as foot shock. The temporal relationship between the CS and the US is critical and leads to different experimental procedures: Delay conditioning consists of co-termination of CSs and USs, while trace conditioning consists of pairings of CS and US that are separated in time by a stimulus-free "trace" interval. These procedures engage different underlying neural mechanisms. Researches have indicated that the HPC and mPFC are involved in trace, but not delay, fear conditioning. Given the role of RE in mediating this neurocircuitry, we hypothesized that RE inactivation leads to a learning deficit only in trace, but not delay, conditioning. First, we sought to determine if RE was activated in different learning phases of trace and delay fear conditioning in rats using cfos expression as an activation index. We found that in general, RE was recruited in the encoding phase of trace and delay fear memory, but not the retrieval phase. Next, we pharmacologically inactivated RE to investigate RE contribution in each learning phases of trace and delay conditioning. Interestingly, our data suggested that pre-conditioning inactivation of RE impaired the acquisition of the trace fear; however, inactivation immediately after conditioning and before retrieval test did not impair the performance, indicating that RE was only necessary during memory acquisition. By contrast, RE inactivation in neither of the time periods affected delay fear learning. In addition, when we brought the RE off-line the entire encoding and retrieval process of trace fear, no learning deficit was observed, suggesting a state-dependent retrieval of trace fear memory. Together, our data revealed the important role of RE in the learning process of trace fear conditioning.

Title: Dopaminergic strategies to rescue deficient fear extinction

Authors: S. B. SARTORI[1], T. M. V. KEIL[1], K. K. KUMMER[2], M. KRESS[3], K. EBNER[1], ***N. SINGEWALD**[1];
[1]Dpt. Pharm. & Tox., Inst. Pharmacy, Univ. Innsbruck, Innsbruck, Austria; [2]Innsbruck Med. Univ., Innsbruck, Austria; [3]Med. Univ. Innsbruck, Innsbruck, Austria

Abstract: Existing treatments of anxiety- and trauma-related disorders, including exposure-based behavioral therapy (EBT) show only partial long-term therapeutic effects. One reason is that the central process underlying EBT, namely the formation of a new, fear inhibitory extinction memory is often deficient in these disorders. A promising option for improvement is the pharmacological boosting of exposure-based therapy (Singewald et al, 2015). We have shown previously that the dopamine bioprecursor L-DOPA facilitates fear extinction in extinction-intact humans and extinction-deficient 129S1/SvImJ (S1) mice (Haaker et al. 2013, Whittle et al. 2016). This was associated with enhanced extinction-induced activity in the infralimbic cortex (IL). We now used a combination of *in vitro* and *in vivo* techniques including microdialysis, multi-electrode array (MEA) recordings and immunohistochemical mapping (utilising e.g. pERK and pCREB as markers for functional dopamine receptor activation) and revealed evidence of blunted dopamine neurotransmission in the infralimbic cortex (IL) of S1 as compared to extinction-competent C57BL/6 mice. Compensation of this deficiency by pharmacologically enhancing local dopamine availability in the IL was sufficient to behaviorally rescue the extinction deficit persistently and protect from the return of fear. While we excluded a possible contribution of adrenoceptors, the exact receptor(s) or combinations of receptors mediating these effects are now being revealed by microinjections of selective dopamine receptor ligands. Taken together, we revealed dysfunctional dopaminergic signaling in extinction-deficient mice and identified the IL as a brain region critically involved in the rescue of deficient fear extinction by dopamine. The results suggest the dopaminergic system as a promising target for the development of pharmacological adjuncts for EBT to overcome extinction resistance and to protect from fear relapse in extinction-impaired individuals.

Title: β-arrestin-dependent opioid signaling positively contributes to reduced conditioned fear and anxiety-like behavior

Authors: *M. KO[1], T. CHIANG[1], A. A. MUKADAM[1], G. E. MULIA[1], J. A. CHESTER[2], R. M. VAN RIJN[1];

Abstract: G protein-coupled receptors (GPCRs) are key drug targets for various neuropsychiatric disorders due to their active role in neuronal signal transduction. To develop GPCR-based drugs with low on-target adverse effects and high effectiveness, it is imperative to identify intracellular messenger systems linked to the therapeutic effects. Here, we aim to dissect the distinct role of downstream GPCR signal transduction in the modulation of anxiety and fear with an emphasis on ligand bias related to β-arrestin-dependent signaling. To address our goal, we utilized the δ-opioid GPCR (δOR), which is implicated in the modulation of emotional behaviors, and two specific δOR agonists that can mediate downstream signaling, primarily ERK1/2, through G protein (TAN-67) and β-arrestin (SNC80). We found that systemic administration of TAN-67 increased whereas SNC80 decreased conditioned fear-related behavior in mice and the behavior was inversely correlated with ERK1/2 activation. The SNC80-induced reduction in fear-related behavior was still present in the β-arrestin 2 global knockout mice; however, we did note that ERK1/2 activation by SNC80 was abolished in the striatum and nucleus accumbens of β-arrestin 1 knockout mice suggestive of a role of this isoform in the modulation of fear. SNC80 also significantly reduced anxiety-like behavior in an elevated plus maze and a dark-light transition test in wild-type but not in β-arrestin 2 knockout mice, implicating β-arrestin 2 in the modulation of anxiety-like behavior. We observed that ERK1/2 activity by SNC80 in the hippocampus and amygdala relied on the presence of β-arrestin 2. Moreover, we were able to attenuate the anxiolytic-like effects of SNC80 by systemic administration of the MEK inhibitor SL327, which indirectly blocked ERK activity in the tested

regions. Thus, it appears that the β-arrestin 2-mediated ERK1/2 activation is an integral component of δOR modulation of anxiety-like behavior. Overall, our results reveal a region-specificity to β-arrestin isoform function in modulating ERK signaling, which appears differentially associated with modulation of anxiety- and conditioned fear-related behavior. Our findings may aid in the development of 'precision medicine' for treating mood disorders.

Abstract: Post-traumatic stress disorder (PTSD) is a memory-related disorder characterised by emotional responses of intense fear as a result of intrusive memory recall. While odours are especially effective at triggering memories of high emotional saliency and intensity more than other sensory cues, the neurocircuitry of olfactory fear memory is not fully understood yet. Here, we investigated the neurocircuitry of olfactory fear memory acquisition and consolidation. We used Pavlovian fear conditioning in adults rats to determine whether recollection of olfactory memories changes the proliferation of newborn neurons or leads to neuroplasticity of neurons in the olfactory pathway, amygdala and the hippocampus which are associated with fear memory. We used the plasticity marker CREB and EdU (5-ethynyl-2'-deoxyuridine) labelling to study neuroplasticity and neurogenesis of different brain regions after olfactory fear memory. Our results showed that the olfactory fear conditioning resulted in a significant increase in number of CREB positive neurons in the medial and cortical subnuclei of the amygdala and the piriform cortex. We also found that there was a significant increase in number of EdU positive neurons in the dentate gyrus of the hippocampus and the glomerular layer of the olfactory bulb 24 hours and 14 days post-conditioning. These findings contributed to the complete understanding of the

neurocircuitry of olfactory fear conditioning and the role of neurogenesis in olfactory fear memory consolidation.

Title: Role of the gut microbiome in mouse territorial aggression

Authors: *C. KWIATKOWSKI[1], S. KASZUBINSKI[2], C. WAELCHLI[1], K. MOON[3], A. L. EAGLE[3], C. MANNING[1], A. MOESER[4], M. E. BENBOW[5], A. ZEOLI[6], A. ROBISON[3]; [1]Neurosci., [2]Integrative Biol., [3]Physiol., [4]Vet. Med., [5]Entomology, [6]Sch. of Criminal Justice, Michigan State Univ., East Lansing, MI

Abstract: Violence is a widespread public health and justice system problem with far-reaching consequences for victims, offenders, and their communities. Aggression, the cognitive and behavioral antecedent to violent action, is mainly understood in terms of the psychosocial risk factors that increase the likelihood of aggressive behavioral strategies. In order to gain a better understanding of the individual-level biological mechanisms that precipitate violence, the current study examines the relationship between the gut microbiome and behavioral aggression in mice. Territorial male CD1 retired breeder mice were screened for aggressive versus passive social interactions using an intruder paradigm with younger male C57Bl6J mice, and aggression was scored based on attack latency, bout number, and bout length. The gut microbiomes of aggressive and non-aggressive CD1 mice were assessed using 16s RNA sequencing of extracted fecal matter to identify correlations between microbial strain abundance and aggressive behavior, and the abundances of several bacterial strains were found to correlate with aggression. In addition, aggressive and non-aggressive mice underwent microbial elimination using chronic antibiotic treatment and subsequent transplantation of the gut microbiome from donor mice expressing an aggressive behavioral phenotype to determine whether gut microbiome directly drives aggressive behavior. Concurrently, activity of the prefrontal cortex (PFC), habenula, amygdala, and nucleus accumbens (NAc) was measured post mortem using immunohistochemistry for the immediate early genes FosB and cFos, thereby identifying a potential role of the gut microbiome in modulation of brain regions involved in aggression and reward. This study elucidates peripheral molecular mechanisms that drive altered brain function

and behavioral aggression, contributing to a more comprehensive biopsychosocial explanation and potential intervention for violence.

Title: Cerebello-thalamo-prefrontal control of fear memories

Authors: *I. A. GEORGESCU, J. L. FRONTERA, H. BABA AÏSSA, C. MAILHES-HAMON, C. LENA, D. POPA;
Inst. de Biologie de l'Ecole Normale Superieure, Paris, France

Abstract: Fear conditioning is mediated by excitatory and inhibitory connections between multiple areas. The role of brain structures such as the amygdala and the prefrontal cortex (PFC) in this form of learning is well established, but recent data indicate an involvement of the cerebellum in emotional disorders. Using a combination of neuroanatomy, behavior, chemogenetic and electrophysiology approaches, we have been studying the involvement of the cerebello-thalamo-PFC pathway in fear conditioning and extinction.
Through stereological injections of retrograde viral tracers in PFC and amygdala, and anterograde virus in the deep cerebellar nuclei, we analyzed the possible link between these areas. We found fibers from the cerebellar fastigial nucleus and neurons projecting to amygdala and PFC in the parafascicular (PF) and mediodorsal (MD) nucleus of the thalamus indicating an anatomical coupling if the cerebellum to these thalamic nuclei.
We also found neurons in the MD activated with a short latency by optogenetic cerebellar nuclei stimulations suggesting the existence of a functional pathway from the cerebellum to MD. MD and PF are known to be involved in fear learning and extinction.
We investigated the effects of transient silencing or excitation of neuronal activity of cerebellar projections to MD and PF thalamic nuclei, during fear conditioning and extinction in mice. We virally expressed inhibitory or excitatory DREADDs in the fastigial nucleus, combined with the injection of retrograde CAV-Cre in the target areas, and we examined the effects during fear

learning and extinction training after clozapine-N-oxide (CNO) injection. We have found changes in the extinction learning induced by the fastigial-MD pathway. These results indicate that the cerebellum exerts a powerful effect on limbic circuits during fear memories.

Title: The endocannabinoid system as a predictor of fear extinction learning - An fMRI study

Authors: *J. SPOHRS[1], M. ULRICH[2], L. BINDILA[3], P. PLENER[1], G. GROEN[2], B. ABLER[2]; [1]Dept. of Child- and Adolescent Psychiatry and Psychotherapy III, [2]Dept. of Psychiatry and Psychotherapy III, Ulm, Ulm Univ., Ulm, Germany; [3]Facility of Endocannabinoids/Lipidomics, Mainz Univ., Mainz, Germany

Abstract: With the legalisation of medical cannabis, its potential to treat fear- and anxiety-related disorders has become of great interest. With a focus on animal models in previous research, translational approaches in human research are mandatory. Lutz et al. (2015) have postulated that endocannabinoids (anandamide (AEA) and 2-arachidonoylglycerol (2-AG)) play a neuromodulatory role in fear-related processes. AEA is degraded by fatty acid amide hydrolase (FAAH), and the single-nucleotide polymorphism (SNP) rs324420 in the FAAH-coding gene has been demonstrated to modulate fear extinction learning (Dincheva et al. 2015).
In the present functional magnetic resonance imaging (fMRI) study, 52 healthy men underwent a Pavlovian fear conditioning paradigm to investigate the neural signals during fear learning (day 1), extinction learning (day 2), and retention (day 3). To elucidate the role of AEA and 2-AG, blood samples were analysed using liquid chromatography-mass spectrometry, and FAAH genotyping was performed.
Replicating the results of meta-analyses (Fullana et al., 2015, 2018), we observed brain activation in the anterior insula (AI), dorsal anterior cingulate cortex (dACC), and ventral striatum related to extinction learning. Across participants, baseline AEA-, but not 2-AG-levels, significantly correlated with the degree of extinction learning in the dACC and the right AI (whole-brain analysis, voxel-level $p < 0.001$, cluster-level $p < 0.05$, FWE-corrected). Using the AI as a seed region, we analysed baseline resting-state fMRI data to explore AEA's modes of action. Highly significant functional coupling, negatively correlating with the degree of extinction, was found exclusively with the right hippocampus (whole-brain analysis, voxel-level $p < 0.001$; cluster-level $p < 0.05$, FWE-corrected). As with fMRI activations, baseline AEA-, but

not 2-AG- levels, were negatively correlated with resting state insula-hippocampal coupling indices (peak voxel at [28, -24, -18]; z-score = 3.35; p = 0.002, FWE-corrected for search volume), suggesting that individual AEA-availability could have modulated the neural network mediating extinction learning. The neural extinction signal did not significantly differ between FAAH genotypes.
Thus, our translational research set-up confirmed the hypothesis of an essential role of endocannabinoids - particularly AEA - in the neurobiology of anxiety-related disorders in humans. As a clinical proof of concept, patients with stress or anxiety disorders and lower AEA levels might be pre-treated with AEA-enhancing drugs to promote extinction learning prior to cognitive behavioural therapy interventions.

Title: 5-HT2A and cfos expression within the orbitofrontal cortex of isolation reared aggressive mice

Authors: *A. AGURTO[1], P. R. MOYA[2];
[1]Univ. De Valparaíso, Valparaiso, Chile; [2]Physiol., Univ. de Valparaiso, Valparaiso, Chile

Abstract: Aggression and violence are problematic symptoms by themselves and pervasive components in psychiatric disorders as diverse as Schizophrenia, drug addiction, Alzheimer and depression, negatively impacting on the psychological lives of patients, family and caregivers. The serotonergic (5-HT) system and frontal cortex have both been involved in the modulation of aggressive behavior in humans and rodent models, of which, the 5-HT1A, 5-HT1B and 5-HT2A receptors are the most studied. However, human and rodent studies on the 5-HT2A receptor involvement in aggression are contrasting, and the lack of specific neuroanatomical correlates as well as the diverse pathologies or models underlying each study of aggressive behavior have made difficult to establish the role of 5-HT2A receptor in modulation of aggression. Using the isolation-reared model of aggression in male CF1 mice, we measured 5-HT2A receptor and c-fos expression through immunohistochemical labelling within the orbitofrontal cortex (OFC) subregions. Blind analysis showed higher 5-HT2A receptor expression in ventral and lateral

OFC of aggressive mice compared to non-aggressive controls while no significant changes were detected in other OFC subregions or control cortices. In addition, c-fos labeled neurons with 5-HT2A receptor expression in the lOFC was 59+/-35% in aggressive mice and 15+/- 9.8% in non-aggressive mice. Ongoing experiments are underway to observe the effects of local administration of 5-HT2A receptor antagonists in the OFC on aggressive behavior and pattern of c-fos activation in other brain areas involved in aggression. Our results suggest that regarding 5-HT2A mediated activity, the ventral and lateral OFC are the most important areas in controlling aggression and that 5-HT2A receptors within the lOFC have a potential role in modulating aggression in this mouse model.

Abstract: The fact that an underestimated figure that a million people reported dying by suicide every year shows the importance of suicide prevention and detection. In this study, a deep learning algorithm was employed to predict people with suicide attempt based on their brain structural imaging. The subjects in our generalized q-sampling imaging (GQI) dataset consisted of 3 groups, which are 64 healthy controls (HC), 51 depression patients (DP), and 33 depression patients with suicide attempts (SA). In the GQI dataset, indices of generalized fractional anisotropy (GFA), isotropic value of the orientation distribution function (ISO), and normalized quantitative anisotropy (NQA) were separately trained in different deep learning models. The training and testing 2-dimensional images were generated from a 3-dimensional volume of each subject, and images sliced from 3 views, i.e. axial, sagittal, and coronal view, were concatenated. The training images were augmented by randomly rotating the image twice. The architecture of the convolutional neural network (CNN) contained three convolution and max-pooling layers. After flattening the output of the last max pooling layer, there followed 4 fully connected layers and a dropout layer. Linear Rectification Function (ReLU) was implemented as an activation

function in each of the aforementioned convolutional layers. The classification results were obtained through a softmax layer. Adam optimizers were employed in the training process, and parameters were updated with cross-entropy loss scores weighted by the sample size. The 5-fold cross-validation accuracy scores of classifications of SA and DP respectively against HC were 0.88 and 0.52 in ISO. In NQA, the accuracy scores were 0.73 and 0.51, respectively. We also applied the same CNN architecture to indices of amplitude of low-frequency fluctuations (ALFF) and regional homogeneity (ReHo) in resting-state functional magnetic resonance imaging (rs-fMRI) and arterial spin labeling (ASL)-based rs-fMRI, as well as voxel-based gray/white matter volume. However, the classification accuracy scores in the other indices were under 0.7. The results suggested that, compared with other brain imaging indices, GQI-ISO retained more distinctive features for our implemented CNN for prediction of suicide attempts. In addition, accuracy scores between SA and DP in ISO revealed a gradient pattern, which could imply that there was a gradient pattern in terms of distinctive neural signatures between the aforementioned groups.

Title: Risk factors for major depressive disorder in general population: A systematic review and meta-analysis

Authors: *D. LIU[1], G. LI[1], L. LI[3], Y. LIU[2];
[1]Sch. of Mental Hlth., [2]Shandong Key Lab. of Behavioral Medicine, Sch. of Mental Hlth., Jining Med. Univ., Jining, China; [3]Jining Taibaihu New District Construction Bureau, Jining, China

Abstract: Motivation: The aim of this study is to conduct a systematic review and meta-analysis of risk factors for major depressive disorder (MDD) among general populations.
Methods: Four English databases (Web of science, Embase, Pubmed, psyINFO) and three Chinese databases (Weipu, CNKI, Wanfang) were searched for cohort or longitudinal studies. Random effect models were used for the combined effect calculations. Funnel plot and Begg's test were conducted to investigate the potential publication biases. All statistical analyses were conducted by STATA Version 14.
Results: A total of 84 studies were included in systematic review. Based on quality assessment with the Newcastle-Ottawa Scale, 71 studies which were more than 5 scores, covering 1,825,324 populations, were included for meta-analysis. The range of followed-up period was from 11 months to 50 years and the median was 5.5 years. Six strongest predictors were as follows:

Anxiety (RR: 1.72, 95% CI: 1.56-1.87), High Life stress (RR: 1.47, 95% CI: 1.28-1.66), Female (RR: 1.46, 95% CI: 1.14-1.77), Physical disease history (RR: 1.42, 95% CI: 1.35-1.50), High work stress (RR: 1.18, 95% CI: 1.03- 1.34), and Highly educated (RR: 0.82, 95% CI: 0.64-1.00). Other risk factors (Obesity, Current smoker, Former Smoker, Low social support, Loss a job, Have a new job, Family history of mental disorders, Parental divorce and self-mental disorder history) and protective factors(Physical activity and Low work stress) were also reported. The incidence rate of MDD was 9% (95% CI: 7%-10%) based on 60 related studies. With subgroups analysis, the intercontinental incidences varied widely. The incidence of MDD of North America was 13% (95% CI: 11%-16%), followed by Asia (9%, 95% CI: 7%-10%) and Europe (6%, 95% CI: 5%-7%). There were gender differences of incidence of MDD. Incidence of MDD in females (11%, 95% CI: 9% -13%) was higher than that of males (5%, 95% CI: 2%-7%).
Conclusion: It is crucial to summary a theoretical framework according these risk factors of MDD. It would provide clues for public health strategy development and individual prevention measures. More researches are needed to confirm the causalities of these risk factors and MDD.

Title: Predictive factors for major depressive disorder in the elder population: A systematic review and meta-analysis

Authors: *G. LI[1], D. LIU[1], L. LI[2], Y. LI[1], Y. WU[1], Y. LIU[1];
[1]Jining Med. Univ., Ji ning, China; [2]Jining Taibaihu New District Construction Bureau, Ji ning, China

Abstract: Motivation: The aim of this study is to conduct a systematic review and meta-analysis of predictive factors for major depressive disorder (MDD) in the elder population.
Methods: Four English databases (Web of science, Embase, Pubmed, psyINFO) and three Chinese databases (Weipu, CNKI, Wanfang) were searched for cohort or longitudinal studies. Random effect models were used based on significant heterogeneity. Funnel plots and Begg's test were both conducted to investigate the potential publication biases. Stata version 14.0 was used for all statistical analyses.
Results: A total of 89 studies were included in this systematic review. Based on quality assessment with the Newcastle-Ottawa Scale, 39 studies which were more than 5 scores, covering 226,248 elderly participants, were included for meta-analysis. The strongest five predictors were as follows: physical function limitation (RR=2.08, 95% CI: 1.37-2.79), sleep

disturbance (RR=2.07, 95% CI: 1.16-2.97), cognitive function limitation (RR=1.97, 95% CI: 1.31-2.64), obesity (RR=1.12, 95% CI: 1.03-1.20) and physical activity (RR=0.88, 95% CI: 0.76-0.99). Other risk factors (current smoker, alcohol user, family history of mental disorders, marital status and self-mental disorders history) and protective factors (social contact) were also reported. The range of followed-up period of all 39 studies was 1-21 years and the median was 4 years.
Conclusion: It is crucial to summary a theoretical prevention framework according these risk factors of MDD among the elderly. It provided clues for the policy-makers to prevent late-life MDD and to facilitate MDD remission among the elderly. More researches were needed to confirm the causalities of these risk factors and MDD in the elder population.

Title: Mapping brain structural abnormality in depressed patients with suicide ideation using GQI

Authors: *M.-T. CHEOK[1], V.-H. CHEN[2,3], Y.-H. TSAI[4], J.-C. WENG[1,3];
[1]Dept. of Med. Imaging and Radiological Sci., [2]Sch. of Med., Chang Gung Univ., Taoyuan, Taiwan; [3]Dept. of Psychiatry, [4]Dept. of Diagnos. Radiology, Chang Gung Mem. Hosp., Chiayi, Taiwan

Abstract: Over 300 million people are suffering from various degrees of depression worldwide. The order of depression severity is a significant risk factor for suicidal behavior. The integrity of white matter is considered to be associated with depression psychopathology. In light of this, we used generalized q-sampling imaging (GQI) to investigate the white matter integrity in major depressive disorder (MDD) patients with suicide ideation.
In our study, 3T MRI (Verio, Siemens) was used to acquire GQI images of 52 healthy control (HC) and 35 MDD patients with suicide ideation (ID), and sort out as the first comparison. The second comparison is related to the HC and 48 MDD without suicide ideation (non-ID) patients. Lastly, the third comparison is between 35 ID patients and 48 non-ID patients. Eddy current correction with FSL (FMRIB Software Library) and spatial normalization with Statistical Parametric Mapping (SPM) were performed. The GQI indices, including normalized quantitative anisotropy (NQA) and generalized fractional anisotropy (GFA), were calculated using DSI

Studio. Paired sample t-test was used to detect the significant changes with SPM. Additionally, age, gender, and education years were varied across the subjects and used as covariates in this study.
In the first comparison, we found significant white matter integrity decreased in the corpus callosum, right cingulate gyrus and right superior temporal gyrus in ID compared with HC. In the second comparison, a significant reduction in right caudate and corpus callosum was found in the non-ID compared with HC. More severe demyelination in callosum, left anterior cingulate, and left medial frontal gyrus impairments were observed in ID compared with non-ID in the third comparison.
We found significant differences of white matter integrity between the MDD and HC group in the corpus callosum, cingulate and the frontal area, which are responsible for emotional processing, stress response. These results supported the severity of white matter demyelination directly affect the severity of MDD. It is also worth noted that the demyelination is severer at the anterior part of corpus callosum and left cingulate gyrus in suicide ideation patients. Corpus callosum plays a pivotal role in the integration of interhemispheric information, including higher cognitive functions and impulsive action. Anterior cingulate involved in the cognitive and emotional regulation of behavior, especially the left anterior cingulate was associated with improved response stability. All of these results indicated that suicide ideation affects brain structure and could be used as imaging biomarkers for clinical diagnosis.

Title: A prospective cohort study investigating factors associated with depression in Chinese training residents

Authors: *F. SHEN[1], Z. LIU[2], Y. ZHOU[3], W. LI[4];
[1]Bio-X Institute, Shanghai Jiao Tong Univ., Shanghai, China; [2]Bio-X Institutes, Shanghai Jiao Tong Univ., Shanghai, China; [3]Bio-X Institutes,Shanghai Jiao Tong Univ., Shanghai, China; [4]Shanghai Jiao Tong Univ., Shanghai City, China

Abstract: IMPORTANCE. High rates of depression is commonly reported in medical internships. Identifying associated risk factors could help to improve the diagnosis and intervention of depression.

OBJECTIVE. To identify factors associated with depression or depressive symptoms before and within internship training.
METHODS. Participants were recruited from multiple hospitals in China and the United States. Medical students who were going to start their internship, were invited to enroll this survey. Demographic characteristics were collected and the depressive symptoms of PHQ-9 scale were assessed for subjects before internship. During internship, subjects were assessed the depressive symptoms using PHQ-9 in every quarter. Besides, many other factors were included as baseline (before internship) or within-internship factors based on statistical models.
RESULTS. The mean score of PHQ-9 depressive symptoms reported by subjects significantly increased from 3.98 in pre-internship to 7.14 during internship in China, and it increased from 2.64 to 5.73 in the United States. The proportion of participants who met PHQ-9 criteria for depression increased from 8.58% to 23.43% after internship in China, meanwhile it augmented from 3.98% to 35.61% in the United States. Further, factors of lower baseline scores of depressive symptoms and personal history of depression before internship, increased work time and lack of sleep within internship, and high perceived stress before and during internship, were associated with a greater increase of depressive symptoms scores in both China and the United States. The depressive symptoms scores showed age-related only in China, whereas gender, marital,
neuroticism and early family environment were identified as associated factors only in the United States. Interestingly, Chinese interns reported less medical errors than that of American interns.
CONCLUSION. In the present study, we conduct a prospective cohort study of intern health in China and the United States. We assessed and investigated depression related factors using mood scale and questionnaire survey before and within internship, and identified several factors associating with the development of depression. These findings may help to improve the early diagnosis and intervention, reduce medical errors and prevent the suicide of interns.

Title: Mindfulness intervention in autism increases middle cingulate cortex activity during self-reflection which predicts depression alleviation

Authors: *B. A. PAGNI[1], M. WALSH[1], E. FOLDES[1], A. SEBREN[1], M. DIXON[1], L. BAXTER[2], C. RIECKEN[1], C. HAYNES[1], A. MACOMBER[1], A. CLARK[1], C. WEBB[1], M.

CATCHINGS[1], J. ALVAR[1], B. B. BRADEN[3];
[1]Arizona State Univ., Tempe, AZ; [2]Neuroimaging, Barrow Neurolog. Inst., Phoenix, AZ; [3]Dept. of Speech and Hearing Sci., Arizona State Univ. - Tempe Campus, Tempe, AZ

Abstract: Adults with autism spectrum disorder (ASD) experience high rates of depression and anxiety. There is some evidence that Mindfulness-Based Stress Reduction (MBSR) is effective in reducing depression and anxiety, however, the neural mechanisms and benefit beyond support groups are unknown. Functional MRI (fMRI) research shows adults with ASD do not activate the ventral medial prefrontal cortex (vmPFC) and middle cingulate cortex (MCC) during self-reflection as seen in neurotypicals. Mindfulness training regulates self-reflection neural activation in NT adults, making this a likely mediator of symptom-reducing effects in adults with ASD. We investigated whether MBSR would increase blood-oxygen-level dependent (BOLD) response in regions activated during self-reflection, compared to a support/education control group, and if the BOLD signal change correlated with changes in depression and anxiety. Twenty-eight adults (nine women; mean age=31.8±12.9, range=18-64; mean IQ=106±18.5, range=70-139) were randomly assigned to a MBSR group (n=15) or a support group (n=13). All participants met ASD criteria on the ADOS-2 and both groups met for two-hours once/week for eight weeks with homework. Pre- and post-intervention fMRI scans were collected for the self-reflection task where participants: (1) reflected on whether or not the word displayed was a trait they possessed (self-condition), and (2) made a judgement about the positive valence of words (word-condition). Self-reported symptoms were assessed via the Beck Depression Inventory-2 and the State-Trait Anxiety Inventory. Within group comparisons were performed with paired t-tests and correlations with Pearson product-moment. The MBSR group demonstrated significant depression reduction with a moderately large effect size ($t(14)=3.31$, $p=0.005$, $d=0.66$), while the control group approached significance ($t(12)=1.82$, $p=0.09$, $d=0.40$); neither intervention significantly reduced anxiety symptoms. We found increased activation in right MCC ($p=0.018$, small-volume family-wise error corrected [FWE]) in the Self>Word contrast after MBSR intervention that negatively correlated with depression alleviation ($r(11)=-0.49$, $p=0.04$). There were no changes in vmPFC for the MBSR group or either region for the control group. Seed-to-voxel connectivity analysis revealed that MBSR increased functional connectivity between right MCC and pre/postcentral gyrus (p=0.001, FWE). This study suggests that MBSR may be effective for reducing depression in adults with ASD over and above a support/education group, and the neural mechanism may be increased right MCC activation during self-reflection.

Title: Changes in brain activation to angry faces in adolescent participants with depression symptoms

Authors: A. ABDULSADYKOVA, ***A. L. BOKDE**;
Trinity Col. Dublin, Dublin, Ireland

Abstract: Introduction: Depression has been associated with altered processing of emotional face stimuli compared to healthy groups. The hypothesis is that the 'sub-clinical depression' group would show altered activation to emotional faces compared to healthy control group in the prodromal stages of the disease. Data & Methods: The brain activation, measured using fMRI, for angry and neutral faces were evaluated in 425 adolescents from over 2000 recruited for the IMAGEN study (Schumann et al., 2010). The symptoms of depression were quantified using the Development and Well-Being Assessment (DAWBA) (Goodman et al., 2000) at baseline (BL) and follow-up 2 (FU2). There were 3 groups: clinical depression (scores 4 or 5 on DAWBA), subclinical depression (scores 1- 3), and healthy controls (score 0). There were 41, 179 and 205 participants in the clinical, subclinical and healthy groups, respectively. The average age at BL was 14.39 ± 0.5 years and at FU2 were 18.9 ± 0.68 years. The groups were matched for age and sex ratio (40% male). A 'face network' and a 'depression network' were defined using meta-analysis through neurosynth.org website. The results presented are the angry versus neutral face contrast and the ANCOVA statistical models include center, age, sex as covariates of no interest (additional covariates are mentioned in results). Statistical results are Bonferroni corrected. Results: Activation differences at FU2, controling for FU2 age and BL depression score, there were statistically significant effect of group in right IFG_1 (IFG_1, coordinates -18, -11, -26), and left IFG_2 (IFG_2, coordinates 9, -38, -20). Posthoc t-test revealed higher activation in the right IFG_1 in healthy group (EMM= 0.79; SEM=0.04) than in subclinical depression group (EMM=-0.61; SEM=0.036), at p=0.018. For IFG_2 ROI, healthy controls showed higher neural activity (EMM=0.156; SEM=0.05) than participants with clinical depression (EMM= -0.093; SEM=0.08), p=0.026. An ANCOVA model applied to brain activation at BL, found differences in activation in right hippocampus the clinical depression group (EMM=-0.185; SEM=0.071), than in the subclinical depression group (EMM=0.038; SEM=0.04; p=0.019) and the healthy

group (EMM=0.064; SEM=0.044; p=0.009). In the right IFG_1 brain region the activityt was higher in subclinical depression (EMM=0.118; SEM=0.043) than in clinical depression group (n=41; EMM=-0.128; SEM=0.076), p=0.015. Discussion & Conclusion: The symptoms of depression are associated with changes in brain activation in hippocampus and right IFG about 4 years preceding the appearance of the symptoms.

Title: Stimulus valence contextually modulates network profiles of the hippocampus and dlPFC in episodic memory: Assessing borderline personality disorders with co-morbid depression

Authors: *T. J. ATTISHA[1], E. L. KALLABAT[1], T. D. MERAM[1], P. H. SOLOFF[2], A. Z. CHOWDURY[1], V. A. DIWADKAR[1];
[1]Psychiatry & Behavioral Neurosci., Wayne State Univ. Sch. of Med., Detroit, MI; [2]Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract: Background: Memory processing is affected by emotion, especially in disorders of emotion dysregulation, including borderline personality disorder (BPD) and major depressive disorder (MDD). MDD is frequently comorbid with BPD (Yoshimatsu et al., 2014), but how comorbidity affects the brain's connectivity profiles is unknown. Because episodic memory formation is driven by the hippocampus and prefrontal cortex (Preston & Eichenbaum, 2013), we studied how *stimulus valence* differentially affected network profiles of the hippocampus (during memory encoding) and/or the dorsolateral prefrontal cortex (dlPFC) (during recognition of encoded associations) in BPD patients with or without co-morbid depression (BPD_{MDD+}, BPD_{MDD-}), and healthy controls (HC).
Methods: Task-based fMRI data collected in 36 BPD patients and 27 HC were analyzed (BPD_{MDD+}=12; 3.0T Siemens Trio). During the task, memory for images (drawn from the International Affective Pictures System (IAPS) (Lang et al., 1993) presented during Encoding epochs was tested in subsequent Recognition. Standard methods (SPM 8) were used to process fMRI data. Psychophysiological Interaction (PPI) (Friston et al., 1997, $p<.05$, cluster level) estimated network profiles of the Hippocampus and dlPFC. A second level analyses was modeled with two factors: Group (BPD_{MDD+}, BPD_{MDD-}, HC) and stimulus valence (positive, negative and neutral). Inter-group differences were investigated under each valence.

Results: (a) Encoding and Recognition of positive and neutral valenced images induced similar effects: BPD_{MDD+} displayed *hyper-modulation* by the hippocampus and dlPFC (BPD_{MDD+} > BPD_{MDD-}; BPD_{MDD+}> HC) across the memory network. (b) Negatively valenced images: BPD_{MDD+} displayed both *hyper-modulation* (BPD_{MDD+}>BPD_{MDD-}), and *hypo-modulation* when compared to HC (BPD_{MDD+} < HC).
Discussion: Our results suggest that the effects of comorbid depression (BPD_{MDD+}) are complex and non- "linear" and that stimulus valence exerts complex modulatory effects on network function. An absence of negative valence induces *hyper-modulatory* profiles (positive and neutral) of the hippocampus and dlPFC in BPD_{MDD+}, consistent with models suggesting that depression drives inefficiency in brain networks (Wagner et al., 2006; Zhi et al., 2018). However, negative valence appears to interact with the depressive phenotype, inducing *hypo-modulatory* effects. This shift is a class of "affective interference" observed in disorders of emotion regulation (Soloff et al., 2015). Studying the effects of the comorbidity may help unravel the complex relationships between dysfunctional brain network profiles and clinical traits.

Title: Correlates of brain network hierarchies with rumination in major depressive disorder

Authors: *Y. JACOB, L. S. MORRIS, K.-H. HUANG, M. SCHNEIDER, G. VERMA, J. W. MURROUGH, P. BALCHANDANI;
Icahn Sch. of Med., New York, NY

Abstract: Major depressive disorder (MDD) patients exhibit higher rumination levels; repetitive thinking and focus on negative states. Rumination is known to be associated with aberrant activity in the brain default mode network (DMN) regions, yet, the underlying whole-brain network topological organization remains unclear. Implementing a graph-theory analysis we tested whether whole brain network connectivity hierarchies during fMRI resting state are associated with rumination. We hypothesized that the functional network topological

organization will distinguish between MDD patients and healthy controls (HC) and will also associate with individual differences in self-reported rumination scores (RRS). Applying this data-driven approach on 21 MDD patients and 21 HC, we found that MDD patients exhibited the same hierarchy in the network as HC during rest. However, within the MDD group, lower strength of a DMN related region - the right precuneus - was associated with greater rumination scores (r=-0.77, p<0.0002, q *FDR*<0.05) (Figure 1A). There was also a negative trend within the HC group (r=-0.34, p=0.18). We then applied the Dependency Network Analysis (DepNA), a newly developed graph theory method to quantify networks' node importance according to its connectivity influence. The DepNA revealed that within the MDD group, greater rumination tendency was associated with decreased influence of the left medial orbito-frontal cortex (mOFC) on the right precuneus (r=-0.71, p<0.0007, q *FDR*<0.05)(Figure 1B). Lastly, we used an information theory entropy measure that quantifies the cohesion of each network's correlation matrix. We show that the subjects with higher rumination scores exhibit higher entropy levels within the DMN i.e. decreased overall connectivity within the DMN (r=0.47, p<0.05). These results emphasize the general DMN involvement during self-reflective processing related to maladaptive rumination among MDD. More specifically, the influence of the mOFC on the Precuneus might serve as a target for clinical neuromodulation treatment.

Title: No anhedonia for music in major depressive disorder

Authors: *A. POINCOT, S. SPIVACK, D. TOSSAVAINEN, S. E. MCCLELLAND, G. LENNER, L. CRANMER, P. WALLISCH;
New York Univ., New York, NY

Abstract: There is a prevalent view that major depressive disorder (MDD) is accompanied by anhedonia, the inability to experience pleasure from everyday activities that used to be enjoyable. We tested this hypothesis in a high-powered sample of participants exhibiting a wide range of depression scores as operationalized by the Beck Depression Inventory (BDI). These participants listened to a representative corpus of music samples and rated them in terms of their appraisal. We found no statistical association between BDI scores and music appraisal ratings, with an empirical correlation coefficient indistinguishable from zero. This challenges prevalent notions that MDD is associated with anhedonia and supports prior work suggesting a dissociation between mood and musical appreciation, leaving the possibility of rescue from MDD through individually targeted music therapy.

Title: Cortical and subcortical deficits observed in individuals with seasonal affective disorder

Authors: *N. B. RODRIGUES[1], W. SWARDFAGER[2], A. LEVITT[3], P. GIACOBBE[3], N. LIPSMAN[4];

Abstract: The heterogeneity of Major Depressive Disorder (MDD) has made it notoriously difficult and expensive to investigate changes to neural structure between episodes of depression and remission. Further, it remains undetermined whether patients suffering from Seasonal Affective Disorder (SAD), a subtype of MDD, have volumetric cortical and subcortical deficits. As depressive episodes and euthymic periods can be reliably predicted in SAD based on the season, the disorder offers a unique naturalistic model to investigate whether neural structures change between states. The aim of this exploratory study was to characterize atypical cortical or subcortical volumetric properties during periods of depression and euthymia. This study recruited ten participants with a confirmed diagnosis of winter-SAD and ten healthy controls between the ages of 18 to 65. There were no statistically significant differences in gender, age, ethnicity or body mass index between the two cohorts. Participants were scanned using a 3T MRI to generate high resolution T1-weighted structural images (192 volumes, $1mm^3$ voxels). The volumes were reconstructed, preprocessed, segmented and parcellated using the FreeSurfer v6.0 automated pipeline. The thickness, volume and surface area for cortical regions and the volume of subcortical regions were extracted and analyzed using a general linear model, covarying for age and intercranial volume, during the winter and summer. In order to correct for multiple comparisons, the family-wise error was set at $p < 0.005$. There was no significant difference in volume or surface area, however, there was a significant reduction in the cortical thickness of the superior frontal gyrus in both the left and right hemisphere of SAD patients in the winter and summer months compared to healthy controls ($p < 0.005$). Additionally, there was a statistically significant volumetric reduction in the left and right pallidum in SAD patients compared to healthy controls in the summer and winter ($p < 0.005$). This study presents novel evidence that patients suffering from SAD have structural abnormalities to the bilateral superior frontal cortex, a region associated with modulating impulse control and high order executive function, and the bilateral pallidum, which is a central node in the motivation and reward limbic pathway (de Boisgueheneuc et al., 2006; Hu et al., 2016). These results are further corroborated by cognitive studies that reported cognitive impairments persist during depressive and remitted periods in SAD patients (Hjordt et al., 2017). Taken together, this study helps to characterize why certain cognitive deficits may not ameliorate in MDD.

Title: Elevated glutamate transporter expression in females with depression

Authors: B. E. POWERS[1], ***M. SODHI**[2];
[1]Mol. Pharmacol. and Therapeut., [2]Loyola Univ. Chicago, Maywood, IL

Abstract: Suicide leads to 40,000 deaths per year in the US and is particularly prevalent in patients with major depressive disorder (MDD). The pathophysiological mechanisms leading to MDD and suicide are unclear. Accumulating evidence indicates that abnormal function of the glutamate system contributes to the efficacy of antidepressant treatments, and that antidepressant efficacy includes modification of the activity of the dorsolateral prefrontal cortex (DLPFC). We have previously shown increased glutamatergic gene expression in the DLPFC of females but not males with MDD. Here, we have tested the hypothesis that abnormal expression of the genes encoding the glutamate transporters and the transporters of monoamine neurotransmitters occurs in the DLPFC in MDD and suicide. We extracted RNA from the gray matter of the DLPFC from three groups of subjects: MDD suicides (MDD-S, n=51), MDD patients who did not complete suicide (MDD-NS, n=28), and controls (CTRLs, n=32). Laboratory staff were blind to diagnosis during the experiments. We used QPCR to measure the expression of genes encoding transporter proteins within the glutamate (EAAT1, EAAT2, VGLUT1, VGLUT2) and monoamine systems (SERT, NET, DAT, PMAT, VMAT). We used multivariate analysis of covariance to test if these gene expression markers were associated with MDD or suicide. Our results show that females but not males with MDD had higher expression levels of all glutamate transporters relative to CTRLs ($P<0.05$). MDD-S groups of both sexes had higher VGLUT2 expression ($P<0.05$). Analyses of monoaminergic genes revealed lower VMAT1 expression ($P=0.002$) in MDD males, and conversely higher VMAT2 in MDD females ($P=0.004$). MDD females also had higher TPH2 and NET expression ($p<0.05$). Therefore, we report sex differences in the expression of glutamate transporters and some monoaminergic genes in the DLPFC in MDD. Most of these findings are novel, but lower EAAT1 expression in MDD-S replicates previous studies. Altered glutamate transport may contribute to lower DLPFC activity, poor problem solving and impaired executive function observed in patients with severe depression and suicidal behavior.

Title: Mutations of enzymes involved in dietary carbohydrate digestion system in Chinese patients with major depressive disorder

Authors: *N. ZHANG[1], J. LI[2], S. BI[3], W. KUANG[1];
[1]West China Hospital, Sichuan Univ., Chengdu, China; [2]West China Hosp., Chengdu, China; [3]Johns Hopkins Univ., Baltimore, MD

Abstract: Major depressive disorder (MDD) is a neuropsychiatric disorder with the high prevalence and life-threatening risk, and is characterized by a variety of symptoms, such as sadness, anhedonia and decreased interest in daily activities. Genetic analysis is a powerful tool to identify risk variants and to enhance understanding of the etiology of MDD, leading to improvement of early diagnosis and development of more effective therapies. This study was carried out for genetic analysis of Chinses patients with MDD. The study was approved by the West China Hospital Clinical Trials and Biomedical Ethics Committee of Sichuan University, and a total of 121 patients and 78 healthy individuals were recruited from Mental Health Center of West China Hospital. Patients (age between 18 and 65) with MDD were diagnosed according to the DSM-IV (American Psychiatric Association, 2000) by board certified and experienced psychiatrists. Peripheral blood samples were collected from patients and their DNAs were extracted from blood samples. The quality and quantity of DNA extracts were first assessed, and DNA samples with concentrations >20 ng/μL and 260/280nm absorbance ratios between 1.8 and 2.0 were selected for subsequent sequencing analysis. Whole exome sequencing was carried out with high-throughput second-generation sequencing technique using Illumina HiSeq platform PE150. Only sequence reads with $Q_{phred}30$ (indicating an error rate of <0.1%) were used for further analysis. DNA samples collected in parallel from healthy participants served as normal controls.
Series of mutations in enzymes involved in dietary carbohydrate digestion system were identified in all patients, but were not observed in healthy controls. Though multiple mutations were identified, the number of mutations was not correlated to the severity of this disease. Our preliminary data suggested a potential role of enzymes for dietary carbohydrate digestion in MDD pathology. Further analysis will combine other neuropsychological and psychoradiological assessments in search for the relationships between its genotype and endophynotype of MDD.

Abstract: Introduction: The depression is a disease or mental disorder that is characterized for a Deep sadness, soulish decay, low selfsteem, loss of interest for everything and decrease of the psychic functions. According to World Health Organization (OMS) in the old adult, the depression affects to more of 350 millions of people in the world, contributing to raise the morbi-mortality, which decreases the life quality. The depression isn't something normal in the process of aging and the majority of the old adults feel satisfied with their lifes. However, is a problem of mental health. The **object** is determine the impact of a intervention to decrease the depression in the old adults. The **methodology** of the estudy is of type quasiexperimental. The population were 20 residents of the house of the third age. The sample was 6 old adults identified with some level of depression, applied a pre-test and post-test with a intervention through a program of activities with 13 sessions with a duration of 5.5 hours a week, doing differents activities physical and recreational. In the **results** the avergae of age was of 74.17 years old (DE= 6.274; 66-80). The gender that predominates is male (67%), the civil status of higher frequency free union and widower. In the pre-test s found 4 people (67%) with moderate depression and 2 people (33%) with severe depression, while that in the post-test was deleted the degree of depression in 3 people (50%), 2 (33%) moderate depression and just 1 person (17%) remained with several depression. It **conclude** that the depression in the old adult, in terms of prevalence, is every time higher; also is a disease that induce a important inability, what facilitates the presence of new pathologies or the aggravation of the already existing. Is essential implement programs multidisciplinary to the integral approach of the old adults that can attend differents aspects how their nutrition, medical treatment, so that they are avoided some status of depression and improves the life quality of the old adult.

Title: A longitudinal fMRI study of reward processing in adolescents with depression

Authors: *S. M. JACKSON, P. VIDAL-RIBAS, D. M. NIELSON, G. O'CALLAGHAN, A. STRINGARIS;
Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Background: Diminished striatal activity during reward anticipation is related to Major Depressive Disorder (MDD) and has been shown to precede the onset of MDD. However, it is unclear whether reward processing aberrations are a cause or consequence of depressive symptoms. Additionally, we want to learn how such reward processing aberrations can predict clinical course.
Methods: Participants were 155 adolescents aged 11-17, 99 MDD (59.5% female), 10 subthreshold MDD (sub-MDD) (80.0% female), and 45 healthy volunteer (HV) (65.2% female). Volunteers were assessed for diagnoses and inclusion criteria: IQ > 70; and a lack of mania, schizophrenia, substance abuse, or medical illness that could cause MDD symptoms. Eligible participants were invited to complete the Monetary Incentive Delay task during fMRI scans. These scans were collected again in MDD participants after 4 months, 8 months, and in all participants after 12 months. We collected the Mood and Feelings Questionnaires (MFQ) at each scan, providing a self-report of depressive symptoms. The clinical assessment was repeated at 12 months. Reliability of the MFQ was assessed using intraclass correlation (ICC) and hierarchical linear models were used to examine changes in MFQ score over time. A contrast for the neural activity during anticipation of winning rewards versus a control cue was analyzed across time and subjects.
Results: The MFQ ICC from baseline (n=76) to 4 months (n=52), 8 months (n=24), and 12 months (n=13) was 0.477, 0.62, and 0.45, respectively. For changes in MFQ as modelled by MFQ ~ Time * Sex + (Time|Subject), there was a main effect of time as well as a time by sex interaction; over time, depressive symptoms improved significantly more in males than in females. Across time and subjects, there was a significant cluster of activity in the ventral striatum (VS) with a focal point in the caudate ($F=20.97$, $p<0.01$, cluster corrected).
Conclusions: The reliability of the MFQ over time is promising for understanding the course of depression. Furthermore, the model of MFQ provides a basis for exploring predictions of clinical course. Finally, the significant cluster of activity in the VS suggests that the anticipation of reward results in activation in this region robustly over time and across subjects.

Title: Affective interference on OFC and dACC brain network profiles in borderline personality disorder: An fMRI study

Authors: *E. L. KALLABAT[1], T. J. ATTISHA[1], T. D. MERAM[1], P. H. SOLOFF[2], A. Z. CHOWDURY[1], V. A. DIWADKAR[1];
[1]Psychiatry & Behavioral Neurosci., Wayne State Univ. Sch. of Med., Detroit, MI; [2]Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract: Introduction: Borderline Personality Disorder (BPD) is often characterized by co-morbid major depressive disorder (MDD), yet the co-morbidity's effects on the brain's functional profiles is unknown. Previous studies provide evidence for dysfunction of brain network profiles of the dACC and OFC in both BPD and MDD (Kaiser et al., 2015; Soloff et al., 2017; Wolf et al., 2012). We assessed the effects of affective context on neural processing during a Go No-Go task, and dysfunction in evoked network profiles of the dACC and the OFC in subjects that have BPD with co-morbid depression (BPD_{MDD+}) compared to those without co-morbid depression (BPD_{MDD-}; HC). Network analyses focused on a) dACC given its role in cognitive control and mediation of allocation of resources during complex processing, and b) on the OFC given its role in regulation of affect and impulse control.
Methods: 42 BPD subjects (BPD_{MDD+}=30) and 27 HC subjects underwent fMRI (3T) while performing the Go No-Go task. The task required subjects to respond ("Go") or withhold a response ("No-Go") based on target class (facial valence). In each block of trials, faces were shown briefly (500ms) in a jittered event-related design. fMRI data were processed using standard methods in SPM12. dACC and OFC network profiles were estimated using Psychophysiological Interaction (PPI) (Friston et al., 1997). First level PPI maps for each subject were forwarded to a second level analyses with two factors: Group (BPD_{MDD+}, BPD_{MDD-}, HC) and Valence, permitting assessment of group differences under each valence class ($p<.05$).
Results: From dACC seed, BPD_{MDD+} were characterized by increased modulation (compared to BPD_{MDD-} and HC), and BPD_{MDD-} were characterized by decreased modulation (<HC) when responses were gated by *negative* valence. BPD_{MDD+} were characterized by increased modulation (> BPD_{MDD-}) but decreased modulation (< HC), and BPD_{MDD-} were characterized by decreased modulation (< HC) when responses were gated by *positive* valence. And from OFC seed, BPD_{MDD+} were characterized by increased modulation (compared to BPD_{MDD-} and HC), and

BPD_{MDD-} were characterized by decreased modulation (< HC) when responses were gated by *negative* and *positive* valence.
Discussion: The use of valence to gate impulse control induced the following general trends in network profiles: a) $dACC_{(-ve)}$: BPD_{MDD+}>HC>BPD_{MDD-} and b) OFC $_{(-ve, +ve)}$: BPD_{MDD+}>BPD_{MDD-}>HC. These results suggest that the contextual responses of the dACC and the OFC are different in BPD patients with co-morbid MDD, with the OFC being more susceptible to affective interference, consistent with the region's dual commitments to affective regulation and impulse control.

Title: Inflammation moderates changes in resting state connectivity following SSRI treatment in geriatric depression

Authors: *D. SEOK, E. LUNING-PRAK, I. ASELCIOGLU, G. GREEN, Y. SHELINE; Univ. of Pennsylvania, Philadelphia, PA

Abstract: *Introduction:* Previous studies have identified increased levels of serum cytokines like C-reactive protein (CRP) and disrupted patterns of resting state fMRI functional connectivity (FC) in major depressive disorder (MDD), particularly in the elderly. While treatment of MDD with selective serotonin reuptake inhibitors (SSRIs) has been shown to reduce serum concentrations of inflammatory cytokines, it remains unclear (1) whether inflammation related dysfunctions in resting state connectivity improve following treatment and (2) how improvements in symptoms track with changes in FC. *Methods:* 26 adults aged 47-91 diagnosed with MDD according to criteria set by the Diagnostic and Statistical Manual of Mental Disorders (DSM-V) were recruited into a double-blind, placebo controlled study and were randomized to treatment with the SSRI escitalopram (ESC) or placebo for 8 weeks. Symptom severity was assessed using the Montgomery-Åsberg Depression Rating Scale (MADRS). Prior to randomization and again following treatment, participants had blood drawn for CRP levels and underwent MRI scanning on a Siemens Prisma 3 T scanner with a 64-channel head coil. *Results:* A subset of patients (n = 9/26), exhibited high levels of CRP (> 3mg/L), although mean CRP did not differ from controls. At baseline, serum CRP concentration was correlated (in voxel-wise,

whole brain functional connectivity analyses) with reduced FC (corrected $p < 0.05$) between a region in the ventromedial prefrontal cortex (vmPFC) and a number of *a priori* seeds, including the left amygdala and bilateral regions of the caudate and putamen. At follow-up, baseline CRP no longer predicted disrupted connectivity between the vmPFC and the limbic or striatal seeds. Moderation analysis revealed that patients with higher baseline CRP (who had reduced FC at baseline) had the greatest improvements in connectivity at follow-up. In patients with higher inflammation, ESC treatment significantly improved MADRS scores ($p = 0.013$) as well as FC between the vmPFC and caudate and putamen seeds. Further, greater increases in corticolimbic and corticostriatal FC were correlated with greater reductions in symptoms. *Conclusion:* The results from this study reveal different treatment trajectories for patients with elevated inflammation, suggesting that decreased corticolimbic and corticostraital connectivity may serve as a target for anti-inflammatory treatments in populations vulnerable to elevated inflammation, such as the elderly.

Abstract: Mental disorders rank second among the causes of disability worldwide for the year 2020, behind ischemic heart disease, but ahead of all other diseases (OMS). However, current nosological systems have been unsuccessful in unraveling causal explanations, and are inadequate in predicting treatment or prognosis at the individual level. The objective of this work

is to explore the heterogeneity of affective-anxious symptoms syndromes from the perspective of the underlying affected brain networks, specific circuits and volumetric differences associated with behavioral and self-evaluation variables. We applied the GFM-NMF methodology to examine a sample of hospitalizaed patients from the Menninger clinic (Houston, TX). Structural and diffusion-weighted brain images were processed using Freesurfer and Tracula. We searched for biclusters reflecting different volumetric and tractography patterns shared by distinct subsets of patients. Then we evaluated the significance of each bicluster by comparing the differential tractography profile within a bicluster with that exhibited by every other individual not present in the bicluster. Lastly, we cross-correlated the uncovered biclusters with collected descriptions of clinical features of the patients including affective symptoms severity, personality traits, and identified clusters of individuals with high level of sharing of multiple clinical traits and structural connectivity. The results show that these clusters (representing specific biotypes) are highly predictive of clinical outcomes (response to treatment and duration of admission). These biotypes may suggest distinct etiologies in patients diagnosed with affective or anxious symptoms, characterized by differences in brain connectivity leading to distinct symptoms and clinical outcomes.

Veracruzana, Xalapa, Mexico

Abstract: Previous studies revealed that 8% to 12% adolescents experience mood disorders, and which had interfered with adolescent daily life and they social function was affected. Early stress exposure has a wide range of effects impacting cognition, making early trauma a risk factor for

development of mental disorders later in life. The aim of this study was to evaluate anxiety and depression status and its related factors among students aged 15-20 years from Xalapa, Veracruz, Mexico. This was a cross-sectional observational, descriptive study. A sample of students were recruited from two high schools. Problem Oriented Screening Instrument for Teenagers (POSIT), Childhood Adverse Experiences (CAE), Beck Anxiety Inventory (BAI), and Beck Depression Inventory (BDI), were used to measure risk factors, the anxiety and depression symptoms, and some demographic characteristics of students was determined. The preliminary results shown a total of 274 students included in our study (57.6% women, 42.3% men); 17.9% women and 7.7% men presented moderate-severe depression, observing a significant association between female sex and the BDI score (P = 0.015). The association between the presence of risk was made based on the score obtained in the POSIT with moderate-severe depression levels, obtaining an association of variables in 24.5% of adolescents (P = 0.000). Likewise, a statistically significant association was found between 8.4% of the population that presented levels of moderate-severe anxiety and that in turn presented 4 or more CEA (P = 0.021). Later, the score obtained in the POSIT showed that 39.8 % of women and 22.3% of men who presented risk in this instrument was associated with levels of moderate-severe anxiety (P = 0.000) and, finally, the moderate-severe levels of anxiety was associated moreless with women (39.8%) in comparasion with men (22.3%; P = 0.006).
Conclusions: the findings demonstrate that exist a significant association between the presence of risk factors in adolescence, having 4 or more adverse experiences during childhood and that the symptoms related to moderate-severe levels of anxiety and depression are associated with the women, this in high school students in the city of Xalapa, Veracruz.

Title: Prevalence of mathematical anxiety in university students

Authors: *S. ZAMORA LUGO[1], M. CADENA-BARAJAS[3], T. CIBRIAN-LLANDERAL[2]; [1]Doctorado en Neuroetología, [2]Neurofisiologia y Neurobiologia de la Conducta, Inst. de Neuroetologia, Univ. Veracruzana, Xalapa, Mexico; [3]Facultad de Estadistica e Informatica, Univ. Veracruzana, Xalapa, Mexico

Abstract: Mathematical Anxiety (MA) corresponds to the idea that for some people the handling of numbers or situations related to mathematics provokes an emotional response that interrupts performance. Research reports that MA has a negative impact on daily activities. It is known that when exposed to extenuating physical or social challenges such as mathematical processing, the organism gives an endocrine response commanded by the activation of the Hypothalamic Hypophysis Adrenal axis, a circuit responsible for the release of corticotropin which in turn stimulates the adrenal cortex for the release of cortisol. The aim of this study was to describe of Mathematical Anxiety Index (MAI) by areas of knowledge and their comorbidity with the scores of the Beck Anxiety Inventory (BAI). An observational, retrospective, descriptive and transversal study was carried out. A structured questionnaire was carried out in three sections, in the first the participants read and approved the informed consent and general data of Sex, Age and Study Area were collected, Biological Sciences (BS), Health Sciences (HS), Administrative economic (AE), Humanities (Hu) and Technique (Te). Subsequently, the participant answered the MAI questionnaire, which measures the assessment of 20 propositions using a Likert scale to measure attitudes, emotions, and beliefs towards mathematics, the scale goes from Never (1) to Always (5), the MAI is obtained in a range from 0 to 1, the 0 represents an absence of anxiety and the 1 maximum mathematical anxiety. Finally, the BAI was presented to the participant, a Likert-type scale that self-reportedly measures anxiety traits. The questionnaire was applied to 140 students with an average age of 21.5 years (SD=3.4), 50% corresponded to women. The project was submitted and approved by the research ethics committee of the Veracruz Institute of Mental Health, the ethical principles of this research will be based on the guidelines of the Declaration of Helsinki. The analysis of variance confirms that there is a significant influence on the AMI scores ($F_{1,4} = 10.08$, $p = 0.001$) per study area. Multiple comparisons by the Tukey test showed a significant difference between the BS and HS groups ($p = 0.02$), BS and AA ($p = 0.001$) and Hu and AE ($p = 0.01$). In the BAI it is confirmed that there is a significant influence in the IAM scores ($F_{1,2} = 8.95$, $p = 0.03$) by the Sex factor, where a significant difference was found ($p = 0.009$) in the group with low BAI score, observing higher scores in women. The students of the area of Humanities and Biological Sciences, present higher Mathematical Anxiety Index, even when in their areas of study, do not take classes that involve numerical-mathematical processing

Abstract: Background. This study analyzing the probability of occurrence of allostasis, such as physical ailments during adolescence and the development of disorders such as anxiety; Several studies have shown evidence between the allostatic load at an early age generates a long-term vulnerability to develop different psychopathologies. The present study is important because it generates a greater interest in the prevention of mental disorders. **Objetive.** The objective of this study is to observe the probability of occurrence of variables considered chronic stress in adolescence and the severe presence of anxiety and depression. **Method.** Participants were choosen between 18-40 years from Instituto Veracruzano de Salud Mental (IVSM) who presented a diagnosis of anxiety. We applied Beck's anxiety inventory and a questionary about the factors associated with allostasis in adolescence. Descriptive, observational and transversal study. Sampling for convenience. 30% of women and 17% of men presented moderate and severe anxiety. The research protocol and informed consent were prepared according to the principles of the Helsinki code declaration and approved by the IVSM Ethics Committee. The analysis was carried out using software WEKA. **Results:** To explore the causality in the data set, a probabilistic analysis was carried out using Bayesian networks. The results show that in women there are more than 65% chance of suffering from severe anxiety in the presence of chronic stressors in adolescence such as nausea, diarrhea and weakness; in the case of males, none of the probabilities exceeded 50%, the highest being associated with chronic chest pain, which obtained 43%. **Conclusions**. This work opens new ways to prevent anxiety in adulthood with the detection of symptoms in adolescence and a novel instrument is implemented in the field of psychology, the Bayesian networks.

Title: Psychoaffective evaluation of formal and informal caregivers of patients with chronic diseases

Authors: *E. ACOSTA-MARI[1], A. CABALLERO-VELARDE[1], E. MONTES-VILLASEÑOR[2], V. VILLANUEVA-HERNANDEZ[3], T. CIBRIAN-LLANDERAL[1]; [1]Univ. Veracruzana, Xalapa, Mexico; [2]Ctr. Estatal de Cancerología, Xalapa, Mexico; [3]Inst. Veracruzano de Salud Mental, Xalapa, Mexico

Abstract: Stress and overload caused by providing care to a patient or family member can contribute to the origin of affective disorders, immunological alterations, cardiovascular disease and early death. To evaluate the mental health state in relation to the levels of Stress, Anxiety, Depression, Overload and Empathy in formal caregivers (CF) and informal caregivers (CI) in an oncologic center (CeCan) and a psychiatric center (IVSM). An observational, descriptive, transversal, prospective and correlational study was carried out. Sociodemographic data of 22 CF and 22 CI were collected. The Perceived Stress Scale (PSS), the Hospital Anxiety and Depression Scale (HADS), the Davis Interpersonal Reactivity Index (IRI) and the Reading the Mind in the eyes (RME) test were used for the psycho-affective evaluation. They were evaluated 22 IC, 11 from IVSM and 11 from CeCan, the most prevalent gender was feminine in 73.3%, 33.3% of the sample obtained went to junior high school, 40% reached the high school level, 26% graduate or MD. 43.3% are exclusively dedicated to housework while only 10% have full-time work activities, 56% are married or in free union, 86% are brothers, son or mother of the patient. Within the group of FC, 22 participants were evaluated, 11 from IVSM, 11 from CeCan, 71% female, 38% of those evaluated belong to the Psychology service, 28.6% general doctors while 19% doctors with specialty, 38.5% work more than 40h. In the analysis of the psycho-affective evaluation, the median test was used to compare two groups, which reported statistically significant differences in the evaluation of the PSS with an mean of 27.04 (SD: 1.65) and FC of 18.38 (SD: 1.44) (P = 0.031), in the subscale of depression of HADS the IC group obtained a mean of 7.00 (SD: 1.14) while in the CF group it was 2.85 (SD: 0.57) (P = 0.001). In the RME test, the mean of IC was 19.80 (SD: 1.14) while in the FC group it was 35.04 (SD: 1.79) (P = 0.000), and the interpersonal reactivity index of Davis in the subscales of empathic concern (EC) with a mean of 22.80 (DE: 1.01) in IC and of 25.33 (DE: 0.71) in FC and personal distress (PD) with a mean in IC of 16.71 (SD: 0.96) (P = 0.064) and 13.00 (SD: 0.92) in FC. The analysis of the results shows that the CF group obtained a higher mean score in the RME and the EC subscale, which implies higher levels of cognitive empathy, which could be related to a higher academic level. The IC group obtained a higher mean score on the perceived stress scale, on the depression sub-scale and lower skill in tasks involving empathy.

Title: Alterations of the postsynaptic plasticity genes Homer1a and mGluR5 in the dorsolateral prefrontal cortex, amygdala and hippocampus of suicide completers

Authors: *M. GARCIA-GUTIERREZ, A. VIUDEZ MARTINEZ, J. MANZANARES;
Inst. De Neurociencias, Univ. Miguel Hernandez-CSIC, San Juan de Alicante, Spain

Abstract: Converging evidences suggested that the Homer1 family of scaffold proteins, mainly located in the postsynaptic density (PSD) at glutamatergic synapses, appears to play a relevant role in the development of certain neuropsychiatric disorders, such as depression. In this respect, Homer1a, it has been proposed as one of the main isoforms involved in the response to stressful situations and to pharmacological and non-pharmacological antidepressant treatments. This isoform is an essential element for the proper control of glutamatergic neurotransmission regulating the trafficking of metabotropic glutamate receptor mGluR5 from the cell body to dendrites and axons, contributing to control synaptic plasticity. Considering the potential implications of Homer1a for neuropsychiatric disorders, exploring its role in suicide is of special relevance. Here, we analyzed the gene expression of Homer1a and mGluR5 by real-time PCR in the dorsolateral prefrontal cortex (DLPFC), amygdala (AMY) and hippocampus (HIPP) of 26 suicide victims with no clinical psychiatric history or treatment with anxiolytics or antidepressants, and 25 corresponding controls. All samples were matched, as much as possible, for age (C: 48.4±12 years; S: 45.6±15.5 years) and postmortem interval (PMI, C: 21±14.5 h; S: 16.8±5 h). Statistical analyses revealed that there were no significant differences in the DLPFC to any of both genes when comparing S and C groups. Interestingly, S exhibited higher levels of Homer1a and mGluR5 in the AMY (+23% and +29%, respectively) and HIPP (+28% and +29%, respectively) compared to C. These findings provided evidences about a potential association between Homer1a and mGluR5 and suicide. The alterations of Homer1a and mGluR5 gene expression in brain areas close related with emotional response (AMY and HIPP) may represent an opportunity to stimulate the development of further studies designed to evaluate the role of these targets as biomarkers for suicide prevention.

Title: Cell type specific transcriptomic alterations in the prefrontal cortex of abused suicides

Authors: *D. M. ALMEIDA, G. G. CHEN, J. THEROUX, Z. AOUABED, M. DAVOLI, N. MECHAWAR, G. TURECKI;
Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada

Abstract: Introduction: The transcriptome of a cell constitutes an essential piece of cellular identity and accounts for the multifaceted complexity and heterogeneity of cell types within the mammalian brain. Thus, while a wealth of studies have investigated transcriptomic alterations underlying the molecular neurobiology of childhood abuse (CA) and suicide, the use of bulk-tissue homogenates may have masked their ability to determine cell-type specific dysfunctions. Here we employ a cell-type specific investigation of transcriptomic alterations, in prefrontal infragranular pyramidal neurons, associated specifically with a history of CA. **Methods:** Laser captured microdissection (LCM) was used to isolate prefrontal (BA 10) infragranular pyramidal neurons from post-mortem human brain. Subject groups included individuals who died by suicide with and without a history of severe CA, and non-psychiatric controls. RNA sequencing libraries were constructed using SMARTseq v4 cDNA synthesis and Nextera XT indexing. The abused suicide and control groups were used for sequencing. Libraries were sequenced on the HiSeq 4000 using PE 100bp sequencing at a depth of ~40M reads per subject. Validation included all three clinical groups and employed a high throughput qPCR approach. **Results:** We achieved a mapping efficiency of ~80% and captured a wide distribution of transcripts. Differential gene expression analysis revealed significant (FDR <0.10) dysregulation of protein coding transcripts in abused suicides compared to controls (74 downregulated and 45 upregulated). Weighted Gene Co-Expression Network Analysis (WGCNA) was employed to identify a module that negatively associated with CA. Gene ontology (GO) analysis of the members within this module revealed an enrichment of genes related to glutamatergic synapse functioning and nervous system development. During our validation stage, three genes were found to be specifically altered in abused suicides versus non-abused suicides, and controls. These genes included UBE2R2, ACBD4 and UNG; the first of which was found to be a hub gene (highly interconnected gene) within the aforementioned WGCNA module. **Conclusions:** By employing LCM followed by RNA sequencing our work has uncovered cell-type specific changes associated with a history of CA. Our future research will include cell-type specific

whole genome bisulfite sequencing (WGBS) to explore whether epigenetic processes might explain our expression findings.

Title: Blocking hypocretin receptors in the infralimbic cortex of Wistar rats reduces footshock stress-induced ethanol seeking in EtOH-dependent rats

Authors: *J. KIM, R. MARTIN-FARDON;
Scripps Res., La Jolla, CA

Abstract: This study's aim was to assess the role of hypocretin (Hcrt) in the infralimbic (IL) cortex during stress-induced ethanol (EtOH)-seeking behavior following chronic intermittent EtOH (CIE) vapor inhalation in male and female Wistar rats. The study tested whether bilateral intra-IL administration of TCS1102 (TCS), a dual Hcrt-r1/r2 antagonist (0 and 15µg/side), would prevent footshock stress (FS)-induced reinstatement of EtOH seeking behavior at three abstinence (Abst) timepoints following EtOH dependence: acute (A-Abst; 8h), late (L-Abst; 2 weeks), and protracted (P-Abst; 6 weeks). Rats were first trained to orally self-administer (SA) 10% EtOH. Half were then made dependent (EtOH-D) by CIE (14h ON, 10h OFF) vapor exposure for 8 weeks while the other half were exposed to air (EtOH-ND). During weeks 4-6 rats could self-administer EtOH three times/week during acute withdrawal (i.e., 8h following daily CIE vapor cessation). Extinction (EXT) training began at the end of week 6 while rats were still exposed to CIE vapor at the 8h withdrawal timepoint. EXT training continued daily for two weeks. EXT sessions were the same as SA sessions except EtOH delivery was withheld. Once the animals' behavior was extinguished, A-Abst testing occurred (8h following the final CIE vapor session). All subsequent EXT sessions and two remaining tests (L-Abst and P-Abst) were conducted in the absence of CIE.
During CIE, EtOH-D rats escalated EtOH intake, which was corroborated by relatively higher

blood alcohol levels and somatic withdrawal signs compared to EtOH-ND rats. EtOH-D rats also required more EXT sessions to reach EXT criteria compared to EtOH-ND rats, demonstrating a stronger propensity to seek EtOH. Overall (males + females), antagonizing IL Hcrt receptors did not suppress FS-induced EtOH seeking in EtOH-ND rats at any Abst timepoint. On the contrary, TCS induced a consistent reduction in FS-induced EtOH seeking in EtOH-D rats at all Abst timepoints. There were also observable sex differences. Among EtOH-ND rats, TCS did not prevent FS-induced reinstatement in females at any timepoint but prevented reinstatement in males at P-Abst. Among EtOH-D rats, males showed reduced FS-induced reinstatement during A- and P-Abst but not L-Abst while females displayed reduced EtOH seeking at all timepoints. These data suggest that FS-induced EtOH seeking behavior in EtOH-D rats is at least in part due to dysregulated Hcrt transmission in the IL, as shown by the increased efficacy of TCS in preventing FS-induced EtOH-seeking behavior in EtOH-D rats. This distinction may be sex-mediated, given the differences noted between males and female rats in either dependence condition.

Title: Ethanol simultaneously produces rewarding conditioned place preference and aversive conditioned taste aversion in the animal model: A paradoxical effect hypothesis of abused drugs

Authors: *Y.-Q. LIU, A. C. W. HUANG;
Fo Guang Univ. Dept. of Psychology, Yilan Jiaoxi, Taiwan

Abstract: Since 1997, Grigson and her colleagues provided numerous evidence to show the conditioned suppression is due to the reward comparison between the tastant conditioned stimulus (CS) and abused drugs, unconditioned stimulus (US), in termed as the reward comparison hypothesis. However, our laboratory offered conflict data to challenge the reward comparison hypothesis. Recently, we offer alternative viewpoint that the paradoxical effect hypothesis of abused drugs was to revise the reward comparison hypothesis (1997). This hypothesis focused on simultaneously reward and aversion induced by abused drugs in drug addiction. On the initial experiment, rats were conducted an adaptation for 7 days. After that, all of rats were subjected to all compartments 10min for conditioned place preference (CPP) and lickometer 15min for conditioned taste aversion (CTA) served as the baseline. On odd days of

the conditioning phase, the ethanol group was allowed 15 min to drink 0.1% saccharin solution (CS1) and then injected (i.p.) ethanol solution (20%, 2 ml/kg; US). Then, rat was placed in another compartment (CS2) of the CPP box for 30 min. For even days, all rats did not receive the CTA treatment and stayed in the home cage. They were injected (i.p.) a normal saline to place in the other compartment for 30 min. The conditioning phase was 5-ethanol and 5-saline intermittent injections. For CTA test, a 2 x 3 mixed two way ANOVA showed a significant difference occurred in the factor of group ($F1, 7 = 6.21$, $p < 0.05$). Non-significant differences occurred in sessions ($F5, 35 = 0.66$, $p > 0.05$) and the interaction of group and sessions ($F5, 35 = 1.04$, $p > 0.05$). For CPP tests, there was not a significant difference for the unpaired side and the paired side in the saline group ($t = -0.61$, $p > 0.05$). The ethanol group appeared a significant difference between the unpaired and paired sides ($t = -3.65$, $p < 0.05$). In conclusion, this dose of ethanol (20%, 2 ml/kg) could simultaneously produce an aversive effect in conditioned taste aversion and a rewarding effect in conditioned place preference. The present findings challenge the reward comparison hypothesis and support the paradoxical effect hypothesis of abused drugs. The present data should be discussed in the further studies.

Title: Effect of positive allosteric modulation of $GABA_B$ receptors on pathological alcohol choice

Authors: *E. AUGIER[1], G. AUGIER[2], M. HEILIG[2];
[1]Dept. of Clin. and Exptl. Med., [2]Linköping Univ., Linköping, Sweden

Abstract: Alcohol addiction is characterized by a progressive shift of decision making, in which alcohol is increasingly chosen over healthy non-drug rewards. Only a subset of people transition from recreational to addictive alcohol use. By contrast, in commonly used animal models, nearly all rats learn to self-administer addictive drugs, including alcohol and animals have no alternative to drug use. Using an exclusive choice-based method to identify rats that continue to self-administer alcohol at the expense of a high-value natural reward, a sweet solution, we recently found that only about 15% of outbred rats choose alcohol over an alternative high-value reward. Furthermore, these animals display a constellation of behavioral traits that resembles those currently considered diagnostic for alcohol addiction. Among several dysregulations in

GABAergic pathways, we found low amygdala expression of the GABA-transporter GAT-3 in vulnerable rats. Low GAT-3 expression resulted in impaired GABA-clearance, suggesting that rescuing impaired GABA-clearance due to suppressed GAT-3 expression might be a successful therapeutic approach in alcohol addiction.
Recent observations indicate that presynaptic $GABA_B$ receptors inhibit GABA-release within the CeA. In a first experiment, we therefore evaluated the potential of ADX71441 (3 or 10 mg/kg, I.P), a novel positive allosteric modulator of $GABA_B$ receptors that has entered Phase 1 clinical testing, to rescue pathological alcohol choice over high value alternative rewards in male Wistar rats (n=32). We found that the $GABA_B$ PAM potently, dose-dependently and selectively normalizes choice preference in the minority of rats that choose alcohol over a natural reward. This effect is achieved at doses that are not associated with sedation or adverse effects. In a second experiment, we asked whether ADX71441 could also rescue choice preference for alcohol over a sweet solution in rats when this preference is induced as a result of alcohol dependence. To this end, we characterized a population of male rats for alcohol vs sweet choice preference (n=63), and exposed them to the alcohol vapor inhalation procedure. We found that a history of physical alcohol dependence increased the proportion of rats that choose alcohol over an alternative reward to about 45% of the population and therefore assessed the effect of the $GABA_B$ PAM on dependence-induced alcohol choice. Together, our results indicate that targeting $GABA_B$ receptors is a valid strategy to rescue impaired GABA-clearance in pathological alcohol choice and extend previous data indicating that $GABA_B$ PAMs merit being tested clinically as a therapeutic for alcohol addiction.

Title: Decreased reward-related brain function to monetary rewards predicts shorter time to substance use disorder occurrence

Authors: *C. P. BART[1], R. NUSSLOCK[2], T. H. NG[1], M. K. TITONE[1], A. L. CARROLL[2], K. S. F. DAMME[2], C. B. YOUNG[3], C. ARMSTRONG[2], J. M. CHEIN[1], L. B. ALLOY[1]; [1]Temple Univ., Philadelphia, PA; [2]Northwestern Univ., Evanston, IL; [3]Standford Univ., Stanford, CA

Abstract: Substance use disorders (SUDs) are a significant global health concern, account for a substantial disease burden, and are associated with reward sensitivity abnormalities. Reward sensitivity is supported by a fronto-striatal neural circuit including the orbitofrontal cortex (OFC), ventral striatum (VS), and dorsal striatum (DS), among other regions. Considerable research has examined reward circuity once addiction has set in, but there is a dearth of research examining if neural reward processing dysfunction constitutes a pre-existent risk factor for SUDs. Also, there is debate about whether SUDs arise from hyper- or hypo-reward sensitivity. The current study aimed to address these gaps in the literature, by examining whether a hyper- or hypo-reward sensitivity in reward-related brain regions prospectively predicted substance use (SU) course. Seventy-nine right-handed individuals (*Mage*=21.52, *SD*=2.19 years, 53% female, 57% White) completed a Monetary Incentive Delay (MID) fMRI task, and a diagnostic interview to assess for SUDs. fMRI images were spatially normalized to MNI space and smoothed using 6mm FWHM Gaussian kernel. We used a general linear model in SPM8 to deconvolve the hemodynamic signal during MID anticipation phase across six trial types (i.e., Win $0.00, Win $1.50, Win $5.00, Lose $0.00, Lose $1.50, Lose $5.00). We generated first-level voxel-wise *t*-statistics per participant to contrast reward vs. non-reward trials. Parameter estimates were then extracted from a priori reward-related regions-of-interest (anatomically defined as bilateral OFC and DS using Harvard Oxford Atlas and Wake Forest Toolbox, respectively). In line with the reward hyposensitivity model, we found that decreased activity in the DS (Wald=7.66, *p*=.01, HR=.20, 95% CI=.06-.62) and OFC (Wald=4.28, *p*=.04, HR=.29, 95% CI=.09-.94) during reward anticipation predicted shorter time to occurrence of SUDs. These findings suggest that when people have reduced positive affect, they seek exogenously what they lack endogenously, putting them at risk for SU. This study has important implications for informing our understanding of the pre-existent risk factors and pathophysiology of SUDs, and can inform prevention efforts through psychosocial and pharmacological interventions for SUDs.

Title: Characterization of glycine receptor subtypes and ethanol sensitivity in the mesolimbic pathway

Authors: *A. I. ARAYA MARTÍNEZ[1,2], S. S. GALLEGOS[1], R. VIVEROS[1], L. SAN MARTÍN[1], L. G. AGUAYO[1], R. J. HARVEY[3];
[1]Physiol., Univ. of Concepcion, Concepcion, Chile; [2]Pharmacol. and Toxicology, Univ. de Chile, Santiago, Chile; [3]Fac. of Science, Health, Educ. and Engin., Univ. of the Sunshine Coast, Queensland, Australia

Abstract: Introduction
Glycine receptors (GlyRs) are primarily expressed in spinal cord and brain stem neurons. However, recent studies in mesolimbic regions, such as the ventral tegmental area (VTA) and nucleus accumbens (nAc), have reported the presence of GlyRs of an undetermined subunit composition. It is possible to identify GlyRs based on their sensitivity to glycine (Gly), picrotoxin (PTX), general anesthetics, GTP-γ-S and ethanol (EtOH), among others. It is important to understand the properties of GlyRs in the limbic network because their presence might contribute to the rewarding effects of EtOH. The aim of this study was to characterize GlyRs properties in two regions of the reward circuit: prefrontal cortex (PFC) and VTA using Wild Type (WT), Knock In alpha 1 (KIα1) and Knock Out alpha 2 (KOα2) mice.
Results
Using electrophysiological techniques and examining concentration-response curves (CRC) in WT mice, we detected that the EC_{50} of Gly was 71±7 μM in PFC and 34±2 μM in VTA. As a comparison, the EC_{50} in nAc was 66±10 μM. Interestingly, most neurons recorded in the KOα2 mice displayed a very small current even with 1000 μM glycine preventing a complete analysis. VTA neurons, on the other hand, responded reasonably well to glycine. The values for the current density were 5±2 pA/pF in PFC neurons, 0.7 ± 0.2 pA/pF in the nAc, and 21±5 pA/pF in VTA neurons. In presence of intracellular GTP-γ-S, the current was potentiated about 80% of control in VTA, but not in PFC neurons suggesting the presence of α3 subunits. Studying the sensitivity of the glycine activated current in neurons from these regions showed that the PTX resistant current was 49±5% in PFC, 58±5% in nAc, and 73±4% in VTA. These values suggest that the GlyR complexes are predominantly of an αβx conformation.
Conclusion
Based on these data, we postulate that GlyRs present in PFC are composed mainly of alpha 2 and alpha 3 subunits that are not potentiated by EtOH or GTP-γ-S. In VTA neurons, on the other hand, heteropentameric alpha 1 GlyRs that are highly sensitive to EtOH seem to predominate. These findings provide important data to identify GlyRs in the mesolimbic system and their possible role in alcohol behavior.

Title: Adolescent alcohol exposure produces sex differences in BNST plasticity following adult stress

Authors: *T. A. WILLS, C. KASTEN, E. HOLMGREN, K. CARZOLI;
Cell Biol. & Anat., LSUHSC, New Orleans, LA

Abstract: Adolescent alcohol is a known risk factor for the future development of alcohol use disorders (AUDs), yet the mechanism that contribute to this increased vulnerability are unknown. Adolescent alcohol exposure may increase this risk by producing adaptations in circuitry involved in stress and negative affect, as these are the primary contributors to relapse. The bed nucleus of the stria terminalis (BNST) is a highly sexually dimorphic brain region that is critical in these behaviors. Our lab finds that withdrawal from chronic intermittent ethanol vapor during adolescence (AIE) in male and female mice increases anxiety-like behavior and glutamatergic transmission in the BNST (through increased glutamate release). AIE also alters BNST plasticity in a sex dependent manner by enhancing NMDAR-plasticity in males and blunting $mGluR_{1/5}$-mediated LTD in females. In the current work, we set out to test the long-term consequences of AIE treatment on BNST plasticity and the effect of an adult stress challenge. Male and female C57BL/6J mice were exposed to two, 4-day cycles of alcohol vapor exposure (16 hr/day) with a 3 day period of rest in between the cycles from PND30-41. In adults (P70+) electrophysiology was performed in the BNST to measure temporal summation of NMDAR-EPSCs, DHPG ($mGluR_{1/5}$ agonist)-induced LTD, and sEPSCs in the absence or one hour following restraint stress (1hr). We found that AIE-induced changes in NMDAR-plasticity and $mGluR_{1/5}$-mediated LTD seen in adolescents were not present in adults under basal conditions (30 days after last alcohol exposure). However, following a stress challenge there was an enhancement of sEPSC frequency and no change in amplitude in mice with an AIE history indicating enhanced glutamate release in the BNST. Further, adult stress plus AIE history produced an enhancement of NMDAR-plasticity in males and an enhancement of $mGluR_{1/5}$-mediated LTD in females. Future work will explore if these sex differences in BNST plasticity are mediated by different cell types, input, and/or projections. The ultimate goal of this work is to identify specific pharmacological targets that could be manipulated to reduce the risk of developing AUDs.

Title: Eplerenone antagonism of central amygdala mineralocorticoid receptors reduces alcohol self-administration in female rats

Authors: *V. MAKHIJANI[1,2], J. BESHEER[1,3];
[1]Bowles Ctr. for Alcohol Studies, [2]Neurosci. Curriculum, [3]Psychiatry, Univ. of North Carolina - Chapel Hill, Chapel Hill, NC

Abstract: Cortisol/corticosterone and the hypothalamic-pituitary-adrenal (HPA) axis are key regulators of alcohol drinking behaviors. While most alcohol research has focused on the functional involvement of corticosterone and its primary target, the glucocorticoid receptor (GR). Recent studies have indicated that the related mineralocorticoid receptor (MR), which binds both corticosterone and aldosterone, may also regulate alcohol drinking. Our lab has demonstrated that systemic antagonism of the MR with spironolactone can reduce alcohol self-administration but not sucrose self-administration in male and female rats. The present study first sought to understand if these effects on alcohol self-administration were due to suppression of MR mediated corticosterone negative feedback. Female rats trained to self-administer ethanol were administered spironolactone (0, 50 mg/kg; IP) prior to a self-administration session, after the session blood was collected to examine plasma corticosterone levels. Spironolactone (50 mg/kg) significantly reduced alcohol self-administration, had no effect on locomotion, and significantly increased plasma corticosterone. There were no significant correlations between alcohol self-administration and plasma corticosterone levels in either treatment group suggesting that suppression of corticosterone negative feedback was not the primary driver of reduced alcohol consumption. Parallel studies from our lab have shown that a predator odor model of stress enhanced alcohol self-administration can increase MR expression in the dorsal hippocampus of female rats, and central amygdala of male rats. To understand if these brain regions were the locus of MR antagonist action, the selective MR antagonist eplerenone (0, 100, 1000, 5000 ng/0.5 uL/side) was bilaterally infused into the dorsal hippocampus or central amygdala of female rats prior to alcohol self-administration. Eplerenone infusion in the hippocampus had no effect on alcohol self-administration or locomotion. Eplerenone infusion in the central amygdala (1000, 5000 ng/0.5 uL/side) significantly reduced alcohol self-administration, and had no effect on locomotion. These studies further support the role of MR signaling in modulating alcohol

drinking behaviors, and highlight the role of central amygdala MR signaling in alcohol self-administration.

Title: Anxiolytic properties of alcohol are elevated in mice with decreased striatal dopamine D2 receptors

Authors: *M. E. BOCARSLY[1], M. BRAVO[1], V. A. ALVAREZ[2];
[1]NIH, Bethesda, MD; [2]Lab. on Neurobio. of Compulsive Behaviors, Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD

Abstract: The literature shows comorbidity between anxiety and the development of alcohol use disorder (AUD). Alcohol has known acute anxiolytic properties. One hypothesis to explain the comorbidity of anxiety and AUD is that alcohol consumption acutely ameliorates the anxiety phenotype and by providing relief enhances the reinforcing properties of alcohol. Animal models are consistent with this clinical observation: rats bred to consume large amounts of alcohol show higher basal anxiety and higher anxiolytic effects of alcohol compared to controls. Despite these behavioral observations, the neural circuitry underlying this comorbidity is unknown. In both humans and rodents, alcohol abuse is associated with low levels of dopamine D2 receptors (D2Rs) in the striatum. Further, in collaboration, our lab has shown that a down regulation of D2Rs on striatal projection neurons (SPN) is associated with anxiety-like behaviors. From these data, we hypothesize that striatal dopamine signaling might underlie the comorbidity of these two disorders. Here, we used transgenic mice with a targeted deletion of the D2R on SPNs, to better understand the common neurobiology underlying anxiety and AUD. Mice with a knockout or knockdown of D2Rs on SPNs show increased anxiety-like behavior on the elevated zero maze, open field and light-dark box compared to littermate controls as well as elevated basal serum corticosterone levels. The D2R knockout and knockdown mice also show decreased preference for 1% sucrose compared to littermate controls, indicating anhedonia. When administered ethanol (1.2 g/kg; i.p.) these mice show enhanced anxiolytic effects of alcohol as measured on the before mentioned behavioral tasks. Interestingly, mice with low levels of D2Rs on SPNs show increased D2Rs in the central amygdala, which have known effects on anxiety-

like behaviors. To better understand the circuitry driving the anxiolytic properties of alcohol we are further examining the role of D2Rs in the amygdala on anxiety and AUD. Taken together, these data begin to describe the neural circuitry underlying and perpetuating the anxiolytic effects of alcohol and comorbidity of anxiety and AUD.

Title: The effect of ethanol exposure on BDNF levels in enriched and socially isolated rats

Authors: *E. C. BRASE[1], T. J. WUKITSCH[1], J. P. RACK[1], M. E. CAIN[2];
[2]Psychological Sci., [1]Kansas State Univ., Manhattan, KS

Abstract: Brain-derived neurotrophic factor (BDNF) is a protein that helps promote synaptic plasticity and regulate addiction-related behaviors. Both ethanol exposure and rearing environment manipulation have independently altered BDNF levels. The current research project examined differentially reared rats' BDNF levels as a result of adolescent intermittent ethanol (AIE) exposure. Male Long-Evans rats arrived in the lab on postnatal (PND) 21 and were randomly assigned to either isolated (IC), enriched (EC), or standard condition (SC) environments for a 30-day rearing period. Rats then underwent AIE treatment, consisting of an injection of either ethanol (2.0 g/kg w/v; i.p.) or an equivalent volume of saline for controls. Injections occurred from PND 27-49 on a schedule of one injection every other day for approximately four weeks to model binging. To determine blood ethanol content (BEC), blood samples were collected from the saphenous vein 30 minutes after the penultimate ethanol administration. BEC was quantified and analyzed to determine differences in alcohol metabolism based on environmental condition. 24 hours after the last AIE treatment, rats underwent a 30-minute locomotor test as a measurement of novelty response and anxiety-related behavior. Preliminary findings suggest that EC rats had less overall total, margin, and center distances traveled (cm) than IC and SC rats, with no main effect of treatment and no interaction between condition and treatment. The next day at PND 51 (late adolescence), rats were euthanized, and brains were extracted and flash frozen. Hippocampal and medial prefrontal cortex tissue samples were collected and homogenized to extract protein, then equilibrated prior to performing a pooled sample ELISA to quantify each experimental condition's total hippocampal and mPFC

BDNF levels. We hypothesized that AIE would reduce BDNF levels across environmental conditions, that ethanol exposed IC rats would have the lowest hippocampal and mPFC BDNF levels, and that control EC rats would have the highest BDNF levels. The ELISA results found no differences between groups; however, hippocampal and mPFC BDNF levels differed from one another as in prior literature. These preliminary results suggest that while environmental manipulation effectively altered locomotor behavior, the environmental manipulation or AIE exposure did not alter BDNF levels in either brain area. It is possible that the length and dosage of ethanol exposure were not enough to alter BDNF expression, that changes may be occurring in other brain areas such as the striatum, or that there are changes occurring in BDNF precursors, such as CREB.

Title: Differentiated vulnerability and resilience factors influencing control over alcohol desire in social drinkers

Authors: *C. LARKIN, R. SINHA, D. SEO;
Yale Univ. Sch. of Med., New Haven, CT

Abstract: Heavy drinking is a significant public health problem resulting in maladaptive social functioning and adverse health consequences. The current study used functional magnetic resonance imaging (fMRI) and daily smartphone app to examine specific neural and behavioral factors underlying heavy drinking. Participants were sixty-nine adult healthy individuals (30 female; age M = 26.6; SD = 7.14) comprised of heavy (N=17; 13 female) and moderate (N= 52; 17 female) drinkers, with no demographic differences. Participants completed a 2-hour fMRI scan with exposure to stress, alcohol, and neutral-relaxing visual cues. Follow-up self-assessments of mood, stress, alcohol-related behaviors were collected daily for 30 days via a mobile app. Individuals' drinking patterns were categorized with the Cahalan Quantity-Frequency Scale and the Alcohol Use Disorders Identification Test. Neural imaging results indicated that heavy drinkers showed greater striatal response to alcohol cue compared to moderate drinkers ($p<0.001$, whole-brain corrected). Analysis of daily behaviors using decision

trees revealed a group difference in difficulty in controlling desire for alcohol (DCD) with greater difficulties in heavy drinkers ($F(1, 1810) = 15.76$, $p<0.001$). Among all subjects, higher stress management ability was the strongest predictor of lower daily DCD ($F(1, 1808) = 29.61$, $p<0.001$). Analysis of moderate drinkers found stress regulation was the strongest predictor of DCD ($F(3, 1283) = 16.00$, $p<0.001$) with high regulation associated with low DCD. Analysis of heavy drinkers found the strongest predictor of DCD was argumentativeness, one of characteristics associated with behavioral inhibition, with higher stress regulation associated with lower DCD ($F(1, 448) = 31.36$, $p<0.001$). These results suggest that while argumentativeness is the predominant vulnerability factor for DCD among heavy drinkers, a resilience relationship exists between high stress regulation and reduced DCD for all subjects. These exploratory results suggest specific vulnerability and resiliency factors associated with heavy drinking. Heavy drinkers may have greater vulnerability to alcohol urges, explained by behavioral disinhibition which has been linked to heightened striatal activity. Heavy drinkers may have difficulty controlling alcohol desire when they are exposed to vulnerable situations (e.g., alcohol exposure or interpersonal confrontation) but may be more resilient when they are able to exert emotional control in stressful situations. This finding may bear therapeutic implications for the role of stress management in the treatment of problematic alcohol use.

Title: Sex differences in ethanol and CRF effects on central amygdala GABAergic signaling in alcohol-dependent and naive rats

Authors: *D. KIRSON, S. KHOM, F. P. VARODAYAN, R. R. PATEL, M. ROBERTO; Neurosci., The Scripps Res. Inst., La Jolla, CA

Abstract: Alcohol dependence, equivalent to moderate to severe alcohol use disorder (AUD), is a chronically relapsing disease characterized by a loss of control over seeking and consumption

of alcohol. AUD has been linked to altered functioning of brain stress systems, as chronic alcohol use recruits these systems leading to the negative affective states seen in withdrawal, the relief of which drives further drinking. Both AUD and stress/anxiety disorders have been found to exhibit sex-specific differences among the population. Women are more likely to have an anxiety or mood disorder than men, and men are more likely to abuse alcohol than women. However, women develop addiction more quickly, and are more likely to relapse into repetitive drug use. The central nucleus of the amygdala (CeA) functions as a neuropeptidergic hub of stress and anxiety processing, and GABAergic signaling within the CeA is involved in the regulation of alcohol consumption. We have previously shown dysregulation of GABAergic and stress related peptide systems (e.g., corticotropin releasing factor/CRF) in the CeA following alcohol dependence, but mainly in male rats. In this study, we used whole cell patch clamp electrophysiological recordings to examine basal CeA GABAergic spontaneous inhibitory postsynaptic currents (sIPSC) and the effects of alcohol and CRF in both alcohol naïve and alcohol dependent Sprague-Dawley female rats induced by chronic intermittent alcohol vapor treatment. Basal sIPSC characteristics of frequency, amplitude, and kinetics were not different between naïve males and females, indicating no differences in GABA release or postsynaptic $GABA_A$ receptor functions. However, chronic alcohol vapor treatment in females did not increase sIPSC frequency as it does in males. Additionally, acute alcohol (44mM) had no effect on sIPSC characteristics in naïve or chronic alcohol treated females, in contrast to the increase in sIPSC frequency we have routinely found in males. These results provide important insight into sex differences in CeA neuronal functions with alcohol that may contribute to the development of alcohol dependence.

Title: Serotonin 2A receptor agonist treatment improves circuit and behavioral consequences of alcohol exposure

Authors: *B. A. KIMMEY, A. CROICU, N. SHADANI, R. E. WITTENBERG, A. OSTROUMOV, J. A. DANI;
Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Alcohol abuse remains one of the leading causes of preventable death. A number of risk factors including stress and a history of alcohol use can trigger the initiation or resumption of severe problem drinking making clinical management of alcohol use disorder (AUD) difficult. For this reason, novel pharmacotherapeutic strategies targeting the molecular- or circuit-level neural adaptations giving rise to AUD are needed. Emerging evidence suggests that the ventral tegmental area (VTA), a reward nucleus implicated in drug abuse, is a critical substrate of experience-dependent plasticity which drives aberrant alcohol drinking. Our work, among others, demonstrates that inverted GABA-mediated inhibition of VTA GABA neurons, as reflected by a depolarized $GABA_A$receptor reversal potential (E_{GABA}), contributes to increased alcohol (ethanol) consumption in rodents. This heightened ethanol-induced excitability of VTA GABA neurons results from chloride dyshomeostasis and is mediated by reduced function of the K^+-Cl^- cotransporter, KCC2. Targeting this molecular adaptation, therefore, represents a novel strategy to mitigate AUD in vulnerable populations. KCC2 is modulated *in vivo* by a number of intracellular effectors. Among these, activation of metabotropic 5-HT_{2A}-type receptors (5-HT_{2A}Rs), which increase PKC signaling downstream of receptor stimulation, was shown to enhance KCC2 function following spinal cord injury. This interaction extends to the VTA, as our preliminary data suggest that downregulated KCC2 is restored by 5-HT_{2A}R agonist treatment following stress exposure. Here, we reveal that KCC2 function is comparably diminished by both acute and chronic ethanol exposure in mice. Acute injection of an intoxicating dose of ethanol or protracted ethanol drinking in a two-bottle choice paradigm robustly diminished chloride transport function and depolarized E_{GABA} in VTA GABA neurons. Treating mice with the 5-HT_{2A}R agonist, TCB-2, after ethanol exposure, strengthened chloride extrusion and hyperpolarized E_{GABA} to the pre-ethanol state. In parallel, TCB-2 reduced ongoing ethanol drinking behavior. Restoration of KCC2 function following TCB-2 treatment was achieved by direct chloride transport modulation in VTA GABA neurons downstream of 5-HT_{2A}R activation. Taken together, these results suggest that KCC2-mediated chloride transport dysregulation is a potential target for limiting AUD. Moreover, we provide novel mechanistic insight into the therapeutic action of 5-HT_{2A}R agonists on alcohol-induced neural adaptations in VTA GABA neurons.

Title: Glucagon-like peptide-1 system is modulated by acute and chronic exposure to alcohol: Findings from human laboratory experiments and a brain postmortem study

Authors: *B. D. BROWNING[1], M. FAROKHNIA[1,2], H. SUN[3], P. SUCHANKOVA KARLSSON[5], L. FARINELLI[1], M. LEE[1], F. AKHLAGHI[6], L. LEGGIO[1,2,4,7];

Sci., Univ. of Rhode Island, South Kingstown, RI; [7]Dept. of Behavioral and Social Sci., Brown Univ., Providence, RI

Abstract: Glucagon-Like Peptide-1 (GLP-1) is a 30-amino acid peptide primarily produced by endocrine cells in the intestines. GLP-1 is an incretin and regulates glucose homeostasis, appetite, and food intake via central (e.g., hypothalamus) and peripheral (e.g., pancreas) pathways. GLP-1 also acts as a neuropeptide and both the peptide and its receptor (GLP-1R) are expressed in the brain. Previous data indicate that GLP-1 signaling may play a role in biobehavioral mechanisms underlying reward processing related to not only food but also alcohol and drugs of abuse. Indeed, rodent studies suggest that GLP-1R may represent a novel therapeutic target for alcohol use disorder (AUD). Therefore, it is also important to understand how excessive alcohol drinking may affect the endogenous GLP-1 system. To this end, we conducted a series of secondary analyses on human laboratory experiments to examine the effect of alcohol administration on peripheral blood GLP-1 concentrations in heavy-drinking individuals. Specifically, four separate alcohol administration sessions were conducted: oral self-administration (variable dose), oral fixed dose, intravenous self-administration (variable dose), and intravenous fixed dose. Repeated blood samples were obtained during each session and GLP-1 concentrations were measured via a bead-based multiplex ELISA assay. In all four experiments, acute administration of alcohol consistently resulted in significant reduction of peripheral GLP-1 concentrations (p's < 0.05). Next, we looked at the GLP-1R gene expression in postmortem brain tissue from patients with AUD and healthy controls (New South Wales Tissue Resource Centre, University of Sydney). GLP-1R mRNA was extracted from five brain regions (i.e., prefrontal cortex, ventral tegmental area, nucleus accumbens, amygdala, and hippocampus), and real-time quantitative PCR with TaqMan gene expression assay was run. Results showed that fold change in GLP-1R mRNA in the hippocampus was significantly higher in patients with AUD compared to healthy controls ($p = 0.007$). Collectively, these data elucidate how exposure to alcohol influences the GLP-1 system, both in the periphery and in the brain. Future studies should replicate the present findings and investigate whether targeting the GLP-1 system may represent an effective pharmacological approach to treat AUD.

Title: Effects of TrkB activation by alcohol withdrawal-mediated secretions of BDNF following chronic alcohol exposure

Authors: *A. J. PAYNE, J. N. BRUNDAGE, A. L. STOCKARD, M. A. NUMA, S. C. STEFFENSEN;
Brigham Young Univ., Provo, UT

Abstract: Brain-derived neurotrophic factor (BDNF) is implicated in varied physiological processes. Its main receptor in the central nervous system is tyrosine receptor kinase B (TrkB), and the main ligand for TrkB in the central nervous system is BDNF. It has been shown previously that activating TrkB can cause a downregulation of the chloride-exporting potassium chloride cotransporter 2 (KCC2), presumably resulting in a decreased chloride gradient. It is hypothesized that this down-regulation, caused by an increase in BDNF levels, creates hyperexcitable GABA neurons in the ventral tegmental area (VTA) due to a reduced efficacy of inhibitory currents. Here we investigate this mechanism of adaptation in the context of chronic alcohol exposure. We demonstrate that BDNF levels are elevated in the VTA during withdrawal from chronic alcohol exposure. We also observe that blocking TrkB activity decreases alcohol seeking behavior. Further, we investigate the expression patterns of KCC2 in connection with chronic alcohol administration. Additional work is underway to validate this mechanism and further elucidate its putative role in alcohol dependence and its potential as a treatment target.

Title: Mesolimbic circuit function underlying individual alcohol drinking

Authors: *S. E. MONTGOMERY[1], C. MOREL[1], B. JUAREZ[2], M. FLANIGAN[1], E. S. CALIPARI[3], S. J. RUSSO[1], E. J. NESTLER[1], M.-H. HAN[1];
[1]Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Pharmacol., Univ. of Washington, Seattle, WA; [3]Pharmacol., Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: Harmful alcohol use remains a serious public health issue, resulting in 3 million global deaths per year and contributing to more than 200 disease and injury conditions. Within the United States, the prevalence of Alcohol-Use Disorder (AUD) has increased significantly from 8.5% to 12.7% over the last 10 years and whose complex etiology has limited the number of effective therapeutics currently available. An interesting phenomenon in alcohol drinking is the variability of consumption occurring within the human population; some individuals drink casually while others drink in an uncontrolled manner, escalating their consumption and eventually developing alcohol dependence. To understand the circuit-specific functions underlying this phenomenon of individual alcohol drinking variability, we utilized isogenic C57BL/6J mice, an inbred mouse strain typically used to study alcohol-drinking behaviors. This mouse model provides the unique opportunity to investigate the neurophysiological mechanisms underlying low and high alcohol drinking behaviors, independent of genetics. Furthermore, it is known that a hallmark of the progression of AUD is the dysfunction of dopamine (DA) neurons projecting from the ventral tegmental area to the nucleus accumbens (VTA-NAc), a neural circuit critical to encoding the salience of both drug and naturalistic stimuli. Using *in vivo* fiber photometry calcium imaging and *in vivo* electrophysiological recordings, we are now able to determine the neural population response of the VTA-NAc DA circuit before and after the establishment of alcohol drinking phenotype, to illuminate the transition to low or high alcohol drinking profiles. Our preliminary data show that the magnitude of the primary reinforcing VTA-NAc DA response to rewarding and salient stimuli correlates with future establishment of alcohol preference. Further, alcohol-induced neuroadaptations differentially affect naturalistic behaviors in mice, including exploration and response to reward, and determine heightened or blunted responses to future alcohol exposure. By assessing the VTA-NAc DA neuronal profile of activity during naturalistic mammalian behaviors prior to and after alcohol exposure, this project will provide novel insight into physiological and real-time predictors of future, individual alcohol drinking phenotypes and how alcohol actively and reciprocally attenuates or exacerbates VTA-NAc DA circuit function, leading to subsequent maladaptive behaviors.

Title: Uncovering the genetic basis of courtship and naive odor preference in *Drosophila*

Authors: R. OLIVER[1], N. REGER[2], *F. J. VONHOFF[1];
[1]Univ. of Maryland Baltimore County, Baltimore, MD; [2]UMBC, Baltimore, MD

Abstract: We are testing how the relationship between genetics and sociability in the fruit fly *Drosophila* melanogaster triggers an addiction-like state preceding their first exposure to alcohol. Previous research demonstrated that sexual deprivation in *Drosophila* males caused them to consume alcohol at a higher rate. In addition, flies show a certain degree of naïve ethanol odor preference (NEOP) because they are innately lured to fermented fruit. It has been previously suggested that flies with high NEOP levels may be predisposed to consume more alcohol through adulthood. We tested virgin and mated flies of different ages in T-maze traps containing apple juice supplemented with ethanol in one arm. Our data indicate that courtship status was relevant to NEOP in males, but not females. Three-day-old virgin males showed a significantly higher NEOP to 23% ethanol than those that just mated. By contrast, females of all ages consistently avoided the side containing the 23% ethanol, independent of their mating status. Moving forward, we plan to uncover some of the genetic and cellular mechanisms that contribute to this dynamic phenomenon, as it is a pivotal step to understand the neurobiology of addiction.

Title: Prefrontal and orbitofrontal cortex neurons are differentially activated during passive and active alcohol acquisition: Influences of individual preference and chronic exposure

Authors: *B. KAMINSKA, M. L. BERKOWITZ-CERASANO, D. E. MOORMAN;
Univ. of Massachusetts, Amherst, MA

Abstract: Chronic and compulsive alcohol (ethanol, EtOH) use results in impoverished health and well-being, but the neural roots of this disease are still poorly understood. The goals of our studies are to understand how neuronal ensembles encode EtOH preference and motivation, and how this encoding changes in compulsive EtOH use and addiction. These studies focus on the rodent medial prefrontal cortex (mPFC) and orbitofrontal cortex (OFC) - areas with strong ties to reward preference, motivation, and addiction. Our studies test the hypotheses that specific patterns of mPFC and OFC neuronal activity encode individual differences in EtOH use and that these patterns are altered after chronic EtOH exposure.
To address these hypotheses, 6 female and 6 male Wistar rats were conditioned to drink 20% EtOH using homecage intermittent access for 1 month (acute exposure) or 3 months (chronic exposure). All rats were then implanted with intraoral catheters and drivable tetrode arrays. We recorded from mPFC and OFC neurons during 1) a passive classical conditioning task in which tone cues predict outcome (EtOH, sucrose, or quinine) delivery directly into the mouth and 2) an active classical conditioning task in which tone cues predict outcome availability at a reward port. Preference for EtOH was characterized by final homecage consumption, resistance to quinine adulteration, taking intensity during active task, and oromotor responses to intraoral EtOH in the passive task. We have thus far recorded 721 neurons from 5 rats (3 female, 2 male) in the 1 month exposure group:102 neurons in prelimbic mPFC, 185 in infralimbic mPFC and 434 in OFC. Across these populations, ~70% of mPFC and ~75% of OFC neurons responded significantly to one or more cues and/or outcomes. Neurons responded to most combinations between active/passive task and sucrose, EtOH, and quinine cues/outcomes, with an overall bias towards sucrose and EtOH associated cues and outcomes. Neurons primarily responded to a single cue (e.g., passive EtOH) or to outcome- or action-specific pairs of cues (e.g., passive and active sucrose cues). Additional recordings and analyses are underway to identify contributions of individual preference and exposure history to neural firing. The current results indicate that mPFC and OFC neurons are strongly influenced by EtOH-associated cues, outcomes, and behaviors and that we can identify the neural correlates of EtOH value relative to outcomes with more stable valence (e.g., sucrose or quinine). Based on our previous work and preliminary analysis, we also expect, that neural signals vary in relation to individual preference and motivation to seek/consume alcohol.

Title: Transmembrane AMPA regulatory protein-γ8 (TARP) knockout male mice show blunted operant responding for and reinstatement to alcohol

Authors: *S. P. FACCIDOMO[1], J. L. HOFFMAN[1], S. TAYLOR[1], M. KIM[1], C. W. HODGE[2]; [1]Alcohol Studies Ctr., [2]Psychiatry, UNC Chapel Hill, Chapel Hill, NC

Abstract: Alcohol has long been shown to disrupt glutamatergic function and related behaviors that can lead to the escalation of drinking and long-term alcohol abuse. The AMPA receptor (AMPAR) specifically has profound effects on synaptic and behavioral plasticity which are critical to the development of alcohol seeking behaviors and addiction. Transmembrane AMPA regulatory proteins (TARPs) are required for AMPAR trafficking and tethering of the receptor to excitatory synapses. The TARPs can modify AMPAR channel gating, regulate synaptic plasticity, and thereby alter post-synaptic expression and regulate output. The TARP subtype, TARP-γ8, is highly restricted to areas of the brain critical to conditioned alcohol consumption such as the frontal cortex, hippocampus, and basolateral amygdala making it a likely mechanism that mediates behavioral pathologies associated with alcohol addiction. We used two complementary strategies, a TARP-γ8 knockout mouse and pharmacological manipulation, to test the hypothesis that TARP-γ8 activity modulates the positive reinforcing effects of alcohol. TARP-γ8 KO mouse were physically and behaviorally similar to wild-type (WT) control mice. Importantly, there were no differences between the TARP-γ8 KO mice and WT controls in voluntary home-cage alcohol drinking or the sedative-hypnotic properties of alcohol. However, TARP-γ8 KO mice showed significantly reduced alcohol-reinforced lever pressing in operant conditioning chambers as compared to WT control mice. In addition, TARP-γ8 KO mice showed a blunted increase in operant alcohol self-administration following a concentration-induced escalation procedure, faster extinction of alcohol-reinforced operant responding and an absence of alcohol-seeking during a cue-induced reinstatement test. In the pharmacological study, systemic administration of JNJ-55511118, a selective negative modulator of AMPARs bound to TARP-γ8, decreased operant alcohol self-administration in WT mice, but had no effect in TARP-γ8 KO mice. Together, these data strongly suggest that TARP-γ8 regulation of AMPAR activity is required for the positive reinforcing effects of alcohol, which are crucial in the acquisition, maintenance and relapse of alcohol addiction. This work moves the field forward in

understanding the molecular mechanisms by which alcohol hijacks reward processes and has potential for the development of new pharmacotherapeutic strategies.

Title: Molecular and physiological dysregulation of Kv1.1 contribute to alcohol withdrawal induced hyperexcitability within the hippocampus

Authors: *D. L. DOBBINS[1], H. X. EGIDO-BETANCOURT[1], A. T. GOLDSTEIN[1], T. SMITH[1], K. F. RAAB-GRAHAM[2], D. W. GODWIN[1];

Abstract: Chronic use of alcohol perpetuates inhibition within the brain causing compensatory changes which are long lasting and lead to the symptoms associated with alcohol withdrawal (WD) syndrome. As individuals relapse and undergo repeated WD cycles kindling-like processes occur and lead to neuronal hyperexcitability. Thus, with each WD episode the severity and risk for potentially lethal seizures increase. To date little is known about the underlying molecular mechanisms responsible for shifting a neurons intrinsic properties toward a hyperexcitable state. Previous studies indicate hyperexcitability during WD may be mediated in part by specific ion channels that are differentially regulated by signaling pathways controlling protein synthesis, specifically mTOR. Increased mTOR activity has been observed during WD, is associated with many forms of epilepsy, and can repress the expression of the voltage-gated ion channel Kv1.1. Importantly, Kv1.1 contributes to the action potential frequency and helps set the resting membrane potential. Thus, we hypothesize WD mediated increase in mTOR activity reduce Kv1.1 expression and activity, leading to increased excitability. To test this, we subjected mice to a chronic intermittent exposure paradigm to assess the state of mTOR signaling and expression of Kv1.1 with repeated WD. Expression of these targets and local field potentials were examined in the hippocampus. Our results demonstrate repetitive WD cycles increase

mTOR activity and transcriptionally downregulate Kv1.1. This decrease in transcript suggests less Kv1.1 could be locally synthesized to prevent a further shift in excitability with additional WD episodes. We administered the chemoconvulsant pentylenetetrazol (PTZ) during WD to examine this possibility and found alterations to Kv1.1 and mTOR increased seizure susceptibility and correlate with seizure severity. Physiological dysregulation of these targets during WD were also observed by examining alterations to population spike activity with the administration of the mTOR inhibitor, Rapamycin, and 4-Aminopyridine (4AP). This study demonstrates mTOR and Kv1.1 dysregulation contribute to WD-induced hyperexcitability as observed through their aberrant molecular and physiological regulation within the hippocampus. These findings inform mechanisms of seizure activity during alcohol WD and present potential therapeutic targets to improve treatment for these events.

Title: Dopamine D2 receptor in ethanol induce behavioral sensitization

Authors: *N. M. DELGADO, C. M. SIERRA, P. R. SABANDAL, K. A. HAN;
Univ. of Texas At El Paso, El Paso, TX

Abstract: Males rarely court other males in *Drosophila melanogaster*. However, ethanol experience causes disinhibited inter-male courtship that is augmented with repeated ethanol exposures. Our previous work uncovered the requirement of dopamine signaling and the D1-like Dopamine/Ecdysone receptor, but not D1 or D5 receptors, for this type of ethanol-induced behavioral sensitization. The role of the D2-like DA D2 receptor (dD2R), however, remains uncharacterized and this study addresses this knowledge gap. To do this, we exposed the wild-type *Canton-S* (*CS*) and D2 receptor mutant (*d2r*) males to ethanol till sedation every day and monitored the behavioral responses including initial sensitivity, tolerance development, locomotor response and disinhibited courtship. Compared to *CS*, *d2r* flies exhibited normal initial sensitivity to the sedative effect of ethanol but displayed reduced tolerance, blunted locomotor response as well as substantially dampened behavioral sensitization to the disinhibition effect of ethanol. These findings reveal multiple roles of dD2R in ethanol-induced

behaviors. We found that re-expression of either of the three major D2 receptor isoforms differing in the third intracellular loop in either all or mushroom body neurons fully rescued the *d2r*‘s sensitization phenotype, indicating that the functional site of dD2R for sensitization is the mushroom body neurons. We are in the process of mapping the neural sites for the dD2R role in locomotor response. Our research may provide novel insights into the mechanisms that dD2R mediates multiple effects of ethanol.

Title: Voluntary exercise protects against ethanol induced sensitization of kappa opioid receptors in the nucleus accumbens

Authors: *J. BRUNDAGE, K. BILLS, J. SANDRES, B. RICHMOND, S. STEFFENSEN, J. YORGASON;
Brigham Young Univ., Provo, UT

Abstract: Despite many advances in treatment options, the relapse rate for alcohol use disorders (AUD) remains around 50%. It is vital for recovering addicts that we better understand the mechanism of addiction in order to prevent relapse and speed the healing process. Exercise has long been prescribed as part of alcohol abuse disorder treatment despite the fact that the exact way it affects the reward system is largely uncharacterized. Recent work in our lab has shown that a regiment of aerobic exercise decreases the efficacy of K-Opioid Receptors (KOR), a protein upregulated by endogenous opioids and heavily involved in alcohol seeking behavior and alcohol abuse disorder.KORs are part of the endogenous opioid system, which is strongly associated with positive and negative reinforcement of alcohol abuse. In the addicted brain, they are known to modulate seeking behavior by attenuating dopamine (DA) release in the nucleus accumbens (NAc). Dopamine release in the NAc is highly related to seeking behavior in addiction. As stated above, previous data has shown that KORs are upregulated in alcohol addicted mice. In different studies, upregulated KORs were also linked to increased seeking behavior in mice. In this study, we found that a regiment of aerobic exercise was protective against ethanol induced sensitization in the KORs compared to non-exercised controls. This was

determined by changes in DA release as measured by *ex vivo* cyclic voltammetry. Similarly, aerobic exercise decreased seeking behavior compared to non-exercised controls in drinking in the dark models.

Title: Role of extended amygdala in ethanol reward seeking altered by developmental adversities

Authors: *M. BJORNI, G. ETEM, N. ROVERO, A. QUAN, H. HENDERSON, M. BELNAP, L. HALLADAY;
Psychology, Santa Clara Univ., Santa Clara, CA

Abstract: Millions of adults and over half a million youth in the United States suffer from Alcohol Use Disorder (AUD), a chronic brain disease that leads to continued use of alcohol despite its negative health, social, and occupational effects. Yet we lack an exact understanding of the physiological mechanisms that underlie alcohol reward seeking behavior and how they might be affected by developmental adversities. To address this, we investigated the neural mechanisms underlying the ability of early life stress and/or exposure to alcohol in adolescence to alter adulthood alcohol seeking behavior. To model early life trauma, mice underwent maternal separation procedures in the first two weeks of life, which has been shown to lead to later behavioral deficits. Mice were separated from their mothers for 4 hours (PD2-5) or 8 hours (PD6-16) a day before being weaned early, at PD17. Control mice were left undisturbed in their home cage for the full preweanling period (< PD23). To model adolescent alcohol exposure, mice were given free access for 4 consecutive nights a week to either a 20% ethanol solution or water during adolescence (weeks 5-8 of life). We examined the contribution of specific neural mechanisms to natural versus ethanol reward preference by manipulating neural activity in the bed nucleus of the stria terminalis (BNST) or the central amygdala (CeA) using chemogenetics, as BNST and CeA have been implicated in reward seeking and addiction. Mice received surgical microinjections of inhibitory or excitatory DREADDs (Designer Receptors Exclusively Activated by Designer Drugs) into BNST or CeA after reaching adulthood (i.e., week 8). Mice were then trained in an operant task to discriminate between a natural (10% sucrose) and ethanol reward (10% sucrose + 10% ethanol). After discrimination training, mice were presented with both levers simultaneously for the first time in a preference session. Data collected on the first preference test day provided insight to whether stress and/or adolescent alcohol exposure

affected the preference for responding to sucrose- versus sucrose + ethanol-rewarded levers. Through DREADDs activation, we manipulated neural activity on a second preference test day, using the first preference day for baseline comparison. Our preliminary data indicate that developmental adversities alter reward seeking in adulthood and that manipulating neural transmission in the BNST and CeA affects performance on our preference task. These findings contribute to our greater understanding of the neural mechanisms that influence alcohol seeking behavior, and thus help the scientific community on its goal towards developing better, targeted AUD treatments.

Title: Pharmacokinetics of ethanol in male and female Japanese quail

Authors: *S. E. EATON, J. E. JAGIELO-MILLER, M. A. PRENDERGAST, C. K. AKINS; Dept Psychol, Univ. Kentucky, Lexington, KY

Abstract: In humans, females tend to absorb and metabolize ethanol at different rates than males. Specifically, at similar doses, females achieve higher blood ethanol concentrations (BECs) and have faster elimination than males. Japanese quail may be an ideal model for studying the effects of ethanol consumption and sex differences. Birds are more sexually dimorphic than mammals, and hormones can easily be manipulated without surgery. Because relatively little research has examined ethanol effects in quail, there is not much information on metabolism and elimination differences between males and females. Understanding the absorption and metabolism rates of ethanol is critical to developing a working model of alcohol use disorder. Therefore, we aimed to document the BEC profile in male and female quail. Male (n=12) and female quail (n=6) were gavaged with 0.75 g/kg ethanol daily for 7 days or received 2-3 g/kg. Blood samples were taken 30, 60, 120, and 240 minutes after administration on day 1 and 7. Samples were analyzed for ethanol content. The findings indicate that the 3 g/kg dose produced higher BECs than the 0.75 g/kg dose [$F(1,3)=263.41$, $p<.05$]. The area under the curve (AUC) was similar between both males and females treated with 3 g/kg, p= n.s. Additionally, the rate of absorption and elimination for both males and females treated with 3 g/kg was similar, p=n.s. However, female quail treated with 0.75 g/kg appeared to eliminate ethanol quicker than their male counterparts [$F(2,10)=15.81$, $p<.05$]. Specifically, females had lower BECs than males at 240 min following gavage [$F(1,5)=20.47$, $p<.05$]. Both males and females treated with 0.75

g/kg had similar AUC, p= n.s, but the slope from peak to 240 min differed significantly, [$F(1,2)=24.97$, $p<.05$]. The elimination difference between sexes may be due to gastric or hepatic metabolic and alcohol dehydrogenase differences between the sexes. Additionally, both males and females had higher BECs on day 7 than on day 1 [$F(1,9)=19.04$, $p<.05$]. This increase across days may be due to remaining unmetabolized ethanol in the bloodstream from the previous day, suggesting quail metabolize alcohol slowly.

Title: Reinforcing effects of cocaine are modulated by dopamine-independent actions of modafinil: Possible involvement of gap junctions

Authors: M. MEREU, T. HIRANITA, C. J. JORDAN, L. E. CHUN, J. P. LOPEZ, M. A. COGGIANO, J. C. QUARTERMAN, G.-H. BI, J. D. KEIGHRON, Z.-X. XI, A. H. NEWMAN, J. L. KATZ, ***G. TANDA**;
NIDA-IRP, Baltimore, MD

Abstract: Modafinil has been shown to block the dopamine (DA) transporter, a mechanism shared by cocaine, methylphenidate, and other psychostimulants. Modafinil is clinically available for the treatment of narcolepsy and other sleep disorders. Recently, its non-medical use as a “smart drug” is raising concerns regarding its potential for abuse by populations that might also use illicit substances. In this study, we compared the potential for abuse of modafinil with that of methylphenidate, another prescribed medication, and their interactions with the reinforcing effects of cocaine in rats trained to self-administer cocaine. We also assessed changes in DA levels in the nucleus accumbens shell, a brain area related to reinforcing effects of drugs, using microdialysis procedures in rats. Methylphenidate (0.03-1.0 mg/kg) maintained intravenous self-administration behavior at comparable levels as active doses of cocaine (0.03-1.0 mg/kg), whereas modafinil (0.1-10 mg/kg) failed to do so at any dose tested. Nonetheless, both modafinil (10-32 mg/kg, i.p.) and methylphenidate (1.0-10 mg/kg, i.p.) pretreatments potentiated cocaine self-administration. Cocaine, at self-administered doses, produced dose-related stimulation of DA concentrations in the nucleus accumbens shell. Methylphenidate (1.0-

10 mg/kg, i.p.), but not modafinil, (10-32 mg/kg, i.p.), enhanced cocaine-induced stimulation of DA levels, indicating that the effects of methylphenidate on cocaine actions are DA-dependent, while those of modafinil are not. Modafinil is known to facilitate electrotonic coupling between cells by actions on gap junctions. Carbenoxolone, a gap junction inhibitor, reduced the potentiation of cocaine self-administration produced by modafinil but not by methylphenidate. In conclusion, modafinil shares with cocaine and methylphenidate an important action at the DA transporter, but the present data indicate a unique pharmacological stimulant profile, lacking abuse potential and facilitating electrotonic coupling. These results, together with clinical studies, further suggest a potential therapeutic use of modafinil in patients with cocaine use disorder.

Title: The role of dietary and synaptic zinc on cocaine abuse vulnerability

Authors: *J. L. GOMEZ, K. WRIGHT, M. MICHAELIDES;
Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Zinc (Zn^{2+}) is an essential life element, and dysregulation or deficiency is associated with various disorders. Zn^{2+} is highly concentrated in the brain where it is thought to exert effects on synaptic plasticity, neurotransmission, protein/enzyme function, and transcriptional regulation. Zinc can be found in two forms, bound (structural) and labile (free). This unbound free zinc can be co-packaged into vesicles and co-released with glutamate acting as an allosteric modulator. Thus, free zinc is tightly regulated by a family of 24 transporters that move zinc around the cell. Our lab has focused on ZnT3 (Slc30a3), the transporter that shuttles zinc into glutamate vesicles. Previous research by our lab has demonstrated that artificially manipulating striatal zinc, via chelator, causes a reduced level of cocaine sensitization with long lasting effects. Additionally, dietary or genetic manipulation alters reward and sensitivity to cocaine without effecting normal mouse behavior. This project explores the manipulation of dietary zinc and ZnT3 as a factor of cocaine abuse vulnerability.

Title: Minocycline prevents chronic restraint stress-induced cocaine sensitization and morphological changes of microglia within nucleus accumbens core

Authors: ***M. P. AVALOS**, E. A. GOROSTIZA, M. SANCHEZ, A. S. GUZMAN, D. RIGONI, F. A. BOLLATI, L. M. CANCELA;
DPTO DE FARMACOLOGIA, FACULTAD DE CIENCIAS QUIMICAS, UNC, IFEC-CONICET, Cordoba, Argentina

Abstract: It is well known that individuals suffering from stress disorders are vulnerable to developing drug abuse. In animal models, studies from our lab showed that exposure to restraint stress engenders long-lasting neuroadaptations on glutamatergic system within Nucleus Accumbens (NA) which enables sensitized response to cocaine (Esparza et al., 2012, Garcia-Keller et al., 2013) and facilitation of cocaine self-administration (Garcia-Keller et al., 2016). On the other hand, our previous findings evidenced a role of glutamate in enduring psychostimulant-induced sensitization at the immune level in a parallel way to that occurring in the limbic system (Assis et al., 2009, 2011). However, there is no description so far of which is the role played by microglia in stress-induced cocaine sensitization. The aim of this study was to evaluate the effect of minocycline, a potent inhibitor of microglia activation, in chronic restraint stress-induced cocaine sensitization and morphological changes of microglia within NA core. Thus, Sprague Dawley rats were exposed to restraint stress 2 h daily for a week. From day 16 to day 21 after the first stress session, all animals were treated with minocycline (30 mg/Kg/12 h) or vehicle (DMSO 5%/12 h). On day 21, locomotor activity was measured following saline or cocaine challenge (15 mg/Kg). Then, in order to examine fluorescence intensity and the morphology of microglia, immunofluorescence by labeling Iba-1 was performed. Our results pointed out that minocycline was able to prevent chronic stress-induced cocaine sensitization suggesting that microglia play a key role in this phenomenon. Interestingly, stress induced hyper-ramification of microglia and enhancement of Iba-1 fluorescence intensity within NA core. Likewise, minocycline prevented those morphological changes of microglia and restored the expression of

Iba-1. Accordingly, we propose that microglia could contribute to the development of pathological neuroadaptations within NA core following chronic restraint stress to trigger cocaine sensitization. These results strongly prompt to think that minocycline might be considered as a promising therapeutic agent in preventing the comorbidity between stress and drug abuse. Next findings will attempt to deepen the study of these chronic restraint stress-induced changes to promote addiction-related disorders.

Title: Enhanced reward motivation and sensitized fear in adult rats exposed to a single trauma during early development

Authors: *M. M. COBB[1], A. N. HOFFMAN[1], A. GOLD[1], M. S. FANSELOW[1], P. J. KENNEDY[2];
[1]Psychology, UCLA, Los Angeles, CA; [2]Psychology, Univ. of California Los Angeles, Los Angeles, CA

Abstract: The prevalence of comorbidity between post-traumatic stress disorder (PTSD) and substance use disorders and obesity, suggests altered reward processing in individuals suffering from PTSD. Early life stress (ELS) such as repeated maternal separation increases both the risk for development of PTSD related symptoms and addiction-like behaviors in adulthood. Less is known about the long-term effects of a single, painful traumatic experience during early development. Here we exposed male juvenile rats (PND 19) to 15 unpredictable footshocks (1mA, 1s) over a 90 minute session and tested for sensitized fear learning and reward-seeking behavior in adulthood. Our findings replicate previous data showing that adult rats exposed to this paradigm of ELS demonstrate sensitized fear learning, a component of PTSD (Poulos et al., 2014). We next trained control and ELS rats to self-administer sugar pellets on an FR1 schedule of reinforcement followed by progressive ratio (PR) testing. We found that control and ELS rats did not differ in their acquisition of sugar self-administration however, ELS rats had a significantly higher breakpoint during the PR test. These data indicate that a single trauma during early development may have lasting effects on reward processing and valuation. Ongoing behavioral studies are investigating changes in motivation for drugs of abuse in combination with both longitudinal microPET and qRT-PCR analyses in striatal circuits to identify

developmental changes in dopamine receptor function and expression following early life trauma.

Title: Conditioned place preference to cocaine in leptin receptor deficient diabetic (db/db) mice

Authors: *D. C. AGUIAR[1], J. A. S. L. GOMES[2], P. H. GOBIRA[3];
[1]Pharmacol., Univ. of Minas Gerais- UFMG, Belo Horizonte, Brazil; [2]Inst. of Biotech., Federal Univ. of Uberlandia, Belo Horizonte, Brazil; [3]Univ. of São Paulo, Ribeirao Preto, Brazil

Abstract: Introduction: The neurobiological mechanisms that regulate the response to addictive drugs are complex, and several evidence have been shown the link between neural control of appetite regulation and substance abuse. Leptin, an important adipose hormone, it´s circulating levels reflect the body's energy stores in adipose tissue. It regulates energy balance and appetite control via leptin receptors expressed in central nervous system. Previous data indicate that leptin signaling is critically involved in cocaine-conditioned reward. The infusion of the leptin receptor antagonist during cocaine conditioning increased the cocaine-conditioned place preference and the infusion of the leptin in nucleus accumbens core disrupts acute cocaine effects. Complementing these findings in animals, the leptin serum levels is inversely correlated with the severity of crack use in humans. Although data indicate that leptin signaling is inversely correlated with cocaine effects, the role of leptin signaling in regulating the intensity of the learned response to cocaine after this drug is no longer present remains unclear. Therefore, our objective was evaluate the reinforcing effects of cocaine and the persistence of memory of the conditioned reward response to cocaine in leptin receptor deficient diabetic (db/db) mice using a conditioned place preference (CPP) procedure. Methods: The CPP test consisted of four phases, namely pre-conditioning (day 1), conditioning (days 2-7), testing (day 8), and extinction (days 9-14). For the procedure, male db/db mice and their wild-type (WT) littermates (16-20 weeks old) were given intraperitoneal injection of cocaine (15 mg/kg, days 3, 5 and 7) or vehicle (days 2, 4 and 6) immediately before they are placed in their respective drug-paired chamber of CPP apparatus. During the test and extinction phase, no drug was delivered and the time spent in each compartment was registered. The CPP index was calculated according to the time spent in the

drug-paired side subtracted by the time spent in the vehicle-paired side. Results: In the test session, both groups showed significant preference for the cocaine-paired chamber ($p<0.05$ different from pre-test session, Two-way ANOVA, followed by Bonferroni). However, during the extinction phase the db/db mice presented an impairment of the extinction response in the CPP test compared to WT mice ($p<0.05$, Two-way ANOVA). Conclusion: Our data demonstrated that db/db mice displayed a more persistent memory of the cocaine-conditioned reward and suggest that the leptin signaling is also able to interfere in cocaine-CPP extinction phase.

Title: Cocaine vs food choice: Neurobiological findings under a CRR

Authors: *J. J. CHOW, J. S. BECKMANN;
Univ. of Kentucky, Lexington, KY

Abstract: Choice procedures have become increasingly more common in attempts to determine the neurobehavioral mechanisms governing substance use disorders. However, in most choice procedures the relative rate of reinforcement across the drug and non-drug option vary depending on the choices that individual subjects make. Moreover, the relative rate of reinforcement is a known mediator of preference and previous research has demonstrated that differential experience with drugs of abuse, such as cocaine, can lead to differential neural adaptations. Thus, under choice procedures with this issue, the neurobiological findings regarding drug vs non-drug choice can become difficult to interpret. Herein, we utilized a controlled reinforcer ratio (CRR) schedule to investigate the role of the orbitofrontal cortex (OFC) and nucleus accumbens (NAc) on cocaine choice. Adult male Sprague Dawley rats were first trained under a series of establishing procedures to acquire food and cocaine self-administration. Rats were then placed on a CRR schedule. The CRR consisted of 5 blocks, with 6 trials/block, where the dose of cocaine increased as a function of block (0, 0.032, 0.10, 0.32, and 1.0 mg/kg/infusion) on one option, while the other option consistently offered a single 45-mg palatable-food pellet across all blocks. Under the CRR, both levers would extend on trial start, however only one reinforcer was randomly made available. Through the randomization of reinforcer availability, preference was measured via the time spent on a given alternative. Following stability of choice training under

the CRR, rats underwent two independent-test sessions where they were placed in a condition for either food preference or cocaine preference; with the second test session being the opposite. After the test sessions rats were perfused and brains were collected. Brains slices for the OFC and NAc were collected and underwent fluorescent *in situ* hybridization and fluorescent immunohistochemistry for cFos expression for food and cocaine preference, dependent on the order of presentation during the test sessions. Results revealed that behavioral measures, via the matching law, were not correlated with cFos expression when the relative rate of reinforcement was equal in either the OFC or NAc. However, when the relative rate of reinforcement was in favor for cocaine, an increased number of cFos positive cells for cocaine was observed in the OFC. Overall, these results revealed that neuronal activity for cocaine is related to cocaine intake, and not preference. In all, these findings provide impetus for careful considerations regarding the procedures used in investigating drug versus non-drug choice.

Title: 5-HT$_{1B}$ receptor agonist attenuation of cocaine self-administration persists after a period of relapse

Authors: *R. GARCIA[1], S. SCOTT[1], T. LE[1], S. DOYLE[1], A. ESQUER[1], J. VALENZUELA[1], K. M. BLATTNER[2], B. E. BLASS[2], J. L. NEISEWANDER[1];

Abstract: The selective 5-HT$_{1B}$ receptor (5-HT$_{1B}$R) agonist, CP94253, enhances cocaine self-administration (SA) during maintenance of drug-taking but attenuates SA after three weeks of forced abstinence in male rats. Here we examined if the effects of CP94253 produced a similar abstinence-dependent attenuation on SA in female rats. Additionally, we examined if these attenuating effects persist or revert back to enhancing SA during a period of relapse (i.e., resumption of SA). Male and free-cycling female rats were trained to lever press for cocaine (0.75 mg/kg, IV), for a minimum of two weeks, on a fixed ratio 5 schedule of reinforcement. Rats underwent ~21 days of forced abstinence following stable performance for cocaine SA. After, rats were tested for the effects of acute treatment with either vehicle or CP94253 (5.6 mg/kg, SC) on both the training dose and a lower dose of cocaine (0.075 mg/kg, IV) for the first

and second hour of the test, respectively. Rats then resumed cocaine SA on the training dose for equal number of days as the initial training phase. Rats were then tested again with either vehicle or CP94253 done previously. We found that similar to male rats, CP94253 attenuated cocaine SA in female rats following abstinence. During resumption of SA, all rats demonstrated similar self-administration similar to the initial training phase. Interestingly, CP94253 attenuated SA in male and female rats when tested after resumption of cocaine SA. These results demonstrate that the abstinence-dependent attenuation effects of CP94253 on cocaine self-administration remain even after resumption of cocaine SA without abstinence. The findings suggest that CP94253 and other selective 5-HT_{1B}R agonists may have clinical efficacy as anti-relapse treatments for cocaine use disorders.

Title: The effects of a selective 5-HT_{1B} receptor agonist on cocaine demand before and after abstinence from self-administration in freely cycling female rats

Authors: *S. N. SCOTT[1], G. L. POWELL[1], R. GARCIA[1], A. M. GARCIA[1], O. I. VILLARREAL[1], K. M. BLATTNER[2], B. E. BLASS[2], J. L. NEISEWANDER[1];
[1]Sch. of Life Sci., Arizona State Univ., Tempe, AZ; [2]Sch. of Pharm., Temple Univ., Philadelphia, PA

Abstract: In male rats, the selective 5-HT_{1B} receptor (5-HT_{1B}R) agonist, CP94253, enhances the reinforcing value of cocaine during daily drug-taking, but attenuates the reinforcing value of cocaine after 21 days of abstinence. We recently found that in female rats, CP94253 decreases cocaine self-administration during daily drug-taking at intermediate doses of cocaine regardless of estrous cycle phase; however, it is unclear whether the CP94253 effects are due to enhancement or attenuation of cocaine reinforcement. In this study, we used a behavioral economics analysis to address this question. This approach evaluates the consumption of a specific drug across a range of prices, where price is controlled using either the response requirement necessary to receive drug or by the concentration of drug received. The analysis yields two important parameters: demand intensity (Q_0) and elasticity of demand (α). Demand intensity measures consumption at an unconstrained price, while elasticity measures sensitivity

in consumption due to changes in price. The current study applied behavioral economic analysis to investigate whether CP94253 influences the demand for cocaine during the active drug-taking phase and after 21 days of abstinence in female rats. Female Sprague-Dawley rats were trained to self-administer 0.75 mg/kg, i.v. cocaine initially on a fixed ratio 1 (FR1) schedule of reinforcement for 2 hours/day and then on a within-session dose-reduction procedure where 9 doses (1 mg/kg to 0.01 mg/kg i.v.) were available for 5 min each in descending order. Once rats had less than 25 percent variability in elasticity across 3 consecutive days, they were tested for the effects of CP94253 on cocaine demand. Rats were pretreated with 5.6 mg/kg s.c. CP94253 or vehicle 15 minutes prior to testing using the same dose-reduction procedure as above. Preliminary results suggests CP94253 increased cocaine demand elasticity but had no effect on demand intensity. This suggests that CP94253 pretreatment decreases cocaine consumption as the effort necessary to acquire drug increases. This study is ongoing and if the results are reliable, then our findings are consistent with CP94253 attenuates the reinforcing properties of cocaine as a function of effort and have important implications for developing treatments for cocaine dependence.

Title: Alpha synuclein critically modulates motivation for rewarding stimuli and shows dynamic changes in subcellular localization within ventral tegmental area axon terminals after systemic cocaine administration

Authors: O. TRUBETCKAIA[1], A. E. LANE[1], L. QIAN[1], P. ZHOU[2], ***D. A. LANE**[1];
[1]Feil Family Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY; [2]Brain and Mind Res. Inst., Weill Cornell Med., New York, NY

Abstract: Addiction is difficult to overcome because drugs of abuse produce relatively permanent changes in the function of dopamine (DA) neurons involved in reward and motivated behaviors. The activity of ventral tegmental area (VTA) DA neurons is a balance of excitatory and inhibitory inputs coming from multiple brain regions, which is disrupted with repeated drug use causing a shift to increased glutamate activation of these cells. However, it is still unknown

what causes the functional shift in DA activation originally incoming from striatal inputs, which mediate the initial rewarding/hedonic effects of drugs, to cortical inputs that drive drug craving and compulsive drug intake. A potential candidate for modulating afferent information to VTA DA neurons is alpha-synuclein (α-syn), an abundant neuroprotein found predominantly in axon terminals. A-syn is elevated in blood and brain tissue samples obtained from human addicts and in brain regions undergoing developmental glutamatergic plasticity. However, very little is known about the normal function of α-syn or its contribution to addictive behaviors. As such, we examined the subcellular localization of α-syn and changes in drug-related behaviors of normal C57BL/6J and α-syn knockout (*C57BL/6N-Snca^{tm1Mjff}/J*) mice before and after systemic cocaine administration. Electron microscopic characterization of α-syn shows that cocaine-mediated presynaptic α-syn upregulation is highly dynamic and targets specific axon terminals depending upon the duration of cocaine exposure and whether cocaine was systemically present during evaluation. For instance, we show glutamatergic axon terminals with α-syn labeling adjacent to non-labeled glutamate terminals both making synaptic contacts onto the same DA dendrite. The highly precise presynaptic distribution of α-syn makes it strategically positioned to collectively fine-tune the complex afferent input to VTA dopamine neurons and regulate dopamine output. Repeated cocaine administration also upregulates postsynaptic α-syn where it is seen around endocytic vesicles and multivesicular bodies (MVBs) where it facilitates exosome release and is necessary for normal MVB formation. Our behavioral studies compliment the changes seen in the subcellular α-syn distributions and demonstrate that α-syn is necessary for preference to rewarding stimuli and for the cognitive flexibility needed for changing previously learned behavioral strategies, two critical factors influencing addiction.

Title: Lipid profiles of brain extracellular vesicles of cocaine-treated mice

Authors: *M. SAITO[1,2], R. LINN[1], A. HASHIM[1], H. SERSHEN[1,2], B. BARRETO[1], M. SAITO[1,2], E. LEVY[1,2];

Abstract: Repeated use of cocaine induces addiction and other adverse effects through changes in the expression and functions of specific proteins, lipids, and RNAs, including molecules relevant to the rewarding pathway. Exosomes, endosome-derived small extracellular vesicles (EVs), are secreted from many cell types, eliminate cellular toxic materials, and carry various molecules that affect physiological and pathological functions of recipient cells. Cocaine's effects may also be partially mediated by exosomes uniquely modified by cocaine. In this study, the effects of cocaine on lipid profiles of brain EVs were examined, because some of the exosomal lipids are considered signaling molecules. 3-month-old mice (both sexes) were injected with saline (control) or cocaine (10 mg/kg) daily for two weeks. Under this condition, mice acquired locomotor sensitization and CPP to cocaine. 30 min after the final injection, small brain EVs released into the extracellular space were isolated [Perez-Gonzalez et al. J Biol Chem 2012, 287:43108] using OptiPrep density gradient centrifugation as the final step, which separated three EV fractions with different densities. We found that cocaine treatment differentially affected the amount of EVs in these fractions: decreased EVs with the medium density and increased EVs with the highest density. Then, we analyzed the major lipids of these EVs by HPTLC. In both control and cocaine samples, the lipid compositions of these three EV fractions were different. Specifically, sphingolipids (e.g., ceramide and gangliosides) were highly enriched in EVs in the lowest density group compared to brain homogenates. For example, in the control animals, ceramide was 45±8 times more enriched in the lowest density EV group compared to 7±0.4 times enrichment of cholesterol. Cocaine treatment increased the amounts of cholesterol, phosphatidylcholine, phosphatidylethanolamine, and GD1a ganglioside, but no changes in phosphatidic acid and phosphatidylserine in EVs with the highest density, along with the increase in the EV protein levels of this density group. Also, despite the decrease in the protein level of EVs with the medium-density by cocaine treatment, gangliosides, including GD1a, increased in this fraction. Thus, cocaine treatment uniquely altered distribution of EVs with different densities and also altered EV's lipid profiles. Especially cocaine affected the content and distribution of gangliosides profoundly. This may be related to previous studies suggesting that gangliosides enhance the rewarding properties of cocaine.

Title: Behavioral and electrophysiological evidence for "high risk" cocaine addiction identified in a subset of outbred Long Evans rats

Authors: *N. J. BEACHER[1], A. DAO[4], M. KARNAM[2], S. J. LEICHNER[3], J. KULIK[5], A. P. PAWLAK[5], M. O. WEST[3];

Abstract: A troubling component of drug addiction is subsequent drug relapse after a period of abstinence. A substantial portion of the addicted population is susceptible to relapse triggered by drug-associated cues. During abstinence, 'drug-craving' can be triggered by drug-cues which re-invigorate drug-associations in motivational brain regions such as the nucleus accumbens (Nac). As such, identifying differences in cue reactivity is important for the long term prevention of drug-relapse. Cue reactivity differences have been studied in humans and animals using an autoshaping test, which identifies two distinctive behavioral phenotypes; Sign-trackers (ST) and Goal-trackers (GT). This phenomenon is thought to involve incentive salience, where the "self-rewarding" predictive-cue becomes associated with future reward. Historically, GT have been largely ignored in drug addiction modeling and have been overshadowed by a common focus on their ST counterparts despite recent literature suggesting group similarities. Our study asked whether individual differences in STGT phenotype would predict differences in drug seeking behavior and Nac firing patterns across a 14-day cocaine self-administration (SA) paradigm. Following autoshaping, adult male long evans rats received 14 days' training (6 hours/day) in a tone discrimination paradigm where cocaine availability was contingent on a nose poke response during a 30 sec tone S^D. Single unit Nac responses to the tone S^D were tracked for the same neuron during different behavioral events the same day (Hits vs. Misses) and compared between High vs. Low Intake and GT vs. Non-GT groups. Despite overall behavioral and electrophysiological group similarities, we identified Nac FR patterns unique to High Intake GT: "silent" neurons on Misses were "active" during Hits within the same session. Behaviorally, the same subset of High Intake GT animals demonstrated high uncued drug seeking (evidence of drug craving) and significantly different drug level on Hits vs. Misses (evidence of an inability to titrate). Results suggest a novel model for studying individual differences in drug abuse vulnerability and advance our understanding of Nac firing patterns that contribute to relapse.

Title: Plastic changes in central nuclei of the amygdala driven by natural reward and addictive learning

Authors: *L. D. BIJOCH, M. PEKALA, J. KLOS, S. MITRA, L. KACZMAREK, A. BEROUN;
Lab. of Neurobio., Nencki Inst. of Exptl. Biol., Warsaw, Poland

Abstract: Since few years, drug addiction is considered to be a disease based on plastic changes on synapses in different brain regions. Similar changes can be observed also as results of natural forms of memory formation and it is believed that they encode information - engrams. Thus, in this study we were trying to determine how much similarities shares the initial exposure to addictive substances with natural reward learning. Both addictive and positive experiences are known to have strong emotional context, so we focused our experiments on two specific brain pathways of the limbic system: connections between posterior Basolateral Amygdala (pBLA) and medial or lateral part of Central Amygdala (mCeA or lCeA).
In our studies we used adolescent mice of both sexes. Our model of "addictive" experience was cocaine intraperitoneal injections, while sucrose self-administration represented the natural reward one. To ensure pathway specificity, viruses carrying information about channelorodopsin 2 were injected into pBLA. In such mice, after natural or addictive experience, plastic changes were studied by whole-cell patch clamp recordings with use of optogenetic stimulation.
Collected data indicate that both cocaine injection and sugar administration lead to changes in pBLA-to-mCeA pathway. In both paradigms, we observed similar generation of silent synapses - immature synaptic contacts. Silent synapses contain mostly NMDA receptors (and not AMPAR) and may function as indicator of plastic changes. Results indicate that these synapses increase their effectiveness (we observed LTP-like changes) after both sugar and cocaine treatment. However, specifically after cocaine injections we also observed indicators of plastic changes in lCeA and these changes were accompanied with decreased activity of neurons in that nucleus (LTD-like changes).
Thus, drug exposure affects the pathway processing positive memories (pBLA-to-mCeA) similarly as natural learning do. However, at the same time it also decreases the activity of lCeA, which is known for inhibiting mCeA. Thus, such reduction leads to disinhibition of mCeA and even stronger activation of mCeA. Our results shed light on controversies around considering

addiction as a form of simple, appetitive learning. We are also describing principles of cocaine experience, which is related with both LTD and LTP processes in the amygdala at the same time.

Title: Retinoic x receptor alpha signaling in the nucleus accumbens contributes to cocaine- and opioid-induced transcriptional and behavioral alterations

Authors: *A. GODINO, M. SALERY, R. FUTAMURA, C. J. BROWNE, F. J. MARTINEZ-RIVERA, P. J. HAMILTON, D. M. WALKER, E. J. NESTLER;
Nash Family Dept. of Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Addictive behaviors are thought to depend largely on long-lasting drug-induced transcriptional adaptations in key regions of the brain's reward circuitry. It is therefore critical to characterize the precise molecular mechanisms through which such transcriptional changes are first established following drug exposure to sustain drug-related associative learning. While some key players in this process have been identified, the extremely complex nature of the transcriptional programs triggered by drug exposure suggests more subtle and fine-tuned mechanisms of regulation. To that end, we predicted upstream regulators of genes whose expression levels were altered after prolonged withdrawal from cocaine self-administration and also positively associated with addiction-like behavioral features, and identified Retinoic X Receptor alpha (RXRa) as a putative key transcriptional mediator in the nucleus accumbens (NAc). We further investigated the contribution of RXRa, a transcription factor and nuclear receptor for retinoids also known as NR2B1, to the transcriptional and behavioral adaptations induced by drug exposure. First, we used RNA-sequencing to assess the transcriptional consequences of viral-mediated RXRa overexpression in NAc neurons, in order to confirm its role in driving addiction-relevant gene networks. Second, bidirectional manipulation of RXRa expression levels in the NAc using overexpression and knockdown strategies modulated conditioned place preference behavior for both cocaine and morphine in both male and female mice. However, pharmacological inhibition of RXRa canonical function seemingly failed to

elicit similar behavioral effects, suggesting a more complex mechanistic role for RXRa in drug-associated reward learning. Consequently, we are now examining the role of non-canonical mechanisms for RXRa function, such as a hypothetical interaction with CREB - a well-characterized plasticity-related transcription factor implicated in addiction mechanisms. Together, this study demonstrates a novel role for RXRa in the formation of drug-related memories, and paves the way for future studies of retinoid signaling in the context of drug abuse.

Title: CREB-mediated activation of Zfp189 in nucleus accumbens drives behavioral responses to psychostimulants, but not opiates

Authors: C. D. TEAGUE[1], C. J. BROWNE[1], R. FUTAMURA[1], F. J. MARTINEZ[1], P. MEWS[1], A. MINIER-TORIBIO[1], A. GODINO[1], Z. S. LORSCH[1], R. L. NEVE[2], ***P. J. HAMILTON**[3], E. J. NESTLER[1];
[1]Friedman Brain Inst., Mount Sinai Sch. of Med., New York, NY; [2]Neurol., Massachusetts Gen. Hosp., Cambridge, MA; [3]Anat. and Neurobio., Virginia Commonwealth Univ. Hlth. Syst., Richmond, VA

Abstract: Repeated administration of psychostimulants or opiates elevates cyclic AMP-responsive element binding protein (CREB)-mediated transcription in the nucleus accumbens (NAc), a major brain reward region. Over-expression of CREB in NAc decreases the rewarding effects of both psychostimulants and opiates, indicating that CREB activity in this region regulates the addictive properties of these drugs. However, manipulations of this kind cause transcriptional changes at hundreds or thousands of gene loci, limiting mechanistic insight. To clarify this complexity, we generated a novel fusion construct consisting of the nuclease-dead, RNA-guided, DNA-binding protein Cas9 tethered to the active form of CREB (S133D) (dCas9-CREB). When combined with viral delivery methods, this enables us to target CREB to specific gene loci within mouse brain. Here, in mouse NAc, we targeted CREB to the *Zfp189* gene, which is implicated in the regulation of excitatory synaptic transmission and is activated by CREB in

animal models of psychostimulant abuse. We assessed the causal contribution of the CREB-*Zfp189* interaction to psychostimulant- versus opiate-induced behaviors. Our experiments were carried out in male and female mice on a C57 background between 8-10 weeks of age and sample sizes were calculated to yield sufficient statistical power. We observed that co-delivery of herpes simplex virus (HSV)-dCas9-CREB and HSV-*Zfp189*-sgRNA to the NAc elevates *Zfp189* gene expression (mRNA) relative to non-targeting controls. CREB-mediated activation of *Zfp189* in both male and female mice reduces conditioned preference behaviors for cocaine, but does not affect morphine preference. Further, inducing CREB-*Zfp189* interactions potentiates locomotor responses to cocaine, yet does not alter locomotor responses to morphine. We are currently performing drug self-administration, brain slice electrophysiology, and spine morphological analysis to explore these divergent drug responses. These experiments indicate that CREB's action at *Zfp189* causally contributes to CREB's ability to reduce the rewarding effect of psychostimulants. However, CREB-*Zfp189* interactions in the NAc did not affect behavioral responses to morphine, suggesting that CREB's capacity to reduce the rewarding properties of opiates is not mediated by CREB's action at *Zfp189*. This work is evidence that *in vivo* neuroepigenetic editing allows us to model a single drug-induced molecular interaction and identify its causal contribution to the broader syndrome, and that a potential psychostimulant-specific transcriptional mechanism may reveal therapeutic targets for psychostimulant addiction.

Abstract: Adolescence, a time of heightened sensitivity to rewarding stimuli, is associated with vulnerability to psychiatric disorders. Male rodents that experience adolescent social isolation stress (SI) form stronger preferences for drugs of abuse in adulthood. However, little is known about how females respond to SI. Our preliminary data suggest that SI reverses sex differences in adult reward-associated behaviors and permanently reduces baseline sex differences in anxiety-related behaviors. Given these behavioral alterations, we tested the hypothesis that SI alters the transcriptome in a persistent and sex-specific manner in the nucleus accumbens (NAc), ventral tegmental area (VTA), and prefrontal cortex (PFC). Mice were isolated or group housed (GH) from P22 - P42, then GH until ~P90. Transcriptome-wide changes in NAc, VTA, and PFC were investigated by RNA-seq after acute or chronic cocaine or saline administration. SI reduces sexually dimorphic gene expression across all three brain regions. Further analysis revealed that SI results in expression profiles in males that more closely resembles GH females, suggesting that SI "feminizes" the male transcriptome. Importantly, when SI females are exposed to the first dose of cocaine, their transcriptional profiles resembled GH males in the NAc and PFC but not VTA, suggesting that SI "masculinizes" the female transcriptional response to acute cocaine. This effect is lost after chronic exposure to cocaine in the PFC. Together, these data suggest that SI has region-specific effects on sex-specific transcriptional responses to cocaine. Currently, we are utilizing gene co-expression network analysis to identify reward-circuitry conserved key drivers of the sex-specific transcriptional responses to cocaine which are reversed by SI. We predict that these key driver genes will have enormous sex-specific therapeutic potential given their conservation across multiple brain regions. Together, these data show that SI disrupts sex-specific adolescent development of transcription throughout the reward circuitry.

Title: Cell type-specific morphological and transcriptional adaptations to cocaine in the nucleus accumbens

Authors: *M. SALERY[1], A. GODINO[1], M. K. FAUSTIN[1], R. FUTAMURA[1], C. J. BROWNE[1], J. F. FULLARD[2], P. ROUSSOS[2], E. J. NESTLER[1];

Abstract: Pathological motivation for drug-seeking and consumption, along with the high risk of relapse observed after long periods of withdrawal, are thought to result from persistent adaptations in brain circuits involved in reward learning. In the nucleus accumbens (NAc), drug exposure affects neuronal physiology differently among distinct cell populations, with D1- and D2-expressing medium spiny neurons (MSNs) exhibiting divergent cellular responses. While remodeling of NAc connectivity is known to depend on stable changes in the synaptic architecture of MSNs, the relative contribution of each MSN subtype in this process remains unclear. To tackle this issue, we performed a cell type-specific analysis of dendritic morphology following long-term withdrawal from chronic cocaine exposure. A Cre-dependent virus expressing channelrhodopsin-2 (ChR2) fused to EYFP was injected into the NAc of D1-Cre and D2-Cre transgenic mice. Due to its plasma membrane targeting, EYFP-coupled ChR2 allowed for clear resolution of dendritic spine morphology within D1 or D2 MSNs, demonstrating divergent adaptations in synaptic organization within the two NAc neuronal subpopulations in response to cocaine. Beyond the D1- vs D2-MSN dichotomy, the activation level of individual NAc neurons can be used to further segregate neuronal ensembles that are recruited during drug exposure. The identification and molecular characterization of these specific subsets of neurons is critical to deepen our understanding of how drugs of abuse reshape neuronal networks. The immediate early gene *Arc* is a highly reliable marker of activity used to define neuronal populations recruited during learning processes. In the NAc, Arc is induced by cocaine and stands as a pertinent tool to identify drug-activated MSNs. We use the tamoxifen-inducible ArcCreER^{T2} mice, which allow for the stable expression of fluorescent reporters in Arc-positive cells, to permanently label neuronal populations activated by cocaine. Then, we isolate these tagged cells or their nuclei with Fluorescence Activated Cell Sorting (FACS) and perform single-cell RNA sequencing to phenotype the cell types recruited during distinct phases of cocaine exposure, as well as to characterize the transcriptional signature specific to activated cells. Together this study employs new methods to advance our understanding of the neuronal processes engaged in subsets of neurons that are specifically recruited during and after exposure to cocaine. Title: Cell type-specific transcriptional patterns in nucleus accumbens differentiating cocaine versus morphine exposure: Actions of ΔFosB

Authors: *C. K. LARDNER[1], P. J. HAMILTON[2], A. RAMAKRISHNAN[1], H. G. KRONMAN[1], D. M. WALKER[1], L. SHEN[1], E. J. NESTLER[1];

Abstract: The onset and persistence of drug addiction is, in part, effected via cell-type specific mechanisms of transcription in the brain. However, between classes of abused drugs, little is known about the overlap of transcriptional mechanisms and how these converge and diverge to effect an addictive phenotype. Within nucleus accumbens (NAc), ΔFosB, a Fos family transcription factor, accumulates in D1 medium spiny neurons (MSNs) following repeated exposure to cocaine, but in both D1 and D2 MSNs after chronic morphine. This phenomenon makes ΔFosB and its downstream effectors promising therapeutic targets but it is unknown how ΔFosB coordinates the unique effects of stimulants and opiates. To determine the D1- vs D2-MSN specificity of ΔFosB targets, we fused dCas9 to the transcription factor CREB to selectively induce ΔFosB in a MSN-specific manner. We then performed RNAseq in male and female whole NAc after ΔFosB induction as well as evaluated the effects of ΔFosB activation in D1- or D2-MSNs on cocaine and morphine place conditioning. We found both MSN-subtype and drug dose-dependent effects of ΔFosB induction on cocaine and morphine reward. Our RNAseq data reveal that ΔFosB induction in D1- or D2-MSNs, or both, each account for distinct gene expression changes. Understanding the cell type-specific roles of ΔFosB in mediating cocaine and morphine action clarifies their divergent and convergent mechanisms and reveals new avenues for therapeutic development. Moreover, our method for studying the genomic patterns coordinated by a single transcription factor more broadly serves as a novel mode of investigation into understanding how cell type-specific transcription and epigenetic patterns interact with environmental input to guide behavior.

Ctr., New Haven, CT

Abstract: Addiction is a devastating disorder that is exceptionally difficult to treat due to the high propensity for relapse even long after terminating use. The persistence of addiction is mediated by drug-induced changes in the physiology of reward-processing regions of the brain. Dysregulated signaling within the nucleus accumbens (NAc) is thought to play a critical role in promoting drug-seeking and relapse. Determining these changes may reveal more effective targets to treat drug addiction and relapse. However, the molecular details underlying these adaptations remain incompletely understood. Here, we extend previous work focused mainly on candidate proteins of interest by examining whole-proteome changes induced by cocaine self-administration that persist through extended abstinence. Mice underwent 6 days of intravenous cocaine or saline self-administration followed by a period of 24 hours or 45 days of forced abstinence, after which mice were euthanized and the NAc was extracted. NAc synaptosomes were purified and ran on lipid chromatograph tandem (LC-MS/MS) mass spectrometry follow by label free quantification in collaboration with the Yale/NIDA neuroproteomics core. In this preliminary study, we are able to show lists of synaptic proteins with induction or repression after self-administered cocaine followed by different time points of withdrawal. Interestingly, long-term withdrawal is associated with repression, rather than induction, of protein expression. Further extension of this proteomic study will lead to the characterization of synaptic proteins in various brain reward regions and make important advances in our understanding of the molecular basis of addiction and relapse.

Title: E2F3a transcription factor regulates cocaine- and morphine-related behaviors in males and females in a cell-specific manner

Authors: *F. J. MARTINEZ-RIVERA[1], A. TORRES-BERRÍO[1], P. J. HAMILTON[2], A. M. MINIER-TORIBIO[1], C. J. BROWNE[1], Y. YIM[1], R. FUTAMURA[1], R. L. NEVE[3], E. J. NESTLER[1];

Abstract: The development of drug addiction is characterized by epigenetic changes in the brain reward circuit, leading to the transition from recreational drug use to drug dependence. Most of these epigenetic processes, such as histone modifications, chromatin remodeling and alterations in the expression of transcription factors, have been well characterized in the nucleus accumbens (NAc). Our group recently identified the transcription factor E2F3 as a novel upstream regulator of cocaine-induced gene expression in the NAc. Consistent with this, we also demonstrated that viral manipulations of the E2F3a isoform in NAc, but not of E2F3b, enhances cocaine-induced locomotor and conditioned place preference (CPP) behaviors in adult male mice. Interestingly, further cell-specific analyses revealed that E2F3a acts as a key upstream regulator of *Fosb*and induces expression of the canonical addiction-mediating transcription factor, ΔFosB, in D1 receptor-expressing medium spiny neurons (D1-MSNs) selectively. Here, we used viral-mediated gene transfer combined with CPP to assess whether E2F3adifferently regulates drug-rewarding behaviors depending on: 1) sex, 2) MSN cell type and 3) type of drug. Our preliminary results showed that selective E2F3a overexpression in D1-MSNs increased cocaine CPP in female mice, whereas E2F3a overexpression in D2-MSNs has no effect. Current experiments withmorphine CPP will reveal the influence of E2F3a in a sex and drug specific manner.Together, our results highlight E2F3a as a novel regulator of drug-elicited transcriptomic modifications in D1-MSNs.

Title: Microbiome depletion disrupts transcriptional homeostasis and reduces persistence of cocaine sensitization

Authors: ***K. R. MECKEL**[1], R. S. HOFFORD[2], J. B. HANKS[1], N. L. MERVOSH[2], P. ROUSSOS[3], D. D. KIRALY[2];

Abstract: Psychostimulant addiction represents a public health crisis leading to extensive morbidity and mortality. Despite this, there are currently no FDA-approved medications for treatment of psychostimulant use disorders. Increasing evidence suggests that the bacterial composition of the gut microbiome significantly affects brain and behavior in models of psychiatric disease. Our lab has previously demonstrated that depletion of the gut microbiome significantly affects the formation of cocaine conditioned place preference and locomotor sensitization. However, no currently published studies have examined the role of the gut microbiome in modulating the persistence of cocaine-induced changes in neuronal or behavioral plasticity. Given that prevention of relapse following abstinence is the most clinically challenging issue in treating patients with substance use disorders, studies examining the effects of microbiome manipulations in relapse relevant models are critical for the development of translational strategies in this space. For these studies mice had their microbiome depleted with non-absorbable antibiotics in their drinking water and were compared to untreated controls. Locomotor sensitization was induced with five daily injections of cocaine, and after 28 days of withdrawal a cocaine challenge was given to assess the persistence of locomotor sensitization. Despite normal development of sensitization, antibiotic-treated mice exhibited significantly reduced persistence of locomotor sensitization after prolonged withdrawal. To identify molecular signatures underlying these behavioral changes, animals were sacrificed 60 minutes following drug administration, and the nucleus accumbens was dissected out for RNA-sequencing analysis.

While cocaine-challenged control animals showed changes in approximately 200 genes, antibiotic-treated mice had significant changes in 3,610 genes. To further interrogate gut-derived factors that might be playing a role in these changes seen in microbiome-deficient mice, key bacterial metabolites, the short-chain fatty acids (SCFA), were replenished via the drinking water in a series of experiments. When levels of these metabolites were restored to normal in microbiome-deficient mice, the persistence of locomotor sensitization returned to normal. Taken together, these findings suggest that the microbiome may serve as a key homeostatic regulator of persistence of behavioral response and regulation gene expression in the brain, and suggest that the microbiome has potential as a translational research target.

Title: Granulocyte-colony stimulating factor during abstinence from cocaine self-administration alters expression of glutamatergic synaptic proteins in nucleus accumbens

Authors: *R. S. HOFFORD[1], T. EUSTON[1], R. WILSON[3], T. T. LAM[3], E. S. CALIPARI[4], D. D. KIRALY[2];
[1]Psychiatry, [2]Psychiatry / Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]Yale/NIDA Neuroproteomics Ctr., New Haven, CT; [4]Pharmacol., Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: Recent work from our laboratory implicates granulocyte-colony stimulating factor (G-CSF) as a neuroimmune modulator of cocaine reward. Levels of G-CSF are increased in blood and brain following cocaine administration and levels of G-CSF correlate with cocaine intake. Injections of G-CSF enhance low-dose cocaine self-administration in a threshold task, and inhibition of G-CSF in the nucleus accumbens (NAc) prevents formation of cocaine conditioned place preference. However, treatment with G-CSF during extinction of cocaine self-administration accelerates extinction, and administration during abstinence attenuates cue-induced cocaine-seeking. Given the importance of associative and instrumental learning mechanisms in tests of cocaine reward, we hypothesize that G-CSF is producing these varied

effects by enhancing the learning mechanisms that mediate these behaviors. Thus, animals experience increased cue sensitization during active intake, but also faster extinction learning during extinction and reinstatement. Since the molecular actions of G-CSF in brain are unclear, the current set of experiments utilized data-independent acquisition proteomics to compare protein expression changes in NAc from rats given daily injections of G-CSF or saline during abstinence from cocaine self-administration. Due to the variation in cue-induced reinstatement occurring within the G-CSF treated group, additional comparisons were conducted between G-CSF "responders" (i.e. those that had the lowest cue-induced reinstatement scores) and G-CSF "non-responders" (i.e. those that had the highest cue-induced reinstatement scores). Proteomic analysis identified 125 proteins differentially regulated between responders and non-responders. Pathway analysis indicated that many of these proteins localize to glutamatergic synapses (top gene ontology terms included glutamateric synapse, cell membrane, postsynapse, and regulation of chemical synaptic transmission). When protein expression was graphed against lever presses during cue-induced reinstatement, levels of the glutamatergic synaptic scaffold protein Shank3 significantly correlated with cue-induced reinstatement in all rats, but levels of GluA1 correlated with lever presses in G-CSF treated rats only. While much work needs to be done, these analyses suggest that G-CSF might alter cocaine-seeking by affecting the composition of glutamatergic synapses in the NAc.

Title: Investigating the role of granulocyte colony stimulating factor as a regulator of the striatal proteome

Authors: *T. J. EUSTON[1], R. S. HOFFORD[1], R. WILSON[2], T. LAM[2], D. D. KIRALY[3]; [1]Psychiatry, Icahn Sch. of Med., New York, NY; [2]Yale Univ., New Haven, CT; [3]Psychiatry / Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Pathologic use of illicit drugs represents a major public health concern and creates significant economic and social costs. Addiction to cocaine and other psychostimulants remains a major cause of this morbidity. The pathophysiological mechanisms that lead to persistent and

dysregulated drug use remain incompletely understood, and there are currently no FDA-approved pharmacotherapies for treatment of psychostimulant use disorders. There is growing evidence that dysregulation of the immune system plays a role in the pathophysiology of multiple psychiatric disorders including major depressive disorder and schizophrenia. While cocaine is known to have immunomodulatory effects, the link between these immune interactions and pathological use behaviors has only recently been investigated. We recently identified granulocyte-colony stimulating factor (G-CSF) as a cytokine that is increased in serum and brain by chronic cocaine. Peripheral administration of G-CSF enhances cocaine place preference and cocaine intake in a self-administration model, and also facilitates cocaine-induced neuronal activation in the nucleus accumbens and prefrontal cortex. While G-CSF has clear effects on synaptic and behavioral plasticity, the molecular mechanisms underlying these effects remains unclear. To interrogate changes induced by G-CSF in the setting of active cocaine treatment a 2 x 2 design was utilized with animals injected with Saline or Cocaine (7.5mg/kg) and PBS or G-CSF once daily for seven days. This was followed by discovery proteomics analysis of the nucleus accumbens (NAc) using data-independent acquisition mass spectrometry analysis. As expected, there were many proteins that were significantly altered by one week of cocaine treatment. However, treatment with G-CSF alone resulted in regulation of an even larger number of proteins, and co-treatment with the two resulted in the largest number of significantly regulated proteins - suggesting a significant interaction between the two. Gene ontology analysis of samples from G-CSF + Cocaine treated animals showed that there was a strong upregulation of proteins associated with the synaptic compartment, with a number of both pre and postsynaptic proteins demonstrating significant alterations. Confirmatory Western blot analysis demonstrate similar increases in levels of PSD-95 and GluR1 by G-CSF + cocaine in a separate cohort of animals. These findings complement our previous work and suggest that in the presence of G-CSF the ability of cocaine to cause synaptic remodeling is enhanced.

Title: High risk of cocaine addiction in adolescents: Differential contribution of diverse cortical areas

Authors: D. HUANG[1], S. IM[2], J. M. CIALDELLA[2], A. V. SALINAS[2], *Y. Y. MA[1]; [1]Pharmacol. and Toxicology, Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Binghamton Univ., Binghamton, NY

Abstract: The cerebral cortex, particularly the anterior cingulate cortex (ACC), the prefrontal cortex (PrL) and the infralimbic cortex (IL), play an important role in relapse of drug taking. However, only a few studies have examined the contribution of the primary (M1) and secondary (M2) motor cortices in the persistence of addiction as a habituated behavior. In order to closely mimic the chronic drug history, most addiction researchers have attempted to model drug exposure with extended daily sessions (≥ 2-6 hrs) during a prolonged period of time (≥10 days). However, during adolescence, even brief exposure to the drug can lead to devastating behavioral, emotional, and cognitive consequences, predisposing the young brains to drug addiction and other mental disturbances. Inspired by the fact that the adolescent stage is usually when the drug taking behaviors are initiated, we predicted that this age group is exquisitely sensitive to the abusive potential of drugs. This vulnerability of adolescents may be fully masked by extended drug administration. Thus, limited drug exposure, i.e., intravenous self-administration (IVSA) of cocaine, 1 hour per day for 5 days, was used in the current experiments in order to explore the neuronal substrates of high addiction risk among adolescent Sprague-Dawley rats using whole-cell patch clamp recordings of pyramidal neurons in the IL, PrL, ACC, M1 and M2. Relative to 1 day after adolescent cocaine IVSA (i.e., 1 day withdrawal, abbreviated as WD 1) and WD45 after adolescent saline IVSA, our data showed a significantly incubated cocaine seeking, and increased excitability (indicated by an increased number of spikes induced by current injections of increasing intensities) in the M2, but not in the IL, PrL, ACC and M1, on WD 45 in rats with a cocaine IVSA history during their adolescent stage. Although, relative to adult saline IVSA, cocaine IVSA during the adult stage lead to increased excitability in the M2 on both WD1 and WD45, no difference of M2 excitability was observed in rats with a history of cocaine IVSA between WD1. vs. WD45. Further analysis showed increased membrane input resistance of pyramidal neurons in the M2 from adolescent cocaine IVSA-treated rats on WD45, but not WD1; however, no membrane resistance change was detected in adult cocaine IVSA-treated rats on WD1 or WD45. Our conclusions are that (1) limited drug exposure can be used as an addiction model to explore the vulnerability of drug addiction among adolescents, and (2) membrane input resistance-induced excitability changes in the M2 may be a novel neurobiological target for preventing relapse of addiction.

Title: Sex differences in effects of voluntary exercise during extinction of cocaine-seeking behavior

Authors: *R. J. MORALES SILVA[1], U. GELPI-DOMÍNGUEZ[2], D. NIEVEZ-TORRES[4], A. ECHEVARRIA- RIVERA[2], M. T. SEPULVEDA-ORENGO[3];
[1]Basic Sci., [3]Dept. Basic Sci., [2]Ponce Hlth. Sci. Univ., Ponce, Puerto Rico; [4]Univ. of Puerto Rico, Ponce, Puerto Rico

Abstract: One of the main problems in cocaine addiction is the high incidence of relapse. Several studies have shown that physical activity, such as exercise, can prolong drug abstinence and alleviate drug-seeking symptoms in humans. Although recent clinical trials have successfully incorporated exercise as part of the treatment for drug addiction, it is still unknown how exercise affects cocaine-induced molecular processes, thus leading to reduced drug-seeking behavior. Studies in hippocampus have shown exercise increases levels of brain-derived neurotrophic factor (BDNF). Moreover, studies showed that infusion of BDNF into the nucleus accumbens core (NAc) and/or medial prefrontal cortex (mPFC) decreases cocaine seeking behavior. We hypothesized that aerobic exercise would increase of BDNF levels in the NAc and PL, leading to reduced cocaine-seeking behavior in male and female rats. To test our hypothesis, we used an addiction model of cocaine self-administration. Rats were exposed to 12 sessions of short-access cocaine self-administration, followed by 16 sessions of extinction. After each extinction session, rats were placed in boxes equipped with a running wheel for a period of 6 hrs. Once extinction was achieved, they were subjected to a cue-primed reinstatement session to access cocaine-seeking behavior. After the behavioral protocol, levels of the proteins tropomyosin receptor kinase B (TrkB), BDNF receptor, and BDNF from NAc and mPFC from male and female rats were measured by western blots. As in previous studies, our preliminary data suggest that concurrent access to a wheel (6 hrs) during extinction from cocaine self-administration reduces reinstatement of cocaine-seeking in male rats. However, the effects of exercise in female rats seems to be estrus cycle dependent. Preliminary data from female rats suggests that exercise increases TrkB receptor levels in the mPFC, but not in the NAc from female rats, which may correlate with reduced cue-primed reinstatement in estrus female rats. We are currently examining TrkB receptor and BDNF protein levels in male and female rats for comparison. Sex-specific differences in the effects of voluntary exercise on cocaine-seeking behavior might be related to differences in hormonal levels between males and females.

Title: Functional sex differences in glutamate trafficking and their potential role in cocaine addiction-like behavior

Authors: *M. C. KNOUSE[1], A. U. DEUTSCHMANN[2], L. A. BRIAND[1];
[1]Psychology, [2]Temple Univ., Philadelphia, PA

Abstract: Despite the fact that more men are diagnosed with substance use disorder, women exhibit a faster transition from use to abuse, increased craving during withdrawal, and poorer treatment outcomes. Furthermore, as our cultural expectations of men and women have changed, there has been an increase in drug and alcohol use in women and this increase is likely to persist. Preclinically, female rodents show stronger behavioral responses to drugs of abuse during initiation, escalation, and reinstatement of drug seeking. These behavioral differences are accompanied by alterations in structural plasticity within the mesocorticolimbic reward system. However, very little work has been done to determine what functional sex differences exist in glutamate transmission in these circuits. The goal of these experiments was to determine functional sex differences in reward circuitry that may underlie behavioral sex differences in addiction. We found that female mice exhibit alterations in short-term plasticity within the nucleus accumbens core, indicative of differences in presynaptic glutamate transmission. To determine which inputs might be responsible for these presynaptic changes, we performed *ex vivo* optogenetics to specifically interrogate medial prefrontal (mPFC), ventral hippocampal (vHIPP), and basolateral amygdalar (BLA) projections to the nucleus accumbens core. We found that the sex differences seem to be primarily driven by alterations in mPFC and vHIPP inputs. Examination of whole cell recordings in the mPFC demonstrate that female mice may have increased glutamate transmission within this NAc projection region, as indicated by an increase in inward rectification. Work is ongoing to further elucidate functional sex differences in ventral hippocampal projection neurons. Taken together these findings suggest there are functional sex differences at many levels without the mesocorticolimbic reward system and gaining a better understanding of these differences could provide insight into sex-specific treatments for addiction.

Title: A sex-specific role for PICK1 in the prefrontal cortex during cocaine seeking

Authors: *M. M. WICKENS, J. M. KIRKLAND, L. A. BRIAND;
Psychology, Temple Univ., Philadelphia, PA

Abstract: Protein interacting with C-Kinase 1 (PICK1) is a postsynaptic scaffolding protein that regulates glutamate receptor trafficking. PICK1 binds to GluA2 AMPA subunits leading to the subsequent internalization of AMPA receptors. Global knockout of PICK1 and local infusion of PICK1 inhibitors into the nucleus accumbens dampen cocaine taking and seeking. However, nothing is known about the role of PICK1 in the prefrontal cortex. As glutamate receptor trafficking within the prefrontal cortex (PFC) is altered by cocaine administration, examining the role of proteins involved in trafficking could shed light on the mechanisms underlying addictive phenotypes. The current study examined how site-specific knockout of PICK1 in the PFC affects food and cocaine taking and seeking in both male and female mice. Prefrontal knockout of PICK1 did not affect food self-administration or the acquisition of an operant response in either male or female mice. Additionally, no differences in cocaine intake or responding were seen following PFC knockout of PICK1 during the self-administration phase. However, when we examine cocaine seeking during a cue-induced reinstatement session, we find that male mice with a PFC-specific PICK1 knockout exhibit a decrease in cocaine seeking compared to GFP-injected control male mice. In contrast, female mice exhibit an increase in cue-induced cocaine seeking following prefrontal knockout of PICK1. These results suggest that PICK1 in the prefrontal cortex is playing opposing roles in cocaine seeking in male and female mice. This suggests that the synaptic mechanisms underlying substance use disorder could be distinct in males and females and sex-specific treatments may be needed.

Title: Investigating neuroadaptations underlying sex differences in cue-induced cocaine craving

Authors: C. M. CORBETT, Y. SHIFMAN, *J. A. LOWETH;
Cell Biol. and Neurosci., Rowan Univ. Sch. of Osteo. Med., Stratford, NJ

Abstract: Although clinical studies indicate sex differences in both cocaine addiction and relapse vulnerability, the majority of preclinical studies in this area have been conducted with male rats. Our recent work has focused on investigating differences in cue-induced relapse vulnerability between adult male and female rats and assessing how this changes across the estrous cycle. Interestingly, we and others have found that females show enhanced cue-induced seeking behavior compared to males at certain withdrawal time points and that the estrous cycle has a significant impact on the time-dependent intensification ("incubation") of cue-induced cocaine craving that occurs during withdrawal from extended-access self-administration. More specifically, female rats in estrus show enhanced incubation of cue-induced cocaine craving compared to females in non-estrus. To investigate neuroadaptations that are driving these sex differences, we conducted western blots in males and females following both early and late withdrawal from extended-access cocaine self-administration and assessed changes in glutamatergic signaling pathways in corticolimbic regions involved in drug-seeking behavior. We also assessed whether these neuroadaptations were affected by changes in estrous cycle. These studies will help identify mechanisms that could be driving sex differences in cue-induced relapse vulnerability.

Abstract: Early environmental experience impacts susceptibility to drug abuse later in life. In particular, rearing rats in enriched (EC), impoverished (IC), or social (SC) conditions results in rearing-induced neurobiological, neurochemical, and behavioral changes (Bowling, Rowlett, & Bardo, 1993). When EC rats are provided the opportunity to self-administer drug during adolescence and early adulthood, they self-administer less drug, and reinstate at lower rates compared to IC or SC rats. This suggests that enrichment during childhood protects rats, making them less susceptible to addiction during adolescence and adulthood. We believe that it may be the glutamatergic system in particular, that is responsible for this protective effect based on work implicating accumbal GluA1 in cocaine self-administration (Pierce & Wolf, 2013), and reinstatement (Anderson et al., 2008). The current study sought to determine if glutamatergic pathways altered during the rearing period, produce the protective effect observed in EC rats. We hypothesize that glutamatergic signaling is altered in EC compared to IC and SC rats during rearing, resulting in greater GluA1 expression of the nucleus accumbens (NA), prelimbic cortex (PL), and infralimbic cortex (IL) of EC rats compared to IC and SC rats following reinstatement of cocaine seeking behavior. Female Sprague-Dawley rats arrived in the lab at 21 days of age, and were assigned to either EC, IC, or SC contexts, where they were reared for 30 days. Following the rearing period rats underwent standard 2-hr cocaine (0.1 mg/50 μL bolos) or saline self-administration, extinction, and reinstatement. Following cue-induced reinstatement brains were extracted and processed for immunoblotting. Immunoblotting was used to quantify GluA1 protein levels in the NA, PL and IL of differentially reared rats. During cue-induced reinstatement EC rats displayed attenuated cocaine-seeking behavior compared to SC rats. Following cue-induced reinstatement, GluA1 protein levels are reduced in the NA, IL and PL of rats that underwent cocaine self-administration, compared to saline self-administration, independent of rearing group. These results contrast previous research showing an upregulation of GluA1 in the accumbens following cocaine-primed reinstatement.

Title: Age-related alterations in morphine and cocaine seeking behavior as measured by conditioned place preference

Authors: *R. A. SHETTY[1], R. CHAUBEY[1], R. BUI[2], M. J. FORSTER[1];
[1]Univ. Of North Texas Hlth. Sci. Ctr., Fort Worth, TX; [2]Emory Univ., Atlanta, GA

Abstract: The latest reports published by agencies such as Substance Abuse and Mental Health Services Administration and the National Survey of Drug Use and Health have indicated a steady rise of substance use between the ages of 50-65. However, the potential health care issues stemming from increased drug use in the aging population is poorly understood. We hypothesize that normal aging entails an impaired function of reward pathways that diminishes the rewarding potency of abused drugs and concurrently increases drug-seeking behavior. Therefore, to better understand the nature of the aging/substance abuse interaction, we studied the effects of morphine and cocaine in drug naïve C57BL/6 mice from age groups representing young adulthood (2-3 months) and senescence (17-18 months) in a conditioned place paradigm (CPP). Our results suggests that responsiveness to illicit drugs are markedly different in older drug-naïve age groups when compared with young adults. Furthermore, stable drug-seeking and drug-avoiding behavioral phenotypes that were previously observed in young mice were altered with advanced age. These results suggest, that neurobiological changes during aging modify drug-seeking behavior in a manner that may facilitate addiction/dependence.

Title: Adolescent social isolation stress alters synaptic plasticity in the nucleus accumbens: Role of neuroimmune signaling

Authors: *A. MCGRATH[1], L. A. BRIAND[2];
[2]Psychology, [1]Temple Univ., Philadelphia, PA

Abstract: People who experience traumatic events early in life are at increased risk to develop substance use disorders (SUDs) later in life. This phenomenon has also been replicated in animal models. For instance, previous data from our lab has shown that adolescent social isolation leads to increased motivation for cocaine and greater vulnerability to cue-induced relapse in adulthood. However, little is known about how adolescent social isolation alters the brain to make an individual more vulnerable to addiction. Cocaine exposure leads to many neuroadapations in the nucleus accumbens, including increased dendritic spine density. These changes in dendritic spines can be long-lasting and have been theorized to play an important role in the maintenance of cocaine craving even after long periods of abstinence. The current studies utilize the adolescent isolation stress model that elicits increased addiction-like behavior in mice. We found that adolescent social isolation stress leads to a persistent increase in spine density in both the core and shell regions of the nucleus accumbens in adulthood. These increases in spine density were region specific as we did not see changes in spine density in the prefrontal cortex of adult mice exposed to adolescent social isolation. Both stress and cocaine have been shown to activate microglia and our isolation stress model also alters cytokine expression. Experiments are underway to determine how disrupting microglial activation alters the effects of adolescent social isolation. The findings of the current studies will provide insight into potential interventions to decrease vulnerability to SUDs in individuals who have experienced stress early in life.

Title: Role of endocannabinoid signaling in cocaine-taking and cocaine-seeking behavior following chronic electric footshock stress-induced escalation of cocaine self-administration in rats

Authors: *J. R. MCREYNOLDS[1], J. C. MATHY[1], R. SCHAPS[1], K. A. SHANNON[1], C. P. WOLF[1], D. M. STARCK[1], C. J. HILLARD[3], J. R. MANTSCH[2];
[1]Biomed. Sci., [2]Marquette Univ., Milwaukee, WI; [3]Med. Col. Wisconsin, Milwaukee, WI

Abstract: Stress is an important contributing factor to addiction and is problematic as stress is unavoidable in daily life. Addiction can be characterized by a loss of control over drug intake

that is modeled by escalating patterns of drug self-administration (SA). We have shown that a stressor, electric footshock stress, administered daily at the time of SA induces an escalation of cocaine intake in rats under short-access conditions (2-h/day). Stress-induced escalation of SA is likely the consequence of long-lasting neuroplastic changes that involve neurobiological mediators that connect stress-responsive and reward systems in the brain, such as the endocannabinoid system (eCB), likely occur in regions implicated in both stress and reward, such as the nucleus accumbens (NAc) shell and ventral tegmental area (VTA). We hypothesize that repeated stress at the time of SA induces a persistent increase in eCB signaling, particularly in the NAc shell and VTA, which results in escalation of cocaine use and increased susceptibility to later reinstatement. Male SD rats were trained to SA cocaine (0.5 mg/kg/inf) on a FR 4 schedule in 4 X 30 min SA sessions separated by 5-min drug-free periods. Some rats received shock in the SA chamber during the 5 min drug-free period over 14 days. Systemic administration of the CB1R antagonist AM251 (1 mg/kg), intra-NAc Shell or intra-VTA infusions of AM251 (1, 3 µg) prior to the SA session attenuated cocaine intake in stress-escalated rats. Interestingly, cocaine SA increases CB1R binding and repeated stress at the time of SA further increases CB1R binding in the VTA while neither self-administration condition changes CB1R binding in the NAc. Studies examining changes in VTA DA neuronal activity and NAc shell DA signaling, via fiber photometry imaging of GCaMP6f or dLight, are currently ongoing. Separate groups of rats were tested for reinstatement of drug-seeking behavior to a priming injection of cocaine, footshock stress, or the pharmacological stressor yohimbine. Rats who received shock during SA demonstrated augmented reinstatement to cocaine, footshock stress, and yohimbine. Furthermore, as with SA, the CB1R antagonist AM251 given prior to injection of cocaine (10 mg/kg, ip) significantly attenuated cocaine-primed reinstatement only in stress-escalated rats. Studies examining the contribution of eCB signaling to stress-induced reinstatement are ongoing. These data suggest that stress-induced neuroplastic changes occur, likely in the eCB system, in regions of the brain that influence expression of escalated cocaine intake and augmented cocaine-primed reinstatement and these changes may be glucocorticoid-dependent.

Title: Goal-directed and habitual cocaine seeking: Further assessment of noncontingent cocaine as a method to cause satiety and outcome devaluation

Authors: *B. JONES, H. SPENCER, T. H. KIM, R. J. SMITH;
Dept Psychological and Brain Sci., Texas A&M Univ., College Station, TX

Abstract: Addiction has been hypothesized to stem from a failure to exert goal-directed control over habits. To evaluate the role of habits in addiction, our lab recently developed a novel outcome devaluation procedure to assess goal-directed and habitual responding for intravenous (IV) cocaine in rats. We hypothesized that noncontingent administration of IV cocaine would mimic preferred blood levels, resulting in temporary satiety and outcome devaluation. Previously, our lab found that pre-training NMDA lesions of dorsomedial striatum (DMS) caused rats to be insensitive to outcome devaluation, whereas lesions of the dorsolateral striatum (DLS) caused rats to be sensitive to outcome devaluation. Supporting the validity of this procedure, these findings are consistent with established roles of DMS and DLS in goal-directed and habitual responding, respectively. We found that non-lesioned rats show a great degree of variability in their sensitivity to outcome devaluation, regardless of schedule of reinforcement. This may reflect individual differences in response strategies for cocaine self-administration, or instead may be explained by differences in preferred cocaine levels, which might affect sensitivity to non-contingent cocaine. Here, we sought to evaluate individual differences in preferred levels of cocaine using pharmacokinetic modeling to estimate cocaine levels during free access self-administration sessions. Male Sprague Dawley rats were trained on a seeking-taking chained schedule of cocaine self-administration (0.5 mg/kg/infusion). Outcome devaluation was carried out via noncontingent administration of IV cocaine followed by evaluation of responding on the seeking lever for 10 minutes under extinction conditions. Similar to our previous results, we found variability among animals in their sensitivity to outcome devaluation. However, there was no correlation between sensitivity to outcome devaluation and preferred blood levels of cocaine. In addition, there was no difference in preferred blood levels of cocaine when comparing animals with DMS or DLS lesions, despite clear differences in sensitivity to outcome devaluation. Finally, pharmacokinetic modeling revealed that noncontingent IV cocaine (1 mg/kg) resulted in blood levels that are greater than the preferred levels for all animals, indicating that this dose might result in temporary satiety across animals. These findings support the premise that noncontingent IV cocaine induces temporary satiety, and that individual differences in subsequent responding are related to differences in response strategy (goal-directed vs. habitual), rather than differences in satiety.

Title: Can agony fuel ecstasy? Cocaine and opioid patients carrying a genetic variant linked to over-response of the stress (cortisol) system demonstrate heightened limbic brain response to appetitive drug cues

Authors: *A. R. CHILDRESS, K. JAGANNATHAN, R. CRIST, III, P. REGIER, G. ARAUCO-SHAPIRO, S. DARNLEY, M. TAYLOR, J. J. SUH, Z. MONGE, T. FRANKLIN, R. WETHERILL, K. YOUNG, M. GAWRYSIAK, R. SZUCS-REED, K. KAMPMAN, C. P. OBRIEN, D. D. LANGLEBEN;
Psychiatry, Univ. PENN Perelman Sch. Med., Philadelphia, PA

Abstract: AIM: Preclinical research highlights intimate, "hot-wired" inter-connections between the brain's stress and reward systems -- such that (behavioral or pharmacologic) activation of the stress circuitry (“agony”) can boost the taking (“ecstasy”), and cue-triggered seeking, of drug rewards. We wondered whether genetics known to increase stress (cortisol) reactivity might also be reflected in stronger cue-triggered limbic brain responses, a relapse-relevant phenotype in addiction. A small pilot study in cocaine patients (CPDD, June 2019) provided support for this hypothesis. To confirm these findings in an expanded, diverse cohort, we compared drug cue-triggered limbic activation in cocaine and opioid patients with, and without, a genetic vulnerability linked to higher response of the cortisol stress system (i.e., the minor allele of rs3800373, for the FKBP5 gene).
METHODS: Using event-related BOLD fMRI, we scanned detoxified, stabilized, treatment-seeking cocaine and opioid inpatients (n=56 total) during quasi-random presentations of 500 msec evocative (cocaine or opioid, aversive, sexual) and comparator (neutral) cues, 48 presentations per cue category. We analyzed (SPM 8) pre-planned contrasts, comparing carriers of the minor vulnerability allele (TG, GG; n=31) for rs3800373 of FKBP5, vs. TT homozygotes (n=25) carrying the major allele. Our anatomical focus was nodes of the mesolimbic dopamine system, a critical substrate for drug reward and drug cues.
RESULTS: Consistent with our hypothesis, the cohort of cocaine and opioid patients with a

genetic variant (TG,GG) linked to greater stress (cortisol) responding demonstrated a robust brain response to drug cues in multiple nodes of the mesolimbic system, including the ventromedial prefrontal (orbitofrontal) cortex, amygdala, striatum, pallidum, insula and midbrain (parametric T maps thresholded from 2 to 5, for display), as well as the posterior cingulate and visual association cortex. The activation pattern in TT homozygotes was circumscribed (limited to portions of the striatum, inferior frontal gyrus, and visual cortex).
CONCLUSION: These findings in a diverse cohort highlight both the important "cross-talk" between the brain's aversive and appetitive motivational systems, and the genetic contributions to this interaction by FKBP5, a gene with proposed roles in anxiety/PTSD, depression, chronic pain, and addiction. Refining the genetic links between "agony" (stress) and "ecstasy" (drug-related phenomena) could offer future gene-level targets for prevention of relapse, and potentially, for addiction itself.

Title: Rats using habitual, dorsolateral striatum-dopamine-dependent response strategies to self-administer cocaine are resistant to cue extinction compared to goal-directed rats

Authors: *B. N. BENDER, M. M. TORREGROSSA;
Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Cue exposure therapy is a potential treatment for substance use disorders that involves repeated, unreinforced exposure to drug-associated cues. Although cue exposure has shown promising results in preclinical models, its effects are more modest in clinical settings. Habitual components of human drug seeking that are often not captured by animal models could contribute to this lack of translation. Cue extinction had been shown to reduce reinstatement of cocaine seeking in animals likely using non-habitual, goal-directed strategies that rely on dopamine in the dorsomedial striatum (DMS). However, it is not known how cue extinction affects habitual cocaine-seeking behavior, which relies on dopamine in the dorsolateral striatum

(DLS). Therefore, in the present study, we examined if our model of cue exposure has differential efficacy in rats trained under two schedules of reinforcement that facilitate either goal-directed (fixed ratio; FR) or habitual (second-order, SO) behavior, respectively. Adult, male, Sprague Dawley rats were trained to self-administer cocaine intravenously for 20 days under different schedules of reinforcement. One group was implanted with DLS guide cannula. To examine whether behavior was dependent on DLS dopamine at different timepoints during training, rats were given drug-seeking tests following bilateral intracranial microinfusion of the non-specific dopamine antagonist cis-flupenthixol (10 μg) or vehicle. After FR training, dopamine antagonism in the DLS did not affect drug-seeking behavior, suggesting that behavior was not DLS-dopamine-dependent, and was therefore goal-directed. However, after SO training, dopamine antagonism in the DLS significantly reduced drug-seeking behavior, suggesting habit formation. A separate group of rats underwent cue extinction (120 or 240 cues) or a control procedure (0 cues) following training, and then underwent cue-induced reinstatement. In rats trained to self-administer cocaine on FR schedules to facilitate goal-directed responding, 120 and 240 cues reduced reinstatement, but only 240 cues reduced reinstatement in rats trained on SO schedules exhibiting habitual behavior. Additionally, western blot analysis revealed increased expression of proteins involved in synaptic plasticity in the dorsolateral striatum of rats habitually seeking cocaine. Overall, the present study suggests that different reinforcement schedules can be used to facilitate goal-directed and habitual cocaine seeking, and rats using more habitual response strategies are resistant to the effects of cue extinction compared to rats using goal-directed response strategies.

Title: Distinctive roles of hippocampal ten-eleven translocation methylcytosine dioxygenase 1 (TET1) and TET3 in the acquisition of morphine self-administration in rats

Authors: *J.-J. ZHANG, F.-Z. JIANG, W. ZHENG, N. SUI;
Inst. of Psychology, CAS, Beijing, China

Abstract: DNA methylation represents an appealing mechanism for long-lasting changes in brain functions responsible for learning, memory, and various neuropsychiatric disorders including substance use disorder. Conversely, the DNA demethylation, induced by ten-eleven translocation (Tet) family of methylcytosine dioxygenases, may represents a novel approach to ameliorate various behavioral problems associated with drug addiction. In this study, we determined the necessary role of TET1 and TET3 in the acquisition of morphine self-administration (SA) in rats. First, we showed that the expression of TET3 in the hippocampal CA1 region but not in the nucleus accumbens (NAc) shell was significantly up-regulated after one day but not seven days of morphine SA (0.3 mg/kg/infusion) training or after the yoked morphine injection. Similarly, the expression of TET1 in the CA1 but not in the NAc shell was significantly down-regulated after seven days of morphine SA training but not after one day or the yoked morphine injection. Saccharin SA training did not affect the expression of TET1 and TET3. More importantly, virally knocking down TET3 expression in the CA1 enhanced the acquisition of morphine SA, whereas overexpression the catalytic domain of TET1 by AAV-TET1(CD)-OE in the CA1 significantly attenuated it. Together, these findings reveal a previously unknown epigenetic mechanism of morphine-reinforced excessive operant responding and provide a new insight into how TET1 and TET3 differentially respond for the DNA methylation in neuropsychiatric disorders *in vivo*.

Title: Escalation and reinstatement of fentanyl self-administration in male and female rats

Authors: *S. MALONE, L. HAMMERSLAG, M. BARDO;
Psychology, Univ. of Kentucky, Lexington, KY

Abstract: Purpose: Opioid use disorder is characterized by increased intake over time and a high likelihood of relapse. This study determined if escalation of fentanyl self-administration between male and female rats over extended (6-hr) sessions enhanced craving as measured by fentanyl- and yohimbine-induced drug seeking following a period of extinction.
Methods: Adult Sprague-Dawley rats (12 male, 12 female) were trained to self-administer (SA) i.v. fentanyl (2.5 ug/kg/infusion) across seven 1-hr sessions, followed by 21 additional SA sessions of either 1- or 6-hr duration. Both groups were then extinguished on 14 consecutive 1-hr

sessions and reinstatement was assessed following pretreatment with either fentanyl (10 or 30 ug/kg, s.c.) or yohimbine (1 or 2 mg/kg, i.p.)
Results: During the initial 1-hr acquisition sessions, a lever x session interaction showed that responding increased across sessions on the active lever only, and a lever x sex interaction indicated that females responded on the active lever more than males. After rats were split into 1- and 6-hr SA groups, a linear regression analysis indicated that the change in intake across sessions depended on group, with an increase in the 6-hr group only. Escalation in the 6-hr SA group also occurred when only the first hour was considered. Overall fentanyl SA was greater in females in the 1-hr SA group, but not the 6-hr SA group. Across extinction sessions, 1- and 6-hr SA groups decreased active lever responding similarly; however, females responded more than males in the 1-hr SA group. Fentanyl induced a dose-dependent reinstatement of fentanyl seeking, with no difference between 1- and 6-hr SA groups. Yohimbine also induced a dose-dependent reinstatement of fentanyl seeking; however, there was a significant interaction between yohimbine dose and group. Only the 1-hr SA group showed increased fentanyl seeking with 1 mg/kg yohimbine, whereas only the 6-hr SA group showed increased fentanyl seeking with the 2 mg/kg yohimbine. With both fentanyl- and yohimbine-induced reinstatement, females showed overall greater responding in the 1-hr SA group, but not the 6-hr SA group.
Conclusion: These results demonstrate that fentanyl self-administration escalates with extended access, and that sex differences in intake are no longer evident after escalation. Females trained with 1-hr SA sessions responded more overall than males during acquisition, extinction, and both reinstatement conditions. Regardless of sex, extended access potentiated yohimbine-induced drug-seeking, but not fentanyl-induced drug-seeking, indicating that escalation of opioid intake increases vulnerability to stress-induced relapse.

Title: The effect of an acute food-deprivation stress on heroin seeking after punishment-imposed abstinence in rats

Authors: *C. BORGES, A. CHISHOLM, D. RIZZO, N. QUTEISHAT, T. CAPOLICCHIO, A. ROMANO, U. SHALEV;
Psychology Dept., Concordia Univ., Montreal, QC, Canada

Abstract: The punishment-imposed abstinence model has been used to better mimic the self-imposed abstinence that humans initiate due to the adverse consequences associated with drug taking. The voluntary abstinence model has been used in experiments using different types of substances of abuse such as methamphetamine, cocaine and alcohol, however, it has never been done with heroin. Furthermore, it is known that acute stress plays a key role triggering relapse in humans and animal models. We have previously demonstrated a robust acute food-deprivation-induced reinstatement of extinguished cocaine and heroin seeking, which can be readily translated to humans. In order to study the effect of acute food deprivation on heroin seeking after a punishment-imposed abstinence, 10 male Long Evans rats were trained to self-administered heroin (0.1 mg/kg/infusion) under a seek-take procedure with the 'seek' lever under RI30 and the 'take' lever under FR1. Heroin infusions were also associated with a presentation of a 20 s light-tone cue. After the establishment of stable responses on the seek-take chain, a mild foot shock was delivered on 30% of the completed seek links instead of the extension of the take lever. Foot shock intensity was increased by 0.1 mA per daily session until the rats stopped taking the drug. Once the voluntary abstinence was achieved, heroin seeking was tested following 21 h food deprivation and under sated condition, in a counterbalanced within-subject design. Tests were conducted under extinction conditions or with heroin available.

Title: Development of a mouse model of compulsive-like oral fentanyl self-administration

Authors: *S. MONROE, K. SCHUH, A. K. RADKE;
Miami Univ., Oxford, OH

Abstract: Fentanyl is commonly prescribed for postoperative pain and is regarded by the Drug Enforcement Agency as one of the most significant drug-related threats to the U.S. Much illicit heroin is contaminated with fentanyl, and as many as 4 out of 5 heroin users report that their opioid use began with prescription opioids, suggesting that fentanyl's relationship to the opioid epidemic is profound. Despite continuing efforts, opioid addiction is poorly treated and relapse

rates remain high. Integral to this cycle is the emergence of compulsive drug use, or continuing to use despite the associated negative consequences. As such, the development of preclinical research investigating the neurobiology and behavioral mechanisms that mediate aversion-resistant opioid use is vital.
With this goal in mind, 35 C57BL/6J mice (n=18 female, 17 male) self-administered oral fentanyl (10μg/ml) for 2 h, 5 d/week in operant chambers outfitted with a cup for drug delivery. Rewards were earned on a fixed ratio (FR1) schedule of reinforcement in which a correct response delivered 50 μl of fentanyl solution. Self-administration was monitored for 15 sessions. To investigate aversion-resistant drug-seeking, we utilized two measures of compulsive-like seeking in two separate cohorts. In cohort 1, the bitter tastant quinine was added to the fentanyl solution over a series of days in increasing concentrations after the initial 15 sessions (0, 100, 250, and 500 μM). Both male and female mice robustly self-administered fentanyl under these conditions, and quinine did not reduce fentanyl consumption at any concentration in either sex. A two-bottle choice task was next done in the home cage to confirm mice find the selected concentrations of quinine aversive. This experiment showed that mice significantly reduce their consumption of water when it is mixed with quinine and exhibit a strong preference for plain water. In cohort 2, a conditioned suppression paradigm was used to elicit a fear response to a cue that predicts a footshock (0mA, 0.25mA, or 0.55mA). Animals were then returned to self-administration and presented with the cue to determine whether they continue to respond for fentanyl in the presence of the cue. Results suggest that mice demonstrate resistance to punishment under this paradigm.
Together, our results suggest that these methods may be useful in studying aversion-resistant opioid seeking in mice, including the underlying neurobiological mechanisms that contribute to opioid dependence.

Title: Dissecting the role of dorsal hippocampus in reinstatement of drug seeking behavior

Authors: *T. MARKOVIC, N. MASSALY, J. GARCIA, J. YI, J. MORON-CONCEPCION; Anesthesiol., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Opioid misuse and addiction represents an alarming national health issue with 40 to 60 percent of patients relapsing after periods of abstinence. Long term maintenance of associations between the reinforcing effects of the drug and the environment in which they are administered are a leading cause of relapse. Indeed, exposure to the "drug-environment" can lead to drug cravings and drug seeking behavior. Numerous studies indicate that glutamatergic transmission in the dorsal hippocampus (dHPC) is crucial for the formation of the learned associations between the rewarding effects of opioids and the context in which they are given. Additionally, dHPC projects to nucleus accumbens, a key area for processing of cue-predicted reward related behaviors. Thus we hypothesized that dHPC is necessary for relapse in drug seeking behaviors induced by drug-associated contextual cues. In this study, I demonstrate the necessity of dHPC in contextual cue-induced reinstatement of opioid self-administration. To assess the role of dHPC in reinstatement of drug seeking I used a chemogenetic (DREADD) approach to selectively silence dHPC excitatory neurons. My findings demonstrate that silencing excitatory dHPC neurons during re-exposure to drug-context significantly attenuates drug-seeking reinstatement. Importantly, control groups injected with control virus or DREADD ligand alone showed robust reinstatement. In addition, silencing dHPC did not alter either short term or long term memory as measured using an object location task. This result demonstrates that the observed attenuation of reinstatement is not due to memory retrieval impairment but rather to a selective disruption of drug-reward association. While these findings uncover the necessity of dHPC in cue induced reinstatement, the exact changes in activity of dHCP driving relapse are yet to be uncovered. To this end I am utilizing fiber photometry to investigate the dynamics of dHPC activity during both, the extinction and reinstatement of drug-seeking behavior . Such experiments will lead to a better understanding of the temporal resolution of hippocampal networks activity underlying context induced relapse in opioid-seeking behavior.

Title: Rat behavioral changes due to implanted striatal magnetic particles activated with externally-applied magnetic fields

Authors: *D. N. TECENO[1], P. WALIA[1], M. BATISTA-LINHARES[1], L. O. MAIR[2], S. JAFARI[2], P. STEPANOV[2], O. HALE[2], C. ROPP[2], A. HEVAGANINGE[2], I. N. WEINBERG[2], F.

Abstract: While many techniques are available to manipulate deep brain structures (optogenetics, deep brain stimulation (DBS), ultrasound, transcranial magnetic stimulation, etc.) to treat psychiatric and neurologic disorders, there are critical issues that decrease clinical utility. For example, DBS is invasive and only able to directly impact a small portion of the brain at a time. The goal of the current study is to determine if mechanical stimulation of neurons could serve as an alternative mechanism for neurological manipulations to treat various disorders. Recent data has shown that mechanical stimulation of neurons depolarizes cells and increases their firing rate. Here we developed a technique to engineer magnetic nanorods that can be implanted into neural tissue. We then designed a magnetic coil to provide external magnetic stimulation to the implanted nanorods. Particle injected animals (n=15) were stereotaxically implanted with magnetic nanorods, while control animals (n=13) experienced sham surgeries. One week following surgery, animals were placed in a small open field within the magnetic coil. Animals were acclimated to the field for 1-minute, followed by 4 minutes of low-magnitude (5mT, 20 Hz) external magnetic stimulation. The magnet was then turned off and the animal remained in the field for an additional 2 minutes. Total locomotion, rotations, and vacuous chewing behaviors for the duration of the experiment (7 minutes) were scored by a blind observer. Results showed no difference in overall locomotion or number of rotations. However, particle implanted animals showed significantly increased levels of chewing behavior compared to sham animals. An additional group of animals (particle implanted n=7, sham n=7) were euthanized eight weeks post-operation and 1-hour post-magnetic stimulation. Brains were sliced (25nm) and appropriately stained to observe neuronal activation, immune responses, and particle spread surrounding the injection site. Results showed no difference in immune response between groups. Additionally, increased neuronal activation was observed in the piriform cortex and cingulate gyrus of animals implanted with nanorods. These data demonstrate the ability of mechanical stimulation of striatal neurons to modify rat behavior. Behavioral tests examining the efficacy of magnetic particle stimulation for attenuation of oxycodone reinstatement are currently being investigated. Potential future applications of the technology include the use of wearable generators of low magnetic fields applied to intra-nasally administered magnetic nanoparticles.

Title: Effects of Nalfurafine on Oxycodone Self-Administration in Adolescent Male and Female Mice

Authors: *Y. ZHANG[1], M. KREEK[2];
[1]Rockefeller Univ., New York, NY; [2]The Rockefeller Univ., New York, NY

Abstract: Prescription opioid oxycodone abuse has affected millions of adolescents and young adults in the United States. Kappa opioid agonists can counterbalance the euphoria effects of mu opioid agonists, such as oxycodone. Nalfurafine is a clinically used kappa agonist in Japan for the treatment of pruritus; its effects on oxycodone self-administration (SA) in adolescents have not been studied. **Objective:** The current study examines the effects of nalfurafine on oxycodone SA in adolescent male and female mice. **Methods:** Adolescent mice (5 week old) first received surgery during which a catheter was implanted into their jugular vein. After recovering from the surgery, mice were then placed into the self-administration chambers and allowed to self-administer oxycodone, two hour per day for 14 days. Following 14-day oxycodone SA, each mouse was then injected with a single dose of nalfurafine (0, 50, 20, 10 ug/kg, s.c.) 10 min before oxycodone self-administration for four consecutive days, respectively. **Results:** The high dose of nalfurafine (50 ug/kg) significantly reduced oxycodone SA; lower dose of nalfurafine (20 ug/kg) did not significantly affect oxycodone SA. The lowest dose of nalfurafine (10 ug/kg) may have increased oxycodone SA in the same mice. **Conclusion:** This is the first study to examine the effects of nalfurafine on oxycodone SA in adolescent mice. The effect of nalfurafine on the rewarding property of oxycodone will be further studied.

Title: Decreased cocaine but increased opioid reward in offspring of males exposed to morphine during adolescence

Authors: *P. WALIA, A. M. TOORIE, D. N. TECENO, T. D. PATTON, E. M. BYRNES, F. M. VASSOLER;
Dept. of Biomed. Sci., Tufts Univ., North Grafton, MA

Abstract: Since the late 1990's, the United States has been suffering through an opioid epidemic. A growing body of evidence indicates possible transgenerational effects that extend the impact of opioid exposure to future generations. The goal of these experiments is to examine the effect of adolescent male opioid exposure on the next (F1) generation's drug self-administration behavior and developmental neuronal gene expression as well as potential mechanisms that may contribute to the transmission of these effects using a rat model (Sprague Dawley). Males were administrated increasing doses of morphine (5-25mg/kg, s.c.) for 10 days during adolescence (P30-39). Age-matched control males received saline injections at equivalent volumes. Animals were left drug-free until adulthood (P70-80) when they were mated with drug-naïve females (n = 24). Brains from F1 offspring were collected on P1, P7, P28, and P70. Male and female offspring were also examined for drug (morphine, oxycodone, or cocaine) self-administration in adulthood (P60-80). After mating, testes and spermatozoa from the cauda epididymis were collected from F0 males and acetylated H3 was examined. Results show that F1 animals have increased levels of opioid self-administration yet decreased cocaine self-administration. Male F0 seminiferous tubules displayed increased levels of acetylated histone H3 indicating developmental differences in spermatogenesis and genome packaging. Experiments examining developmental neural gene expression differences are ongoing. The results demonstrate that opioid exposure in the F0 generation has lasting effects, making future generations vulnerable to the harmful impact.

Title: Effect of chemogenetic activation of thalamo-accumbens projections on the augmentation of heroin seeking induced by chronic food restriction

Authors: *A. CHISHOLM, D. RIZZO, É. FORTIN, V. MOMAN, N. QUTEISHAT, J.-P. MANOLIADIS, T. CAPOLICCHIO, A. ROMANO, P. PARSA, J. GASPARRI, C. BORGES, U. SHALEV;

Abstract: Drug addiction is a chronic disorder that is characterized by compulsive drug seeking and involves switching between periods of compulsive drug use, abstinence, and relapse. In both human addicts and animal models of addiction chronic food restriction has been shown to increase rates of relapse. Previously, our laboratory has demonstrated a robust increase in drug seeking following a period of withdrawal in chronically food-restricted rats compared to sated rats. To date, the neural mechanisms that mediate the effect of chronic food restriction on drug seeking have not been elucidated. Evidence from our laboratory indicates that chemogenetic activation of the paraventricular nucleus of the thalamus (PVT) reduces heroin seeking in chronically food-restricted rats. The PVT sends glutamatergic projections to the Nucleus Accumbens (NAc). Thus, the objective of the current study was to study the effect of chemogenetic activation of the PVT- NAc Shell and Core neuronal pathways on heroin seeking under food restriction conditions.
Male Long Evans rats were injected with a viral vector carrying an excitatory Designer Receptor Exclusively Activated by Designer Drug (DREADD) into the PVT, and implanted with a guide cannula aimed at the NAc Shell or Core. Next, rats were trained to self-administer heroin over 10 days (0.1 mg/kg/infusion; i.v.). Following training, rats were removed from the operant conditioning chambers and placed into drug withdrawal for 15 days. Over the withdrawal period, rats were exposed to a mild food restriction (90% of baseline body weight) or were given unrestricted access to food. On the 15th day of the withdrawal period, a drug-seeking test was conducted in which rats were intracranially injected with CNO (1.0 mM) into the NAc Shell or Core, to activate the PVT-NAc pathway, or vehicle. Injectors' placement was verified using immunohistochemistry.
All rats reliability learned to self-administer heroin. As expected, food-restricted rats demonstrated an augmented heroin seeking during the heroin-seeking test in comparison to sated rats. Preliminary data indicate that activation of the PVT-NAc Shell pathway attenuates heroin seeking in chronically food-restricted rats.

Title: Role of the ghrelin system in oxycodone self-administration and brain stimulation reward

Authors: *Z.-B. YOU[1], E. L. GARDNER[1], A. MOORE[1], T. BUCK[1], C. J. JORDAN[1], B. HUMBURG[1], G.-H. BI[1], Z. XI[1], L. LEGGIO[2];

Abstract: Prescription opioid abuse is currently a serious worldwide public health problem. Identifying novel mechanisms underlying opioid addiction and developing innovative medications for treatment of opioid use disorders are high priorities in addiction research. Ghrelin is an orexigenic hormone secreted primarily from stomach and acts via the growth hormone secretagogue-receptor 1a (GHS-R 1a, a.k.a. ghrelin receptor) in regulating food intake and reward. Ghrelin has also been found to modulate mesolimbic dopamine transmission and regulate the rewarding effects of alcohol and psychostimulants. Much less is known about the role of the ghrelin system in contexts associated with prescription opioid misuse and abuse. In this study, we assessed responses of ghrelin in bloodstream and brain ghrelin receptors to oxycodone self-administration and self-administration-related behaviors, and the effects of ghrelin receptor antagonism on such behaviors using the selective ghrelin receptor antagonist JMV2959. We found that acquisition of oxycodone self-administration (0.1 mg/kg/infusion) in rats is associated with significant elevations in plasma ghrelin concentrations. Acquisition of oxycodone self-administration significantly altered mRNA expression of ghrelin receptors in the ventral tegmental area/substantia nigra (VTA/SN), a brain region critical for drug reward and motivation. Pretreatment of oxycodone trained rats with JMV2959 (0-5 mg/kg, i.p.) dose-dependently reduced oxycodone self-administration tested under either 0.05 or 0.0125 mg/kg/infusion of oxycodone. JMV2959 pretreatment also dose-dependently decreased the breakpoint for oxycodone self-administration tested under progressive ratio reinforcement. JMV2959 pretreatment (5 mg/kg, i.p.) in mice significantly inhibited intracranial self-stimulation maintained by optogenetic activation of VTA dopamine neurons. Our findings indicate that oxycodone and oxycodone experience is associated with development of hyperactivity of endogenous ghrelin in rats and suggest a contributory role of ghrelin signaling in the maintenance of oxycodone self-administration and in motivation for oxycodone-taking behavior. Thus, manipulations of ghrelin systems may represent a feasible approach for treatment of prescription opioid addiction. Supported by funds from NIDA-IRP

Title: CRF-5-HT interactions and motivation for stress-induced opioid relapse

Authors: N. MCCLOSKEY, C. LI, *L. G. KIRBY;
Ctr. for Substance Abuse Res., Lewis Katz Sch. of Med. at Temple Univ., Philadelphia, PA

Abstract: Previous studies have shown that stressors can inhibit 5-HT neuronal activity and release by stimulating release of the stress neurohormone corticotropin-releasing factor (CRF) within the serotonergic dorsal raphe nucleus (DRN). CRF effects on 5-HT DRN neurons are indirect, mediated by CRF-R1 receptors located on GABAergic afferents. Our laboratory is pursuing the potential role of these neurochemical interactions in stress-related psychiatric disorders including substance abuse. More recently, we have demonstrated a unique sensitization of 5-HT DRN neurons to GABAergic inhibition that is correlated with relapse to multiple drugs of abuse including opioids and in multiple models of stress-induced relapse. Furthermore, stimulation of GABA afferents to 5-HT DRN neurons is both necessary and sufficient for stress-induced relapse of previously extinguished morphine conditioned place preference (CPP). The current study demonstrates that stimulation of CRF-R1 within the DRN with the CRF-R1-preferring agonist ovine CRF reinstates morphine CPP in the absence of a stressor. Furthermore, intraDRN pretreatment with the CRF-R1 antagonist NBI 35965 blocks swim stress-induced reinstatement, indicating that this circuit is both necessary and sufficient for stress-induced opioid relapse. We also examined the role of this circuitry in stress-induced negative affect with ultrasonic vocalizations (USVs). USVs are naturally emitted by rats in response to environmental challenges: 50 kHz calls indicate positive affective responses to stimuli such as social interaction whereas 22 kHz calls indicate negative affective responses to stimuli such as pain, stress and drug withdrawal. We found that a footshock stressor, commonly used in models of stress-induced reinstatement of drug self-administration, elicits strong 22 kHz distress calls in rats. However, if animals are pretreated with intra-DRN NBI 35965, these 22 kHz distress calls are

significantly blunted. These data collectively support the hypothesis that stressors can elicit negative affective responses via their impact on CRF-5-HT circuits that motivate opioid relapse.

Title: Environmental enrichment reduces cue-induced heroin-seeking in male and female rats

Authors: L. LOUGHLIN[1], S. EWING[2], *R. RANALDI[1,2];
[1]Psychology, Queens Col., Flushing, NY; [2]The Grad. Center, CUNY, New York, NY

Abstract: Previous studies have shown that environmental enrichment (EE) implemented after the development of a heroin self-administration habit significantly reduced cue-induced reinstatement of heroin-seeking behavior in male rats. Although EE seems to be a beneficial behavioral intervention for male rats, the potential for similar benefits in females has yet to be explored. The aim of the current study is to test whether or not EE reduces cue-induced reinstatement of heroin seeking in females as it has been shown to in males. In the current study rats were trained to self-administer heroin with contingent cues (stimulus light above the lever and pump sound) present. Afterwards, they were randomly assigned to either EE (novel stimulus objects and running wheel) or standard housing (non-EE). This was followed by extinction, which consisted of fifteen sessions in which lever pressing did not result in heroin nor heroin-associated cues. On the sixteenth day, a cue-induced reinstatement session occurred in which the drug cues were presented non-contingently twice, two minutes apart, at the start of the session and contingently upon active lever pressing for the remainder of the session. Thus far, results show that exposure to EE significantly reduces responding in reinstatement for males and we are finding similar patterns in the females. The findings demonstrate that EE can reduce cue-induced reinstatement of heroin seeking in both male and female rats. As such, these findings suggest that environmental enrichment may be a useful behavioral therapeutic strategy for the treatment of heroin use disorder in both sexes.

Title: Does the A118G mu-opioid receptor polymorphism predict sensitivity to reward downshifts?

Authors: *A. M. DANIEL, B. K. RUSHING, K. TAPIA;
Texas A&M Univ. - San Antonio, San Antonio, TX

Abstract: Understanding the emotional reaction to loss, or psychological pain, is a critical problem for the field of mental health. Animal models of loss have pointed to the opioid system as a nexus of psychological pain, physical pain, and substance abuse. However, few attempts have been made to connect the results of animal models of loss to human behavior. Allelic differences in the human mu opioid receptor gene, notably the A118G single nucleotide polymorphism, have been linked to individual differences in social rejection, substance abuse, and PTSD symptoms. The present study explored the relationship between the A118G SNP and behavior in a reward downshift task in humans. Participants were trained to touch a target on a screen for points for 10 trials, and subsequently received 8 trials with an 8:1 reduction in points. The relative change in the number of button presses following the downshift was the primary variable of interest. Then, participants were tested in the cold pressor test to assess pain sensitivity. Finally, participants provided a sample of DNA which was screened for the A118G mutation in the mu opioid receptor. DNA was extracted from the saliva sample and amplified by polymerase chain reaction. Amplification was confirmed by agarose gel electrophoresis and amplified DNA was purified. Sequencing was outsourced and sequencing traces analyzed. All behavioral data was collected prior to genotyping to ensure that the experimenter was blind to genotype during training. We found that A-heterozygotes were more sensitive to the downshift, exhibiting a transient decrease in button pressing during the downshift. G-carriers were insensitive to the reward downshift. In the cold pressor task, there was insufficient evidence to link genotype with pain sensitivity. The insensitivity to reward downshifts we observed are counterintuitive in the context of previous studies in which G-carriers exhibited increased sensitivity to physical pain. However, based on evidence that the mu opioid system plays a critical role in comparing hedonic values, we propose a new hypothesis about individual differences in reward downshifts. The present results can be understood by considering that individuals that have a normally functioning mu receptor are capable of making comparisons across a wide range of experience. However, for G-carriers in which the mu receptor function is reduced, hedonic values may be rendered all-or-nothing, such that all rewards are more equally rewarding and all pain is more equally painful.

Title: Fentanyl vapor self-administration in mice: A novel non-invasive preclinical opioid addiction model

Authors: ***M. ORTIZ**[1], K. MOUSSAWI[2], B. J. TUNSTALL[2], R. C. MARCHETTE[2], G. F. KOOB[3], A. BONCI[2], L. F. VENDRUSCOLO[2];
[1]Natl. Inst. On Drug Abuse, Baltimore, MD; [2]NIDA, Baltimore, MD; [3]NIAAA, Bethesda, MD

Abstract: Opioid addiction is a growing public health concern in the United States with fentanyl usage accounting for more than half of opioid overdose fatalities. Intravenous drug self-administration in mice has been frequently used to study the reinforcing effects of drugs. However, intravenous self-administration studies require surgery and are complicated by limitations of catheter failures, the likelihood of which increases with duration of self-administration training. Here, we developed a non-invasive fentanyl vapor self-administration model of opioid addiction in mice, which circumvents the pitfalls of intravenous self-administration. First, we conducted a dose-response function of the analgesic and locomotor effects of vaporized fentanyl to determine an effective fentanyl concentration. Mice were then trained to self-administer fentanyl vapor on a fixed ratio 1 (FR1) schedule of reinforcement in an air-tight operant chamber equipped with both active and inactive nosepoke holes. Poking the active nosepoke operandum resulted in vaporized fentanyl delivery to the operant chamber for approximately one minute. A light cue was paired to the drug delivery. Mice readily learned to self-administer fentanyl in 1-hour sessions. Fentanyl levels in the blood were proportional to the dose of vaporized fentanyl. Following self-administration, mice went through extinction training where they were placed into the operant chambers in the absence of light cues and fentanyl vapor. After extinction, mice exposed to the light cue reinstated drug seeking. Further, mice allowed long access (LgA; 12 h/session) to fentanyl escalated drug intake over the course of 14 sessions, whereas mice allowed short access (ShA; 1-hour sessions) to fentanyl exhibited stable fentanyl self-administration over time. The LgA mice showed more naloxone-precipitated signs of somatic withdrawal when compared to ShA mice. In summary, we developed and validated a non-invasive fentanyl vapor self-administration model that recapitulates the main features of intravenous models. Advantages of this model include: 1) utilizing a vast repertoire of behaviorally selected and genetically modified mouse lines, 2) conducting prolonged experimental protocols that require extensive training (i.e., LgA sessions) or longitudinal studies

without the risk of catheter failure, and 3) facilitating *in vivo* calcium imaging and electrophysiology experiments that require a tether in freely moving mice.

Title: GluA1 protein levels in the nucleus accumbens core and shell after the incubation of oxycodone craving

Authors: A. WHEATLEY[1], M. E. WOLF[2], ***M. T. STEFANIK**[1];
[1]Psychology and Neurosci., North Central Col., Naperville, IL; [2]Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The recurring desire to take drugs, even after years of abstinence, is among the most insidious features of addiction. It is often triggered by cues previously associated with drug use. Cue-induced craving progressively intensifies (‘incubates’) over weeks of forced abstinence or withdrawal. This ‘incubation of craving’ has been reliably observed during withdrawal from different classes of drugs of abuse in rodents and humans. Recently, prescription opioid abuse and dependence has increased to epidemic levels. A prominent contributor to this trend is oxycodone (Oxy), a semisynthetic opioid, and the most widely prescribed opioid painkiller. Currently, however, little is known about the incubation of Oxy craving.
Incubation for psychostimulants depends on time-dependent strengthening of AMPA receptor (AMPAR) transmission onto medium spiny neurons in the nucleus accumbens (NA) through the accumulation of high-conductance, GluA2-lacking, Ca^{2+}-permeable AMPARs (CP-AMPARs). Our studies assess the incubation of *Oxy* craving and underlying neuroadaptations in the NA. It is hypothesized that expression of the incubation of Oxy craving also depends on strengthening of NA synapses via CP-AMPAR inclusion.
Male Sprague Dawley rats underwent 10 days of extended-access Oxy self-administration (6hr/day, 0.15mg/kg/infusion). Rats returned to the operant chamber for a 30-min test on withdrawal day 1 (WD1), and either WD15 or WD30, measuring the time course of cue-induced seeking. Results show that incubation of oxycodone seeking occurs at maximal levels around WD15. Next, animals were killed at each time point, and tissue from the NA (both core and shell

sub-regions) was biotinylated to test whether Oxy incubation is accompanied by elevated cell-surface levels of homomeric GluA1 receptors, the type of CP-AMPAR that is increased after incubation of cocaine craving. Preliminary results indicate that increased GluA1 levels parallel drug-seeking behavior in the NA core. Current studies are underway examining AMPAR receptor composition in the NA shell. By understanding incubation's cellular basis, we gain insight into mechanisms underlying the persistent vulnerability to relapse.

Title: Individual variation in the vulnerability and resilience to opioid dependence

Authors: *B. N. KUHN, A. T. ROBERTS, P. W. KALIVAS;
Dept. of Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: There has been a significant rise in opioid use disorder (OUD) in the United States over the past decade, making the understanding of the genetic and behavioral components that contribute to OUD necessary to explore. In the current study, rats underwent various testing procedures to assess the behavioral determinants associated with vulnerability versus resilience to opioid dependence. A heterogeneous stock rat line was used in order to better capture genetic and behavioral diversity within a rodent model. Stress and anxiety-related behaviors were assessed via the elevated-plus maze and an open field test, while analgesic thresholds were determined using a tail-flick test. Next, rats underwent 3 weeks of long-access (LgA, 12-hr sessions) heroin self-administration training, immediately followed by a progressive ratio test to determine the motivation to work for the drug. Following 4 more sessions of LgA, rats underwent a within-session extinction training and heroin-induced reinstatement (0.25 mg/kg, s.c.) test and then 6 days of extinction training. Immediately following the last day of extinction training, a test for cue-induced reinstatement was performed. The behavioral measures previously mentioned to assess stress, anxiety and analgesic threshold were repeated. Data thus far demonstrates that both male and female rats learn to acquire heroin self-administration at the same rate, and do not differ in their motivation to work for heroin, or in reinstatement of drug-seeking behavior. However, a correlation was present between total distance travelled during the open field test and cue-induced drug-seeking behavior. In fact, if rats are characterized based on

a high level of locomotor activity (high-responders, HRs) versus a lower level of locomotor activity (low-responders, LRs) in the open field test, HRs show greater rates of heroin-induced and cue-induced drug-seeking behavior compared to yoked-saline control rats. The HR/LR model is commonly used to examine individual variation in the acquisition of drug-taking behavior, particularly psychostimulants, but here we show that this model may also be relevant for predicting individual variation in drug-seeking behavior following heroin self-administration. These data highlight the value of focusing on individual variation in drug-seeking behavior and progress our understanding of behavioral differences that may be associated with vulnerability versus resilience to OUD. Further testing will focus on the genetic, epigenetic, and gut microbiome factors that contribute to individual variation in heroin dependence.

Title: Cellular specificity of matrix metalloproteinase activation on accumbens medium spiny neurons during heroin relapse

Authors: *V. CHIOMA[1], A.-C. BOBADILLA[2], P. W. KALIVAS[3];
[2]Dept. of Neurosci., [1]Med. Univ. of South Carolina, Charleston, SC; [3]Neurosci. Res., Med. Univ. S Carolina, Charleston, SC

Abstract: Heroin abuse is a leading cause of drug overdose-related deaths in the United States, highlighting a need for further research elucidating effects of maladaptive neuroadaptations following prolonged heroin use. Activation of the tetrapartite synapse in nucleus accumbens core (NAcore), which comprises of pre- and postsynapse, astrocytic processes, and surrounding extracellular matrix (ECM), has been linked to increased relapse vulnerability. Specifically, degradation of the ECM by activated matrix metalloproteinases (MMPs) is involved in both constitutive and transient extracellular synaptic remodeling. Following chronic heroin self-administration and extinction training, transient increases in MMP-9 activity in NAcore were elicited after 15 mins of cued heroin seeking compared to heroin-extinguished and saline control rats. Although increases in MMP-2,9 fluorescence can be localized to the soma and dendritic processes of medium spiny neurons (MSNs) in accumbens, it is unknown which specific cell types harbor changes in MMP activity under heroin-extinguished and cued reinstatement

conditions. We hypothesized that D1-receptor expressing MSNs express increased pericellular localization with MMPs during transient cued heroin seeking, while D2-receptor expressing MSNs express increased localization following extinction. We used an AAV cre-dependent mCherry virus to transfect accumbens MSNs in D1 and D2 cre-dependent rats and measured the localization of activated MMP-2,9 after FITC-gelatin microinjection under extinguished and reinstated conditions. For D1 MSNs, we observed increased MMP-2,9 localization with dendritic surfaces in reinstated animals compared to both yoked saline controls and heroin-extinguished animals. While D2 MSNs showed increased MMP-2,9 localization only in heroin-extinguished animals, but MMP-2,9 localization after 15 min reinstatement was reduced to yoked saline levels. We also investigated whether the previously mentioned increased MMP activity selectively around D2 MSNs is mediated by extinction training. Next, we used pharmacological MMP-2,9 inhibitors to determine which were contributing to increased localization, specifically around D1 MSNs during reinstatement and D2 MSNs after extinction. Finally, we studied the involvement of tissue inhibitors of metalloproteinases (TIMPs) in NAcore during reinstatement to determine if local MMP inhibition around D2 MSNs is necessary for cued heroin seeking. These findings reveal how NAcore extracellular matrix signaling underlying constitutive and transient synaptic plasticity relies in part on specific cell-types.

Title: Adolescent nicotine exposure alters ventral tegmental area inhibitory transmission and enhances morphine reward learning in adulthood

Authors: *R. E. WITTENBERG[1], B. A. KIMMEY[1], A. J. EISCH[2,1], J. A. DANI[1];
[1]Neurosci., Univ. of Pennsylvania, Philadelphia, PA; [2]Anesthesiol. and Critical Care Med., Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Opioid use disorder is a rapidly-growing source of preventable mortality. Identifying underlying neural mechanisms that give rise to opioid abuse is critically needed. Paralleling the recent rise in opioid abuse, nicotine use in adolescence has escalated**.** The long-term consequences of prior exposure to nicotine remain poorly understood. Our lab has shown that the acute effects of adult nicotine exposure in the ventral tegmental area (VTA), and on drug reinforcement behavior, are persistent until adulthood if nicotine exposure occurs during

adolescence. Others have revealed male ICR mice given nicotine during adolescence show greater preference for a morphine-paired context during adulthood relative to mice that receive saline during adolescence. However, the effect of sex and strain on the ability of early exposure to nicotine to enhance later drug-context association is unknown. Also, the underlying neural mechanisms that drive the ability of early nicotine exposure to enhance associative learning in adulthood, and whether these mechanisms differ when nicotine is given in adolescence as compared to acutely in adulthood, are unknown. To target these knowledge gaps**,** we exposed adolescent mice to nicotine (0.5mg/kg, i.p.) daily for two weeks and probed the behavioral- and circuit-level adaptations in morphine reward when the animals were adults. We examined the influence of adolescent or adult nicotine exposure in male and female mice on two measures of associative learning in adulthood: morphine conditioned place preference (presented here) and touchscreen autoshaping (in progress). As in male ICR mice, two weeks of adolescent nicotine in male C57BL/6J mice enhanced time spent in the morphine-paired compartment relative to mice that received saline during adolescence. Likewise, a single acute injection of nicotine given 15h prior to the first morphine-context pairing in adulthood also enhanced morphine place conditioning. These behavioral changes corresponded with an alteration in VTA GABA signaling. VTA GABA neurons demonstrated a depolarizing shift in the GABA reversal potential and paradoxical heightened action potential firing in response to morphine following adolescent nicotine exposure, as compared to animals treated with saline during adolescence. Together, our data show adolescent nicotine exposure enhances morphine reward learning in adult mice in concert with increased excitation in VTA GABAergic circuitry. We are now testing the impact of these altered GABA neurons on VTA-striatal circuits as well as the role of sex-specific differences in this heightened reward sensitivity to morphine following adolescent nicotine exposure.

Title: Effects of acute oxycodone on brain stimulation reward in male and female rats using intracranial self-stimulation

Authors: N. CONSTANTINO[1], S. PAGE[2], M. MAVRIKAKI[1], T. LINTZ[1], *E. H. CHARTOFF[2];
[1]Psychiatry, [2]Harvard Med. Sch., Belmont, MA

Abstract: Oxycodone has potent analgesic effects, but also produces sedation and has a high abuse liability, making it one of the most widely misused prescription painkillers. Oxycodone can elicit rewarding and reinforcing effects, as it is readily self-administered. Despite epidemiological studies examining prevalence rates of opioid use disorder in men and women, little is known about biologically-based sex differences in the effects of oxycodone on reward processes. We recently showed that male rats will initially self-administer more oxycodone than females—an effect that normalizes after extended self-administration. This raises the possibility that oxycodone is more rewarding in males. Alternatively, oxycodone may be less rewarding in males, resulting in higher levels of intake to achieve the same reinforcing effects. To test this, we used intracranial self-stimulation (ICSS), which measures the ability of a drug to facilitate or depress brain stimulation reward. This is measured either by a decrease in the frequency of stimulation that first sustains operant responding (stimulation threshold), or by an increase in the percent maximum control rate of responding (%MCR). We administered acute injections of oxycodone (0.1, 0.3, 1.0, and 3.0 mg/kg, IP) to adult male and female Sprague Dawley rats in a within-subjects design, with each rat receiving increasing followed by decreasing doses once every 2 days. Using both analysis methods, we show that oxycodone can both facilitate and depress ICSS responding over the 90-minute ICSS session, with higher drug doses having profound motor-suppressing effects within the first 45 minutes, followed by emergence of reward facilitation. Males show a nominally greater increase in reward-related effects of oxycodone compared to females, as well as a reduced motor-suppressing effect. These data support our hypothesis that oxycodone facilitates reward function more in males than females, which is consistent with males initially self-administering more oxycodone. Consistent with other work showing development of opioid-induced reward facilitation over time, the second administration of some oxycodone doses produced a greater rewarding effect compared to the first. In conclusion, oxycodone produces broadly similar effects on reward- and motor-related processes measured with ICSS in males and females, although there are significant sex differences that may ultimately influence opioid misuse.

Title: Evaluation of the opioid receptor pharmacology of the Kratom (Mitragyna speciosa) alkaloids Mitragynine and 7-Hydroxymitragynine in cell membranes and rats

Authors: *T. HIRANITA[1], S. OBENG[1,2], J. LEON OYOLA[2], A. E. PENNINGTON[1], M. E. REEVES[1], L. F. RESTREPO[1], J. S. FELIX[1], A. PATEL[1], N. P. HO[1], J. L. WILKERSON[1], C. R. MCCURDY[2], L. R. MCMAHON[1];
[1]Pharmacodynamics, Univ. of Florida Col. of Pharm., Gainesville, FL; [2]Medicinal Chem., Univ. of Florida, Col. of Pharm., Gainesville, FL

Abstract: Of the approximately 40 alkaloids identified in the Southeast Asia medicinal and recreationally used plant *Mitragyna speciosa* (kratom), the alkaloids mitragynine and its metabolite 7-hydroxymitragynine have received much attention due to their opioid receptor pharmacology. However, details of this opioid pharmacology have not been fully established. Here, receptor binding in CHO cell membranes and drug discrimination in rats were used; the extent to which pharmacological actions vary as a function of route of administration was of particular interest. Mitragynine had 91-fold less affinity than morphine to displace [^{3}H]DAMGO binding to human μ opioid receptors (Ki: 600 and 6.57 nM, respectively). In rats discriminating mitragynine (32 mg/kg, i.p.), its ED_{50} value for producing discriminative stimulus effects was 9.7 mg/kg. The μ-opioid receptor agonists morphine (0.32-32 mg/kg) and fentanyl (0.0056-0.32 mg/kg) produced a maximum 65% and 75% mitragynine-lever responding, respectively. When administered p.o., mitragynine was 5.9-fold more potent than when it was administered i.p. In rats discriminating morphine (3.2mg/kg, i.p.), its ED_{50} value for producing discriminative stimulus effects was 1.75 mg/kg. Fentanyl (0.0032-0.32 mg/kg) and the low efficacy μ-opioid agonist nalbuphine (1.78-32 mg/kg) fully substituted for the morphine discriminative stimulus (ED_{50}: 0.018 and 8.2 mg/kg, respectively). 7-Hydroxymitragynine fully substituted for morphine and was 4.4-fold more potent (ED_{50} = 0.40 mg/kg). Mitragynine, when administered i.p. and p.o., produced up to 74% and 76% morphine-lever responding; potency p.o. was 3.8-fold less potent than i.p. (ED_{50}: 99.0 and 26.4 mg/kg, respectively). The opioid receptor antagonist naltrexone (0.032mg/kg, i.p.) shifted the dose-effect function of mitragynine rightward and downward due to the failure of naltrexone to antagonize the rate-decreasing effects of mitragynine. Naltrexone produced surmountable antagonism of the morphine discrimination dose-effect function (8.4-fold). The present results strongly suggest that 7-hydroxymitragynine is a more selective μ agonist than mitragynine. Opposing differences in the potency of mitragynine when it is administered p.o. versus i.p. in the mitragynine versus morphine discrimination procedures are consistent with pharmacokinetics yielding different metabolites that translate into different pharmacodynamic profiles.

Title: Ultrasonic vocalizations (USVs) during intravenous oxycodone self-administration and context-elicited reinstatement in male rats

Authors: *S. J. SIMMONS[1], W. H. HAURY[1], R. E. GREENBAUM[1], J. M. SCHWARTZ[2], H. M. DEUTSCH[2], A. J. EISCH[1,3];
[1]Anesthesiol. and Critical Care Med., [2]Children's Hosp. of Philadelphia Res. Inst., Philadelphia, PA; [3]Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Opiates were linked to 42,000 overdoses in the United States in 2016, and prescription opioids - like oxycodone - have contributed to the current opioid epidemic. Self-reports suggest oxycodone possesses “unparalleled addictive potential”, and measuring this subjective ‘likability’ of oxycodone in animals is important to better evaluate oxycodone’s abuse potential. To meet this need, we recorded ultrasonic vocalizations (USVs) - interpreted to reflect affective states based on emission frequency - in rats trained to self-administer oxycodone intravenously. Adult male Long-Evans rats (n=7) trained (3h/d, 6d/wk, 18d; “acquisition”) to bar press for 3-s infusions of oxycodone (days 1-12: 0.10 mg/kg/inf; days 13 to 18: 0.05 mg/kg/inf). Rats then extinguished bar pressing in an alternate physical context (3h/d, 6d/wk, 12d; “extinction”). After extinction, half of the rats were returned to the oxycodone-paired context for reinstatement (ABA; n=4) while half were placed in the extinction context (ABB; n=3). USVs were recorded on days 1 and 13 of acquisition and during reinstatement. Preliminary results show rats acquired and extinguished oxycodone self-administration behavior comparably as in prior work. During acquisition, rats emitted 50-kHz USVs 242% more often prior to the first oxycodone infusion on day 13 vs. day 1 [T-=1.00, p=0.080] as has been seen in cocaine self-administering rats. During reinstatement, ABA rats pressed 268% more vs. extinction day 12, while ABB rats only pressed 48% more vs. extinction day 12 [t(5)=3.045, p=0.029]. Consistent with prior work, these data show that an oxycodone-paired context elicits drug-seeking after the operant response is extinguished. Regarding USVs during reinstatement, ABA rats emitted 319% more 50-kHz USVs compared to ABB rats [U(ABB)=6.00, p=0.057]. These novel data show that rats emit more 50-kHz USVs when placed in a context used previously for oxycodone self-administration

relative to USVs emitted when rats are returned to the extinction context. These data support the development of an anticipatory response that may reflect individual differences in 'likability' associated with oxycodone. Future studies will probe the circuitry hypothesized to underlie the contextual learning shown to imbue physical environments with salience and relapse-driving properties.

Title: Gut-brain interactions in intravenous fentanyl self-administration

Authors: *M. REN[1], S. LOTFIPOUR[2];
[1]Univ. of California Irvine, Irvine, CA; [2]Emergency Med. & Pharmacol., UCI, Irvine, CA

Abstract: The United States is currently experiencing an opioid addiction epidemic. The number of drug-related deaths has spiked over the last five years primarily due to fentanyl. It is therefore necessary to investigate the mechanisms mediating fentanyl's motivational properties in order to assist in the development of successful treatment strategies. Our lab has developed a rat model of intravenous fentanyl self-administration to investigate factors that influence fentanyl intake, including sex, drug dose, and gut bacteria. Gut bacteria communicate with the brain, and vice versa, via the gut-brain axis to regulate brain function, mood, and behavior. Preclinical research has shown a significant impact of intestinal bacteria on regulating addiction-related behaviors. We show that male and female Sprague Dawley adult rats are able to learn response requirements via reinforced nosepokes to acquire fentanyl infusions at 1.25 or 2.5 versus a 0 μg/kg/infusion dose on an escalating schedule of reinforcement, i.e. fixed ratio schedule (FR) 1, 2, 5 and progressive ratio. Additionally, males treated with prolonged oral antibiotics vs. water have decreased discrimination of response requirements for fentanyl, suggesting a role of gut bacteria in drug-related behavior, including the motivation to attain an opioid reinforcer. Our findings provide feasibility for an intravenous fentanyl self-administration animal model and uncover potential factors mediating drug intake, which may lead to effective addiction interventions to decrease opioid-related deaths.

Title: Relation between acute withdrawal from morphine and predictors of drug abuse risk in rats

Authors: W. WHITE, *I. M. WHITE;
Psychology, Morehead State Univ., Morehead, KY

Abstract: In a prior study, when morphine (5 mg/kg) was periodically administered to rats, considerable individual differences were seen in activity 12 to 24 hours after administration. Some animals had a very large decrease in activity by the end of the day following administration. The reduction in activity appeared to be a sign of acute withdrawal, and these animals appeared to be acute withdrawal sensitive. On the other hand, other animals showed no decrease in activity, and they appeared to be acute withdrawal insensitive. The present study began to assess how the measure of acute withdrawal was related to other measures that predict drug abuse. Twenty male, Wistar rats were run on an assessment of acute withdrawal. Every five days rats received a dose of morphine, either 2.5, 5, or 10 mg/kg, and their activity was monitored for the next 24 hours. Results produced by morphine were compared to those produced by saline. In addition, several other measures thought to be predictive of drug vulnerability were collected. These included time spent in closed and open arms of an elevated maze (a measure of anxiety); distance moved in a novel open field (a measure of sensation seeking); and distance moved in response to a moderate dose of amphetamine (0.5 mg/kg) before and after repeated morphine treatment (a measure of cross sensitization). All measures produced considerable individual differences. Higher anxiety, lower sensation seeking, and lower cross sensitization were modestly related to intensity of acute withdrawal produced by morphine (5 mg/kg). Relating measures may provide clues about common mechanisms and suggest how measures might be combined to produce better predictors of drug vulnerability.

Title: A smartphone-based tool for neuroeconomic prediction of treatment outcomes in opioid use disorder treatment

Authors: *A. MELLIS[1], A. B. KONOVA[2], S. LOPEZ-GUZMAN[3], T. BURLEIGH[4], H. BAYER[5], P. W. GLIMCHER[6];
[1]NYU Langone Hlth., New York, NY; [2]Rutgers, New Brunswick, NJ; [3]Escuela de Medicina y Ciencias de la Salud, Univ. del Rosario, Bogota, Colombia; [4]Unaffiliated, New York, NY; [5]Datacubed Hlth., New York, NY; [6]Ctr. Neural Sci., New York Univ. Ctr. for Neural Sci., New York, NY

Abstract: Since the turn of the century, the annual rate of opioid overdose deaths has nearly quadrupled. However, even participants who receive the current front-line treatment for opioid use disorder, medication assisted therapy (MAT), are likely to relapse and drop out of treatment. However, given that most treatment facilities are operating near full capacity, determining how to deploy limited resources to those at highest risk of relapse and dropout is critical. Mobile health applications provide unique opportunity for monitoring using ecological momentary assessments, improving the resolution of predictions. Our past work in an opioid MAT program (86% male, 50% white, average age = 48.1) has demonstrated that a combination of neuroeconomic tasks and clinical assessments can provide accurate posterior probabilities of opioid use events, above the predictive power of clinical assessments alone.
To address this need we developed a gamified neuroeconomic tool for deploying these assessments on a daily basis to subjects in MAT programs. We specifically developed incentive-compatible gamified versions of the Levy risk task (Levy et al., 2010) and a standard intertemporal choice task (Kable & Glimcher, 2007). Our neuroeconomic tasks use restricted choice sets (20-35 trials, rather than 120-150), calibrated to determine task performance in under 3 minutes and can provide accurate estimates of risk attitude, ambiguity attitude and discount rate. We embedded these tasks in a commercial gamified environment and in a non-OUD cohort found high levels of compliance across subjects. We combined these tasks with other instruments that measure daily self-reports of treatment compliance, relapse to illicit opioid use, craving, and exposure to drugs, to produce a suite appropriate for use in a MAT cohort. In a pilot project, participants recruited from a MAT program are scheduled to complete 21 days of mobile

assessment to demonstrate the feasibility and acceptability of a mobile health app in an outpatient MAT setting.

Title: The long-acting glucagon-like peptide-1 receptor agonist, Liraglutide, reduces heroin self-administration and relapse in rats

Authors: *J. E. DOUTON, S. BALLARD, P. S. GRIGSON;
Dept. of Neural and Behavioral Sci., Pennsylvania State University, Col. of Med., Hershey, PA

Abstract: Drug addiction is commonly understood as the usurpation of reward-related learning processes that alters the normal functioning of the brain reward system and directs the individual to exclusively seek and take drug. However, the motivated state of an individual when craving drug is similar to the state observed in animals that crave food when hungry, water when thirsty, or salt when sodium deficient - where there is only one goal and no substitute. In this context, drugs of abuse appear to have an effect on the 'need' system, affecting the overall metabolic state of the individual. Recently, much research has focused on the effect of feeding-related hormones, such as glucagon-like peptide-1 (GLP-1), on non-feeding motivated behaviors involving drugs of abuse. Here, we assessed the effects of the long acting GLP-1 receptor agonist, liraglutide (Lir), on heroin use and addiction. Rats had the opportunity to self administer heroin for six hours for a total of 10 days. After drug-taking behavior was acquired, rats were treated for 12 days with vehicle or 1mg/kg of Lir daily, one hour before being placed in the experimental chamber. Thereafter, rats began a 15-day abstinence period in which daily treatment with vehicle or Lir continued. Following abstinence, a test was performed to assess cue-induced reinstatement and drug-induced relapse. Here, we show that chronic treatment with Lir significantly reduced two key components of heroin addiction: heroin self-administration and drug-induced reinstatement of heroin seeking behavior (i.e.relapse). One hour pretreatment with Lir, however, was not effective in reducing cue-induced reinstatement. Importantly, while

effective in reducing both self-administration and 'relapse', prolonged treatment with this dose of Lir did not affect blood glucose or body weight. Taken together, these findings show that the long acting GLP1-R agonist, Liraglutide, is a candidate for the treatment of relapse in individuals with an opioid use disorder and even for the reduction of heroin taking for individuals motivated to begin the process of quitting.

Title: Differences in behavioral response to morphine in a genetic model of temperament

Authors: ***M. A. EMERY**[1], C. AYDIN[1], E. K. HEBDA-BAUER[1], P. M. MARAS[1], A. PARSEGIAN[1], A. V. STEFANOV[1], A. TANG[1], S. J. WATSON, Jr.[2], H. AKIL[2];
[1]Mol. and Behavioral Neurosci. Inst., [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Our lab has developed a genetic model of temperament using a selective breeding strategy based on degree of locomotor response in a novel environment. Using this strategy, we have generated and maintain two lines of rats with distinct behavioral and neurochemical phenotypes, termed selectively-bred high-responders (bHRs) and low-responders (bLRs). Our prior work using these lines have demonstrated that their temperamental differences affect their propensity to seek and take psychostimulant drugs. Specifically, bHRs demonstrate a higher basal propensity to take drugs, due to a broadly sensation-seeking phenotype; whereas bLRs appear less susceptible at baseline but will seek and take drugs in response to psychosocial stress. Further, gene expression studies have revealed broad differences in gene expression levels between these two lines which are likely to mediate the differences in temperament. Notably, gene expression differences include members of the endogenous opioid system in multiple reward-related brain areas. In addition to basal differences in the opioid system, exposure to stress during adolescence alters opioid gene expression differentially between the two lines. However, to date bHR/bLR differences in the response to morphine have not yet been

characterized. Here, we characterize behavioral responses of bHR and bLR rats to morphine in a variety of behavioral paradigms, including locomotor sensitization, conditioned place preference, and rate of analgesic tolerance development. In addition, we expand the characterization of basal differences in the expression patterns of opioid system components between these lines. Results reveal strain differences in the behavioral response to morphine. Further, basal differences in the biology of the endogenous opioid system as well as differences in the biological response to morphine administration may, at least in part, mediate these differential behavioral responses. These findings provide a foundation to use this model to probe the genetic and neurobiological antecedents that mediate individual differences in the path to develop and maintain opioid addiction.

Abstract: A significant portion of prescription opioid users self-administer orally rather than intravenously; however, most animal opioid research has been conducted using the intravenous route. These models have demonstrated that cues associated with intravenous use are sufficient to cause relapse. Our first objective was to determine whether oral drug-associated cues are sufficient to cause relapse. It is also clinically shown that preference to self-administer orally at least partially relates to the user's sex, leading to our second objective to determine whether sex differences exist in susceptibility to relapse. Mice orally self-administered escalating doses of oxycodone under postprandial and non-postprandial conditions and exhibited robust cue-induced reinstatement of extinguished drug-seeking behavior. An additional group of mice showed that oral self-administration under non-postprandial conditions is sufficient to support cued reinstatement. Because we discovered that female mice earned significantly more mg/kg oxycodone than male mice, subsequent gonadectomy studies were conducted to evaluate the

effects of gonadal sex steroids on oral self-administration. Contrary to our initial hypothesis that these procedures would reverse the female to male imbalance of oxycodone oral self-administration, we found that ovariectomy prandial-dependently enhanced, while orchiectomy across dose and prandial-independently suppressed oxycodone self-administration. These studies establish that 1) oral drug cues are sufficient to cause reinstatement that is independent of prandial conditions, 2) earned oral oxycodone is larger in female mice compared with male mice, and 3) gonadectomy produces divergent effects on oral oxycodone self-administration between sexes. Future projects regarding these findings will focus on the neuronal role of ventral tegmental area neurons during the extinction-reinstatement phase of our paradigm, leptin receptor antagonism outcomes during postprandial conditions, and further investigation of gonadal steroid hormones with attention on their organizational effects.

Title: Exploring the impact of biological sex on oxycodone place conditioning behavior in male and female rats

Authors: *J. A. BABB[1,2], N. CONSTANTINO[3], M. HAMMOND[3], G. B. KAPLAN[4,2], E. H. CHARTOFF[1,3];

Abstract: Prescription opioid misuse can escalate to opioid dependence and opioid use disorder and continues to represent a major factor in the ongoing U.S. opioid epidemic. Women report different motivations for initiating drug use and experience different acute and chronic effects of drugs than men. Despite evidence that sex may impact addictive behavior in humans, preclinical rodent models investigating drug-seeking behavior have largely omitted females. In this study, the rewarding properties of the prescription opioid oxycodone were evaluated in adult male and

female rats using a well known rodent behavioral paradigm: place conditioning. A repeated measures ANOVA was used to analyze the effect of sex on pre- and post-conditioning preference for drug-associated contexts. In response to two days of twice daily conditioning sessions with 3mg/kg oxycodone and saline, both male and female rats acquired significant conditioned preference for the drug-paired context compared to the vehicle-paired context (main effect of conditioning; $F_{(1,14)} = 45.6$, $p<0.001$), and to a similar degree (no main effect of sex or sex by conditioning interaction). Preliminary data suggest however, that although initial context-drug associations are similar across sexes, female rats may take longer to extinguish preference for drug-paired contexts in the absence of drug. Ongoing experiments are exploring this possibility, and potential neural mechanisms underlying this phenomenon. These experiments could provide novel insight into differential opioid seeking behavior between male and female rodents which may lead to novel therapeutic compounds targeted to men and women in a sex-specific manner.

Title: The sigma1 receptor antagonist CM304 enhances the antinociceptive effects of cannabinoid CB1 agonists, but not mu-opioid receptor agonists, in mice

Authors: *S. OBENG[1], S. INTAGLIATA[2], M. MOTTINELLI[2], L. F. RESTREPO[1], P. AVI[1], V. A. TAYLOR[1], M. E. REEVES[1], A. E. PENNINGTON[1], C. R. MCCURDY[2], L. R. MCMAHON[1], T. HIRANITA[1];
[1]Pharmacodynamics, [2]Medicinal Chem., Univ. of Florida, Gainesville, FL

Abstract: There is an overdose epidemic associated with the use of illicitly manufactured as well as prescription mu-opioid agonists. Sigma1 receptor (σ_1R) antagonists in combination with other drugs may provide a viable, safe pharmacological option for treating pain. The present study compared the pharmacological effects of the σ_1R antagonist CM304 alone and in combination with mu-opioid (nalbuphine, morphine and fentanyl) or cannabinoid CB_1 [CP55,940 and (−)-*trans*-Δ^9-tetrahydrocannabinol (THC)] receptor agonists in C57BL/6J mice.

Rectal temperature, tail withdrawal latency from warm water of various temperatures (45°C, 50°C and 55°C) and counts of unhabituated locomotor activity were measured in this order. Basal latency for tail withdrawal systematically decreased from 10 seconds at 45°C to 1.3 seconds at 55°C. Morphine (cumulative 1-100 mg/kg, s.c.) and fentanyl (0.0032-0.32 mg/kg, s.c.) dose-dependently increased maximum possible effects (MPE) up to 100% at 55°C (ED_{50} values: 7.50 and 0.068 mg/kg, respectively). Nalbuphine (3.2-320 mg/kg, s.c.), CP55,940 (0.032-3.2 mg/kg, i.p.) and THC (3.2-320 mg/kg, i.p.) were less active at 55°C (Emax values: 74.0%, 56.6% and 58.2% for nalbuphine, CP55,940 and THC, respectively). CM304 (56 mg/kg) produced an upward shift in the CP55,940 dose-effect function such that 100% MPE was achieved at 3.2 mg/kg CP55,940, while CM304 (56 mg/kg) produced a 3-fold leftward shift in the dose-effect curve of THC. On the other hand, CM304 did not enhance the antinociceptive effects of morphine and fentanyl. In contrast to tail withdrawal latency, there were no consistent effects of CM304 on cannabinoid-induced decreases in rectal temperature and locomotor activity. While CM304 alone did not significantly alter tail withdrawal latency at 55°C, it did decrease activity and rectal temperature. However, CM304 produced an upward shift in the dose-effect function of hyperactivity induced by morphine.
The present results may not support the development of a σ_1R antagonist as an adjunct to opioids for treatment of acute pain. However, the results indicate that an σ_1R antagonist could be used specifically to increase the analgesic effectiveness of cannabinoid CB_1 receptor agonists.

Title: Higher numbers of orexin-expressing neurons are associated with increased motivation for psychostimulants, opioids and palatable food

Authors: *S. L. O'CONNOR[1], M. H. JAMES[1,2], J. E. FRAGALE[1], C. B. PANTAZIS[1], B. S. BENTZLEY[3], A. MOHAMMADKHANI[4], K. A. PORTER-STRANSKY[5], G. ASTON-JONES[1];

Abstract: ***Introduction:*** Orexin signaling is critically involved in the expression of motivated seeking of drugs of abuse and palatable food. Orexins are produced by a discrete population of neurons in caudal hypothalamus, ranging mediolaterally from dorsomedial hypothalamus (DMH) through perifornical (Pf) to lateral hypothalamus (LH). Recent evidence indicates that the number of endogenous orexin-expressing neurons, particularly those in LH, is associated with the magnitude of motivation for cocaine. Further, there is evidence of plasticity in orexin expression, such that chronic exposure to cocaine or morphine is associated with an increase in the number of orexin-expressing neurons. Here we compared these phenomena across several drugs of abuse, including psychostimulants and opioids, as well as palatable foods. ***Methods:*** To examine the relationship between endogenous orexin cell numbers and motivation for drug, male Sprague Dawley rats (8wk) were trained to self-administer cocaine (n=12) or the short-acting opioid remifentanil (n=10), before being tested on our within-session behavioral economics paradigm. Rats were perfused and the number of orexin-expressing neurons was quantified and correlated with demand elasticity, an inverse measure of drug motivation. To examine plasticity of orexin-expression, rats were trained to self-administer cocaine (n=27) or fentanyl (n=13) on an intermittent access (IntA) or short access (ShA) paradigm; we have previously shown IntA to enhance motivation for drug relative to ShA. In a separate group of female Long Evans rats (n=47), binge-like eating was induced by exposing rats to sweetened fat (vegetable shortening/10% sucrose) for 30 min, twice/wk for 4wk. A control group was given ad-libitum access to chow. All rats were perfused 30-150d after drug/binge exposure and orexin-expressing neurons were quantified. ***Results:*** Animals with high baseline demand for cocaine and remifentanil had significantly higher numbers of LH orexin-expressing neurons. High demand for remifentanil was also associated with higher DMH/Pf orexin neurons. IntA to cocaine and fentanyl, as well as a history of binge-like eating, was associated with a persistent increase in orexin cell numbers in LH. IntA to fentanyl was also associated with increased DMH/Pf orexin neurons. ***Conclusions:*** Higher numbers of LH orexin neurons are associated with enhanced 'trait' and 'state' motivation for psychostimulants, opioids and palatable food. The number of DMH/Pf neurons appears to be uniquely linked with motivation for opioids. These data point to the orexin system as a common neurobiological system underlying aberrant motivation across reinforcers.

Title: Microcircuitry of visual attention: Laminar organization of attentional selection in area V4

Authors: *J. A. WESTERBERG, A. MAIER, J. D. SCHALL;
Dept. of Psychology, Vanderbilt Univ., Nashville, TN

Abstract: The modulation of visual responses during attentional selection originates through interactions within and across cortical areas, such as area V4 and the frontal eye field. Anatomical studies have shown that the primary feedforward visual activation in area V4 enters in the middle, granular layers while feedback targets extragranular layers. To investigate the laminar organization of attentional selection in V4, we performed acute laminar recordings in V4 using linear multielectrode arrays in macaque monkeys performing a color singleton visual search task. Fluid reward was earned for shifting gaze to the singleton. While spiking activity across all layers was enhanced following attentional selection of the singleton, the synaptic depolarizations had unique laminar dependencies. Target selection was observed in the current sinks of the CSD almost exclusively in the supragranular layers. This preceded the changes in the population spiking activity. The laminar specificity of this effect suggests that target selection of stimuli either originates in area V4 or is fed back to V4 through its extensive connections with frontal cortex or other cortical areas. These results provide the first description of the temporal evolution of target selection along the layers of extrastriate area V4 in a visual search task, which provide new constraints on the generation of event-related potential indices of visual attention like the N2pc.

Title: Contribution of area V4 to the N2pc event-related potential index of attention

Authors: *M. S. SCHALL, J. A. WESTERBERG, A. V. MAIER, J. D. SCHALL, G. F. WOODMAN;
Dept. of Psychology, Vanderbilt Univ., Nashville, TN

Abstract: Research into mechanisms of visual attention has relied on an event-related potential known as the N2pc, because it indicates where and when attention is allocated. The N2pc was discovered and characterized in humans, so its neuronal origins are unknown. Several investigators have conjectured that extrastriate visual area V4 can be a generator of the N2pc based on the similarity of patterns of modulation. Our group has been investigating that conjecture. We have established that the N2pc manifests in macaque monkeys performing visual search. We have established that inverse solutions of the N2pc identify a current generator in the vicinity of V4. Now, to determine most directly whether V4 contributes to the generation of the N2pc, we performed laminar recordings of area V4 concurrent with extracranial EEG in macaque monkeys performing visual search for a singleton. A target stimulus (red or green) was presented among several distractors (homogenous green or red) in an array around a central fixation point. Monkeys shifted gaze to the singleton to earn fluid reward. With field potentials recorded across all cortical layers, we calculated current source density (CSD) of net synaptic depolarizations. On a trial-by-trial basis we compared the magnitude of CSD and polarization of the N2pc. Trial-to-trial variability in the synaptic depolarizations of V4 explained a significant amount of variance in the extracranial voltage fluctuations during the N2pc. This relationship was found only when the singleton was the preferred color of the recorded location. These results demonstrate that V4 is a contributor to the extracranial index of attentional selection.

Title: Microcircuitry of visual attention: Attentional priming in area V4

Authors: *J. D. SCHALL, J. A. WESTERBERG, A. V. MAIER;
Dept. of Psychology, Vanderbilt Univ., Nashville, TN

Abstract: Behavioral priming improves performance in psychophysical tasks. To investigate the neural mechanisms of visual priming, we recorded neural spiking and field potentials across all layers of area V4 in monkeys performing visual search under conditions of priming of popout. In this task response accuracy and time improve with repeated presentation of the same singleton in a search array (e.g., red among green), and performance is impaired when feature assignments change. Neurophysiological substrates of these behavioral changes have been discovered in the frontal eye field (FEF) (Bichot & Schall 2002 J Neurosci). We investigated whether area V4 contributes to priming of popout. Monkeys performed a color pop-out task where the sequences of trials were such that priming would occur. Acute linear electrode arrays were introduced into V4 and recorded neural activity across the layers during task performance. Both synaptic depolarizations, measured through current source density (CSD), and neural spiking were measured. As expected, priming of pop-out improved search performance. We found that priming coincided with earlier target selection time measured across all layers of V4 in neural spiking and in the supragranular layers in CSD sinks. The laminar specificity of the changes in target selection time in the CSD suggest that V4 either generates the priming effect or inherits it from another cortical area, perhaps FEF, rather than through bottom-up changes in visual processing from earlier visual areas. These results provide new information about the mechanisms of visual memory and provide new constraints on the generation of event-related potential indices of visual attention like the N2pc.

Title: Speed-accuracy tradeoff of visual processing in supplementary eye field: Comparison with frontal eye field and superior colliculus

Authors: *T. R. REPPERT, R. P. HEITZ, J. D. SCHALL;
Vanderbilt Univ., Nashville, TN

Abstract: Two macaque monkeys performed visual search with speed-accuracy tradeoff (SAT) cued in short blocks of emphasis on either speed or accuracy of responding. With cued emphasis on speed, behavioral responses were quicker, and error rate, higher. Different stimulus arrays supported higher or lower efficiency search during each recording session. During less efficient search, the SAT performance curve shifted to slower responding with increased error rate. We quantified and compared effects of SAT and search efficiency on visually-responsive neurons in SEF, FEF, and SC. Previously, we showed that visual response magnitude was greater in FEF and SC when speed was emphasized (Heitz and Schall 2012; Reppert et al. 2018). We found the same to be true in SEF. In SC, we observed an interaction of search efficiency and SAT condition on response magnitude, with response magnitude elevated in the Fast condition during inefficient search but elevated in the Accurate condition during efficient search. In SC, we also observed no effect of search efficiency on response magnitude. In FEF there was no interaction of search efficiency and SAT condition on response magnitude, nor was there a main effect of search efficiency. Previously, we showed that TST was earlier in FEF and SC when speed was emphasized (Heitz and Schall 2012; Reppert et al. 2018) and that neurons in SEF do not produce TST (Purcell et al. 2012). Here, we found that ~1/3 of visually-responsive SEF neurons distinguished the target from distractors. Among those SEF neurons, we observed an interaction of SAT condition and search efficiency on TST, with TST delayed in the Accurate relative to the Fast condition during more efficient but not less efficient search. As observed previously in FEF, we observed TST delayed during less relative to more efficient search, but this was not found in the sample of SC neurons. These results complement prior observations of SAT-related effects in

SC and FEF and extend our understanding of the distributed neural circuitry that accomplishes SAT of visual search.

Title: Separate modifiability of stages of target selection for visual search in macaques

Authors: *K. A. LOWE[1], T. R. REPPERT[2], J. D. SCHALL[1];
[1]Psychology, [2]Vanderbilt Univ., Nashville, TN

Abstract: The computational and neural architecture supporting visual search has not been elucidated despite many years of investigation. We employed the logic of separate modifiability through multi-dimensional factorial manipulations to address these fundamental questions. We trained two male macaque monkeys to perform visual search with selection on color and response on shape of a singleton. One monkey was novice, and the other had experience with other color-shape visual search tasks. We manipulated separately *singleton identifiability* (color similarity of singleton and distractors) and stimulus-response *cue discriminability* (elongation of singleton cuing pro/anti/no saccade). Using a powerful mathematical approach known as systems factorial technology, we distinguished alternative processing architectures (series or parallel) and stopping rules (exhaustive or self-terminating). The novice monkey used a coactive strategy in which singleton identification and cue discrimination are pooled to produce responses. The experienced monkey used a parallel exhaustive strategy in which singleton identification and cue discrimination were completed separately but in tandem to produce responses. The signatures of different processing architectures offer novel hypotheses to guide analysis of the neural signals in frontal eye field (FEF) sampled during task performance.

Title: Effects of an orexin-2 receptor agonist on attention in rats following loss of cortical cholinergic projections

Authors: *S. A. BLUMENTHAL[1], E. B.-L. MANESS[2], J. R. FADEL[3], J. A. BURK[1]; [1]Psychological Sci., [2]Applied Sci., William and Mary, Williamsburg, VA; [3]Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: Deterioration to the basal forebrain cholinergic system (BFCS) is linked to age-related cognitive impairment, specifically to the pathology of Alzheimer's disease (AD). Animals with BFCS damage perform poorly on learning, memory, and attention tasks, indicating cognitive deficits. The orexin neuropeptide system, comprised of two neuropeptides (orexin A and orexin B), has also been implicated in the cognitive decline associated with aging, likely due to the role of orexins in promoting attention. Two orexin receptor subtypes exist, orexin 1 (Ox1R) and orexin 2 (Ox2R). Studies have examined the effects of stimulation and blockage of both receptors together and Ox1R alone on attention; but no studies have examined the role of Ox2Rs in attention through the use of Ox2R agonists. Ox2Rs may be implicated in attentional processes and the loss of orexin neurons seen in age-related cognitive decline. In order to examine the role of Ox2Rs in attention following BFCS deterioration, the present study administered the Ox2R agonist, YNT-185, to rats given intrabasalis infusions of either saline (n = 12) or 192 IgG saporin (n =11), an immunotoxin which selectively destroys the BFCS. Animals received infusions of YNT-185 to the lateral ventricle (LV) in doses of 0, 1, 10, and 100nM across four separate sessions and performance was then assessed on a sustained attention task requiring discrimination between signal and non-signal trials through lever presses. The 100nM dose of YNT-185 improved attentional performance, as compared to the 0nM dose, for rats given the immunotoxin, but worsened performance for rats given saline lesions. YNT-185 may be efficacious in aiding attentional function in animals with vulnerable cholinergic systems but may lead to overexcitation for those with intact cholinergic function.

Title: Dual orexin receptor antagonism attenuates dizocilpine-induced attentional impairments in a rat model of acute psychosis

Authors: *E. B.-L. MANESS[1], S. A. BLUMENTHAL[2], J. BURK[2];
[1]Applied Sci., [2]Psychological Sci., William and Mary, Williamsburg, VA

Abstract: Schizophrenia (SZ) is a psychiatric condition wherein those afflicted demonstrate a combination of positive symptoms, such as hallucinations and delusions, as well as negative symptoms, including alterations of processing that disrupt sociality, mood, and cognition. Widespread failure of corticofugal inhibition caused by reduced NMDA receptor input to GABA interneurons results in mesolimbic overstimulation, leading to sensory disturbances and psychosis. Current antipsychotic medications are known to produce unpleasant physiological side effects like sedation, Parkinsonism, and diabetes; additionally, they can bring forth or exacerbate negative and cognitive symptoms. As such, exploring alternative pharmacotherapies which alleviate the positive symptoms of SZ while boosting motivational and cognitive integrity is a worthwhile endeavor. The lateral hypothalamic orexinergic system, a widespread neuromodulatory network involved in wakefulness, appetitive drive, and incentive- and fear-linked behaviors, plays a key role in regulating excitatory neurotransmission throughout the central nervous system. The sedative-hypnotic nature of orexin receptor inhibitors is hypothesized to calm subcortical hyperexcitation while sparing cognitive function. In the present study, the dual orexin receptor antagonist filorexant (MK-6096) was intracerebroventricularly infused following acute intraperitoneal administration of dizocilpine (MK-801), an NMDA receptor antagonist, and performance was assessed in a visual sustained attention test. 0.1 mM of filorexant normalized signal detection impairments induced by dizocilpine without diminishing performance on its own. Additionally, dizocilpine-linked trial omissions were reduced following filorexant infusions. Based on these findings, drugs which dampen orexin receptor activity may restore attentional and motivational abilities for those with SZ, possibly by assuaging subcortical hyperactivity and normalizing cortical function.

Title: Sustained attention leads to brain region specific changes in glutamine synthetase

Authors: *J. BONANNO[1], E. KHARITONOVA[1], T. WANG[1], L. A. NEWMAN[2];
[2]Dept. of Psychological Sci., [1]Vassar Col., Poughkeepsie, NY

Abstract: Research suggests that astrocytic dysfunction contributes to neurodegenerative diseases and neuropsychiatric disorders such as Alzheimer's disease, attention-deficit/hyperactivity disorder (ADHD), and schizophrenia. We examined healthy astrocytic activity during sustained attention to better our understanding of how these processes can go awry. We focused our study on the role of astrocytes in glutamate and GABA recycling. In the glutamate-glutamine cycle, astrocytes take up neuronally secreted glutamate and GABA and convert it to glutamine to send back to neurons for continued neurotransmission. This process, facilitated by the astrocyte-specific enzyme glutamine synthetase (GS), prevents neurotoxicity and allows for phasic signalling in the synapse. In this study, we assessed changes in GS levels during a sustained attention task (SAT) in Long Evans rats. The animals were first trained on the water reinforced SAT. Those that reached criterion performance on the SAT were sacrificed 15 minutes after the completion of the task along with animals that did not reach criterion performance. An additional group of cagemate controls was also examined to assess the effects of any training on the SAT. GS levels were quantified in the prelimbic cortex (PL), hippocampus, and dorsolateral striatum using immunohistochemistry. We found a brain region specific effect of GS. While rats that reached criterion performance on the SAT had higher GS levels in the PL and the upper limb of the dentate gyrus (ULDG), rats that failed to learn the task had lower levels of GS expression in the PL and ULDG. Our results suggest that success on the sustained attention task may be dependent on sufficient GS levels in the prefrontal cortex and hippocampus. These findings shed light on the dynamic changes in glutamate and GABA recycling in astrocytes during cognition and may point to dysfunctional astrocytes as a therapeutic target in neurodegenerative diseases and neuropsychiatric disorders.

Title: Inhibition of glutamine synthetase in the prelimbic cortex with methionine sulfoximine during sustained attention: Possible compensatory mechanisms?

Authors: *A. D. CASCONE[1], S. ZHANG[1], W. XIE[1], E. KHARITONOVA[1], M. LEONG[1], L. A. NEWMAN[2];

Abstract: Healthy astrocytes are known to recycle glutamate and GABA, the major excitatory and inhibitory neurotransmitters, from synapses. Glutamine synthetase (GS) in astrocytes is responsible for the synthesis of glutamine from glutamate and the transportation of glutamine into neuron, where it is resynthesized into glutamate or GABA. The present study examined the importance of glutamate recycling mediated by GS in a sustained attention task (SAT). The task evaluated sustained attention performance in Long-Evans rats utilizing light signals of varying length (500ms, 100ms, 25ms), non-signal trials, and a variable intertrial interval. After the subjects reached criterion performance, they underwent bilateral prelimbic cortex cannulae implantation which accommodates microinjections of methionine sulfoximine (MSO). Since MSO is an irreversible inhibitor of GS and the enzyme must be replaced after inhibition, we collected data for a week after injection to assess the recovery from MSO. We also waited for recovery of criterion performance before giving a new injection. After recovering from surgery and reaching criterion performance, each subject received 0.5 µL of 10mM, 2mM, or 0.4mM of MSO or the vehicle, 0.9% saline, in a counterbalanced order 15 minutes prior to the SAT. We hypothesized that there would be a dose-dependent effect of MSO on SAT performance, with the greatest performance decline occurring after 10mM injection, a milder decline after 2mM injection, and a slight improvement after 0.4mM injection. Repeated-measures ANOVAs did not reveal any significant dose-dependent effects of MSO on SAT performance. However, analysis of the first exposure to MSO suggested a significant effect of initial MSO exposure on SAT performance. For the 500ms signal trials, subjects who have previously been exposed to MSO performed significantly better on SAT than those who are naïve to MSO, regardless of injection dosage. This finding suggests compensatory mechanism(s) in response to MSO administration. Future studies will examine the initial effect of MSO exposure on SAT performance and compensatory mechanisms, such as overproduction of GS after inhibition with MSO.

Title: Effects of medial prefrontal cortical administration of the orexin-1 receptor antagonist, SB-334867, on attentional performance in rats

Authors: *J. A. BURK[1], R. PATEL[1], E. MANESS[1], S. BLUMENTHAL[1], J. R. FADEL[2]; [1]William and Mary, Williamsburg, VA; [2]Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: Orexin neurons project from the lateral hypothalamus to numerous brain regions where orexin receptors (Ox1R and Ox2R) reside. The medial prefrontal cortex (mPFC), specifically, is important for executive attention, allowing for the processing of different sources of information. Since the mPFC is dense with both orexin-1 and orexin-2 receptors (Ox1R, Ox2R), orexin may play a key regulatory role in mPFC-mediated attention. Male Fischer Brown Norway F1 (FBNF1) hybrid rats were used in this experiment. Each rat received 6 infusions total—two mock saline infusions and four drug doses (vehicle, 0.25ug/uL, 0.5ug/uL, 1ug/uL). To avoid confounding effects, the order of drug dose administration was random and each infusion was at least 48-hrs apart. After infusing the drug into the left or right mPFC, the rats were tested on a modified attention task, where a distracter (flashing houselight) was presented. We observed trends for improvement in post-distracter performance, when the lowest dose (0.25ug/uL) was administered to the right mPFC. Also, accuracy on non-signal trials following the distracter task improved when the lowest dose (0.25ug/uL) was administered to either hemisphere of the mPFC. These results indicate that orexin-1 receptors in the medial prefrontal cortex contribute importantly to attentional performance.

Title: Dissociable attentional effects of dopaminergic and cholinergic lesions to the anterior cingulate cortex

Authors: *M. K. CLEMENT, C. S. PIMENTEL, J. A. SWAINE, A. J. PIMENTEL, D. HUTCHINS, J. A. MCGAUGHY;
Psychology, Univ. of New Hampshire, Durham, NH

Abstract: Prior work from our lab has shown that excitotoxic lesions to the anterior cingulate cortex (ACC) impairs the ability of rats to filter certain types of distracting stimuli (Newman and McGaughy 2011). Specifically, rats with lesions of the ACC cannot filter distractors that have been made salient through pairing with reinforcement. In contrast, these same subjects can filter distracting stimuli that have not been predictive of reward. The present study investigates the effects of neuromodulator specific lesions of the same region to determine how specific neuromodulators contribute to the attentional function of ACC. Cholinergic or dopaminergic deafferentation of the ACC was achieved using either 192 IgG saporin (n=10) or dopamine transporter saporin (n=10). Lesions were restricted to the rostral portion of the area and did not spread to nearby prefrontal sub-regions e.g prelimbic cortex. After lesioning, subjects were tested in an attentional set-shifting task (Birrell and Brown 2000). While both cholinergic and dopaminergic lesions increased distractibility, these deficits were not as severe as those produced after excitotoxic lesions (n= 8). In contrast to excitotoxic lesions, both cholinergic and dopaminergic lesions also impeded formation of an attentional set. Because dopaminergic lesions produced impairments in many stages of the tasks, we hypothesized that these subjects had a more general impairment in stimulus processing. In order to address these broader processing impairments, we analyzed the data to determine whether lesioned rats showed more sensitivity to novel stimuli, or made more perseverative errors. The implications of these data for understanding the unique contributions of acetylcholine and dopamine to attentional processing in the ACC will be discussed.

Title: The effects of lesions to anterior cingulate cortex or mid-cingulate cortex on distractibility in rats

Authors: M. K. CLEMENT, C. S. PIMENTEL, ***J. A. MCGAUGHY**;
Univ. of New Hampshire, Durham, NH

Abstract: Dysfunction in the anterior cingulate cortex (ACC) has been linked to cognitive impairments in many neuropsychiatric disorders including but not limited to depression, schizophrenia and addiction. Studies in humans, non-human primates and rats have shown this region is critical to many aspects of attention including ignoring salient distractors and conflict monitoring. Unfortunately, many brain imaging studies define the ACC broadly confounding the function of ACC and the more posterior portion of the gyrus, the mid-cingulate cortex (MCC). This failure to maintain consistent anatomical boundaries has impeded progress in understanding the function of both regions. Recent advances in the cross-species definitions of the both the ACC and MCC by Vogt and Paxinos (2014) provides an important foundation to begin to explore the function of these regions using rodents. The present study used Long-Evans rats to compare the function of the ACC (n =8) and MCC (n= 6) in an attentional set-shifting task (Birrell and Brown 2000). Lesions to the ACC, but not the MCC, increased distractibility to salient distractors previously predictive of reinforcement. The dissociable effects of MCC and ACC lesions will be discussed in the context of connectivity differences between the two regions. Moreover the implications for translational neuroscience of functional distinctions along the rostro-caudal gradient of the cingulate cortex in rats will be discussed.

Title: Silencing of striatal cholinergic interneurons disrupts attentional-motor interactions

Authors: *C. AVILA[1], A. J. KUCINSKI[2], M. SARTER[1];
[2]Psychology, [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Falls in patients with Parkinson's disease (PD) are associated with loss of basal forebrain (BF) cholinergic neurons and thought to reflect impairments in the attentional supervision of slow and low-vigor movement, the latter resulting from striatal dopamine (DA) loss. We previously established a rat model of PD falls which reproduce the combined cholinergic-dopaminergic losses seen in patients (dual, DL rats), and which exhibit a high propensity for falls during the traversal of dynamic surfaces (Michigan Complex Motor Control Task; MCMCT). Moreover, similar to PD fallers, these rats were impaired in executing cue-triggered turns, but not cue-triggered stops, while walking on a treadmill (Cue Triggered Turning Task; CTTT). Collectively, these results have suggested that BF cholinergic loss deprives the striatum of information about extero- and interoceptive movement cues, including stepping errors. Loss of such information interacts with impaired striatal movement sequencing and selection to produce falls and impaired cued turning behavior. In the striatum, cholinergic interneurons (ChIs) are positioned to integrate cortical and thalamic afferent information about movement cues with the dopaminergic mediation of action selection and sequencing. We therefore predicted that silencing these interneurons, specifically in the dorsomedial, striatum, is sufficient to reproduce high fall rates and cued turning impairments seen in DL rats. Cre-recombinase-dependent AAV expressing the inhibitory M4-type DREADD receptor, or an m-Cherry expressing control construct, was bilaterally infused into the striatum. Following surgeries, rats first underwent MCMCT testing, consisting of a total of 48 traversals of the rotating rods. In rats expressing the inhibitory DREADD, CNO (5.0 mg/kg) nearly completely reproduced the fall rates seen previously in DL rats. Rats then underwent 14 days (20 trials per day) of testing on the CTTT. CNO reduced the rate of cue-evoked turns but had no effects on cue-evoked stops, again mirroring effects found in DL rats. Additional tests confirmed that administration of CNO neither disrupted the animals' ability to turn *per se* nor induced a preferred turning direction. These results support the hypothesis that striatal ChIs mediate the integration of external and proprioceptive cues into complex movement sequences such as those required to traverse complex surfaces or turning. Furthermore, restoring ChI function in PD

fallers may be a useful therapeutic target to reduce falls and complex movement deficits in PD patients.

Title: Reduced choline clearance *in vivo* in mice expressing a choline transporter subcapacity variant associated with low attentional control in humans

Authors: *E. DONOVAN[1], C. AVILA[1], V. V. PARIKH[3], A. ANTCLIFF[2], R. D. BLAKELY[4], M. SARTER[5];
[2]Dept. of Psychology, [1]Univ. of Michigan, Ann Arbor, MI; [3]Psychology & Neurosci., Temple Univ., Philadelphia, PA; [4]Biomed. Sci., Florida Atlantic Univ. - Charles E Schmidt Co, Jupiter, FL; [5]Psychol, Univ. of Michigan Dept. of Psychology, Ann Arbor, MI

Abstract: Cholinergic signaling in cortex mediates the detection of cues in attention-demanding contexts. Spontaneous, genetically-imposed or degeneration-induced loss of cholinergic function in humans and rodents reliably results in detection deficits and associated impairments in attentional control, including distractor vulnerability. The high-affinity choline transporter (CHT) is an essential step regulating the capacity of cholinergic terminals to synthesize and release acetylcholine. We previously demonstrated that humans who express a subcapacity CHT variant (rs1013940 of SLC5A7; I89V) exhibit increased distractor vulnerability and attenuated right frontal activation during performance. When expressed in COS-7cells, this variant reduced choline clearance by about 50% (Okuda et al., 2002). Mice encoding an Ile89Val substitution were generated using CRISPR/Cas9 methods and continued to be backcrossed onto C57BL/6 female. Because synaptosomal choline uptake assays unexpectedly failed to reveal the impact of this variant, experiments were designed to generate presumably more sensitive, high-temporal resolution measures of choline clearance *in vivo*. Choline oxidase was immobilized on the surface of Platinum electrodes fabricated onto ceramic backbones (Quanteon), inserted into the cortex of anesthetized mice, and choline currents were measured amperometrically (+0.7 V vs. an Ag/AgCl reference). To determine the capacity for choline clearance, pressure ejections of 5.0 mM choline, via glass micropipettes with tips positioned between choline-sensitive and control electrodes. We previously demonstrated that the time required for the choline current to decline between 40-80% of peak amplitude ($T_{40\text{-}80}$) is significantly lengthened in the presence of hemicholinium-3 (HC-3) and thus indicative of CHT capacity (Parikh et al. 2006). Consistent with previous data, $T_{40\text{-}80}$ in wild type mice was 1.3 s. In contrast, in heterozygous I89V mice,

such clearance required 2-fold more time (2.2 s). Additionally, T_{40-80} choline clearance was robustly slower in homozygous I89V mice compared to wild-types (6.2 s). Ongoing experiments determine choline clearance in the presence of HC-3, the capacity for ACh release evoked by trains of depolarizing stimuli, and the subcellular distribution of CHTs. Moreover, the attentional capacities of I89V mice will be determined. This evidence forms the basis for I89V mice as a model to determine the neurobiological mechanisms via which such CHT variants produce phenotypes in healthy humans, and increased risk for traumatic brain injury and a range of psychiatric and neurodegenerative disorders.

Title: Behavioral and neural evidence for inhibition of return in barn owls (tyto alba)

Authors: *T. LEV-ARI[1], Y. ZAHAR[2], A. AGARWAL[2], Y. GUTFREUND[3];
[1]Neurosci., Technion - Israel Inst. of Technol., Haifa, Israel; [2]Neurosci., Technion, Haifa, Israel; [3]Neurosci., The Technion, Haifa, Israel

Abstract: Inhibition of return (IOR) is the reduction of detection speed and/or detection accuracy of a target that is in a previously attended location. This phenomenon, discovered and studied thoroughly in humans, is believed to reflect a brain mechanism to control the allocation of spatial attention in a manner that enhances efficient search. Findings that IOR is robust, apparent at a very early age and seems to be dependent on midbrain activity suggest that IOR is a universal attentional mechanism in vertebrates. However, studies in non-mammalians species are lacking. To comparatively explore this hypothesis we tested for IOR in barn owls using the classical Posner cueing paradigm. Two barn owls were trained to initiate a trial by fixating on a fixation point at the center of a computer screen and then turn their gaze to the location of a target when it appears. In all experimental trials a short, non-informative cue appeared before the target, with a cue to target onset asynchrony (CTOA) varying from 66 to 633ms. The cue was either at a location predicting the target (valid) or in a location not-predicting the target (in-valid). Using infrared reflectors tracking system (OptiTrack) we measured the owl's gaze position on screen throughout the trial. The barn owls response times (RT) to the valid targets compared to the in-valid targets shifted from facilitation (lower RTs) to inhibition (higher RTs)

when increasing the CTOA. In one owl the shift to inhibition occurred at a CTOA of 433ms and in the second at a CTOA of 633ms. To facilitate comparison with humans we measured in 15 human subjects the RTs when performing the same task. Results were comparable between humans and owls. In addition, we recorded multiunit responses in the optic tectum (OT) of head-fixed owls, passively viewing a similar cueing paradigm as in the behavioral experiments. At short CTOAs (<250ms) neural responses to the target in the receptive field (RF) were usually enhanced if the cue appeared earlier in the RF (valid) and suppressed if the cue appeared outside the RF (in-valid). This was reversed at longer CTOAs where neural responses were suppressed in the valid conditions and enhanced in the in-valid conditions. Thus, our results support the notion that IOR is a basic mechanism in the evolution of vertebrate behavior and suggest that the effect appears as a result of interaction between lateral and forward inhibition in the tectal circuitry.

Title: Comparative animal consciousness is multimodal and nonbinary

Authors: *L. N. IRWIN;
Biol. Sci., Univ. of Texas At El Paso, El Paso, TX

Abstract: Speculations about the capacity for consciousness in different animals is usually expressed as a binary possibility – either it exists or it doesn't. And among those animals in which it is presumed to exist, consideration is seldom given to varying degrees or alternative modes of consciousness. I agree with the likelihood that consciousness has deep evolutionary origins, but assume with most behavioral scientists and philosophers that different species experience it in radically different ways. As an exploratory attempt to construct a taxonomy of modes of consciousness, I propose that it can be studied through proxy behaviors that fall into four categories: Attentive (A), Intentional (I), Interactional (X), and Reflexive (R). Type A behavior is composed of sedentary awareness of surroundings and alertness to exteroceptive input. Type I behavior consists of goal-directed action. Type X behavior requires interaction with other conspecific or allospecific individuals. Type R behavior is activity in which the animal attends to or acts upon its own body, generally with a greater focus on interoceptive input. To test the feasibility of this taxonomy, a variety of vertebrates and invertebrate were observed in 10-20 minute segments in a non-intrusive manner under natural or semi-natural (e.g. zoo and aquarium) conditions. The average percent of total observational time each animal devoted to

each of the four proxy behaviors was tabulated (summing to more than 100% since modes frequently overlapped). In some species, Type A behavior predominated, such as the sea urchin (100% A, 0% I, X, or R) and komodo dragon (100% A, 30% I, 0% X, 5% R). In others, behavior I was most frequent, as displayed by both humans (83% I, 12% A, 60% X, 5% R) and the seahorse (100% I, 25% A, 19% X, 25% R). A tendency toward substantial interactive behavior, Type X, was seen in humans (83% I, 12% A, 60% X, 5% R) and octopi (60% X, 70% A, 40% I, 0% R). While reflexive behaviors, Type R, were displayed by nearly all observed animals, it was never the highest frequency activity. To the extent that these proxy behaviors reflect different modes of consciousness, these results illustrate that they are differentially invoked, without strict phylogenetic correlation, according to the specific lifestyle and ecological niche requirements of each species. A taxonomy such as this, if expanded to include measures of behavioral variety and complexity, and brain metrics associated with cognitive capacity such as brain size and number of neurons, could advance the study of comparative animal consciousness to a more nuanced, detailed, and objective level.

Title: D1 and D2 medium spiny neurons in the nucleus accumbens bi-directionally modulate attentional control behavior of mice

Authors: *M. T. PISANSKY, D. W. LEIPOLD, P. E. ROTHWELL;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Attention is a critical cognitive capacity for organizing and directing motivated behavior. Deficits in attentional control epitomize several neuropsychiatric disorders, including schizophrenia and attention-deficit/hyperactivity disorder (ADHD). Prior research (e.g., Pezze et al., Neuropsychopharmacology, 2007) suggest dopamine signaling in the nucleus accumbens (NAc) modulates attentional performance. Here, we examined the primary cell types of the NAc - D1- or D2-receptor-expressing medium spiny neurons (MSNs) - in attentional control using male and female D1-Cre or A2a-Cre transgenic mice, respectively. Mice were trained on the

five-choice serial reaction time (5-CSRT) task, in which an operant response is withheld until it can be directed to one of five locations indicated by a brief visual cue. We first expressed the Gi-coupled hM4D DREADD in D1- or D2-MSNs, and found that chemogenetic inhibition of D1-MSN activity reduced attention, whereas chemogenetic inhibition of D2-MSN activity enhanced attention. To monitor the activity of these two cell types in real time during 5-CSRT behavioral performance, we are currently using fiber photometry to image spectrally distinct red and green calcium indicators expressed in D1- and D2-MSNs. Preliminary results suggest D1-MSN activity increases on correct trials, whereas D2-MSN activity does not change. These findings highlight a role of NAc microcircuitry in attention and identify cell-type specific targets for treating related impairments in neuropsychiatric disorders.

Title: Effects of attention on Granger causal interactions between cortical layers and cortical areas V1 and V4

Authors: *D. FERRO[1,2], J. VAN KEMPEN[3], M. BOYD[3], S. PANZERI[1], A. THIELE[3];
[1]Neural Computation Laboratory, Ctr. for Neurosci. and Cognitive Systems at Unitn, Inst. Italiano di Tecnologia, Rovereto, Italy; [2]Ctr. for Mind/Brain Sci. (CIMeC), Univ. of Trento, Rovereto, Italy; [3]Inst. of Neurosci., Newcastle Univ., Newcastle upon Tyne, United Kingdom

Abstract: Visual attention improves sensory processing as well as perceptual readout and behavior. How attention shapes interactions between cortical layers within and between sensory areas is poorly understood [1-3].
To investigate this we trained macaque monkeys on a covert feature based spatial attention task, and recorded simultaneously from laminar electrodes in areas V1 and V4 (16 contacts, 150 μm inter-contact spacing). Electrodes were inserted normal to the cortical surface. Receptive Fields (RFs) between V1 and V4 were overlapping. Channel alignment relative to layer 4 was based on current source density and latency analysis.
For all analyses the LFP was locally re-referenced (bipolar LFP) offline. Spectral power in different frequency bands showed relatively small differences along cortical depths (V1 and V4). For V1 LFPs, attention to the RFs resulted in a shift of the low-gamma (~30-50Hz) spectral power peak towards higher frequencies (2-4Hz shift). For V4 LFPs attention to the RFs caused a

decrease in power for frequencies <20Hz and a broad band increase for frequencies >20Hz. Attention affected spectral coherence within V1 and within V4 layers similarly to the spectral power modulation reported above. Spectral coherence across V1 and V4 pairs was increased by attention in beta band (~15-30Hz) and the low-gamma range (30-50Hz).
Attention affected Granger causal interactions (GCI) in a layer and frequency dependent manner in complex ways. These often failed to follow predictions made by feed-forward and feedback models [1,4]. Within V1, attention increased feed-forward efficacy across different frequency bands (2-50 Hz). Within V4, attention mostly increased GCIs in the low and high gamma frequency in a 'downwards' direction within the column, i.e. from supragranular to granular and to infragranular layers. Increases were also evident in an upward direction from granular to supragranular layers. The dominant changes in V1-V4 CGIs were an increase in the gamma frequency range from V1 granular and infragranular layers to V4 supragranular and granular layers, as well as an increase from V4 supragranular layers to all V1 layers.

Abstract: The attentional system (AttS) is important for the adequate survival and behavioral performance of species. Because of legislation changes, it has become a research interest to have a deeper understanding of the effects of cannabinoids (CBs) can have on the SNC. These substances bind to CB1 and CB2 receptors (Rs) of the endocannabinoid system. Studies have reported that the use of CBs can have a negative effect in the AttS. There is little known about the effect that agonism/antagonism selective to CB2 receptor has in the SNC and on the AttS. The aim of this exploratory study is to observe the effect CBs can have on a temporal bisection attentional task (TBAT) using selective agonists (Anandamide -AEA- and HU308) and antagonists (SR141716A and SR144528), as well as the effect of non-selective agonism (2AG) and antagonism (Co-adm) of CB1/CB2 cannabinoid Rs. Male adult wistar rats were trained in a TBAT using Skinner operant conditioning chambers. The TBAT has 2 phases: Training phase (TrP) and Testing phase (TsP). TrP: trials initiated presenting a tone of either 2s (short -S-) or 8s (long -L-), each of which associated to a specific lever. Correct responses resulted in reinforcer delivery. TsP: sessions included the previous two S and L sounds, and 5 probe duration values (2.52, 3.17, 4.00, 5.04, and 6.35s). TsP registers how many of the 5 probe durations the rat discriminates as a L/S stimulus. After 15 base-line TsP sessions, rats were injected i.p. with previously reported effective doses of either selective or non-selective agonist or antagonist. Rats were evaluated in TsP under influence of these substances for 3 consecutive sessions. Results include: performance in the TBAT (pTBAT), omission errors (OE), bisection point (BP) and Weber's Fraction (WF); they show that, when comparing to control group: experimental groups show tendency to reduce pTBAT, except antagonism selective to CB2, which shows a tendency to improve pTBAT and reduce OE; both AEA and non-selective antagonism significantly increase the number of OE. Both the BP and WF of experimental groups do not significantly differ when compared to the control group. These findings show that CBs have a behavioral effect in the AttS; of particular interest is the effect that agonism and antagonism selective to CB2 has on the AttS.

Title: Characterization of the nitric-oxide signaling cascades underlying short-term and long-term cellular correlates of feeding suppression induced by sensitization training in *aplysia*

Authors: *R. MOZZACHIODI, R. CHATTERJI, S. KHOURY, M. WAINWRIGHT;
Texas A&M Univ. Corpus Christi, Corpus Chrsiti, TX

Abstract: In the mollusk *Aplysia*, exposure to aversive stimuli not only causes a learned enhancement of defensive responses, known as sensitization, but also triggers a concurrent suppression of feeding. Similar to sensitization, feeding suppression can be expressed in the short-term (15 min) or in the long-term (24 h, Acheampong et al. 2012) timeframe, depending on the amount of training. Recent work in our lab revealed that nitric oxide (NO) is required for both short-term and long-term feeding suppression as well as for the underlying decreased excitability of feeding decision-making neuron B51, which is induced by *in vitro* sensitization training (Farruggella et al. 2019).

In this study, we began to characterize the downstream targets of NO modulation of B51 excitability triggered by *in vitro* sensitization training. Because a NO-cGMP pathway is functionally active in B51 and can downregulate its excitability (Goldner et al. 2018), we focused on the contributions of the soluble guanylyl cyclase (sGC) and protein kinase G (PKG) to B51 decreased excitability induced by *in vitro* training. Patterns of electrical shocks delivered simultaneously to pedal nerves P8 and P9 (10-s, 1 Hz, train of 10 500-ms, 60-Hz, 60-V impulses) were used as *in vitro* sensitizing stimuli. Because sGC and PKG activity may selectively contribute to distinct forms of plasticity, we employed single-trial (ST) and four-trial (FT) *in vitro* training protocols, which induce short-term and long-term B51 decreased excitability, respectively (Weisz et al. 2017). B51 excitability was measured prior to and 15 min after ST *in vitro* training, and prior to and 24 h after FT *in vitro* training. The following inhibitors were applied in the recording chamber prior to *in vitro* training: ODQ to block sGC (final concentration: 25 μM in 0.1% DMSO) and KT5823 to block PKG (final concentration: 2 μM in 0.1% DMSO).

ODQ and KT5823 both prevented the long-term B51 decreased excitability. This result indicates that sGC and PKG are necessary for the induction of long-term B51 decreased excitability, thus implicating the recruitment of a NO-cGMP-PKG pathway by FT *in vitro* training. Conversely, ODQ and KT5823 partially blocked the short-term B51 decreased excitability, indicating that sGC and PKG contribute only marginally to short-term plasticity in B51. This finding suggests that NO-mediated mechanisms independent from cGMP are recruited by ST *in vitro* training. Overall, these results indicate that although NO is necessary for training-induced plasticity in B51, distinct downstream cascades are activated in short-term and long-term decreased excitability.

Title: Characterization of the cellular mechanisms underlying memory impairment caused by food deprivation in an invertebrate model

Authors: *X. DENG, R. MOZZACHIODI;
Life Sci., Texas A&M University-Corpus Christi, Corpus Christi, TX

Abstract: Malnutrition can cause severe consequences to brain functions include memory deficits. Using the marine mollusk *Aplysia* as animal model, the mechanisms of an aversive form of learning known as sensitization have been extensively investigated (Kandel 2001). In normally-fed *Aplysia* (i.e., animals fed every two days, 2DFD), strong electrical shocks to the body wall, which mimic the attack of a predator, increase defensive responses, including the tail-induced siphon withdrawal reflex (TSWR). Such stimuli also reduce a non-defensive response, feeding (Acheampong et al. 2012). Sensitization and feeding suppression are concurrently expressed in *Aplysia*. The co-expression of sensitization and feeding suppression is disrupted by fourteen days of food deprivation (14DFD; Mac Leod et al. 2018). Under 14DFD, *Aplysia* completely lack sensitization (Mac Leod et al. 2018). In 14DFD animals, feeding suppression is maintained, but the amount of suppression is attenuated compared to 2DFD animals (Mac Leod et al. 2018). This project aimed to investigate the cellular mechanisms underlying the memory deficits caused by 14DFD. An *in vitro* analog was used to study sensitization and feeding suppression at the cellular level (Weisz et al. 2017). Sensitization training can be mimicked *in vitro* by electrical stimulation of afferent nerves from the body wall (Weisz et al. 2017). Correlates of sensitization and feeding suppression include increased excitability of the tail sensory neurons (TSNs) in the TSWR neural circuit, and decreased excitability of the decision-maker neuron B51 in the feeding neural circuit, respectively (Weisz et al., 2017). TSN and B51 excitability was tested before and 15 min after *in vitro* sensitization training. Four groups of preparations were used: 2DFD with or without training, 14DFD with or without training. Under 14DFD, no difference was observed in the excitability of either TSNs or B51 between the trained and untrained groups. These data suggest that in the starved *Aplysia*, prevented sensitization at the behavioral level may result, at least in part, from the lack of increased TSN excitability at the cellular level. The discrepancy between the absence of decreased excitability in B51 at the cellular level and the presence of an albeit attenuated feeding suppression *in vivo* suggests that

the feeding suppression under 14DFD may be contributed by additional neurons. These results offer insights about the cellular mechanisms of memory deficits caused by food deprivation. Data obtained from *Aplysia* can be used as foundation to elucidate the mechanisms of malnutrition-induced memory deficits and ultimately be used in higher organisms.

Title: Complex interactions of PKA and MAPK pathways contribute to 5-HT-induced dynamics of RSK activation in *Aplysia* sensory neurons

Authors: *Y. ZHANG, R.-Y. LIU, L. J. CLEARY, J. H. BYRNE;
McGovern Med. Sch. of UTHSC at Houston, Houston, TX

Abstract: The protein kinase A (PKA) and mitogen-activated protein kinase (MAPK) pathways play critical roles in mediating serotonin (5-HT)-induced long-term synaptic facilitation (LTF) of the *Aplysia* sensorimotor synapse. To better understand the regulation of kinases by 5-HT, we examined the dynamics of three key elements of MAP kinase cascades: extracellular signal-regulated kinase (ERK), p38 mitogen-activated protein kinase (p38 MAPK) and 90 ribosomal S6 kinase (RSK) after 5-HT treatment, and investigated the interactions among these kinases. Biphasic regulation of p38 MAPK by a single pulse of 5 min 5-HT was reported in our previous study (Zhang et al. 2017). Here, we used immunofluorescence to examine the phosphorylation (i.e., activation) of RSK after one pulse of 5-HT applied to isolated sensory neurons in culture. We found that 5-HT also induced a complex pattern of changes in RSK activity. RSK phosphorylation increased immediately after treatment, returned to basal level at 15 min, followed by a delayed increase at about 45 min, and then a return to basal level at 60 min. RSK activation was blocked by U0126, an inhibitor of MEK, the kinase upstream of ERK, suggesting that *Aplysia* RSK is downstream of the Ras/MEK/ERK pathway (Liu et al. 2018). However, ERK activity did not increase until about 45 min after one pulse of 5-HT. This difference between ERK and RSK dynamics suggests that 5-HT might induce multiple pathways to activate RSK in *Aplysia*. A recent study indicates that a PKA-dependent feedback loop in *Aplysia* sensory neurons activates ERK (Jin et al. 2018). To investigate the role of the PKA pathway in activation of ERK/RSK after one pulse of 5 min 5-HT, we applied the PKA inhibitor KT5720 30 min before and during 5-HT treatment. KT5720 blocked the activation of ERK 45 min after

application of 5-HT. Moreover, it also blocked the activation of RSK immediately after 5-HT stimulation. At that time point, ERK activity still remained near the basal level, suggesting that the PKA pathway contributes to the immediate activation of RSK as well as to the delayed activation of ERK. We also found that BI-D1870, a specific inhibitor of RSK, blocked the activation of p38 MAPK 45 min after application of 5 min 5-HT, suggesting that the delayed activation of that kinase reported in Zhang et al. (2017) may be induced by the ERK/RSK pathway. These data begin to delineate the complex interactions between second messenger pathways after 5-HT treatment. Further study is needed to investigate how they contribute to the efficacy of training protocols to form LTF.

Title: Ribosomal S6 kinase is essential for long-term enhancement of excitability of sensory neurons of *Aplysia*

Authors: *R.-Y. LIU, Y. ZHANG, P. D. SMOLEN, L. CLEARY, J. H. BYRNE;
Dept. of Neurobio. and Anat., McGovern Med. Sch. of UTHSC At Houston, Houston, TX

Abstract: Analyses of long-term synaptic facilitation (LTF) of the monosynaptic connections between sensory neurons (SNs) and motor neurons (MNs) of *Aplysia* and long-term enhancement of neural excitability (LTEE) of SNs have provided key insights into cellular mechanisms of memory. Ribosomal S6 kinase (RSKs) are a family of serine-threonine kinases that are activated by mitogen-activated protein kinase (MAPK) and consequently activate cAMP response element-binding protein (CREB). Our recent studies in *Aplysia* (Liu et al., 2018) reveal roles for the MAPK isoform ERK, and RSK, in the activation of CREB1 and the induction of LTF. In addition, inhibition of RSK expression or its activation significantly reduced LTF, and these impairments were rescued by the Enhanced protocol, a computationally designed protocol with stimuli irregularly spaced in time. This protocol was previously shown to augment normal LTF and long-term memory (LTM) (Zhang et al. 2012). These results illustrate a previously underappreciated role for RSK as a CREB1 kinase and thus as a factor in long-term synaptic plasticity in *Aplysia*. Another cellular correlate of LTM is modulation of the intrinsic excitability of presynaptic neurons. The role of RSK in this form of plasticity has not yet been examined. Therefore, we applied an inhibitor of RSK, BI-D1870 (BID), expecting it to inhibit LTEE. LTEE

was induced by a Standard protocol of regularly spaced 5-HT applications (S). Excitability was examined in four groups: 1) Vehicle (Veh), 2) S alone, 3) BID alone, and 4) BID + S. One-way ANOVA followed by post-hoc comparisons revealed that 5-HT treatment produced a significant increase in the number of stimulus-evoked action potentials at 24 h post-treatment, as compared to Veh, or BID alone. LTEE induced by BID+S group was significantly less than that induced by S group, suggesting that inhibition of RSK impaired LTEE. Next, we examined whether the Enhanced protocol could rescue the LTEE impairment. Four groups were used: 1) S, 2) BID + S, 3) E (Enhanced protocol), and 4) BID + E. One-way ANOVA revealed a significant interaction between groups at 24 h post-treatment. Post-hoc comparisons revealed that LTEE induced by E was significantly greater than that induced by S. LTEE in the BID + E group was significantly greater than in the BID + S group and significantly greater than in the S group. These results indicate that the Enhanced protocol rescued the BID-induced impairment in LTEE. In summary, our results suggest that *Aplysia* RSK is required for both LTEE and LTF. The computationally designed Enhanced protocol not only improves normal LTF and LTEE, but also rescues deficits in LTF and LTEE induced by impaired RSK signaling.

Title: Transcriptional changes fade prior to long-term memory in sensitization of the *Aplysia* siphon-withdrawal response

Authors: T. ROSILES, M. NGUYEN, I. E. CALIN-JAGEMAN, *R. CALIN-JAGEMAN; Neurosci., Dominican Univ., River Forest, IL

Abstract: Forming a long-term memory requires changes in neuronal transcription. What happens, though, as the memory is forgotten? And how does the transcriptional state relate to the maintenance and recall of the long-term memory? To answer these questions we have been systematically tracing the time-course of transcriptional changes evoked by long-term sensitization in the marine mollusk *Aplysia californica*. Our approach captures transcriptional changes in neurons of known behavioral relevance using a within-subjects design, delineating patterns of transcriptional change that are comprehensive and reproducible. We have previously reported that within 24 hours of long-term sensitization training there is a widespread

transcriptional response involving robust changes in over 5% of tested transcripts (about 1,200 of ~22k; Conte, 2017). Within 1 week, however, memory strength fades and nearly all transcriptional changes relapse to baseline (Perez, 2018). Here we report microarray analysis (N = 16) of transcriptional changes 5 days post-learning, a time-point when memory strength has weakened but is still robust. Remarkably, we find that at this intermediate behavioral stage nearly all transcriptional changes have already fully decayed. Thus, most transcriptional changes seem to decay more rapidly than memory expression. This suggests either a) that there is considerable time-lag between transcriptional and behavioral changes (perhaps due to the persistence of translated proteins) or b) that the transcriptional changes evoked after learning are not required for all phases of memory maintenance.

Title: A trial-by-trial associative-learning paradigm is modulated by biogenic amines and can result in trace-conditioning in C. elegans

Authors: E. LEE[1], H. R. HORVITZ[2];
[1]Brain and Cognitive Sci. / Biol., [2]Biol., MIT, Cambridge, MA

Abstract: Associative learning allows animals to adapt to multiple environmental stimuli that occur proximally in space and time. How molecular and cellular interactions control the formation, maintenance and degradation of learned memories in precise spatiotemporal terms under various contexts remains under active investigation. The nematode *C. elegans* can be trained to associate multiple cues and exhibit learned locomotor responses. Comprehensive genetic and cellular manipulation tools and a deep understanding of its neural circuits allow a single-cell level resolution of analysis to be applied to *C. elegans* learning and memory. Short wavelength light is an aversive stimulus that triggers an escape response by *C. elegans* and also causes worms to stop feeding. We have developed a novel trial-by-trial conditioning paradigm for *C. elegans* that utilizes the pairing of a noxious light stimulus and a neutral odor stimulus. After training, worms not only learned to reverse to the once-neutral smell but also learned to stop feeding - a new learned response that has not been previously described. As

neuromodulators are crucial factors in learning and memory processes, we conducted a screen of neuromodulator mutants. Mutants defective in dopamine and octopamine exhibited defects in learning efficiencies. Strikingly, mutants defective in serotonin learned faster and more consistently than wild-type worms. An animal's physiological state could also influence its learning capabilities. For example, worms that were food-deprived for varying amounts of time had a U-shaped curve of learning efficacy. Additionally, serotonin-defective worms that were food-deprived had an altered learning efficacy curve compared to wild-type worms. Finally, temporal order and contiguity of stimuli presentation is a key feature of associative learning. Worms were even able to learn associations in a trace-conditioning procedure in which the light and odor stimuli presentation was separated in time. By studying how temporal variables in learning and physiological states of an animal are modulated and interact with each other at a single-cell level resolution of analysis, we hope to gain a detailed understanding of the molecular, cellular and circuit mechanisms that underlie learning behavior.

Title: Learning-induced switch in a sensory response that anticipates changes in behavioural outcomes

Authors: *P. R. BENJAMIN, Z. PIRGER, Z. LÁSZLÓ, G. KEMENES, I. KEMENES; Neurosci., Univ. Sussex, Brighton, United Kingdom

Abstract: The decision to respond to a sensory stimulus depends on variables such as prior experience. For instance, aversive learning may lead to a change in the anticipated outcomes that reverse the behavioural response to a stimulus. However, the neuronal mechanisms of how this type of learning can alter the decision to perform a certain behaviour is much less understood. We use the model system of *Lymnaea stagnalis* to address the question of how anticipated aversive outcomes can alter the behavioral response to a previously effective feeding stimulus. We found that applying an aversive conditioning paradigm reverses the decision so that the same stimulus inhibits feeding, rather than activating it. By pairing a food stimulus, the CS (conditioned stimulus), with touch, an aversive US (unconditioned stimulus), the feeding stimulatory response to sucrose was reversed to an inhibition of feeding. Key to the understanding of the neural mechanism underlying the switch in the behavioural response is the

PlB (pleural buccal) extrinsic interneuron of the feeding network whose modulatory effects on the feeding circuit inhibit feeding. PlB is excited by touch to reverse the effects of sucrose on the feeding response. Aversive associative learning induces a persistent change in the electrical properties of PlB that is both sufficient and necessary for the switch in the behavioural output.

Title: CRISPRCas9 based genome editing of the FOXP locus in *Drosophila melanogaster*

Authors: *O. PALAZZO[1], B. BREMBS[2], A. EHWEINER[1];
[1]Inst. für Zoologie - Neurogenetik, [2]Univ. Regensburg, Regensburg, Germany

Abstract: The human FOXP2 (Forkhead Box P2) gene has been identified as a key component for the development of language. Such vocal learning is a form of motor learning that proceeds slowly from babbling in toddlers (or subsong in songbirds) towards speech and language in adults (or crystallized song in birds). This particular motor learning process can be conceptualized as operant self-learning, in which the organism learns the correct actions only by evaluating the outcomes of its previous behavior, in the absence of other sensory cues beyond the feedback. In the fruit fly *Drosophila*, the *dFoxP* orthologue has been shown to also be involved in operant self-learning of yaw torque (attempted rotations around the vertical body axis) in tethered flies, an experiment conceptually analogous to vocal learning. The expression, function and mechanisms of action of *dFoxP* remain to be elucidated. In this work, we generated three transgenic lines using the CRISPR/Cas9 technique: a conditional knockout, an isoform-b-specific GAL4 knock-in and a LexA knock-in that targets all three known isoforms. The GAL4 knock-in confirmed previous results of FoxP expression in neurons, but not in Glia. Moreover, strong expression was found in the protocerebral bridge, saddle, vest and superior medial protocerebrum. Interestingly, the mushroom bodies were not labeled by this technique. Antibody stainings and the LexA knock-in revealed a much broader FoxP expression with only ~40% of FoxP neurons expressing isoform b. The conditional knock-down lines yielded weaker behavioral phenotypes in a locomotor experiment (Buridan's paradigm) when the gene was knocked-out in the adult stages compared to knock-out throughout development, confirming the

developmental role of the transcription factor. The three lines were also used in different knock-out and silencing strategies and tested for operant self-learning at the torque meter.

Title: Bitter taste drives pain relief place learning in *drosophila melanogaster*

Authors: N. MEDA[1], G. FRIGHETTO[2], *A. MEGIGHIAN[1], M. A. ZORDAN[3];
[1]Dep of Biomed. Sci. and Padova Neurosci. Ctr., [2]Dep of Gen. Psychology, [3]Dep of Biol. and Padova Neurosci. Ctr., Univ. of Padova, Padova, Italy

Abstract: Place learning is an adaptive behavior which animals use to locate salient stimuli in space. If such stimuli are life-threatening or detrimental, pain-relief is a type of learning used to assess whether a certain action can weaken or abolish noxious stimuli. In analogy to Morris' water-maze and Ofstad's heat-maze, we show how optogenetically-induced bitter-sensing neurons activation urges *Drosophila melanogaster* to find a safe zone free of any bitter taste stimulation.
Adult fruit fly males (8-10 days) expressing, via Gal4/UAS system blue-light sensitive ChannelRhodopsin2 (ChR2) in bitter-sensing neurons were tested in a plexiglass arena encircled by led panels displaying Buridan's paradigm visual stimuli. Eight pc controlled blue-emitting leds, were used to activate ChR2 according to fly position in the arena. An infrared camera online tracked fly movements at 11 fps.
The first experimental step consisted in a training session of 16, 3', trials. During odd trials (trial 1,3,…,15), the fly could find relief from the bitter taste close only one of the two identical Buridan's stripes; during even trials the safe zone was moved to the opposed stripe.
A probe session, without any safe zones, followed immediately the training session.
Single-blind bayesian analysis evidenced that flies perceived bitter taste as a punishing stimulus, and were able to search for a safe zone alternatively between two identical visual markers to relieve the unpleasant stimulation. As our work suggests, optogenetics can be used to assess the behavioural response of an experimental model to a precise and specific sensitive stimulation.

Title: The appetitive long term memory reacts differently to extinction wihtin a narrow time window

Authors: *L. L. WANG[1], Q. YANG[1], B. LU[2], Q. LI[1];
[1]Tsinghua Univ., Beijing City, China; [2]Inst. of Botany, the Chinese Acad. of Sci., Beijing City, China

Abstract: Extinction is widely used as the basis of exposure therapy to treat some psychiatric disorders while the risk of relapse of the enduring traumatic memories after extinction perplexes scientists a lot. Extinction given during the relatively labile period of memory seems attenuate it for a longer time but the exact mechanisms still need to be elucidated. To enhance the extinction effect for the translational purpose, study the molecular and cellular mechanisms of how and how can not the recovery happens is of great importance. Drosophila has been proven to be a powerful genetic model to study neural mechanisms of learning and memory. Here we find different periods of drosophila LTM show different reactions to extinction; extinction given at the late stage of LTM can spontaneously recover with the time decay while the same extinction paradigm given at the early stage of LTM shows no spontaneous recovery. Thus we provide a simpler and operable model to study the spontaneous recovery of extinction. The different reactions of different periods of LTM to extinction indicate a narrow dynamic window of the consolidated *Drosophila* LTM. Further studies about the mechanisms of how extinction recovers and why the early stage LTM shows no recovery may help us find better ways to enhance the extinction effect and make good contributions to the treatment of maladaptive behaviors.

Title: Single-cell RNA-seq identifies differential expression in response to memory formation in *Drosophila*

Authors: *M.-F. M. SHIH[1], T. HIGE[3], G. C. TURNER[4], J. T. DUBNAU[2];
[1]Anesthesiol., [2]Anesthesiology, Neurobio. and Behavior, Stony Brook Sch. of Med., Stony Brook, NY; [3]Biology/Cell Biol. and Physiol., Univ. of North Carolina, Chapel Hill, NC; [4]Janelia Res. Campus, Ashburn, VA

Abstract: Abstract
Drosophila melanogaster is a favorable animal model for neuroscience studies because of (1) relatively simpler circuits orchestrating complex behaviors and (2) powerful genetic tools to characterize and manipulate gene expression and neural activity at high spatiotemporal resolution. A wealth of functional information about circuits-to-behavior has paved the way for single-cell RNA sequencing (scRNA-seq) technologies to identify differential expression within functionally characterized neuronal cell types, in response to different internal states and behavioral manipulations. Here, we established a fly scRNA-seq pipeline by adapting the design of whole-cell in vivo patch-clamping to physically remove single, identified neuronal cell somata, followed by CEL-Seq library preparation. Using this pipeline, we have acquired high-quality transcriptome profiles of 31 dorsal medial paired (DPM) neurons from female adult flies subjected to different olfactory memory training protocols. With this method, we achieve a median detected gene count of 8205 per DPM neuron. The scRNA-seq signal for DPM marker genes, including the reporter *GFP* and the neuronal marker gene *elav*, is strong, while the glial marker gene *repo* is barely detectable. Expression analysis at baseline identified multiple DPM expressed transcripts, and analysis of the effects of behavioral training identified dozens of up- or down-regulated genes. We have made use of the arsenal of genetic tools in *Drosophila*, to perform subsequent manipulations of gene function with this cell type. This provides the means to functionally validate our findings from scRNA-seq. Our results establish proof of concept for a scRNA-seq pipeline to profile gene expression changes after behavioral training in each of the cell types that participate in memory formation and storage in this olfactory task.

Title: Aversive training induces both pre and postsynaptic suppression in *Drosophila*

Authors: *X. ZHANG, N. NOYES, R. L. DAVIS;
Neurosci., Scripps Res., Jupiter, FL

Abstract: The α'β' subtype of *Drosophila* mushroom body neurons (MBn) is required for memory acquisition and early memory retrieval after aversive olfactory conditioning. However, prior *in vivo* functional imaging studies have failed to detect an early forming memory trace in these neurons as reflected by an enhanced G-CaMP signal in response to presentation of the learned odor. Moreover, the status of any potential early cellular memory trace in the mushroom body output neurons (MBOn) downstream of the α'β' MBn remains unknown. Here, we show that aversive olfactory conditioning suppresses the calcium responses to the learned odor in both α'3 and α'2 axon segments of α'β' MBn and in the dendrites of α'3 MBOn immediately after conditioning. Notably, the cellular memory traces in both α'3 MBn and α'3 MBOn are short-lived and persist for less than 30 min. The suppressed response in α'3 MBn is accompanied by a reduction of acetylcholine (ACh) release, suggesting that memory trace in postsynaptic α'3 MBOn may simply reflect the suppression in presynaptic α'3 MBn. Furthermore, we show that the α'3 MBn memory trace does not occur from the inhibition of GABAergic neurons via $GABA_A$ receptor activation. Because activation of α'3 MBOn drives approach behavior, our results demonstrate that aversive conditioning promotes avoidance behavior through suppression of the α'3 MB-MBOn circuit.

Title: The clock neurons acutely regulate memory retrieval in *Drosophila*

Authors: *Y. ZHOU, Y. ZHANG, Y. ZHONG;
Tsinghua Univ., Beijing City, China

Abstract: Time and memory are inextricably linked. Although circadian rhythms have been widely reported to regulate learning and memory, it remains wide open as to how individual or subgroups of clock neurons are acutely involved in encoding or regulating temporal nature of memory. Here, we take advantage of the well-defined circadian system of *Drosophila Melanogaster*, to dissect such mechanism in neural circuit levels. We found that acute activation of clock neurons exerted no effects on memory formation and maintenance, but attenuated retrieval of long-term memory while had no impact on every aspects of short-term memory tested. Genetic dissection allowed us to attribute such acute effects to a subgroup of clock

neurons. We are continuing to make efforts in elucidating the circuits that mediate this effect in an attempt to gaining insights into its mechanisms and functions. Thus, this work identifies a novel function for clock neurons in acute regulation of retrieval of long-term memory.

Title: Screening for neuronal substrate of the inhibitory interaction between two genetically different learning systems in *Drosophila*

Authors: *A. E. ERIKSSON, B. BREMBS;
Inst. für Zoologie - Neurogenetik, Univ. Regensburg, Regensburg, Germany

Abstract: Learning is an essential component for an animal's survival as it enables for better future decisions: such as finding more nutritious food or avoiding harmful stimuli. While the molecular mechanisms underlying learning and memory have been studied extensively, only little is known about the neuronal architecture and the mechanisms for how the different learning systems interact in composite learning tasks. It has been proposed that at least two types of learning are mediated by distinct molecular mechanisms in humans, mice, songbirds, snails and in fruit flies, where one is involved in the effects of the animal's own behavior on the world (self-learning) and a separate one for the relationship of events in the world (world-learning). A fly primarily uses a classical learning system as it explores its environment and learns about the stimuli associated with it. For this initial phase, the world-learning system inhibits self-learning ensuring a flexible memory, independent of the behavioral context within which it was acquired. This inhibition is mediated by the mushroom bodies (MB) in fruit flies: blocking the synaptic output of the mushroom bodies impairs their ability to inhibit self-learning, leading to premature habit formation. For the purpose of this study, we used a two-phase experimental design. The first phase consists of a composite learning task containing both self- and world-learning components, followed by a test phase that isolates the operant component. The MB is composed of 21 different types of output neurons (MBONs) which receive the neuronal activity from the MB for further processing. To map the MBON pathway through which the Mbs inhibit self-learning, we performed a comprehensive screen blocking each of the 21 different types of MBONs and testing them for a loss of the ability to inhibit self-learning. The results from this screen allow us to propose downstream MBON targets which must be associated with the neurons mediating operant self-learning.

Title: FlyBrainLab: An interactive computing platform for the fruit fly brain

Authors: ***M. K. TURKCAN**, T. LIU, C.-H. YEH, Y. ZHOU, A. A. LAZAR;
Dept. of Electrical Engin., Columbia Univ., New York, NY

Abstract: To address the challenge of building a functional map of the fruit fly brain we devised an open-source interactive computing platform called (https://github.com/FlyBrainLab) FlyBrainLab (FBL). FBL is a first-of-its-kind platform built for studying the function of executable circuits constructed from fly brain data available worldwide; its tools and libraries will benefit neurobiologists, computational neuroscientists and computer scientists in their quest of understanding the function of the brain of the fly and other model organisms. FBL integrates the key innovations of the Fruit Fly Brain Observatory ecosystem [1]. Unlike conventional simulation platforms focusing on model execution, FBL champions a synergistic integration of neurobiology and circuit model data into a common NeuroArch graph database. NeuroArch currently features cell-type, connectome, synaptome, neurogenetics, and neurophysiology data from the FlyCircuit, Janelia FlyEM and spike recordings including our own [2]. For brain circuit execution FBL also provides access to the Neurokernel engine operating on GPUs. A high level view of these components is provided by NeuroMynerva, a modern integrated development environment that is built upon and substantially extends JupyterLab. Together, these 3 open-source components enable easy management, rapid loading, effective visualization, and intuitive exploration of neural data (Fig. 1A,B), exploration of circuit diagrams (Fig. 1C,D), code libraries for execution, analysis and biological validation. Furthermore, FBL significantly accelerates the development cycle of models of Drosophila brain circuits. Finally, FBL is scalable to the flood of fly brain data anticipated in the near future. We applied FBL for an extensive comparative analysis of the mushroom body in the adult and larva and an exhaustive comparison of recently published models of the central complex.

Title: Aversive conditioning in the tardigrade, Dactylobiotus dispar

Authors: *T. C. DUMAS[1], S. Y. ZHOU[2], J. P. DEFRANCO[1], N. T. BLAHA[1], A. M. KABBANI[1];
[1]George Mason Univ., Fairfax, VA; [2]Univ. of Virginia, Charlottesville, VA

Abstract: Tardigrades, often colloquially referred to as “water bears”, are microscopic octopedal organisms found in aquatic and terrestrial habitats all over the world. They are well known for their uncommon ability to thrive in extreme conditions as they can enter into a cryptobiotic state known as a “tun”. In the tun state, protective sugars accumulate, glycerol is produced, intrinsically disordered proteins are expressed, and metabolism is effectively terminated. Given

this unique ability, tardigrades present an opportunity to study metabolic constraints on memory consolidation and maintenance. To investigate this further, it was necessary first to determine if tardigrades could be classically conditioned. Four to nine week old tardigrades of the species *Dactylobiotus dispar* were used for all experiments. The sex of the animals was unknown. Tardigrades were trained and tested on a microscope slide with two pieces of wire laid with ends 5 mm apart. A droplet of water was used to connect the two wires and to contain a single tardigrade. An electrical stimulator was connected to the wires to complete the circuit. Naive tardigrades will curl their bodies inward in response to a sufficient electrical shock but will not do so in response to a blue light stimulus. Tardigrades were trained by pairing an electrical shock with blue light. A time interval of either one or four hours passed and the animals were exposed to the conditioned stimulus alone and behavior was recorded. Control conditions during training included shock alone, blue light alone, backward pairing, random pairing, and forward pairing with green or red light. It was found that when forward pairing of shock with blue light was applied to naive tardigrades, an associative memory was retained for at least one hour. When tardigrades were tested four hours after training there was no significant response to the blue light, indicating a time dependent decline in memory performance.This study was able to show that tardigrades are capable of learning and memory and that they can retain an associative memory for one hour after a single pairing of a US and CS. Current experiments involve multiple pairings of the US and CS to induce longer lasting memories. In future experiments, half of the tardigrades will undergo tunning and revival prior to memory testing to investigate the metabolic requirements for memory storage and the possibility of attenuated memory decay in the tun state.

Title: Quest for neuronal cell analogs in nerveless animals: Ultrastructural atlas of cell types and behaviors in Placozoa

Authors: D. Y. ROMANOVA[1], F. VAROQUEAUX[2], M. EITEL[3], *L. L. MOROZ[4];

Abstract: Placozoans are the simplest free-living animals without neurons and muscles, but with complex behaviors. They are descendants of earlier branching basal metazoan lineages and, therefore, critical to reconstructing the genealogy of cell types in Metazoa. For more than 100 years, only one species of Placozoa was known - *Trichoplax adhaerens*. However, Eitel *et al*. (2018) and Osigus *et al*. (2019) described two more placozoan species *Hoilungia hongkongensis and Polyplacotoma mediterranea*. Here, we characterized the ultrastructural organization of *H. hongkongensis* and compared it to known haplotypes of *Trichoplax*. Our data confirm the organizations of ventral and dorsal epithelia and the existence of six major morphological cell classes across Placozoa including crystal and fiber cells, as well as a remarkable diversity of cellular subtypes suggesting both unique lineage-specific adaptations and ecological/functional diversification across Placozoa. Next, we established a culture for *H. hongkongensis* and other placozoans as well as developed standardized assays to reveal both innate and pharmacologically induced behavioral patterns among various haplotypes. Our analyses, combined with molecular profiling of specific cell types and signal molecule candidates, provide novel insights in cellular bases of behaviors in organisms without neurons and muscles.

Title: *De novo* transcriptome assembly and differential expression analysis in the ventral nerve cord of Manduca sexta after nociceptive sensitization

Authors: *R. L. MELTON, D. R. TABUENA, M. FUSE;
Biol., San Francisco State Univ., San Francisco, CA

Abstract: Chronic pain is a prevailing health problem ravaging the United States. Research in this field is primarily limited to vertebrate models. With the extensive ethical and financial limitations of vertebrate research, the development of an invertebrate model for preliminary therapeutic research would greatly broaden our understanding and treatment of chronic pain. The tobacco hornworm, *Manduca sexta*, has a well-defined behavioral defensive strike to noxious or harmful stimuli that provides a gauge of a pain-like state. This state becomes hypersensitized after presentation of a harmful stimulus – assessed by a reduction in the force required to elicit a strike – and this can last up to 19 hours. We use this as a model for injury-induced sensitization, and this has been shown to arise centrally. We have also previously shown that protein synthesis is required within 3 hours of injury in order to maintain sensitization. The goal of this study was to assess transcriptional changes in the CNS associated with long-term sensitization. We first determined whether the brain was required for sensitization, using our previously established *in vitro* electrophysiological preparation. We removed the brains of 5^{th} stage larvae 24 h prior to injury by a pinch. Pinched animals with or without brains showed an increased firing frequency compared to non-sensitized controls, indicating that sensitization occurred without the brain. We therefore used abdominal ganglia to produce *de novo* transcriptomes for control and sensitized states. This transcriptome was developed through Trinity, resulting in 211,719 predicted 'trinity genes' and 2,768,665 transcripts, with a Bowtie2 alignment of 94.56%. Using Trinotate, we annotated 87.49% and 88.45% of our transcriptome with UniProt and TrEMBL, respectively. Differential expression was noted in the transcriptome after injury, including 110 up-regulated transcripts and 38 down-regulated transcripts. To begin characterizing proteins involved in injury-induced sensitization, we mined *in silico* for classical learning and memory/sensitization-induced genes. This resulted in the presence of 2,364 of the 7,078 target genes derived from nervous system gene ontology categories within our transcriptome. Additionally, 68 differentially expressed transcripts were found to be within these gene ontology categories, including Ras GTPase, CASK, and integrin alpha-8. The presence and expression of these classical neuroplasticity genes are a promising start to examining the underlying conservation of long-term injury-induced sensitization in *M. sexta.*

Abstract: Crayfish has been used as a biological model in neurosciences for many years. A relatively “simple” brain and fine adaptation to laboratory conditions make this animal a suitable biological model for studying sensory systems and memory. Recently we demonstrated that this crustacean uses individual recognition memory during the establishment of hierarchical relationships and we are interested in the mnemic capabilities of this crustacean. We used two protocols to investigate if this animal is able to learn through classical conditioning and/or operant conditioning. In the first one we recorded the heartbeat (through an ECG) while applying a light pulse each 40 s. After 6 repetitions of the light pulse we applied a mechanical stimulus (droping of a heavy object in the aquarium). We found that the heart rate diminishes with the mechanical stimulus and that after 14 repetitions the light pulse is enough to induce bradycardia. This association disappeared after 3 days and was sensitive to cold anesthesia. Operant conditioning consisted in the application of an electric shock in the walking legs of a crayfish placed in a conditioning cage. When the crayfish learned to escape the electrical stimulus, we associated an intense light 5 s before the electrical shock. The crayfish learned to avoid the electric shock by escaping to its aquarium when the light was turned on. This response disappeared after 3 days without reinforcement. These experiments show that the crayfish is capable to associate stimuli under classic and operant conditioning.

Title: Laboratory studies of spatial learning in Fiddler crabs (Uca pugilator)

Authors: *F. W. GRASSO[1], E. ISAACS[2], R. TROISE[2];
[2]Psychology, [1]Brooklyn College, CUNY, Brooklyn, NY

Abstract: The use of path integration mechanisms in arthropods, particularly eusocial insects, for navigation appears to be ubiquitous and well-studied. The propensity of fiddler crabs to return their home burrows after foraging trips makes them amenable subjects for studies of spatial navigation in non-eusocial species. Several clever studies of spatial memory in Fiddler crabs in the field suggest that fiddler crabs may navigate using mechanisms in addition to path integration. In a series of behavioral experiments conducted under controlled laboratory conditions, we examined their ability to use allocentric cues to learn spatial locations in spatial tasks that do not involve a home burrow. A study conditioned place preference learning using visual cues showed no evidence for place preference learning but a strong preference for specific types of visual stimuli. A conditioned place preference study that controlled for visual cues found an interaction effect confirming field studies that indicated The results do not provide unequivocal evidence for these abilities but do indicate learning of space in these artificial task in more complex processes, and indicate interference in learning processes by predispositions.

Title: Motor thalamic innervation of NDNF-expressing interneurons in layer 1 motor cortex

Authors: *N. S. M. BERRY[1], R. SHAH[1], L. WAITE[1], K. MELETIS[2], A. SHAROTT[1];
[1]MRC Brain Network Dynamics Unit, Dept. of Pharmacol., Univ. of Oxford, Oxford, United Kingdom; [2]Karolinska Inst., Stockholm, Sweden

Abstract: Basal ganglia (BG) and cerebellar circuits (CB) exert control over ongoing behaviour through their connections with brainstem motor centres and distinct populations of neurons comprising adjacent nuclei in the motor thalamus (BG.MThal and CB.MThal). CB.MThal (the ventral lateral nucleus in rodents) neurons resemble “first order” thalamic neurons, which faithfully ‘relay’ information to the deep layers of sensorimotor cortex. By contrast, BG.MThal (the ventral anterior and ventral medial nuclei in rodents) neurons have the characteristics of “higher order” thalamic neurons, which target the superficial layers of widespread functionally-related cortical areas, particularly Layer 1 (L1). As the apical dendrites of both deep and superficial pyramidal neurons reside in L1, this laminar specificity does not necessarily define the neuron types targeted by thalamocortical synapses. For both parts of MThal, there has been

an assumption that the main postsynaptic targets of thalamocortical neurons in motor cortex are Layer 5 (L5) pyramidal neurons. However, recent evidence has suggested that in L1 of sensory areas, extended neurogliaform (eNGF) interneurons, which are defined by the expression of neuron-derived neurotrophic factor (NDNF), are also an important thalamic target for higher order nuclei. We tested the hypothesis that motor cortical L1 eNGF interneurons receive direct innervation from neurons in motor thalamus. Using an NDNF-Cre mouse, with stereology we demonstrate that the majority of motor cortical L1 NDNF-expressing interneurons coexpressed GAD67 and reelin, consistent with being eNGF interneurons. In addition, we found that many of these interneurons express chicken ovalbumin upstream promotor transcription factor II (COUP-TFII). To further explore the thalamic connectivity and function of these interneurons, we developed an injection technique to restrict viral labelling of neurons mostly to L1. Monosynaptic retrograde rabies viral tracing demonstrated that motor cortical L1 NDNF+ neurons receive synaptic input from several thalamic nuclei. Our preliminary data suggests that BG.MThal neurons provide the largest innervation, consistent with their dense projections to this cortical layer. In contrast, the same experiments using retinol-binding protein 4 (RBP4)-Cre mice demonstrated motor cortical L5 pyramidal neurons receive more inputs from CB.MThal than BZ.MThal neurons. These results suggest that not only do motor thalamic nuclei differ in their preferential laminar targeting of motor cortex, but also in their relative innervation of specific populations of pyramidal neurons and interneurons.

Title: Thalamic stimulation modulates consciousness in anesthetized macaques by restoring spontaneous and evoked fMRI activity in a cortical global neuronal workspace

Authors: *J. TASSERIE[1], L. UHRIG[1], J. D. SITT[2], M. DUPONT[1], S. DEHAENE[1,3], B. JARRAYA[1,4,5];
[1]INSERM, CEA - Neurospin Ctr., Paris Metropolitan Area, France; [2]ICM - Hôpital Pitié Salpêtrière, Paris, France; [3]Collège de France, Paris, France; [4]Foch Hosp., Paris, France; [5]Univ. de Versailles Paris-Saclay, Versailles, France

Abstract: Consciousness can be studied at two different levels: arousal, modulated in part by the central thalamus, and awareness which is characterized by the conscious access to a specific piece of information, thought to be related to a long-range cortical global neuronal workspace. It has been reported that electrical Deep Brain Stimulation (DBS) of central thalamic nuclei could restore arousal in rodents (Shirvalkar et al., 2006) and ameliorate behavior in minimally conscious state patients (Schiff et al., 2007). Here, we use functional MRI and thalamic DBS in macaque monkeys to evaluate the hypothesis that DBS can causally modulate both arousal and awareness through the reorganization of prefronto-parietal networks.
Two Rhesus macaque monkeys were chronically implanted with DBS leads targeting central thalamus. To manipulate the state of consciousness, we applied finely tuned, EEG-monitored propofol anesthesia as previously developed in macaques (Uhrig et al., 2016). We first tested the behavioral effects of thalamic DBS during anesthesia. Then, we performed a series of fMRI experiments at 3T. We studied the effects of thalamic DBS on resting-state brain activity, particularly focusing on a previously described signature of consciousness in the dynamics of resting-state fMRI (Barttfeldt et al., 2015). We also examined task-related fMRI in the ON-DBS and OFF-DBS conditions using the 'Local-Global' auditory paradigm, in which a signature of the conscious processing of auditory regularities was previously described in humans (Bekinschtein et al, 2009) and macaques (Uhrig et al, 2014).
Thalamic DBS robustly induced arousal in anesthetized macaques, with spontaneous motor behavior and eye blinking. When thalamic DBS was switched on, fMRI activity was seen in several cortical areas including in the prefrontal, parietal and cingular cortices. This DBS-induced fMRI activity gradually returned to baseline seconds after the stimulator was turned off. Moreover, thalamic DBS led to a vast reconfiguration of resting-state cortical dynamics by decreasing the function-structure similarity, as previously described for the transition from anesthesia to awake state (Barttfeld et al., 2015). Finally, thalamic DBS restored a broad hierarchical cortical response to global auditory regularities, as previously observed in the conscious state (Uhrig et al., 2014).
Our data demonstrate that thalamic DBS can restore both arousal and awareness in a non-human primate model of loss of consciousness, paving the way to its therapeutical translation in patients with disorders of consciousness.
JT and LU equally contributed to the study.

Title: A computational model of thalamic reticular circuits: Gating of signal processing by top-down control and effects of inhibitory dysfunction

Authors: Q. GU[1], N. H. LAM[2], *J. D. MURRAY[1];
[1]Psychiatry, [2]Physics, Yale Univ., New Haven, CT

Abstract: The thalamus plays a key role in long-range communication in the mammalian brain. In addition to its role as a relay of peripheral sensory signals to cortex, a growing literature has characterized its flexible engagement in higher-order cognitive functions according to task demands. For instance, attentional goals can exert top-down control of thalamic gain to amplify task-relevant signals and filter task-irrelevant signals depending on cognitive needs. However, the thalamic circuit mechanisms supporting this cognitive flexibility are poorly understood. Furthermore, thalamus is thought to be a key site of alteration in multiple neuropsychiatric disorders, in particular through disruption of inhibitory regulation by the thalamic reticular nucleus (TRN). Yet it is mechanistically unclear how synaptic or cellular-level dysfunction can induce behavioral deficits in cognitive tasks.

To study these questions, we developed a biophysically detailed computational model of a thalamic reticular microcircuit, composed of thalamocortical and TRN cells. Each cell type is modeled through Hodgkin-Huxley equations capturing key voltage-dependent active conductances. Circuit dynamics arise through an interplay between the active conductances and regulation by inhibitory synaptic feedback. The *in vivo*-like regime can be constrained through comparison by range of experimental results. Our model can capture *in vivo* circuit dynamics consistent with experiments, including burst and spindle statistics under spontaneous and evoked conditions. Perturbation analysis indicates TRN is crucial in modulating the dynamical regime of the thalamus. In addition, we examined the input-output characteristics of the circuit model, demonstrating how key parameters control the tonic and burst modes of the network, and ultimately the information transmission process. Finally, we altered the circuit models based on hypothesis microcircuit disruptions and functional alterations associated with psychiatric disorders including schizophrenia. We identified specific alterations to coupling strengths and background thalamic inputs as potential candidates to drive the circuit impairments.

In summary, we presented a thalamic circuit model which reproduced experimental observations,

and allowed a circuit-level understanding of the thalamus. The model makes dissociable predictions for optogenetic and pharmacological disruptions, potentially informing future experiments and providing insights to brain disorders and potential therapeutic interventions.

Title: Mediodorsal and ventroanterior thalamic neurons are selective for rules and goals

Authors: *J. M. PHILLIPS[1], N. A. KAMBI[1], M. J. REDINBAUGH[1], E. R. JOHNSON[2], S. MOHANTA[1], Y. B. SAALMANN[1];
[1]Psychology, [2]Univ. of Wisconsin-Madison, Madison, WI

Abstract: The lateral prefrontal cortex (PFC) enables cognitive control in primates, but its extensive connectivity with subcortical structures emphasizes that the PFC does not act in isolation. The lateral PFC is reciprocally connected with at least two thalamic nuclei, forming both closed and open loop circuits in a hierarchically organized cortico-thalamo-cortical network. The projections from distinct PFC regions overlap in both the mediodorsal thalamic nucleus (MD) and ventroanterior thalamic nucleus (VA), especially its medial magnocellular compartment (VAmc). MD and VA are thus well placed to influence information transmission across PFC according to cognitive control demands. In mice, MD synchronizes frontal cortical neurons, increasing their functional connectivity, and supporting their rule maintenance, without expressing rule selectivity itself. In monkeys, lateral PFC and MD show similar responses during spatial working memory tasks, but the contribution of MD to more complex rule-guided behavior, and its interaction with lateral PFC neurons in this context, have not been explored. There is even less information available regarding VA function. How do VA and MD uniquely contribute to PFC neural activity and cognitive control?
To address these questions, we used linear multielectrode arrays to simultaneously record from central MD, medial VA, anterior and posterior area 46 of two monkeys performing a hierarchical

rule-based task. We used diffusion MRI and probabilistic tractography to target electrode arrays to interconnected cortical and thalamic sites. Tractography between the substantia nigra and VA aided in delineating and targeting VAmc, the nigral recipient zone of VA. Structural MRI of electrodes *in situ* verified recording sites.
Spiking activity of single neurons in lateral PFC showed selectivity for abstract rules, concrete rules, and goal target location. Unlike mouse MD, rule selectivity was also a prominent feature of primate MD spiking activity. VA neurons showed selectivity for the rewarded target location. Thus, thalamic neural activity closely resembled PFC neural activity.
Neural ensembles representing abstract rules, concrete rules, and rewarded target locations may be recruited and maintained through PFC-MD/VA interactions involving reciprocal loops. Information about these sequential trial events may be transformed and propagated across hierarchical PFC-subcortical circuits via the open loops, involving unreciprocated cortical projections issuing feedback to "lower" thalamo-cortical circuits. This may facilitate selection of appropriate action based on the combination of preceding rule cues.

Title: Role of the paraventricular nucleus of the thalamus in regulating passive and active fear responses

Authors: *J. MA[1], M. A. PENZO[2];
[1]Natl. Inst. Of Mental Health, Natl. Inst. of Hlth., Bethesda, MD; [2]Natl. Inst. of Mental Health, Natl. Inst. of Hlth., Bethesda, MD

Abstract: The ability to form and retrieve fear memories is critical for animal survival. While significant progress has been made in identifying the neural circuit mechanisms that control the expression of passive (e.g. freezing) and active (e.g. avoidance) fear behavioral responses, little is known about those mechanisms driving the selection of one behavior over the other. The paraventricular nucleus of the thalamus (PVT) is a candidate structure for guiding behavioral selection given its prominent innervation of both the central amygdala (CeA) - which controls freezing behavior - and the nucleus accumbens (NAc) - which controls avoidance behavior. Indeed, we recently demonstrated that PVT projections to the CeA are critical for the expression of freezing behavior following fear memory retrieval (Penzo et a., 2015 *Nature*). However, whether or not the PVT also orchestrates avoidance behavior remains unclear. Here, we have

used a combination of fiber photometry and optogenetics in mice to uncover a PVT-NAc pathway that controls avoidance. Current efforts are being directed at investigating a potential role for the PVT in biasing the selection of freezing and avoidance behavior.

Abstract: Classical models describe the midline together with the intralaminar thalamic nuclei as a non-specific relay node in an ascending reticular activating system involved in signaling arousal. One such nuclei within the midline thalamus is the paraventricular nucleus of the thalamus (PVT), which has been recently implicated in signaling cortical state and stimulus salience. However, how the neural circuits of the PVT are organized into functionally discrete domains and their precise contributions to these processes is unknown. Here we identify to classes of PVT cells, Type I and Type II, that encode different aspects of salient stimuli. Fiber photometry imaging of calcium transients from these two classes showed that while Type I neurons are sensitive to the valence of salient stimuli, Type II neurons are sensitive to stimulus salience and arousal. Because Type I and Type II neurons of the PVT are functionally distinct, we suspected that they target different downstream structures. Indeed, anterograde mapping of the projections of these two subpopulations showed segregated innervation of multiple brain regions including the amygdala, nucleus accumbens and medial prefrontal cortex (mPFC). Notably, Type II neurons of the PVT relay arousal-related information to the mPFC. Moreover, mPFC corticothalamic cells that send projections back to the PVT are similarly modulated by arousal and are involved in a cortical circuit signaling arousal. Overall, we have gathered the first evidence of distinct parallel streams of information arising from the same midline thalamic nuclei. By uncovering this functional diversity, our results challenge current conceptualizations of the PVT.

Title: Pupil dynamics track optimal adjustments of decision making process in rats performing tactile discrimination tasks

Authors: ***S. NARASIMHAN**, B. SCHRIVER, K. LOU, Y. LIU, Q. WANG;
Columbia Univ., New York, NY

Abstract: Under survival pressure, animals must adaptively change their behavior to optimize behavioral outcomes. Perceptual decision making is shaped by the statistical structure of cost, reward, and the sensory world. We investigated this topic by training head fixed rats to perform a Go / No-Go tactile discrimination task while systematically varying the statistics of the sensory environment. For each session, the probability of the presence of the Go stimulus (S+) was randomly set at 80%, 50% or 20%. Animals' behavioral output and pupil size were simultaneously recorded. We found that reaction time decreased as the probability of S+ increased. Impulsive licking did not change across these three paradigms. Interestingly, although Hit and false alarm (FA) rates decreased as the probability of S+ decreased, there was no significant change in perceptual sensitivity across the paradigms. However, the animals became more liberal as the probability of S+ increased, indexed by a decrease in the decision criterion, in line with the optimal adjustment of decision criterion predicted by the signal detection theory. We further used a hierarchical drift diffusion model (HDDM) to model the decision-making process in these paradigms. We found an increase in both decision bias towards Go and drift rate as well as a decrease in decision boundary for the paradigm with 80% probability of S+ presentation as compared with the other two paradigms. The task-evoked pupil responses were bigger when the probability of S+ was lower. Moreover, pupil dilation was positively correlated with the decision boundary and drift rate and negatively correlated with decision bias. Taken together, these results suggested that the animals adaptively changed their action for optimal behavioral yield in response to the changes in sensory environment, and that this adaptive adjustment in decision-making was indexed by their pupil dynamics. This project was supported by NIH R01MH112267.

Title: The interplay between phasic pupil-linked arousal evoked by different cognitive processing components in perceptual decision-making

Authors: *B. J. SCHRIVER[1], Q. WANG[2];
[2]Dept of Biomed. Engin., [1]Columbia Univ., New York, NY

Abstract: Even within an unchanging, fully learned environment, skilled decision makers execute different actions upon encountering identical stimuli. This behavioral variability may be better accounted for by looking at fluctuating behavioral state, which influences sensory processing, perception, and behavior. In perceptual discrimination tasks, the central arousal system is activated in response to stimulus presentation, decision-making, and reward/punishment, evidenced by phasic pupil dilation associated with these processes. We have previously demonstrated that phasic pupil-linked arousal (i.e. phasic pupil dilation) was activated on trials with all four possible behavior outcomes (i.e. hit, false alarm, correct rejection, and miss) in a tactile Go/No-Go discrimination task. However, the individual contribution of the different components of cognitive processing in eliciting phasic arousal, and their functional consequence on behavior remains poorly understood. Here we used machine learning techniques to decompose phasic pupil-linked arousal associated with different components of perceptual decision-making. We found that phasic arousal evoked by stimulus presentation was larger for the Go stimulus than the No-Go stimulus despite the two stimuli being symmetric. For each session, the separation between distributions of phasic arousal evoked by the Go and by the No-Go stimulus was predictive of perceptual performance. Phasic arousal in response to sensory processing was negatively correlated with that in response to decision-making for withheld trials but not for responded trials, suggesting that phasic arousal evoked by both sensory processing and decision-making contributed to the No-Go action. When a Go stimulus was presented, the correct response was primarily determined by the phasic arousal related to sensory processing, while the correct response to the No-Go stimulus was determined by phasic arousal elicited by both sensory processing and decision-making. Drift diffusion modelling revealed significant correlations between phasic arousal and the different decision-making processes. Taken together, these preliminary results suggest that the interplay between phasic arousal evoked by different

cognitive processing components has important functional consequences on forming the choice in perceptual decision-making tasks. The authors would like to thank Sean Perkins and Mark Churchland for their technical assistance and comments. This project was supported by NIH R01MH112267.

Title: Lateral parabrachial neurons expressing tachykinin 1 mediate anorexia, adipsia, and escape behaviors elicited by peripheral threats

Authors: *J. ARTHURS, R. D. PALMITER;
Biochem., Univ. of Washington-HHMI, Seattle, WA

Abstract: Foraging animals must continually weigh the benefit of obtaining food with the potential risk of becoming food themselves. The ability to rapidly switch between feeding or drinking to detecting and escaping from threats is critical to survival. We have identified tachykinin 1 (Tac1)-expressing neurons in the lateral parabrachial nucleus ($Tac1^{PBN}$ neurons) as critical for mediating anorexia, adipsia, and escape behaviors in response to peripheral threats. Chemogenetic activation of $Tac1^{PBN}$ neurons profoundly suppressed the intake of both food and water; it also increased jumping on a hotplate and locomotion in response to a foot shock. Optogenetic activation of $Tac1^{PBN}$ neurons elicited jumping in the absence of a threat. Conversely, functionally inactivating $Tac1^{PBN}$ neurons with tetanus toxin blunted behavioral responses to peripheral threats. Neurons expressing calcitonin gene-related peptide (CGRP) in the external lateral PBN ($CGRP^{PBN}$ neurons) are activated by a wide variety of threats (e.g., foot shock, visceral malaise) and their activation also leads to profound anorexia and adipsia. Fluorescent in situ hybridization and genetic expression of fluorescent proteins revealed substantial overlap in expression of Tac1 and CGRP in the PBN resulting in Tac1-only, Tac1/CGRP, and CGRP-only expressing populations. Chemogenetic or optogenetic activation of the $CGRP^{PBN}$ neurons is sufficient and necessary to establish a robust conditioned taste avoidance (CTA) of a novel food; however, activation of $Tac1^{PBN}$ neurons does not support establishment of CTA, despite the overlap in expression and the fact that Tac1 and CGRP neurons project their axons to most of the same targets in the forebrain. Our next step is to explore how $Tac1^{PBN}$ neurons suppress appetite without causing a learned avoidance of the associated food.

Title: Effects of the cuneiform nuclei on fear and hunting

Authors: ***R. P. BINDI**, N. S. CANTERAS, M. A. X. DE LIMA, C. C. GUIMARÃES DE SOUZA;
Anat., Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract: Fear is a highly conserved emotion emerging from adaptations to the environment across species. Studies have shown that the cuneiform nucleus is involved in defensive behavior and is a sympathoexcitatory area, controlling the defensive response as well as affecting the sympathetic response. Studies with c-fos have shown an increase in activity during nonnoxious, noxious stimuli and during cat exposure. More importantly, this region is deeply connected with central regions in the defensive circuitry, considering those evidences more investigation on this region is needed. To investigate the role of the cuneiform nuclei in encoding active and passive fear-coping strategies, we developed a series of behavioral paradigms. In one the paradigms male Wistar rats age 4 months (n=5) have the possibility to hunt crickets, and the hunting behavior can be readily shifted via optogenetic stimulation. In this case, we saw a markedly increase in defensive behavior and an immediate cessation of the hunting behavior. In the second one, we were able to see the effect of muscimol inhibition (n=4) on the hunting behavior in a new environment, decreasing the latency to the first attack by half of the control group (n=4). We also saw a marked decrease in the freezing behavior towards a cat in the group that received muscimol in the cuneiform during the cat exposure. When the inactivation occurred in the same place they were exposed to the cat (without having the cuneiform inactivated during the predator exposure) the rats exhibited a decrease in risk assessment. With this data it's possible to identify the cuneiform nuclei as a key region to an adaptive fear response and directly affecting the behavioral inhibition system, opening new frontiers to explore and expand the fear related circuitry.

Title: Paraventricular thalamus controls behaviour during motivational conflict

Authors: *E. CHOI, P. JEAN-RICHARD-DIT-BRESSEL, C. CLIFFORD, G. MCNALLY; Psychology, Univ. of New South Wales - Kensington Campus, Sydney, Australia

Abstract: Decision-making often involves motivational conflict due to the competing demands of approach and avoidance for a common resource: behavior. This conflict must be resolved as a necessary precursor for adaptive behavior. Here we show a role for the paraventricular thalamus (PVT) in behavioral control during motivational conflict. We used Pavlovian counterconditioning in male rats to establish a conditioned stimulus (CS) as a signal for reward (or danger) and then transformed the same CS into a signal for danger (or reward). After such training, the CS controls conflicting appetitive and aversive behaviors. To assess PVT involvement in conflict, we injected an adeno-associated virus (AAV) expressing the genetically encoded Ca^{2+} indicator GCaMP and used fibre photometry to record population PVT Ca^{2+} signals. We show distinct profiles of responsivity across the anterior - posterior axis of PVT during conflict, including an ordinal relationship between posterior PVT CS responses and behavior strength. To study the causal role of PVT in behavioral control during conflict, we injected AAV expressing the inhibitory hM4Di DREADD and determined the effects of chemogenetic PVT inhibition on behavior. We show that chemogenetic inhibition across the anterior - posterior axis of the PVT, but not anterior or posterior PVT alone, disrupts arbitration between appetitive and aversive behaviors when they are in conflict but has no effect when these behaviors are assessed in isolation. Together, our findings identify PVT as central to behavioral control during motivational conflict.

Title: Dynamic factors in neuro-evolution

Authors: *D. B. ROSENFIELD[1], I. A. DUBOVOY[2];
[1]Stanley H. Appel Dept. of Neurol., Houston Methodist Hosp., Houston Methodist Neurological Institute, TX; [2]Stanley H. Appel Dept. Neurol., Houston Methodist Neurolog. Inst., Houston Methodist Neurological Institute, TX

Abstract: We **hypothesize** that Emergent Properties in Complex Systems (EPCS) are a driving force in evolution. Salient evolutionary models must incorporate EPCS, including genetics and levels of motor performance.
We contend that neurophysiologic structures forerun the changes seen in evolution. Cerebral interactions in any task are associated with: anatomic loops (e.g., all possible anatomic connections); functional control loops (e.g., all possible anatomic loops that relate to performance); and performance loops (e.g., loops related to the overall problem posed). Modeling these depends upon the task being investigated (many routes can lead to the same solution) but can involve emergent interactions at all organizational levels.
A reductionist perspective can assess these multiple levels of organization, whether studying molecules, the genome, phenotypes, motor interactions or any functional property of the evolving organism. One can apply a reductionist approach top-down (e.g., from psychology to cells to chemistry to physics) or bottom-up (e.g., from physics to chemistry to cells to psychology).
Each approach has limitations: the top-down approach usually describes fewer variables, but it lacks a unique model of the observed behavior produced by the components at that level. Only the bottom-up approach provides such a model, by calculating the behavior of a level from its structure, function, connectivity and current conditions of its component parts. This calculation requires simultaneous measurements of current conditions and understanding input-output properties of the component parts, often not observable at most levels in biologic systems. Whether one measures a model from a top-down or bottom-up perspective, if the evolutionary outcome changes and a new function enhances survival, its connection to the brain must already exist so that the brain can integrate the phenotypic change into established loops.
Thus, when the thumb appears, we contend that the brain already has EPCS emanating from its associated anatomic and functional loops that incorporate how the animal can and will use apposition to make tools. Similarly, we contend that EPCS at a genetic level, interacting with a complex environment and multi-organism activities, produce changes that enhance survival: it is

not random changes in the genome/alleles that provide variation but, rather, the pre-existing EP waiting to manifest.

Title: EEG correlates of reward and effort processing during reinforcement learning

Authors: *D. PALIDIS[1], P. L. GRIBBLE[2];
[1]Univ. of Western Ontario, London, ON, Canada; [2]Brain and Mind Inst., Western University, Canada, London, ON, Canada

Abstract: Human behavior tends to maximize reward and minimize physical effort or energy expenditure. We ask whether neural reinforcement learning processes can support adaptive effort minimization as well as reward maximization. A frontocentral event related potential called the feedback related negativity (FRN) encodes reward prediction error and is thought to be generated by a reinforcement learning process. We hypothesized that the FRN would be modulated not only by reward outcomes but also physical effort. We recorded EEG from human participants while they performed a task in which they were required to accurately produce specific levels of muscle activation to receive rewards. Participants performed isometric knee extensions while quadriceps muscle activation was recorded using EMG. Real-time feedback indicating the combined muscle activation for both legs as a proportion of the target activation was displayed on a computer monitor. On a given trial, the target muscle activation was either “low” (approx. 15% MVC) or “high” (85% MVC). The required effort was determined probabilistically according to a binary choice indicated by button press, such that the ‘correct’ and ‘incorrect’ responses were associated with 20% and 80% probability of high effort, respectively. Periodically the effort contingency was reversed. Participants were told that in order receive a small monetary reward, they must exceed a minimum level of muscle activation indicated by a visual target while remaining as close as possible to the target. Once muscle activation reached the required target level, feedback displaying the magnitude of muscle activation was withheld, so that participants could not see the size of their errors relative to the target. After each trial, binary reinforcement feedback was provided to indicate success or failure. Reward frequency was controlled at approximately 0.5 in both conditions. We found that participants switched responses more frequently after non-reward relative to reward, and more frequently after high effort relative to low effort trials. We observed an interaction between reward and effort; reward affected response switching in the high effort condition but not the low effort condition. Effort

feedback did not elicit an FRN potential. The FRN elicited by reinforcement feedback was not affected by effort, while a late positive potential was sensitive to reinforcement outcome in the high effort condition only. Our results suggest that while the FRN reflects processing only of reinforcement outcomes, a later ERP component reflects an integration between reward and effort that is mirrored in behavior.

Title: Social learning deficits in fronto-temporal dementia

Authors: *S. ABREVAYA, M. GONZÁLEZ GADEA, S. FITTIPALDI, S. ALARCO MARTÍ, A. GARCÍA, F. MANES, L. SEDEÑO, A. IBAÑEZ;
Lab. of Exptl. Psychology and Neurosci., Inst. of Cognitive and Translational Neurosci., Ciudad Autónoma de Buenos Aires, Argentina

Abstract: Previous studies have shown that social reinforcement is a potential facilitator of human learning. This integration between memories and social contextual information, named social learning, is critical to maintain and promote interpersonal interactions and bonds. A relevant lesion model to explore this phenomenon is afforded by the behavioral variant of the frontotemporal dementia (bvFTD), which is characterized by a relative spared episodic memory profile alongside insidious changes in behavior, decline in social and emotional conduct, and deficits in the integration of contextual information. Yet, there is scant evidence on how social cues modulate the behavioral and neural correlates of learning in this disease. To bridge this gap, we obtained high-density EEG measures from 14 bvFTD patients and 27 demographically matched healthy controls as they performed a task that tracks the effects of social and non-social reinforcers during the implicit learning of arbitrary associations between letters and numbers. We analyzed two relevant event-related potentials: the N170, which reflects early perceptual processes involving the structural encoding of faces; and the feedback error-related negativity (fERN), which is modulated after high-conflict responses during decision-making and encodes social rejection and explicit social expectancy violations. We also administered the mini-Social cognition & Emotional Assessment to control for the effects of basic emotional recognition.

Results showed that social reinforcement significantly improved learning and increased fERN modulation in controls, but no such patterns were observed in the bvFTD group. Also, the groups did not differ in their capacity to recognize basic emotions and N170 modulations showed no disparities between conditions or groups. Taken together, these results suggest that bvFTD may involve specific alterations in the integration of social information to reinforce learning, and that this impairment is not secondary to primary deficits in processing of facial emotional stimuli and basic emotional recognition.

Title: A pavlovian over-expectation task to investigate behavior and learning based on imagined outcomes

Authors: *J. TEGELBECKERS[1], G. SCHOENBAUM[3], T. KAHNT[1,2];
[1]Neurol., Northwestern Univ., Chicago, IL; [2]Psychology, Northwestern Univ., Evanston, IL;
[3]Natl. Inst. on Drug Abuse Intramural Res. Program, Baltimore, MD

Abstract: Expectations that guide decisions are typically based on direct experience with action- or stimulus-outcome associations. In novel situations, however, forming expectations requires imagination. The ability to mentally simulate future outcomes but also to learn from violations of these expectations is critical for outcome-guided behavior. In rats, these functions have been linked to the orbitofrontal cortex (OFC). Evidence for a specific role of the human OFC in behavior and learning based on imagined outcomes has, however, not yet been established. To close this gap, we developed a Pavlovian over-expectation task that closely matches tasks previously used in rats. Instead of food pellets, we used food odors as biologically meaningful outcomes in hungry subjects. During a *conditioning phase*, participants (N=9) first learned to associate visual and auditory cues with food odors (A, B, X) or no odor (C, D, Y). Then, during a *compound training phase*, some cues were presented simultaneously (AX and CY) while others continued to be presented in isolation (B, X, D, and Y). The outcome delivered for all cues remained the same as during conditioning. During a final *test phase* performed in extinction,

cues A, B, C, and D were again presented in isolation. On each trial subjects reported the expected outcome via button press. We measured accuracy of outcome predictions, response time, and breathing. Over-expectation as a form of mental simulation of future outcomes was evident in this initial work during the *compound phase*, when compound cue AX led to summation (i.e., significant stronger responding to AX compared to B). In addition, during the *probe test*, responding to A compared to B was nominally reduced, providing evidence for error-based learning (i.e., extinction) based on over-expectation during the compound phase. These results parallel findings in rats using the same task, indicating that we created a valid tool that will allow us to investigate OFC representations of simulated outcomes in humans using functional imaging (data collection ongoing).

Title: Cognitive training based on EEG-neurofeedback to improve working memory in healthy volunteers

Authors: *B. BARBAZZENI[1], E. DÜZEL[3], O. SPECK[2];
[1]Fac. of Medicine, Inst. Cognitive Neurol. and Dementia Research, ESF Intl. Grad. Sc, [2]Fac. of Natural Sciences, Dept. of Biomed. Magnetic Resonance, Otto-von-Guericke-Universität Magdeburg, Magdeburg, Germany; [3]Inst. Cognitive Neurol. and Dementia Res., Magdeburg, Germany

Abstract: Working memory (WM) processes have been associated with brain oscillatory activity, attention and motivation to learn while encoding new stimuli. We investigated whether providing individuals online feedback about their ongoing brain oscillatory activity over several sessions can improve working memory performance. We focused on brain oscillations that are associated with the anticipation of monetary reward for correct performance in a working memory trial. The anticipation of monetary reward has been correlated with increased alpha suppression. Thus, to improve WM in healthy volunteers, we combined working memory training with EEG-Neurofeedback (EEG-NF) to enhance alpha suppression in a monetary-rewarded delayed match-to-sample task (DMST). Individuals were trained over five-days in

double-blinded experiment. We investigated i) whether alpha suppression enhancement increases attention and whether monetary-reward increases motivation to learn while performing the DMST and ii) whether EEG-NF training facilitates the performance of different cognitive tasks, as well. In Reward and No-Reward conditions, participants were trained to suppress alpha receiving a real-time NF or a placebo control NF of their brain activity. Preliminary results show that while performing the DMST, as well as different cognitive tasks the accuracy level did not reach a significant difference when comparing training days, reward conditions and intervention type, although a trend for improvement appeared from the first to the last training day in both interventions and reward conditions. On the other hand, reaction times were significantly improved by real-time NF in Reward ($P = 0.006$) and No-Reward ($P = 0.001$) conditions. Moreover, real-time NF enhanced significantly alpha suppression when compared to placebo control NF.

Title: The striatal feedback response reflects action updating

Authors: *I. C. BALLARD[1], M. DESPOSITO[2];
[1]Univ. of California, Berkeley, Berkeley, CA; [2]Helen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA

Abstract: Decades of neuropsychology and neuroanatomical research has converged on the theory that the striatum is a *gate*: it selects between potential action or goal representations in cortex. In contrast, fMRI investigations often characterizes the striatal BOLD response as a reward prediction error signal arising from midbrain dopaminergic inputs. When a prediction error occurs, it is necessary to update one's goals and gate a new plan of action. We test whether apparent reward prediction error BOLD responses in the striatum are better described as *action updating* responses, and reflective of gating functions rather than the activity of dopaminergic inputs.
Each subject completed two different 2-arm bandit tasks: *learn* and *reversal*. The purpose of the *learn* task was to replicate the finding that striatal BOLD correlates with reward prediction error. However, in this task, *reward prediction error* is confounded with *action updating*. The purpose of the reversal task was to distinguish the predictions of *reward prediction error* and *action*

updating and measure which signal best tracks striatal BOLD.
In the *learn* task, subjects were told that the reward probability of each bandit changes over time and they must learn which arm is better. The *reward prediction error* hypothesis predicts that the striatal response is larger for positive than negative feedback. The *action updating* hypothesis predicts the same pattern: positive feedback tends reinforces the belief that the chosen arm is the good arm, whereas negative feedback reduces confidence in which arm is best.
In the *reversal* task, subjects were told that the good arm gives reward 100% of the time, but periodically the identity of the good arm reverses. Thus, when a subject earns negative feedback, she should switch arms. The *reward prediction error* hypothesis predicts a larger response to positive than negative feedback. In contrast, the *action updating* hypothesis predicts a larger response to negative feedback, because negative feedback indicates the need to gate a new goal.
In the *learn* task, the striatal signal tracked *reward prediction error,* consistent with both hypotheses. Critically, in the *reversal* task, the striatal signal was larger for negative than positive feedback, consistent with *action updating* and inconsistent with *reward prediction error*. That is, making negative feedback more informative increases the striatal response to negative feedback. This finding suggests that the striatal feedback response is related to changes in action policy, consistent with the gating theory of striatal function.

Title: Interacting effects of experimentally-induced helplessness and transcranial direct current stimulation on Pavlovian bias in action selection

Authors: *G. CSIFCSÁK[1], J. BJØRKØY[1], S. KUYATEH[1], H. REITHE[1], V. D. DALOS[2], L. RÓNAI[2], S. SZALÓKI[2], M. MITTNER[1];
[1]Dept. of Psychology, UiT The Arctic Univ. of Norway, Tromsø, Norway; [2]Dept. of Psychology, Univ. of Szeged, Szeged, Hungary

Abstract: Learned helplessness (LH) is a concept closely related to major depression and chronic pain. In our previous study (https://psyarxiv.com/jpq6f/), we induced a state resembling LH in healthy adults by manipulating control over action outcomes (“yoking”) in a reinforcement learning task. We found that yoking was associated with stronger Pavlovian influences over action selection (i.e., enhanced approach tendencies towards rewards and

behavioral inhibition when facing loss), accompanied by alterations in frontal EEG signals reflecting cognitive control and outcome evaluation. These results implicate the involvement of the medial prefrontal cortex (mPFC) in LH-induced modulations of task performance. In the current, pre-registered study (https://osf.io/h45ju/), we aimed at determining if transcranial direct current stimulation (tDCS) targeting the mPFC can reverse the behavioral manifestations of yoking in healthy adults. In a double-blind, sham-controlled study, we randomly assigned 154 healthy adults into one of our six experimental groups: 3 tDCS conditions (active tDCS, sham tDCS, natural history) x 2 LH conditions (yoked, control). Participants performed an orthogonalized Go/NoGo task whereby the yoked group faced the absence of control over outcomes in the first part of the task. Behavioral effects of tDCS and yoking were assessed by analyzing between-group differences in response accuracy and Pavlovian performance bias (PPB), a measure estimating the impact of the Pavlovian valuation system on instrumental choices. For response accuracy, we found worse performance for yoked participants during LH-induction ($F_{1,584}$=12.78, $p<0.001$), but this effect was not modulated by tDCS ($F<2.86$, $p>0.058$). For PPB, however, we found a significant interaction between tDCS type and LH ($F_{2,584}$=3.55, $p=0.029$), indicating weaker Pavlovian bias for LH induction only if yoking was combined with active tDCS ($p<0.001$). The magnitude of the effect was similar during and after the stimulation. Our finding suggests that tDCS above the mPFC enhances cognitive control over Pavlovian bias in action selection, but only in cases when mPFC activity is compromised by LH-induction. We interpret these effects by proposing an inverted U-shape relationship between mPFC activity and cognitive control over Pavlovian action tendencies.

Title: Expectation effects induced by transcranial electrical stimulation: Model-based vs. model-free components

Authors: *E. BJØRKEDAL[1], Z. TURI[2], C. J. JAKOBSEN[1], M. MITTNER[1];
[1]Psychology, UiT The Arctic Univ. of Norway, Tromsø, Norway; [2]Clin. Neurophysiol., Univ. Med. Ctr. Goettingen, Goettingen, Germany

Abstract: The effect of transcranial electrical stimulation (tES) on cognition show great variability between subjects and across studies. Some of the variability could be related to placebo effects of tES, but the placebo effect on cognition or of tES has not been well investigated. We have shown that sham tES induced placebo effects on objective performance and learning rate during reinforcement learning. In the present study, we sought to determine if the placebo effect on objective cognitive performance was associated with increases in model-based versus model-free control of learning. Healthy participants (n=100) did a two-step reinforcement learning task that allowed us to distinguish between model-free and model-based control. The goal of the task was to maximize rewards by choosing, at the first step, among pairs of kiosks that, at the second step, led to lottery tickets that had values determined according to a random walk. The value of the kiosks could be updated either through model-free or through model-based learning. We used computational modelling to model learning performance. Outcome measures were objective performance (amount earned), expectations, learning rate, exploration, and trade off between model-free vs model-based control. Subjects were randomized to three groups who performed the learning task 3 times. The placebo conditioning group received double-blind sham tACS before 2nd and 3rd task with information that it would increase performance. The 2nd task was surreptitiously made easier in order to reinforce the verbal information with experience. The placebo group received identical tACS protocol but no task manipulation. The natural history group simply performed the learning task 3 times. Our preliminary analyses showed that objective performance and model-based control increased in all groups over time, with no differences between the groups. Sham tACS increased expectations of cognitive performance, but we observed no placebo effect on objective cognitive performance or model-based control. However, compared to the natural history group, the placebo manipulation induced changes in the modelled parameters of learning performance. These results suggest that expectations can affect modelled parameters of reinforcement learning in the kind of task used here.

Title: Musical reinforcement learning paradigm in frontotemporal dementia: A model paradigm of abnormal reward prediction

Authors: *E. BENHAMOU, H. SIVASATHIASEELAN, C. HARDY, M.-C. REQUENA-KOMURO, J. JOHNSON, C. GREAVES, L. RUSSELL, K. MOORE, J. ROHRER, J. WARREN;
Inst. of Neurology, Dementia Res. Ctr., UCL, London, United Kingdom

Abstract: Accurate prediction of the emotional consequences of one's actions, seeking reward, avoiding punishment and learning from past experience are integral to normal goal-directed behaviour. These processes are targeted early and prominently in the behavioural variant presentation of frontotemporal dementia (bvFTD): these patients show misdirected reward valuation, inability to regulate goal-directed actions and failure to learn from aversive experience. bvFTD constitutes a unique human disease model of abnormal reward processing and impaired socio-emotional behaviour more generally. However, the deficits these patients develop are difficult to characterise experimentally.
Here we used music as a novel probe of reinforcement learning in bvFTD, capitalising on the frequent abnormalities of musical hedonic valuation exhibited by patients with bvFTD and the well codified potential of musical consonance and dissonance to change the pleasantness of musical stimuli. We hypothesised that, relative to healthy age-matched individuals (n=15), patients with bvFTD (n=15) would display impaired behavioural flexibility during learning in an uncertain musical environment. We designed a three-armed bandit reinforcement learning paradigm using musical stimuli based on: (Experiment 1) four-chord progressions in which the final chord delivered either an expected or unexpected/ rewarding (consonant) or aversive (dissonant) outcome; or (Experiment 2), string quartet samples previously rated as pleasant or unpleasant by healthy older British individuals (n=10). Pupillary responses were recorded simultaneously throughout.
Modelling the data computationally, we found that bvFTD was associated with impaired behavioural detection of the 'optimal' arm and attenuated pupil reactivity to both 'punishing' target chords (Experiment 1) and unpleasant naturalistic music excerpts (Experiment 2), on a trial-by-trial basis. In Experiment 2, the choice stochasticity parameter was significantly higher for the bvFTD group, signifying a failure to match one's choices to the stimuli value difference. Our findings reveal a specific impairment of reward prediction in uncertain environments in bvFTD that might shape the abnormal socio-emotional phenotype of this disorder.

Title: Selective attention and the effects of mismatched priming factors on the evoked response potentials of mental arithmetic processes

Authors: D. H. HUGHES, T. MILLARD, *A. W. CHIU;
Biomed. Engin., Rose-Hulman Inst. of Technol., Terre Haute, IN

Abstract: In this study, we investigated the human evoked-response potentials (ERPs) to incongruences during mental arithmetic processing (MAP), and mismatches in the expected sensory modes. Each human subject, between the age of 18-55, was given 360 simple math problems. During the presentation phase (PP), the problems were presented in one of two possible ways, selected randomly with 50% visually via a computer screen and 50% auditory through the speakers. The PP was followed by a brief pause during which the subjects were instructed to solve the math problems mentally and keep track of the correct solutions. Then, the subjects were presented with two numbers visually and auditorily, during the response phase (RP). The subjects were asked to press a clicker whenever they saw or heard an incorrect solution. The ERP would be labeled as the standard response (S) if the numbers presented both ways were correct. The target response (T) would be produced if one of the numbers was incorrect, and presented in the same mode as the PP stimulus. Finally, the distractor response (D) would be produced if one of the numbers was incorrect but presented in a mismatched mode from the PP stimulus. Consistent with our previous work, the preliminary results showed an increase in the latency and average peak amplitude for T when compared to S. Despite some subject-to-subject variability, the ERPs in the parietal cortical regions exhibited longer D-S delay ($p<<0.05$) when transitioning from a visual PP to an incongruent auditory RP, than from an auditory PP to an incongruent visual RP. In both situations, no significant increase in the peak ERP D/S ratio was found. Even though subjects were not explicitly instructed to focus on a particular sensory mode during the RP, delayed responses to the solution in the RP were observed when there was incongruence in the math solution, with a statistically significant longer D-T delay if they were auditory mismatched responses ($p<<0.01$). There was no statistical difference in the power of the theta and alpha rhythms between the distractor and target responses regardless of the mode of simulation, suggesting that fatigue was not a contributing factor to these observations.

Title: The contribution of dopamine reward prediction errors to temporal representation and motor control

Authors: *W. H. ALEXANDER;
Florida Atlantic Univ., Boca Raton, FL

Abstract: By far the most prominent interpretation of midbrain dopaminergic function suggests that dopamine neurons encode reward prediction errors (RPEs) that serve as the fundamental signal for learning in reinforcement learning frameworks. A vast body of literature has documented the relationship between activity in dopamine neurons and RPEs derived from computational models of learning, making it one of the earliest and strongest links between computational and empirical neuroscience. Despite the amount of evidence supporting dopaminergic signaling of RPEs, two critical deficits in this interpretation remain. First, while computational models of reinforcement learning draw a strong association between dopamine and learning, there is yet to be a similarly strong account for the established role of dopamine in motor control and temporal perception. Second, although dopamine activity is necessary in reinforcement learning frameworks to drive learning, evidence from Parkinson's patients suggests that dopamine signals themselves are not necessary to learn reward associations, but rather to express those associations behaviorally. In this poster I present a new computational model of dopamine function showing how RPEs signaled by dopamine neurons may be used to adjust the temporal receptive fields of neurons in target regions of striatum and cortex. Simulations of the model account for the development of spectral timing units in striatum, effects of temporal delay in choice behavior, and deficits in motor control and temporal estimation in Parkinson's disease. These results suggest that the primary role of dopamine RPEs is to adjust attention to features and time rather than to learn reward associations.

Title: Reinforcer and punishment during decision making: An electroencephalographic study

Authors: *F. A. IRIBE BURGOS, J. P. GARCÍA-HERNÁNDEZ, P. M. CORTES ESPARZA, C. SOTELO-TAPIA, M. A. GUEVARA, M. HERNÁNDEZ-GONZÁLEZ;
Inst. De Neurociencias, Guadalajara, Mexico

Abstract: Decision-making (DM) is defined as the selection of an option from a range of existing alternatives by estimating the possible outcomes of the selection and its possible consequences for present and future behavior. These consequences (reinforcement, pleasant stimulus; or punishment, a non-attractive or aversive environmental object) are capable of modifying an individual's preferences and responses. The dorsolateral, prefrontal, parietal and temporal cortices have been shown to be involved in the processing and evaluating such stimuli, and the connectivity among them allows these cortical areas, with other brain circuits, to complete the perception-action process of DM. Hence, the objective of this study was to determine the electroencephalographic (EEG) differences under reinforcement (*i.e.*, decreased task execution time) and punishment (increased task execution time) on a DM task. Sixteen healthy, right-handed men aged 20-35 volunteered to participate. Electroencephalographic activity was recorded in the dorsolateral prefrontal (F3-F4), parietal (P3-P4), and temporal (T3-T4) cortices during a DM task delivered with reinforcement or punishment. Absolute power (AP) and interhemispheric (rINTER: F3-F4, P3-P4, and T3-T4) and intrahemispheric (rINTRA: F3-P3, F3-T3, P3-T3, F4-P4, F4-T4, and P4-T4) EEG correlations were analyzed for each EEG band: theta (4-7 Hz), alpha1 (8-10 Hz), alpha2 (11-13 Hz), beta1 (14-19 Hz), beta2 (20-30 Hz) and gamma (31-50 Hz). During the reinforcement condition, subjects had higher AP in theta at F3 and T3, and at P3 in gamma compared to the punishment condition. Also during reinforcement, a higher rINTRA between F3-T3 was observed in the theta, beta2 and gamma bands, between P3-T3 in alpha1, and between F4-P4 in gamma. A higher rINTER between P3-P4 was seen in beta1 during reinforcement, while under the punishment condition a higher rINTER was found for alpha1 between T3-T4. These data show that both the functionality and degree of cortical EEG coupling vary during DM according to the type of consequence received after each election. The high rINTER in alpha1 between temporal areas could be associated with greater emotional regulation during punishment, while the high rINTRA among F3-T3-P3 in the

fast bands could be related to the decoding and processing of the reinforcing stimulus, as well as to the processing and maintenance of the association between stimulus and response.

Title: Bioinspired few-shot learning in robotic systems

Authors: *A. MARJANINEJAD[1], D. URBINA-MELÉNDEZ[1], B. A. COHN[2], F. J. VALERO-CUEVAS[1];
[1]Biomed. Engin., [2]Computer Sci., USC, Los Angeles, CA

Abstract: The vast majority of robotic systems in use today rely on hard-coded lookup tables and prescribed trajectories, amounting to little more than error correction. In the context of simulation, some robots are able to 'dream' of new tasks, and apply what they've learned from simulations in the real world. However, animals (or any physical system in general) do not have the convenience of excessive trial and error processes or unlimited simulations to learn how to move, manipulate, and navigate. As commonly used control algorithms sacrifice versatility, robustness, and generality across a wider set of tasks in favor of precision in just a few, what insights from biology can be brought to robotics? We present a bioinspired hierarchical learning approach [1] which, for the first time, demonstrates autonomous learning of different movement patterns in a bio-plausible tendon driven limb. In spite of the limb being an under- and over-determined control problem at the same time [2], it takes only a few minutes of interaction with the environment for our control system to achieve a challenging precision task. This bio-inspired learning approach (both in learning and physical implementation) enable our system to learn how to control its motor activation patterns to propel a passive treadmill in as short as about 10 minutes on average and led to the formation of 'movement habits/personalities" across

independent runs. This line of research (as well as a comparison to traditional methods such as genetic algorithms [3]) can revolutionize the utility of modern robots, as they could functionally resemble vertebrates in both anatomy and physiology (including learning and decision making). Our work sets forth a path for robots to interact with humans and other elements in the environment to learn to act properly in unforeseen scenarios [1]. The interplay of self-learning robotics and soft-body physics may ultimately uncover new insights in the fields of biomechanics and neuroscience and we discuss the implications of such research.

Title: The development of curiosity across adolescence

Authors: *E. TEDESCHI, L. OUYANG, A. RATHE, C. VAN GEEN, C. MARVIN, N. L. TOTTENHAM, D. SHOHAMY;
Columbia Univ., New York, NY

Abstract: Curiosity is a fundamental aspect of learning, but there are open questions regarding the cognitive and neural mechanisms linking curiosity, learning and memory. Previous research has suggested that curiosity may leverage basic reward mechanisms, where information is the reward, and curiosity is the drive to obtain it. This framework makes predictions about how curiosity might change with age. Reward sensitivity is high in children and adolescents, and adolescents have been shown to be better at learning from reinforcement than adults. Anecdotally, curiosity is often linked with youth, and this framework would predict higher curiosity in younger individuals compared to older ones, along with higher curiosity-induced memory for information. We tested these predictions by measuring curiosity and curiosity-related memory in participants ranging from 10 to 30 years old (N=54). Participants completed three tasks measuring curiosity-related behavior. In the first task (Task 1), they read trivia questions and chose to wait for the answer or skip to the next question, with willingness-to-wait as the measure of curiosity. They then read a second set of trivia questions (Task 2) and self-reported their curiosity before receiving the answers. The final task (Task 3) was a visual free

exploration task, which used gaze-contingent eye tracking to allow them to slowly reveal hidden images. The amount each image was revealed was used as a measure of curiosity. Finally, they completed a surprise memory test for the answers to the trivia questions to test the effect of curiosity on memory. Contrary to the predictions, none of the curiosity tasks showed significant age-related declines. Instead, there were trends in the opposite direction: older subjects were more willing to wait for answers in Task 1, had higher average curiosity ratings in Task 2, and explored more in Task 3. On the memory test, older subjects remembered significantly more answers than younger subjects. For all ages, higher curiosity ratings predicted better memory, but there was a significant interaction with age where the effect of curiosity on memory was shallower for younger participants compared to older ones. Overall, curiosity was not higher for adolescents than for adults, as would be predicted by the information-as-reward framework. Furthermore, while memory increased for high-curiosity questions, this effect was blunted in the younger ages, and younger participants remembered fewer answers overall. Further investigation into the development of the relationship between curiosity and learning during adolescence may shed light on the mechanisms underlying curiosity across the lifespan.

Title: Towards a unified computational model of reinforcement learning

Authors: Y.-H. SU[1], C.-Y. CHANG[1], *T.-R. HUANG[1,2];
[1]Dept. of Psychology, Natl. Taiwan Univ., Taipei, Taiwan; [2]MOST AI Biomed. Res. Ctr., Tainan, Taiwan

Abstract: A computational model of reinforcement learning has its potential to quantitatively summarize and explain a large array of behavioral phenomena using only a few model parameters. Furthermore, computational modeling of behaviors has benefited model-based neuroimaging analysis to reveal specific neural substrates and their dynamics involved in reinforcement learning paradigms. However, diversities of model formulations and assumptions have led to conflicting results in attributions of model parameters to corresponding behavioral phenomena among prior literature, which urges a unified model to reconcile existing conflicts within/across paradigms and populations in a coherent framework. Without a model thoroughly

examined by its parsimony and generalizability, the inferred neural substrates from neuroimaging analysis based on arbitrary model candidates could also be misled. On the way towards a unified model, we propose that a systematic sampling approach is more favorable than conventional model-fitting techniques for directly examining parameter-dependent behaviors. Starting from a classic probabilistic selection task (Frank, Seeberger, & O'Reilly, 2004, *Science*) and a basic model having learning rates (for reward and punishment respectively: $0<LRr$, $LRp<1$) and behavioral consistency (formalized by temperature T: $0<T<2$) as model parameters, we demonstrate the power of systematic sampling by not only *replicating* impaired Go learning that have been observed in patient populations, but also *predicting* an unexpected region of impaired NoGo learning in the model parameter space that characterizes high behavioral consistency. In other words, human individuals with low behavioral consistency (i.e., high T) might perform better at avoiding punishments than human individuals with high behavioral consistency (i.e., low T). Moreover, our results imply that only by systematic sampling the qualitative, emergent behavioral changes due to quantitative changes of model parameters could be revealed, and those behavior changes could further serve as a model testifier in future studies. By extending systematic sampling to simulate more experimental paradigms and predicting more emergent behaviors that can be empirically tested, we are paving the way for a global model that not only could deepen and widen our understandings of reinforcement learning at a behavioral level, but also could benefit model-based neuroimaging analysis for investigating reinforcement learning in our brains.

Title: Neural mechanisms underlying human reinforcement learning in a continuous choice space

Authors: *J. LEE, S. KIM;
Inst. of Basic Sci., Suwon, Korea, Republic of

Abstract: Computational, behavioral and neural correlates of human reinforcement learning are well understood in decision making with discrete choices, however, little has been known about more generalized decision making with continuous action space. Here, we designed an fMRI experiment in which subjects search a hidden target in a 2-dimensional space given binary feedbacks. Subjects received a monetary reward each time they selected a point close enough to a hidden target which was randomly set after 12 searches. A "reward zone" centered around a

hidden target continued to shrink only after each rewarded trial, guiding subjects to search a hidden target. We suggested two computational models accounting for individual subjects' search behavior: (1) Maximum a posterior model assuming the Bayesian update of expected reward probability with greedy selection (full expoitation) and (2) maximum information gain model suggesting a choice maximizing the reduction of uncertainty of the expected reward probability (full exploration). For the preliminary fMRI results, we found model-based reward prediction error modulated activities in the ventral striatum compatible with previous related studies and activities in the anterior hippocampus reflecting memory-guided search. We also discuss cortical substrates of arbitrating exploitation versus exploration, predicted by the suggested computational models.

Title: Rational predictions guide information-seeking behavior in temporally uncertain environments

Authors: *E. A. LANG, C. VAN GEEN, E. TEDESCHI, D. SHOHAMY;
Columbia Univ., New York, NY

Abstract: The motivation to acquire information is a fundamental driver of learning and memory. However, the mechanisms by which curiosity affects these constructs remain unclear. In particular, it remains unknown how and whether information-seeking behavior is sensitive to temporal features of the environment. In this experiment, we sought to determine if information seeking is modulated by estimation of uncertainty about the timing of information delivery. Prior work has shown that when seeking monetary rewards, people learn the approximate temporal statistics of their environment and use these statistics in order to maximize reward receipt (McGuire and Kable, 2012). We leveraged this same paradigm to test the extent to which the motivation to acquire information is modulated by temporal statistics of the environment. We tested 70 human participants on a behavioral paradigm in which participants could explore the answers to questions. Participants viewed trivia questions and could choose to wait for the answer, or to skip to a new question at any time. Their choices took place in two environments that differed only in the timing of when the answers were shown: in one environment the temporal distribution of answers was uniform (uniform distribution; UD), while the other utilized

a heavy-tailed distribution (HT). The UD environment was optimized by continuing to wait for the answers to appear, while the HT environment was optimized by skipping to a new question after a certain amount of time. We measured participants' choices (wait or skip), the timing of skip responses, and pupil dilation during choice and waiting epochs. Approximately 20 minutes after encoding, participants underwent a surprise subsequent memory test for the answers to the trivia questions they had been shown. Consistent with previous findings on monetary rewards, we found that participants demonstrated longer wait times in the UD than in the HT environment. However, indicating an overarching influence of curiosity regardless of environment, we also found that a question's curiosity level predicted willingness to wait in both environments. Furthermore, memory was increased for the answers to high-curiosity questions in both environments, with no difference between them. Finally, pupil size at encoding predicted later memory of the answers, potentially revealing a physiological marker of curiosity-modulated subsequent memory. Taken together, these results suggest that people encode and use temporal statistics of the environment in such a way as to maximize receipt of interesting information in temporally uncertain environments, even when that information may be functionally useless.

Title: Participants rely on both absolute and relative position when making inferences about ordered lists

Authors: *T. KAO[1,2], **C. E. MICHAELCHECK**[2], V. P. FERRERA[3], H. S. TERRACE[2], G. JENSEN[2];
[1]New York City Col. of Technology/City Univ. of New York, Brooklyn, NY; [2]Psychology, [3]Neurosci., Columbia Univ., New York, NY

Abstract: Human participants were trained to learn photographic images which belonged to 5 different 5-item ordered lists (e.g. $A_1B_1C_1D_1E_1$; $A_2B_2C_2D_2E_2$; etc) using a transitive inference (TI) paradigm in which only adjacent pairs of items in the ordered lists were presented. Participants were then tested with pairs from derived lists with maintained ordinal positions, in which only one item from one of the original 5 different 5-item ordered lists was selected to be presented with another item from another one of the original 5 different 5-item ordered lists, while maintaining their ordinal positions (e.g. $A_2B_5C_4D_1E_3$). At the start of testing, participants

exceeded chance in selecting the earlier item. This result cannot be explained by TI alone, since the pairs of items that were tested came from these lists that were not presented before. In a second experiment, a different group of participants were trained, as in the previous experiment, but were tested with derived lists with changed ordinal positions, in which only one item from one of the original 5 different 5-item ordered lists was selected to be presented with another item from another one of the original 5 different 5-item ordered lists (e.g. $A_1E_4C_5D_3B_2$), while systematically varying their ordinal positions pairs. At the start of testing, participants exceeded chance in selecting the earlier item, and did so with greater accuracy than the results from testing for first experiment. Our results demonstrate that participants make inferences using knowledge of both absolute, and relative, ordinal position when learning derived lists.

Title: Ventromedial prefrontal damage impairs model based learning

Authors: *L. Q. YU[1,2], A. FILIPOWICZ[2], M. R. NASSAR[1], J. W. KABLE[2];
[1]Carney Inst. for Brain Sci., Brown Univ., Providence, RI; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: The ventromedial prefrontal cortex and orbitofrontal cortex (vmPFC/OFC) have been thought to be important for learning the structure of the environment, especially when such structure is hidden and must be inferred from the available evidence. However, the current evidence linking the vmPFC/OFC to structure learning in humans has been mostly from correlational evidence from functional neuroimaging. Thus, it is unclear whether structure learning is critically dependent on the vmPFC/OFC in humans, and also whether the vmPFC/OFC is uniquely responsible for some forms of structure learning over other prefrontal regions. We use two tasks querying different types of structure learning on groups of individuals with ventromedial frontal (VMF) damage (N=5), individuals with other frontal damage sparing the VMF (N=7), and healthy, age and education-matched controls (N = 24). The first task asks the participants to find the hidden means of two Gaussian distributions, by integrating over the rewarded outcomes drawn from those distributions that are shown to them. The second task puts the participant in two contexts with different hazard rates, which is a higher order hidden

variable that governs the rate of switching between two reward sources. We find that in the first task, individuals with VMF damage produce responses that are significantly further away from the hidden means compared to both control groups, but their ability to respond appropriately to different hazard rate conditions in the second task is relatively less impaired. In contrast, the participants with frontal damage sparing the VMF are impaired on dissociating the two hazard rate contexts. Our data suggest that learning hidden structure is sensitive to VMF damage, and that structure learning becomes more sensitive to lateral frontal damage for higher order hidden variables.

Title: Iron deficiency in college-aged women negatively affects neural measures of feedback and reward processing during procedural and declarative learning

Authors: *M. J. WENGER[1], S. E. RHOTEN[2], A. SAJID[2], T. L. LAWSON[2], L. A. DE STEFANO[1], L. BOOZARY[1];
[1]Psychology, Cell. & Behavioral Neurobio., [2]Psychology, The Univ. of Oklahoma, Norman, OK

Abstract: Of all the nutritional challenges in the world, iron deficiency (ID) is the most prevalent, and can be found at high rates in both developing and developed countries, particularly among infants, adolescents, and women of reproductive age. The negative impacts of ID on physical performance and work productivity are well documented, and there is accumulating evidence that ID has a range of effects on cognition and brain function, including evidence that ID in college-aged women negatively affects academic standing. Biologically, animal models of ID have indicated significant effects on dopamine, particularly D2 receptors and dopamine transporter, which are heavily involved in both learning and feedback/reward processing. The present study examined the extent to which ID affects brain activity and behavior during two types of learning. Two groups of women, one ID and not anemic (IDNA), and a matched group of iron sufficient (IS) participants learned two categorization tasks. The first was a rule-based task, which differentially relies on the medial-temporal/frontal circuits that support declarative memory. The second was an information integration task, which differentially relies on the corticobasoganglial circuits that support procedural memory. Participants performed both tasks while concurrent electroencephalographic (EEG) data was

collected, with our focus here being on three response-locked wave-forms: error-related negativity (ERN), error-related positivity (Pe), and feedback-related negativity (FRN). Stimuli were gabor patches that could vary on spatial frequency, orientation, and amplitude. Both groups of women learned both tasks successfully, with ID exerting negative effects on both reaction times and accuracy. In addition, ID women exhibited reduced amplitudes for the Pe and FRN, but not the ERN, and with differences in the FRN being attenuated with learning. In addition, amplitudes of these waveforms showed reliable relationships with both hemoglobin and serum ferritin. These results suggest that ID may negatively affect both neural signal quality (by way of effects on neurotransmitters) and brain energy expenditure (by way of oxygen transport) during cognitive work.

Title: The effects of hypothesis generation and search patterns on curiosity

Authors: *A. HSIUNG[1], A. KHAN[2], B. NIEVES[2], K. C. DICKERSON[1], S. A. HUETTEL[1], R. ADCOCK[3];

Abstract: Curiosity, the intrinsic desire to seek new information, is a fundamental component of human cognition. Previous research has highlighted curiosity's role in facilitating memory, directing choice, and guiding exploration. Although this research has been integral in understanding how curiosity shapes behavior, the treatment of curiosity as a static state limits our ability to investigate if and how curiosity changes as the state of information accumulated also changes. Pulling from extensive research in decision neuroscience on evidence accumulation, the process of information gain can take a variety of shapes depending on the quality, clarity, and timing of incoming evidence. In order to investigate how these variables interacted with curiosity, we developed a novel paradigm that naturally and dynamically manipulates information gain as a function of time. In our task, participants (N = 262) watched videos of single continuous line drawings that slowly revealed an object over time. Participants were encouraged to report a guess about what the image was going to be as soon as they had formulated one. We found that our videos could be classified into two general information gathering shapes: one was characterized by a sigmoidal shape, where the majority of correct

identifications were concentrated in a short time window. The other was characterized by a linear shape, where correct identification slowly accumulated across the entire video duration. Importantly, our task was highly engaging (M = 8.80/10, sd = 1.67) and elicited curiosity (M = 86.9/100, sd= 7.94), confirming that our paradigm did in fact produce an intrinsic drive for information.Ongoing analyses use these stimuli to probe real-time curiosity ratings as a function of the shape of information gain, and relate these curiosity ratings to subsequent information-seeking behavior: allowing participants to control the speed of reveal for each video and the value of future information using a willingness-to-pay manipulation. Collectively these studies begin to elucidate how the process of curiosity dictates how and what we search for, lending insight into how we can foster its development to enhance learning in both educational and clinical settings for improved health and fulfillment of human potential.

Title: Overlap in stimulus-response rules is insufficient for retrieval of task set memories

Authors: *O. LOSITSKY, D. BADRE;
Brown Univ., Providence, RI

Abstract: How do we form abstract task representations that can be generalized to new contexts, and how do we update these representations when circumstances change? Recent models (Collins & Koechlin, 2012; Collins & Frank, 2016; Qian, Jaeger & Aslin, 2016) have proposed that people group together contexts into an abstract ‘task set’ when these contexts predict similar stimulus-response rules. Based on this work, we hypothesized that previously learned task sets should be retrieved in new contexts to the degree that the stimulus-response rules in the new context match those in the old context. In a series of five behavioral experiments (N=71 participants), we sought to manipulate whether two task sets would be stored within a single memory or two separate memories. In all experiments, participants learned to press one of four keys in response to fractal art images based on probabilistic feedback. Once they achieved a performance criterion, the associations between stimuli and responses changed and had to be relearned (task set B). In the last block, the S-R rules changed again either to the initial set (ABA games) or to a new set (ABC games). Importantly, all changes in task set were hidden and could

only be inferred from feedback. Experiments varied in the number of stimuli (2-4), feedback validity (80-90%), and the number of exposures to task set A prior to testing memory retrieval. In all cases, several minutes elapsed between the initial learning of task set A and its recurrence. Surprisingly, across all five experiments, we found no significant difference in learning speed (trials to criterion) or performance (accuracy or reaction times) between previously learned sets (A) and new sets (C). However, follow-up experiments revealed three conditions under which participants relearned old sets significantly better than new sets: 1) when participants noticed the temporal structure of the experiment and could predict the moment of task set A recurrence, 2) when participants were explicitly instructed about the temporal structure of the experiment and the presence of repeats, and 3) when a contextual cue (background color) uniquely identified which task set applied at a given time, i.e., when the context was visible. Our results suggest that overlap in stimulus-response rules may not be sufficient to trigger retrieval of task sets from long-term memory, and that either salient contextual cues or knowledge of the temporal sequence may be necessary for retrieval. Investigating these mechanisms further may shed light on the role of the medial temporal lobes in encoding and retrieving sets of stimulus-response associations, which has generally been attributed to fronto-striatal circuits.

Title: A novel paradigm for social learning and decision-making: The social multi-armed bandit

Authors: *J. ADRIAN[1], S. SIDDHARTH[2], S. BAQUAR[2], T.-P. JUNG[2], G. DEAK[2];
[1]Cognitive Sci., [2]UC San Diego, San Diego, CA

Abstract: Decision-making is a fundamental human skill. Its study involves usually only a single agent; however, most real-world decision-making is influenced by other agents acting in multifactorial environments. We validated a novel paradigm to study social decision-making: the social multi-armed bandit task. It requires two participants to alternate in choosing between different options that may or may not yield a reward. Each option is associated with a reward probability unknown to the players. Both players observe their own and their partner's choices and subsequent outcomes. They learn and over time make more informed decisions through exploration and integration of their outcomes. Reward probabilities for different options are constant throughout the game but different for each player, such that the options with the highest

reward probability for player 1 has the lowest probability for player 2, and vice versa. Participants also play a solo version of the game to assess how they use 'solipsistic' outcomes to update their decisions. Comparing performance in the solo and dyadic version reveals how people take into account not only their own outcomes but also their partner's. We tested 16 pairs of participants and recorded EEG (14 channels, at 128Hz) and pupillometry during both the solo and dyadic tasks. 50% (16/32) of participants learned which option yielded the most probably reward in the solo game, but did not learn as much in the dyadic version, receiving significantly fewer rewards ($F=47.76$, $p<0.001$). This suggests that these participants automatically integrated their partner's actions and outcomes, though it was detrimental to their overall outcomes. Event-related potentials time-locked to reward onset show qualitatively similar responses, but with attenuated amplitudes in the solo versus the dyadic game. This might indicate that arousal and attention after receiving reward are sustained when a second agent is present but not when playing alone. A similar pattern was observed in pupil response: diameter increased after receiving a reward but the magnitude of the increase was higher in the dyadic versus the solo task. Ongoing studies will disambiguate under which conditions own and other's information is integrated for decision-making.

Title: How the human nervous system defines the dimensionality of energy optimization in walking

Authors: *S. J. ABRAM[1], J. C. SELINGER[3], J. M. DONELAN[2];
[1]Sch. of Engin. Sci., [2]Dept. of Biomed. Physiol. and Kinesiology, Simon Fraser Univ., Burnaby, BC, Canada; [3]Sch. of Kinesiology and Hlth. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: People prefer to move in ways that minimize metabolic energy during walking. Our lab has demonstrated that this preference arises not just through evolution and development, but that people can optimize step frequency and step width, in real-time, to minimize energy. Here, we model this process as reinforcement learning and test our model predictions against human experiments to elucidate how the nervous system may represent the dimensionality of new

energetic cost landscapes in its energy optimization of walking. In this model, we define the cost landscape using either a low-dimensional representation, where control strategies are gait parameters whose energy optimum we have shifted, or a high-dimensional representation, where the amount of control strategies is much larger, such as with combinations of individual motor units. We simulate a protocol that tests for energy optimization in 1-dimensional cost landscapes that shift the energy optimal frequency or width, and a 2-dimensional cost landscape that shifts both the energy optimal frequency and width. We hypothesize that, to learn new energy optimal gaits in real-time, the nervous system reduces the dimensionality of energy optimization to be along relevant gait dimensions. We used our model to quantify our hypothesis and found that, in any cost landscape, the rate of adaptation was indeed faster with the low-dimensional representation compared to the high-dimensional representation. We also determined how each representation's rate of adaptation increased from 1 to 2-dimensional cost landscapes—with the low-dimensional representation that was the same as the respective cost landscapes, the rate of adaptation increased 20-fold, whereas it was roughly the same with any high-dimensional representation greater than 5. To test our hypothesis, we conducted human experiments using a custom-built system that alters the relationship between energetic cost and a given gait parameter. We found that, in 1-dimensional cost landscapes, participants adapted towards the new energy optimum with similar time constants for both the step width (n=8) and step frequency (n=5) dimensions (273 and 247 seconds, respectively). In a 2-dimensional cost landscape, participants (n=7) adapted towards—but did not converge on—the new energy optimal width and frequency with time constants of 303 and 297 seconds, respectively. The similar rates of adaptation in 1 and 2-dimensional cost landscapes suggests that the nervous system may use a high-dimensional representation, however, the smaller adaptations in a 2-dimensional cost landscape suggests that an increase in dimensionality indeed influences energy optimization.

Title: Can I eat this? Event-related potentials are modulated by feedback regarding edibility

Authors: *R. GRAHAM, R. LOPAS, A. ZBOROWSKI, N. CEBALLOS, J. TREFFALLS; Psychology, Texas State Univ. San Marcos, San Marcos, TX

Abstract: Feedback-related negativity (FRN) is an event-related potential (ERP) component that has been shown to be sensitive to feedback during risk-taking, such that the FRN is larger for

negative outcomes. Another ERP wave, the P300, is known to play a role in attentional resource allocation and is typically larger for better outcomes. The present experiment was conducted to examine the sensitivity of the FRN and P300 to processes related to appetitive motivations. Twenty-five undergraduates (15 male, mean age = 21.5 years) viewed ambiguous close-ups of food/drinks or nonfood/drinks, and indicated whether they could consume the objects. Unambiguous feedback about stimulus type was then provided. Analyses focused on ERPs to feedback-related events, specifically ERPs associated with correct judgements (food vs. non-food) and incorrect judgements (food vs. non-food). In line with our expectations, a stimulus type by outcome interaction was observed for the FRN, such that amplitude was largest when participants incorrectly identified nonfoods as foods. The P300 was sensitive to positive feedback, but was highest when participants correctly identified foods. These results provide support for the hypothesis that the FRN is modulated by the magnitude of negative feedback. Additionally, the enhancement of the P300 can be interpreted to represent the salience and reinforcing properties of motivationally-relevant feedback to humans, especially information regarding edibility.

Title: Neural mechanisms of preserving alternative prediction errors

Authors: *N. YINMEI[1], S. WANG[1], J. SU[2], X. WAN[3], J. LI[4];
[1]Beijing Normal Univ., Beiji, China; [2]State Key Lab. of Cognitive Neurosci. and Learning, Beijing Normal Univ., Beijing, China; [3]Beijing Normal Univ. - Beijing, Beijing, China; [4]Peking Univ., Beijing, China

Abstract: Adaptive optimal control in interaction with dynamic changing environments is a central feature of intelligent systems. Precise predictions of the dynamic environment changes are critical for adaptive optimal control. The prediction is trial-by-trial updated on the basis of

the prediction error. In many situations, we need to keep multiple prediction errors simultaneously in the brain and choose one to use and keep the other currently unused ones. How the brains preserve alternative prediction error information? In this presentation, we report this part of results to elucidate the neural mechanism of preserving alternative prediction errors. Thirty-five participants made trial-by-trial predictions in a classical conditioning task. They concurrently made predictions on gain and punishers loss, which were randomly interleaved and stochastically associated, respectively. Thereby, the participants updated the corresponding prediction when the cue was revealed at the beginning of the next trial, and they should also keep the unused prediction error information. The participants reported their prediction value associated with the presented cue by scrolling the cursor position with combination of several button presses in each trial. First, the neuroimaging results showed that during the prediction phase the neural system associated with currently used prediction error and unused prediction error were largely dissociated. The former was in the orienting network, including the middle DLPFC (mDLPFC), parietal cortex, while the latter was in the executive function network, including dorsal ACC (dACC) and frontopolar cortex (FPC). However, there were also some overlapped regions, including primary motor cortex (PMC) and VTA. Secondly, our accompanying study showed that during the feedback phase the current prediction error information was separately encoded in the PMC, caudal ACC (cACC) and rostral ACC (rACC), while the unused prediction error information was still encoded in the dACC and FPC regions. Thirdly, when the coming-out cue was different from the previous cue, the used and unused prediction error information should be switched (switching trials). In the switching trials, the prediction error information generated from the previous trial became unused information, and was encoded in dACC and FPC regions, while the unused prediction error information encoded in dACC and FPC regions in the previous trials switched to Putamen and PMC, driving the current motor action. The overlapped regions of PMC and VTA, however, conveyed the unused prediction error information to the current trial, confounding the current prediction change.

Title: Computational and neural mechanisms of error-based learning in a dynamic environment

Authors: *S. WANG[1], Y. NI[1], J. SU[1], J. LI[3], X. WAN[1,2];
[1]State Key Lab. of Cognitive Neurosci. and Learning, [2]IDG/McGovern Inst. for Brain Res., Beijing Normal Univ., Beijing, China; [3]Sch. of Psychological and Cognitive Sci., Peking Univ., Beijing, China

Abstract: Precise predictions of the dynamic environment changes are critical for adaptive optimal controls. The prediction is trial-by-trial updated on the basis of the prediction error. The environment is often stochastically and unexpectedly changed, thereby, the prediction error brings uncertain information about the environment change. The model-based Bayesian learning is theoretically optimal. However, its computation and implementation are usually burdened, and the underlying neural mechanisms remain elusive. Here we elucidate an neural mechanism to approximate the optimal Bayesian learning as a function of prediction errors. Thirty-five participants made trial-by-trial predictions in a classical conditioning task. To clearly separate the feedback and prediction phases, two different types of cues were randomly interleaved and stochastically associated with rewards (gain) and punishers (loss), respectively. Thereby, the participants updated the corresponding prediction when the cue was revealed at the beginning of the next trial. The participants reported their prediction value by scrolling the cursor position with combination of several button presses in each trial. The right button presses would increase the magnitude and the left ones would decrease the magnitude. The initial position of the cursor was always at the prediction value reported in the previous trial with the same cue type. The optimal Bayesian model revealed that the participants' trial-by-trial learning rates held a linear relationship with the prediction errors. That is, the prediction change could be approximated by a combination of a linear and quadratic function of the prediction error. During the feedback phase, we found that the linear and quadratic components were associated with the primary motor cortex (PMC) and caudal anterior cingulate cortex (cACC), respectively, while the regression beta values of each participant were proportional to the corresponding coefficients. During the prediction phase, the VTA and Putamen activities were associated with the magnitudes of prediction changes, and independently correlated with the above two components in the feedback phase, indicating that VTA and Putamen integrated the learning processes and formed the motivational signals, to drive the motor actions, which were associated with PMC activities again. Taken together, these findings elucidate the neural and computational mechanisms of error-based learning in a dynamic changing environment.

Title: Spontaneous rs-fMRI activity within the classic hippocampal subfields

Authors: *L. M. EZAMA-FORONDA[1], E. PEREDA[2], N. JANSSEN[3];
[1]Psychology, Univ. of La Laguna, University of La Laguna, Spain; [3]Inst. for Biomed. Technologies, [2]Univ. of La Laguna, San Cristóbal de La Laguna, Spain

Abstract: The hippocampus (HP) is a brain structure implicated in Alzheimer's Disease and is thought to play a role in memory formation. The HP contains a number of subfields among which the Subiculum, CA1, CA2/3, CA4 and Dentate Gyrus. However, the functional characteristics of these substructures remain poorly understood. We used resting-state functional magnetic resonance imaging (rsfMRI) to explore whether spontaneous activity within the HP respects the classic hippocampal subdivisions. RS networks have been found to reflect different cognitive states and to depend on the interactions between different brain regions. We collected high-spatial resolution fMRI data and examined whether RS networks could be detected within the HP using a method called Spatially Restricted group-Independent Component Analysis (SR-gICA). If hippocampal substructures serve a functional role, one would expect RS networks detected within the HP to differentiate between hippocampal substructures. In this study, we recruited 33 healthy participants, 16 male and 17 female (mean age 22). The MRI protocol involved a 6 min partial volume GRE-EPI RS scan, and T1w and T2w acquisitions. Preprocessing of rsfMRI data involved the standard FSL FEAT pipeline followed by manual cleaning of ICA components. We obtained subject-specific ROIs for the location of the HP and its subfields from Freesurfer v6.0. A SR-gICA was performed on the 4D rsfMRI data restricted to each participant's entire HP. Obtained components within the HP were evaluated as signal or noise, and their functional connectivity between the hippocampal subfields and between the rest of the brain was explored using Dual Regression (DR). The degree to which a given detected RS network activated a given area of the brain was evaluated using linear regression (LR). The RS-gICA revealed 5 spatially independent RS networks. Careful consideration of their corresponding timecourses and periodograms indicated that IC3 and IC4 were likely of non-neural origin and therefore not considered. Results from DR of IC0-2 revealed they differentially depended on the substructures of the HP. This was confirmed by the LR results that showed that, for example, the subiculum was activated in RS networks IC0 and IC2 but not in IC1. In addition, these three networks differed in their connectivity with the rest of the brain. Here we have provided evidence that spontaneous rsfMRI activity detected within the HP yields networks that differentially depend on the classic divisions of the HP. In future research we will evaluate how spontaneous and task-related network activity within the HP is affected by aging and pathology.

Abstract: People often recognize and remember faces of individuals within their own race more easily than those of other races. While behavioral research has long suggested that the Other-Race Effect (ORE) is due to extensive experience with one's own race group, the neural mechanisms underlying the effect have remained elusive. Predominant theories of the ORE have argued that the effect is mainly caused by processing disparities between same and other-race faces during early stages of perceptual encoding. Our findings support the alternative view that the ORE is further shaped by downstream mnemonic processing mechanisms beyond perception. Using a "pattern separation" paradigm based on computational models of episodic memory, we report evidence that the ORE may be driven by differences in successful memory discrimination across races as a function of degree of interference or overlap between face stimuli. In contrast, there were no ORE-related differences on an analogous working memory task, suggesting that the effect is not simply attributable to perceptual encoding. These findings suggest that the ORE may emerge in part due to "tuned" memory mechanisms that may enhance same-race, at the expense of other-race, face detection.
Our findings highlight the importance of a memory-based account in characterizing the ORE, suggesting future investigations of neural loci of the effect not only include perceptual but also traditional memory processing regions. Until now, neuroimaging approaches have focused primarily on the ventral visual stream's fusiform face area (FFA). However, while the FFA demonstrates significantly higher activity to same-race than other-race faces, these signals are not reliably predictive of ultimate memory for these faces - the hallmark behavior of the ORE. For this reason, we predict activity in medial temporal areas - in particular the perirhinal cortex (PrC) will better predict performance in an ORE task. Previous research has established a role for the PrC in mnemonic and perceptual discrimination of objects with high interference and feature ambiguity. In addition, PrC signal intensity predicts accuracy in both perception of and memory

for face stimuli, while the FFA does not. Taken together, these findings suggest the PrC is vital for interference resolution and ultimate accuracy for facial recognition- both functions that if compromised for other-race faces, would theoretically give rise to the ORE. In order to test the role of PrC in the emergence of the ORE we are adapting our behavioral task design and collecting data from subjects while their brain activity is imaged in the scanner.

Title: Ultrahigh resolution diffusion imaging reveals abnormal medial temporal lobe integrity predicts poor performance on RAVLT delayed recall in the oldest old

Authors: *S. J. GRANGER[1], M. S. LARSON[2], M. T. SATHISHKUMAR[2], A. P. SMITH[2], L. MCMILLAN[2], D. GREENIA[2], M. M. CORRADA[3], C. H. KAWAS[3], M. A. YASSA[2]; [1]Neurobio. and Behavior, [3]Dept. of Neurol., [2]Univ. of California, Irvine, Irvine, CA

Abstract: The number of persons over 90 years of age is expected to grow roughly 4 times by the year 2050 and the resources needed to care for them will only increase as well. Non-invasive imaging methods such as volumetry and functional brain activity are commonly used to study endophenotypes of cognitive decline and neurodegenerative diseases, however, they alone cannot distinguish specific white-matter circuits involved in decline. A more sensitive biological marker that precedes gross gray-matter volumetric change is needed. Using ultrahigh resolution diffusion-weighted MRI, in this cross-sectional analysis, we investigated if microstructural differences within the medial temporal lobe (MTL) were associated with poorer memory performance in people over 90 years old from The 90+ Study. We segmented subfields of the MTL using machine learning techniques and assessed MTL integrity using voxel-wise diffusion-tensor imaging and “model-free” high-angular deterministic tractography methods to create MTL connectomes. Cognitive status was measured as memory performance on the Rey Auditory Verbal Learning Test (RAVLT) delayed recall. Participants were a small cohort of 16 persons (13 females, 3 males), age range 90 to 98 years old, 11 of which had normal cognition, and 5 of which had cognitive impairment with no dementia. Using one-way ANOVA, we provide evidence that tensor-derived measures dissociate MTL subfields and accurately represent tissue

vs. non-tissue samples. Further, we show that distinct MTL structural abnormalities in both fractional anisotropy ($r = -0.6$, $p < 0.01$) as well as mean diffusivity ($r= -0.4$, $p = 0.06$) are negatively correlated with delayed recall ability. Finally, as an exploratory approach, we provide evidence that greater structural connectivity of the entorhinal cortex with the rest of the MTL is associated with poorer delayed recall ability ($r = -0.5$, $p = 0.052$). Together, these results indicate that novel and specific MTL structural abnormalities are associated with poor memory capacity in the oldest old. With the addition of subjects, covariates, and multimodal neuroimaging methods we believe these techniques and results could possibly yield novel insights into the transition to cognitive decline and even Alzheimer's related pathology.

Title: Reduced long-range default mode network connectivity predicts conversion to Alzheimer's disease in older individuals with Down syndrome

Authors: *N. D. DIPROSPERO[1], D. B. KEATOR[2], T. G. VAN ERP[2], E. DORAN[3], I. T. LOTT[3], M. A. YASSA[1];
[1]Dept. of Neurobio. and Behavior, [2]Dept. of Psychiatry and Human Behavior, Univ. of California, Irvine, Irvine, CA; [3]Dept. of Pediatrics, Univ. of California, Irvine Med. Ctr., Orange, CA

Abstract: Individuals with Down syndrome (DS) are at increased risk for developing Alzheimer's disease (AD) and have earlier symptom onset at an average age of 55, compared to age 80 in the general population. Determining preclinical biomarkers of AD is critically important for early diagnosis and effective intervention within this high-risk population and more broadly in the general population, but little is known about the biomarkers that may predict clinical onset in DS. Previous studies in non-DS individuals have shown weaker functional connectivity within the default mode network (DMN) and stronger functional connectivity within the medial temporal lobe (MTL) in cognitively normal older adults in the preclinical stage of AD. However, few studies have investigated functional connectivity as a potential biomarker of AD in individuals with DS ages 40+. 15 non-demented older adults with DS (mean age

51.7±5.3, 47% women) underwent MRI, (including a 1mm MPRAGE scan and a 3mm resting state fMRI scan), PET, and clinical evaluation at their first visit. Participants were followed for two years, returning to the clinic roughly every 12 months for neuropsychological testing and clinician diagnosis for AD. 4 participants transitioned to AD during follow-up. We hypothesized that older adults with DS who subsequently developed dementia would have weaker functional connectivity within the DMN and stronger functional connectivity within the MTL compared to those who remained cognitively normal during follow-up. We also predicted that aberrant functional connectivity would precede cognitive decline, and regions with aberrant functional connectivity would exhibit greater amyloid burden in individuals with DS who transition to AD compared to those who do not transition to AD. Older individuals with DS who later developed AD had weaker antero-posterior DMN functional connectivity one year prior to conversion. Lower levels of functional connectivity between distal DMN hubs is associated with faster cognitive decline. Functional connectivity between proximal DMN hubs and between MTL hubs does not predict AD conversion or precede cognitive decline. Individuals who transitioned to AD had greater amyloid accumulation in DMN hubs relative to those who did not develop dementia during follow-up. Antecedent hypoconnectivity between distant DMN hubs may predict future conversion to AD and faster cognitive decline in older adults with DS. Those who convert to AD exhibit greater amyloid burden in the same DMN hubs with aberrant functional connectivity.

Title: Pattern separation beyond the hippocampus: Neocortico-hippocampal mechanisms of pattern separation in humans

Authors: *S. GATTAS[1], J. J. LIN[2], M. A. YASSA[3];
[1]Electrical Engin. and Computer Science, Med. Scientist Training Program, [2]Biomed. Engin. and Dept. of Neurol., Univ. of California, Irvine, Irvine, CA; [3]Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA

Abstract: Pattern separation is a cognitive process whereby two inputs sharing overlapping content are transformed into two orthogonal, non-overlapping outputs. In the context of memory processing, there is evidence pointing to the involvement of the hippocampus (HC), specifically

DG and CA3, in pattern separation. Reported hippocampal mechanisms of pattern separation include changes in firing rate, recruitment of new coding units, and increases in theta and gamma oscillations. In this study, we aim to further investigate oscillatory mechanisms supporting pattern separation both within HC and between HC and neocortex (NC). In order to do so, we recorded local field potential (LFP) in humans implanted with electrodes for clinical monitoring. Recordings were conducted while patients performed a task in which they indicated whether presented images of objects were identical replicas of previously shown images (repeats) or new ones (similar but not identical, or completely different foils). During successful discrimination between previously encoded images and their similar newly presented counterparts, we observed early (~200ms) theta power and late (preceding subject response) gamma power increases in the HC. Early theta power increases were also observed in NC. Moreover, during the same condition type denoting pattern separation, we observed neocortico-hippocampal theta-gamma phase-amplitude coupling. These reported effects were not observed in three remainder conditions: repeats, new foils, or similar but incorrectly discriminated images. These findings suggest that NC and HC theta power, HC gamma power, as well as neocortico-hippocampal theta-gamma coupling support pattern separation in humans.

Title: Mnemonic discrimination in the oldest old and relationship with volumes of medial temporal lobe and striatal regions

Authors: *M. S. LARSON[1], M. T. SATHISHKUMAR[1], N. DIPROSPERO[1], A. SMITH[2], L. MCMILLAN[2], D. GREENIA[3], M. WITBRACHT[3], M. M. CORRADA[3], C. H. KAWAS[3], J. GRILL[3], M. A. YASSA[2];
[1]Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA; [2]Neurobio. and Behavior, [3]Inst. for Memory Impairments and Neurolog. Disorders, Univ. of California Irvine, Irvine, CA

Abstract: Individuals over the age of 90 are the fastest growing sector of the U.S. population and make up the group at the highest risk for dementia. However, comparatively little is known about how cognitive changes in the oldest old may be linked to structural and functional decline in brain networks. Participants in this study included two groups: older adults - ages 65-85 ($n=40$, $mean_{age}=77.7$, 26 female), and oldest old - ages 90-104 ($n=23$, $mean_{age}=94$, 18 female),

with participants from both groups without dementia diagnosis. Dementia diagnosis was assessed within 6 months of their MRI study visit in clinical interviews at their annual visit with the UCI ADRC Longitudinal Study or their semi-annual visits with the 90+ Study. At their MRI study visit, the Mini Mental State Exam (MMSE), a measure of gross cognition, was administered ($mean_{65\text{-}85}$ =27.07 $mean_{90+}$ =27.37) found to be without significant group differences. We then compared their performance on a mnemonic discrimination task that is sensitive to hippocampal function, and in particular a hippocampal computation known as pattern separation - the ability to discriminate among similar memories and store new experiences with high fidelity. We have previously shown that this ability is compromised with age but have not examined this in the oldest old in detail. Using Welch's unpaired t-test, we found that High and Low Similarity Lure Discrimination Index scores were not significantly different between the groups (LDI High: $mean_{65\text{-}85}$ =0.12, $mean_{90+}$ = 0.13 LDI Low: $mean_{65\text{-}85}$ =0.26, $mean_{90+}$ =0.19). We collected high resolution T1-weighted structural MPRAGE scans on a 3T scanner (90+: 0.80mm isometric, 65-85: 0.65mm isometric) and used FreeSurfer to calculate regional volumes in medial temporal lobe regions, as well as other default mode network regions. All regional volumes were corrected with total brain volume (TBV). In a Welch's unpaired t-test we found significant cohort differences in TBV corrected volumes of the caudate and posterior cingulate (Caudate $mean_{65\text{-}85}$ = 0.002968 $mean_{90+}$ =0.002709, PCC $mean_{65\text{-}85}$ = 0.000719 $mean_{90+}$ =0.0006433). Surprisingly we did not find differences in hippocampal volumes by cohort (HPC $mean_{65\text{-}85}$=0.003053 $mean_{90+}$ =0.002897). Further study is needed with a larger sample size to evaluate sex differences, and to determine if the lack of difference in hippocampal volume is the result of decreased rate of change or simply a greater starting volume in the oldest old. Study is also needed to evaluate the volume of hippocampal subfield differences between the two groups, and if performance on the mnemonic discrimination task is predictive of longitudinal volume change.

Title: The neural circuit bases of prolonged maternal grief for the loss of her child

Authors: *M. T. SATHISHKUMAR[1], ***J. ADAMS**[1], T. Z. BARAM[2], M. A. YASSA[1]; [1]Neurobio. and Behavior, [2]Pediatrics, Univ. of California, Irvine, CA

Abstract: Rationale: Grief is considered an appropriate and time-constrained response to a loss. Yet, mothers who lose their children often experience overwhelming sense of grief that may last for years and decade. The profound grief is often triggered by memories of the lost child or by cues that provoke these memories. Loss of a child upon trauma, war, suicide or drug overdose is common, and the population of grieving mothers is large. Yet, we know little about the neurobiological basis of chronic persistent maternal grief. **Methods:** Here, we explore the impact of prolonged grief on memory and brain circuitry using structural, functional, diffusion and resting state brain magnetic resonance imaging (MRI). We recruited 9 mothers who have experienced a recent loss of a child, (mean age = 61.3 years); and 8 age and demographically matched controls, (mean age = 57.8 years). We assessed cognitive functions, mood and symptoms of grief using Neuropsychological tests. We employed functional MRI and measured grief and control subjects' brain responses to pictures of their own children (dead for the subjects, alive for the controls), deceased celebrities or unfamiliar people. Subjects also rated the level of emotionality they felt about the images.
Results: Comparing measures of brain activation to their own children vs celebrities or unfamiliar people distinguished grieving mothers from the controls. Specifically, increased activation of components of the prefrontal cortex, and especially both left and right inferior frontal gyrus (IFG) and superior frontal gyrus (SFG) was observed in the grief group. These regions contribute to a network involved in emotional regulation, control, and motivational processing.
Conclusion: The disrupted operation of an executive networks balancing motivation (motherhood) and emotional regulation may begin to uncover a potential basis for the overwhelming and persistent grief of mothers losing their children.

Title: Functional connectivity of the medial temporal lobe contributes to spatial discrimination impairments in non-demented older adults with and without memory impairments

Authors: *F. MARQUEZ[1], M. A. YASSA[2];
[1]Univ. of California Irvine, Irvine, CA; [2]Neurobio. and Behavior, Univ. of California Irvine Dept. of Neurobio. and Behavior, Irvine, CA

Abstract: Studies suggest that two neocortical systems interact with subcortical areas (including the hippocampus) to support memory for objects and memory for spatial navigation. The hippocampus is connected to other brain regions via two major limbic tracts: the fornix and the cingulum bundle, which includes the hippocampal cingulum and superior cingulum. In healthy adults (51.8 ± 18.9 years; MMSE: 29.02; RAVLT Delay: 11.52), significant relationships between chronological age and integrity of the hippocampal cingulum and fornix tracts have been described previously, and behavioral assays have shown a relationship between object discrimination and fornix integrity. While asymptomatic older adults have major deficits on object discrimination, they only show subtle deficits on the comparable spatial discrimination task when compared to young adults. If spatial discrimination is supported by hippocampal connections to a broader neocortical network, then deficits in spatial discrimination may be mediated by the integrity of limbic tracts. In this study, older adults (74.6 ± 7.5 years; MMSE: 27.94 ± 1.39 RAVLT Delay: 9.94 ± 4.46) underwent diffusion tensor imaging (2.2 mm nominal isotropic resolution) and completed the object and spatial mnemonic discrimination tasks. Behaviorally, we found a positive correlation between performance on RAVLT Delay and spatial discrimination (r^2=0.271, p=0.0054), but no relationship between performance on RAVLT Delay and object discrimination (r^2=0.002, p=0.80). Targeted tractography analyses revealed that hippocampal cingulum integrity (fractional anisotropy, mean diffusivity, and restricted diffusion) was significantly related to mnemonic discrimination for spatial memory, but not for object memory. These findings support the idea that deficits in spatial memory manifest due to hippocampal disconnection to neocortical systems via the hippocampal cingulum. The results additionally suggest that the integrity of the hippocampal cingulum may be a biomarker that is associated with cognitive changes particularly related to spatial memory.

Title: Spatial memory is protective against Alzheimer's disease

Authors: *S. FOO[1], D. SODUMS[3], V. D. BOHBOT[2];
[1]Psychiatry, [2]Dept. of Psychiatry, McGill Univ., Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada; [3]Johns Hopkins Univ., Baltimore, MD

Abstract: Aim: The hippocampus (HPC) is critical for supporting memory functions, such as spatial memory, and a volume reduction in this structure is associated with future clinical diagnosis of Alzheimer's disease (AD). Previous research in our laboratory demonstrated that spatial memory correlates to grey matter in the HPC. Moreover, MRI SNIPE grading measures in the HPC were previously shown to predict ensuing diagnosis of AD with a 73% accuracy. As such, the aim of the current study was to investigate whether spatial memory is protective against MRI AD pathology.
Methods: Seventy-four healthy older adults (43 female, 31 male; mean age: 65.5 ± 4.2 years) received MRI scans and SNIPE was used to compare their hippocampi to patients with AD versus controls. The MRI SNIPE measure involves computing the similarity of every hippocampal voxel of each participant to a library of manually segmented MRI datasets from the ADNI database consisting of equal numbers both healthy cognitively intact older adults and AD patients. Participants were tested on the Concurrent Spatial Discrimination Learning Task (CSDLT) and the Wayfinding task, both of which are sensitive to spatial memory and hippocampal grey matter. The CSDLT is a 12-arm radial maze in which participants have to learn the location of objects within pairs of arms, after which the presentation of arms is recombined but the reward contingency remains the same (stage 2). Stage 2 errors indicated whether the position of objects on the radial maze was learned in relation to the landmarks in the environment. The wayfinding task measures the ability to build and use a cognitive map of a virtual environment containing landmarks (e.g. pool, shop, etc.). Probe errors measure the participant's ability to find target locations in a straight path in the virtual town, hence measuring spatial memory.
Results General linear modelling was used to regress spatial memory and age on SNIPE scores in men and women separately. Results showed that performance on the wayfinding task significantly predicted hippocampal SNIPE grading scores in men (β = 0.493, $p < 0.01$). The CSDLT task positively predicted hippocampal SNIPE grading scores in women (β = -0.318, $p < 0.05$).
Conclusion: The current study shows that participants with a good spatial memory have higher SNIPE scores, which are predictive of healthy cognition in normal aging. On the other hand, poor spatial memory is associated with lower SNIPE grading in the HPC, which is predictive of increased risk of future AD diagnoses. Sex differences in navigation may help explain differences in the sensitivity of navigation tests to the MRI measures for men and women.

Title: Negative correlation between grey matter in the hippocampus and caudate nucleus in healthy aging

Authors: *V. D. BOHBOT;
Psychiatry, Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada

Abstract: Aim: Spatial memory impairments, as well as decreases in fMRI activity and grey matter in the hippocampus have been documented in healthy older adults engaged in a navigation task. However, navigation in a virtual maze relies on spatial or response strategies known to depend on the hippocampus and caudate nucleus of the striatum respectively. Furthermore, the proportion of people using spatial strategies decreases across the lifespan in favor of response strategies. As such, the aim of the current study was to investigate whether the decreases in grey matter in the hippocampus were associated with corresponding increases in grey matter in the caudate nucleus.
Methods: Thirty-nine healthy older adults (21 women and 18 men; mean age:64.69 ± 4.11 years) were scanned on a 1.5T scanner and were tested on the Concurrent Spatial Discrimination Learning Task (CSDLT), a radial task that dissociates between spatial and response strategies. The CSDLT is a 12-arm radial maze in which participants have to learn the location of objects within pairs of arms, after which the presentation of arms are recombined but the reward contingency remains the same (stage 2). Stage 2 errors indicated whether the position of objects on the radial maze was learned in relation to the landmarks in the environment (use of spatial strategies).
Results: A regression of strategies against structural MRIs showed for the first time in older adults that the response strategy was associated with an increase in grey matter in the caudate nucleus. As expected, the spatial strategy was associated with increased grey matter in the hippocampus, which in turn, was negatively correlated with grey matter in the caudate nucleus. Interestingly, a sex difference emerged showing that among older adult response learners, women response learners have the least amount of grey matter in the hippocampus. This difference was absent among spatial learners showing that the use of spatial memory is protective against grey matter loss in the hippocampus, especially in women.
Conclusion: The current study reports a negative correlation between grey matter in the

hippocampus and caudate nucleus during normal aging. There results are consistent with a negative correlation between these structures previously shown in mice, young adults and in patients with Alzheimer's disease. Since the use of the caudate nucleus has previously been shown to actively inhibit activity and grey matter in the hippocampus, our results suggest that the caudate nucleus may play an active role in hippocampus-dependent memory deficits observed in normal aging.

Title: Landmark-dependent navigation strategy use within a mobile video game declines with age and is associated with better spatial memory performance

Authors: *G. WEST[1], E. PATAI[2], A. COUTROT[3], M. HORNBERGER[4], H. J. SPIERS[5], V. D. BOHBOT[6];
[1]Univ. of Montreal, Montreal, QC, Canada; [2]Exptl. Psychology, UCL Inst. of Behavioural Neurosci., Oxford, United Kingdom; [3]Univ. de Nantes, Rezé, France; [4]Univ. of East Anglia, Norwich, United Kingdom; [5]Univ. Col. London, London, United Kingdom; [6]Dept. of Psychiatry, McGill Univ., Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada

Abstract: Sea Hero Quest (SHQ) is a mobile video game designed to measure human spatial navigation ability through gameplay. The game involves navigating a boat in search of sea creatures in order to photograph them. Previous studies have focused on the game's wayfinding and path integration levels. The focus of the current research was to examine performance within the radial arm maze optional bonus section, completed by more then 40,000 people globally. The radial maze levels contain six pathways surrounded by proximal and distal landmarks (e.g., rock, hut, volcano) and consists of two parts: in Part 1, three of the six pathways are blocked and the player is required to navigate the boat to visit the three open pathways to collect a star fish that pops out of the water. In Part 2, all six pathways are made available and the player is required to visit the pathways that were unavailable during Part 1 to collect the remaining three star fish. Errors, as defined as visiting a previously entered pathway were recorded. When the radial arm maze level is completed, the player is asked a multiple-choice question about how they found the star fish (i.e., a counting strategy vs. a landmark-based strategy). The player's navigation strategy was established based on the second trial (in the second experimental level) because the first one was considered practice. We also obtained demographic data from each player (i.e., age, sex, country, & growing up in a city vs rural environment). Results showed that the use of landmarks

declined with age. This was predicted by the large body of research that has demonstrated reduced spatial memory, structure and function of the hippocampus with age. In addition, people who used landmark-based strategies in the radial arm maze displayed moderately better spatial memory performance within the game's wayfinding levels. These results confirm previous observations from smaller studies showing a decreased use of spatial strategies with age, as well as the relationship between landmark-dependent navigation strategy use and spatial memory performance using a substantially larger and representative sample size from various regions world-wide.

Title: Human ripples in spatial memory

Authors: *T. GEDANKIEN, J. MILLER, J. JACOBS;
Dept. of Biomed. Engin., Columbia Univ., New York, NY

Abstract: The ability to remember trajectories between locations is central to human experience. However, the precise neural mechanisms underlying spatial memory in humans remain elusive. In rodents, previous research has linked the occurrence of sharp-wave ripples (SWRs) during sleep and awake rest to good spatial memory. Recent findings in rodents and humans have also linked good memory to coupling between ripples in the cortex and medial temporal lobe (MTL) during sleep. These findings support the theory of systems consolidation, thereby ripples facilitate memory transfer between the hippocampus and cortex. Here, we tested the hypothesis that awake ripple-like events in humans, like SWRs in animals, play a role in spatial memory. We also investigated how ripples spread within and across the human MTL and cortex. We analyzed intracranial recordings from epilepsy neurosurgical patients as they performed a hybrid spatial-memory virtual task. We detected ripples in the 80-120-Hz band, using previously published methods. Within the MTL, we found three classes of ripple events based on their spatial spread: those seen in a single channel in time (single events), those seen simultaneously across nearby channels (cluster events), and those seen simultaneously in distant channels (coupled events). Across sixteen subjects, we found that ripples were most prominent in hippocampal CA1 region and during the feedback phase of the spatial task. These results suggest

a role of hippocampal ripples in facilitation of human learning and memory consolidation related to feedback.

Title: Direct electrical stimulation of the human cortex modulates narrowband low frequency oscillations

Authors: *U. R. MOHAN[1], J. JACOBS[2];
[2]Dept. of Biomed. Engin., [1]Columbia Univ., New York, NY

Abstract: Low frequency oscillations across the cortex underly coordination of brain networks in humans and play critical roles in cognition. Researchers have used direct electrical brain stimulation to treat a range of neurological and psychiatric disorders in which these oscillations are impaired. Direct electrical stimulation holds the potential to modulate these cortical oscillations; however, we do not yet have a detailed understanding of how stimulation alters narrowband low frequency oscillations. Therefore, to fill this gap in our understanding, we investigated the effects of different types stimulation on narrowband low frequency oscillations. We collected human electrocorticographic recordings from neurosurgical epilepsy patients while systematically delivering stimulation at different combinations of frequency and amplitude at specific locations. In order to understand how stimulation affects oscillations, we measured the amplitude and frequency of narrowband oscillations before and after stimulation events. Overall, 10Hz direct electrical stimulation can enhance or diminish the amplitude of a narrowband low frequency oscillation or altogether change the frequency of that oscillation. Low frequency stimulation often induces or enhances ongoing low frequency narrowband oscillations while decreasing oscillation frequency. Whereas our previous work shows that low frequency stimulation primarily inhibits local neuronal activity, these results show that low frequency stimulation modulates specific features of narrowband oscillations. This implies that the impact of brain stimulation on cortical activity is much more nuanced than excitatory and inhibitory effects. By characterizing the link between brain stimulation and low frequency oscillations, our results provide insight into how brain stimulation protocols may be designed to modulate specific features of endogenous network oscillations.

Title: Predictive cognitive map representations by human single neurons

Authors: I. MOMENNEJAD[1], A. PATEL[1], C. S. INMAN[2], R. E. GROSS[3], B. C. LEGA[4], L. ROBINSON[5], C. A. SCHEVON[1], G. MCKHANN[6], A. WATROUS[7], R. J. BUCHANAN[8], ***J. JACOBS**[1];

Ctr., Dallas, TX; [6]Dept. of Neurol., Columbia Univ. Med. Ctr., New York, NY; [7]Neurol., Univ. of Texas at Austin, Austin, TX; [8]Neurosurg., Seton Brain and Spine Inst., Austin, TX

Abstract: In previous work we show that multi-step predictive maps, known as the successor representation (SR), can best explain flexible human decision making. We showed this for reward and transition revaluation, when structures of rewards and transition change (Momennejad et al. 2017). Here, we test the hypothesis that single cells in human MTL learn and update such predictive map representations. We used a virtual navigation study in which the predictive maps would be used for making value-based decision-making. We measured single neuron recordings (Behnke-Fried electrodes) in epileptic patients while they engaged in navigation and reward-based decision making in virtual environments, following the design of our past experiment. Each virtual environment has two sequential tracks, each with three connected rooms that are linear tracks (seq 1: rooms 1-3-5, seq 2: rooms 2-4-6). The eventual reward value of each sequence is seen once the patient opens the briefcase in the third room (room 5: $20, room 6: $5). During relearning, participants experienced partial changes to the environment that reflected 'reward revaluation' (final briefcase cash value changes) or 'transition revaluation' (suddenly room 3's door opens to room 6, room 4's door opens to room 5: the architecture is restructured). Patients needed to integrate this new information to make optimal decisions between rooms 1 and 2 at test. SR predicted that rooms that are connected, one-step or multi-step, would show more similarity to each other, and this multi-cell similarity pattern would reflect changes in the world. To test the SR hypothesis, we computed pairwise correlations between mean firing rates of hippocampal cells for each pair of rooms to construct a 6X6 matrix of neural similarity among the 6 rooms. We compared the resulting matrix with SR's predictive representation. Preliminary results comparing changes before and after transition revaluation

show that the 6-roomX6-room matrix of multi-cell correlations reflects the change in the structure of the environment and revaluation behavior: Multi-cell correlations increased for rooms, 1-step and 2-step away, that were not connected before but are now connected.

Title: The spatiotemporal structure of human cortical traveling waves correlates with cognitive processes

Authors: *H. ZHANG[1], J. JACOBS[2];
[2]Dept. of Biomed. Engin., [1]Columbia Univ., New York, NY

Abstract: A broad range of research has found correlations between brain oscillations and features of cognitive processes. However, we still do not understand the physiological role of these oscillations. One hint of a functional role for brain oscillations came from our recent discovery that many oscillations in the human cortex behaved as traveling waves, propagating across the surface of the brain, much like a wave moving across the ocean. This suggested a role for brain oscillations in coordinating the activity of large groups of neurons across space and time in the cortex. Here we further test this idea by examining the timing and directional features of traveling waves in relation to behavior during a memory task. We examined direct recordings of traveling waves from neurosurgical patients who had electrodes implanted in their brains for clinical needs. The patients performed verbal working and episodic memory tasks and we used a novel analytic framework to measure the properties of individual traveling waves and compare their features to task events. Using this framework, we identified two novel functional roles of traveling waves in human cognition. In both tasks, traveling waves generally propagated in a posterior-to-anterior direction, although some patients showed the opposite propagation direction. When a probe stimulus was presented in the working memory task, subject's reaction times correlated with the position on the cortex of of the traveling wave (i.e., the traveling wave's spatial phase). This indicates that the location of individual traveling waves on the surface of the cortex correlate with how rapidly a subject will respond to a new stimulus, consistent with the idea from previous studies that brain oscillations could reflect a "cortical

scanning" process. We also examined the phase of traveling waves during the recall phase of our free recall task. Traveling waves in many subjects exhibited particular spatial phase patterns ~1 s prior to recall. Among the waves propagating in an anterior-to-posterior direction, more waves showed phase resets before recall implicating these waves in the top-down flow of information during memory retrieval, suggesting that a role for traveling waves in supporting memory recall by spatially organizing cortical activity. More broadly, our work demonstrates a new role for brain oscillations in cognition, by organizing the large-scale spatio temporal structure of neural activity in relation to the timing of behavioral events.

Title: Low theta oscillations in the anterior hippocampus predict successful encoding of spatial and verbal memories in humans

Authors: *S. E. QASIM, J. MILLER, J. JACOBS;
Biomed. Engin., Columbia Univ., New York, NY

Abstract: A preponderance of research has demonstrated that theta oscillations in the human hippocampus vary during memory encoding, depending on whether the encoded cue is subsequently recalled or not. This "subsequent memory effect" (SME) has been observed across a range of low frequencies throughout the hippocampus, suggesting that hippocampal theta oscillations play a role in the successful encoding of memory. However, recent work has identified functional and regional distinctions in theta oscillations at different frequencies in humans, suggesting that low theta (1-5 Hz) and high theta (5-10 Hz) may play distinct roles in memory circuits. Furthermore, numerous studies have now shown that connectivity, function, and genomic anatomy significantly vary along the longitudinal axis of the human hippocampus, suggesting that the different poles of the hippocampus may feature distinct memory circuits. This led us to hypothesize that that successful memory encoding would engage distinct theta oscillations along the longitudinal axis of the hippocampus in humans. We analyzed data from depth electrodes implanted in neurosurgical patients who performed a verbal memory task (n=405 hippocampal electrodes) and/or a spatial memory task (n=266 hippocampal electrodes). We found that increases in low theta oscillations (1-5 Hz), specifically, predicted successful

memory encoding, primarily in the anterior hippocampus, during both verbal and spatial memory encoding. Furthermore, successful verbal memory encoding was best predicted by low theta power in the right-anterior hippocampus, while successful spatial memory encoding was best predicted by low theta power in the left-anterior hippocampus. High theta power did not predict spatial memory encoding, whereas decreases in high theta power (5-10 Hz) predicted subsequent memory across the entire left hippocampus, but not the right, during verbal memory encoding. These results suggest that variations in theta oscillations across the anterior-posterior axis, as well as across hemispheres, may play an important role in the strength of memory encoding and the type of memory encoded. These results also further demonstrate the distinct functional and anatomical characteristics of low and high theta oscillations in the human hippocampus.

Title: Dimensionality reduction in human hippocampal dentate/CA3, but not CA1 support pattern separation

Authors: *H. ZHANG[1,2], I. SKELIN[2], M. A. YASSA[3], J. J. LIN[1,2];
[1]Biomed. Engin., [2]Neurol., [3]Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA

Abstract: The ability to discriminate between the similar experiences (i.e. pattern separation) is essential for episodic memory, but the underlying neural mechanisms are unclear. Hebb and Marr proposed that the dentate gyrus (DG) separates neural activity patterns by expanding dimensionality of neural ensembles, enabling downstream decoder neurons in CA3 to orthogonalize signals. However, the neurophysiological signature of ensemble code expansion and reduction at hippocampal subfield resolution in humans is absent. Recent work in primates suggests that local field potentials (LFP) gamma bursts reflect the convergence of neural ensembles to transient attractor states (Lundqvist et al., 2016). To test the Hebb and Marr hypothesis, we analyzed the dynamics of gamma bursts recorded from hippocampal subregions (DG/CA3 and CA1) of presurgical patients undergoing seizure localization.
Five patients performed a pattern separation task in which they were asked to discriminate similar (lure), novel and repeat images from previously encoded stimuli. We reconstructed the high-frequency component (45-300 Hz) of the LFP by implementing Ensemble Empirical Mode Decomposition (EEMD) and calculating the time-frequency response during the stimulus

presentation at the retrieval period (2000 msec). The spectrum dimensionality was calculated for each of the 500 msec moving window by participation ratio (PR) from its spectral principal component space (Gao et al., 2017; Vítor Lopes-dos-Santos et al., 2018&2011). In DG/CA3, we found an initially increased dimensionality, followed by rapid dimensionality reduction for correct lure rejections compared to lure false alarms ($p<0.05$, Wilcoxon test). Critically, this conditional difference in dimensionality was not present in the downstream CA1 subfield. At single trial level, correct lure rejection trials are characterized by the transient dimensionality reduction in the DG/CA3, lasting ~500 msec. In contrast, the lure false alarm trials were characterized by both increased and decreased dimensionality periods of variable durations. In summary, these results provide neurophysiological evidence for the Hebb and Marr model of code expansion and reduction in DG/CA3 for pattern separation.

Title: Distinct functional connectivity patterns predict the peri-ripple population activity in human amygdala and temporal cortex

Authors: *J. J. LIN[1,2], H. ZHANG[2], B. L. MCNAUGHTON[3,5], I. SKELIN[4];
[1]Neurol., Univ. of California, Irvine, Irvine, CA; [2]Biomed. Engin., [4]Neurol., [3]Univ. of California Irvine, Irvine, CA; [5]Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Sharp wave/ripples (SWRs) are the windows of memory reactivation and hippocampal-cortical/subcortical communication during offline states. Various memory consolidation models propose the initial storage of memory traces in distributed cortical/subcortical networks, followed by their gradual integration and loss of hippocampal-dependence through the establishment of horizontal connectivity. We hypothesized that the local field potential (LFP) synchrony between the cortical/subcortical populations activated around the time of SWRs (peri-SWR; +/- 250 ms relative to SWR peak) is necessary for enabling this process, but the functional connectivity mechanisms synchronizing these populations are

unknown.
We analyzed the overnight sleep (nREM phases 2-4) LFP from hippocampus, amygdala and temporal cortex, from 12 human subjects undergoing presurgical localization of epileptic foci. The peri-SWR active populations were defined at the single electrode level, based on significant modulation of high gamma activity (HGA; 70-200 Hz) - a proxy measure of spiking activity. Functional connectivity was quantified for 3 frequency bands (delta 0.5 – 4 Hz; theta 4-8 Hz; alpha 8-12 Hz) using the baseline-corrected phase locking value (PLV), an index of phase offset consistence between the LFP oscillations. PLV was averaged at the region-of-interest (ROI) pair level, the ROI-pair grand average was computed over all subjects and compared to distribution based on 200 trial-shuffling permutations. Significant increases or decreases were defined as >97.5% or <2.5% of shuffled distribution, respectively.
Within temporal cortex, the peri-SWR decreased in theta PLV between the active populations (electrodes with significant HGA modulation). In contrast, there were no PLV changes between the inactive populations (electrodes with no significant HGA modulation). Inter-regional theta PLV between the amygdala and temporal cortex increased between active populations and decreased between non-active populations.
This functional connectivity pattern could allow selective recruitment of anatomically distributed neuronal populations during peri-SWR windows, which could facilitate the formation of horizontal connections, resulting in gradual independence of distributed memory traces from hippocampus.

Title: Changes in frequency power during anesthesia induction with propofol: A comparison between frontal cortex and the mesial temporal lobe

Authors: S. MA[1], ***M. R. PAFF**[2], I. SKELIN[3], H. ZHANG[4], J. LIN[1];
[1]Dept. of Neurol., Univ. of California, Irvine, Irvine, CA; [2]Dept. of Neurosurg., Univ. of California, Irvine, Orange, CA; [3]Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [4]Biomed. Engin., Univ. of California Irvine, Irvine, CA

Abstract: The neural mechanisms by which anesthetic agents induce loss of consciousness (LOC) are poorly understood despite their common use for sedation and general anesthesia. Propofol-induced anesthesia has been associated with the increased power of slow delta and alpha oscillations on scalp EEG and ECoG after LOC, however, how Propofol influences the

oscillatory activities of deep structures, such as the mesial temporal lobe (MTL) is unclear. To test if Propofol has a similar effect on the oscillatory activity of MTL compared to cortex, we performed intracranial recordings in four patients implanted with multiple depth electrodes for invasive epilepsy monitoring during anesthesia induction with Propofol. The targets of the depth electrodes included the amygdala, hippocampus, orbitofrontal cortex, and anterior cingulate cortex. The recording was carried out from ten minutes prior to induction to fifteen minutes following LOC. Contacts residing within the gray matter of the target structures were referenced to a contact in the white matter. We compared the spectrograms of the LFP of the target structures from 5 minutes before the administration of Propofol to 5 minutes following LOC. Z-scored power changes within individual frequency bands were examined, including the slow oscillation (0.1-1 Hz), delta (1-3 Hz), theta (4-7 Hz), alpha (8-12 Hz), beta (13-25 Hz), low gamma (25-40 Hz), and high gamma (40-100 Hz). In the cortical area (including the orbital frontal cortex and anterior cingulate cortex), a significant broadband (0.1Hz-40Hz) power increase is observed in all patients (all $p < 0.05$, paired t-test). However, in the MTL (including hippocampus and amygdala), the power change varies from patient to patient; both increases and decreases compared to baseline prior to induction of anesthesia. which renders the grand average of power change in MTL not statistically significant. In summary, these uncorrelated spectral power changes between the cortex and the MTL suggest functional dissociations in these two structures, which may link to a putative mechanism of LOC and the retrograde amnesia caused by anesthesia.

Title: Feedback-tuning of single neurons: Evidence for distributed learning signals in the human brain

Authors: I. SKELIN[1], *H. ZHANG[2], A. DEDE[4], S. VADERA[3], M. PAFF[3], I. SEN-GUPTA[1], L. MNATSAKANYAN[1], F. P. K. HSU[3], E. A. BUFFALO[5], R. T. KNIGHT[6], J. J. LIN[1]; [1]Neurol., [3]Neurosurg., [2]Univ. of California Irvine, Irvine, CA; [4]Physiol. and Biophysics, [5]Dept. of Physiolgy and Biophysics, Univ. of Washington, Seattle, WA; [6]Psychology, Univ. of California Berkeley, Berkeley, CA

Abstract: During learning, humans utilize action outcome feedback, but the details of implementation at the individual neuron and network levels are largely unknown. The Wisconsin Card Sorting Task (WCST) consists of 12 possible rules, classified in 3 different dimensions (color, shape and texture), with the current rule unpredictably switching intra- or extra-dimensionally. This experimental schema provides a suitable model for investigating the neural and behavioral dynamics underlying feedback assessment during rapid rule acquisition and switching. We recorded ~250 isolated single units from the hippocampus (HIPP), amygdala (AMY), orbitofrontal (OFC) and anterior cingulate cortices (ACC), over 6 behavioral sessions in 4 patients with pharmacoresistant epilepsy undergoing presurgical evaluation. Single unit feedback tuning was assessed by contrasting the activity during the feedback phase (1500 msec) when the 'correct' or 'incorrect' message was displayed on the screen. Peri-stimulus trial histograms (PSTH) were constructed by averaging the individual unit activity separately on correct and incorrect trials (200 msec windows, 2 msec step size). Statistical significance of feedback-tuning was assessed for each time bin, using a two-tailed t-test with 100 permutations of trial labels. We identified feedback-tuned neurons in all four structures (ACC 37.3%; OFC 30.2%; AMY 24.3% and HIPP 8.1 %), with a significantly lower proportion in the hippocampus (chi-square test, p's < 0.005). Individual unit feedback-tuning modulations included both increased or decreased activity during both correct or incorrect trial feedback. The presence of anatomically-distributed feedback signals at the single neuron level provides evidence for a network-level integrative mechanism that utilizes this information to update the task representation and guide decision-making. Future work focuses on network-level interactions including directionality of information flow and task-state dependence.

Title: Integrating memories: How congruency and reactivation aid integration of old and new memories

Authors: *M. T. VAN KESTEREN[1], P. RIGNANESE[2], P. GIANFERRARA[3], L. KRABBENDAM[1], M. MEETER[1];

[1]Vrije Univ. Amsterdam, Amsterdam, Netherlands; [2]Inst. Pasteur, Paris, France; [3]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: In everyday life we continuously build up knowledge, which is important for forming consistent knowledge schemas that organize information and guide future learning. Successful knowledge building has been suggested to occur through reactivation of prior knowledge during new learning in item-specific perceptual brain areas. This reactivation is proposed to yield integration of new with old memories, supported by the medial prefrontal cortex (mPFC) and medial temporal lobe (MTL). Possibly as a consequence, congruency of new information with prior knowledge is known to enhance subsequent memory. Yet, it is unknown how reactivation and congruency interact to influence memory integration, and how these factors affect educational learning. To investigate this question, we used an AB-AC inference paradigm. University students first studied an AB-association followed by an AC-association, so B (a scene) and C (an object) were indirectly linked through their common association with A (an unknown pseudoword). Moreover, BC-associations were either congruent or incongruent with prior knowledge (e.g. a bathduck in a bathroom, or a hammer in a bathroom), and participants were asked to report subjective reactivation strength for B while learning AC. Behaviourally, both the subjective congruency and reactivation measures enhanced subsequent associative memory for the inferred BC-association. In the brain, these analyses yielded parametric effects of congruency and reactivation on activity patterns in perceptual areas (such as the Parahippocampal Place Area; PPA), the MTL, and the mPFC. Moreover, mPFC exhibited larger connectivity to the PPA for more congruent associations. Currently, we are running additional Representational Similarity Analyses (RSA) to investigate how these factors may affect the similarity of patterns throughout the brain. These outcomes show beneficial effects of both congruency and reactivation strength on memory formation, and provide insights into the neural mechanisms underlying these processes. With these findings, we aim to better understand and improve everyday knowledge building techniques, such as regularly practiced in e.g. educational situations.

Title: Anterograde interference of reactivated memories only during the first hour after training: Evidence of an early reconsolidation loop

Authors: *A. E. CLAIN[1], B. A. WRIGHT[1,2,3];
[1]Dept. of Communication Sci. and Disorders, [2]Inst. for Neurosci., [3]Knowles Hearing Ctr., Northwestern Univ., Evanston, IL

Abstract: During learning, memories are transformed from a fragile to a stable state through a process of consolidation. There is growing evidence that when consolidated memories are accessed they re-enter a state of instability, during which they can be modified, and then must be consolidated again. This cycle of reactivation and reconsolidation has been demonstrated by showing that if a reminder of a consolidated memory is given days to months after an initial training session, that memory becomes vulnerable to retrograde interference. We previously reported behavioral evidence in humans of a mechanism similar to reconsolidation, but in which reactivated memories are susceptible to anterograde interference only within 24 h of the initial training. In that investigation, we documented anterograde interference of a reactivated memory 30 min, but not 24 h, after the initial training. Here we investigated the susceptibility of reactivated memories to anterograde interference at two intermediate time points: 1 h and 6 h. As previously, we used a perceptual-learning paradigm for which we had identified a case in which learning on a target task--interaural-level-difference discrimination (L)--was disrupted by training on a non-target task--interaural-time-difference discrimination (T)--in the anterograde (TL), but not retrograde (LT), direction. Then, also as previously, we used the task order that elicited anterograde interference (TL) in a paradigm akin to that typically used to test for reconsolidation. Listeners practiced a bout of L in isolation and sometime later practiced TL. This regimen yielded no improvement on L the day after training if the TL pair was trained 30 min after the initial training (previous data), suggesting that the initial bout of L was reactivated by the reminder and that both bouts of L were disrupted by the anterograde interferer. However, when the TL pair was trained 1 h (n=9), 6 h (n=7), or 24 h (previous data) after the initial training, listeners improved on L from the initial bout to the test bout the next day, suggesting that after 1 h the initial bout of L was no longer vulnerable to anterograde disruption during reactivation. Furthermore, the >1-h groups already showed improvement at the reminder bout of L, while the 30-min group did not (though learning on L normally emerges by 30 min), suggesting that resistance to anterograde interference at the reminder bout itself is associated with subsequent protection of the initial memory. These data imply that the first hour after training is a distinct stage of memory formation during which recently acquired memories can be reactivated and then disrupted by anterograde interference.

Title: Sleep age and race linked to neural pattern similarity of associative memory

Authors: *E. HOKETT, S. MIRJALILI, A. L. DUARTE;
Georgia Inst. of Technol., Atlanta, GA

Abstract: Compared to young adults, older adults tend to have both worse sleep quality and episodic memory. It has been suggested that sleep fragmentation may interfere with memory consolidation and in turn, memory accuracy. Because these findings have been established in racially homogeneous samples, it is unclear how these effects extend to racial/ethnic minority groups. Racial/ethnic minorities have demonstrated worse self-reported sleep quality than non-minorities, which could interfere with sleep-based memory consolidation. Individual differences in the degree of reinstatement of neural activity present during learning at the time of retrieval has been shown to support episodic memory accuracy. Thus, we hypothesized that individual differences in sleep quality would decrease pattern similarity between neural oscillations at encoding and retrieval. To test this hypothesis, we recruited a diverse sample of young and older adults and measured their sleep quality for one week using accelerometry. Participants' EEG was monitored as they performed an associative memory test to determine relationships between memory-related neural oscillations, behavioral memory performance, and sleep quality. We found that greater neural pattern similarity between encoding and retrieval was related to better memory performance. Furthermore, Black participants, across age, demonstrated greater sleep fragmentation, which was associated with reduced pattern similarity and reduced memory performance. Thus, poor sleep quality is associated with episodic memory at both the behavioral and neural level. This research illuminates important relationships among habitual sleep quality, episodic memory, race, and age. Future research should include both age and race as variables of interest in order to further investigate the detrimental effects of poor sleep on memory.

Title: Multiple memories can be simultaneously reactivated during sleep as effectively as a single memory

Authors: *E. SCHECHTMAN[1], J. W. ANTONY[4], A. LAMPE[2], B. WILSON[1], K. A. NORMAN[5], K. A. PALLER[3];
[1]Northwestern Univ., Evanston, IL; [2]Northwestern Univ., Evnaston, IL; [3]Dept. of Psychology, Northwestern Univ., Evanston, IL; [4]Princeton Neurosci. Inst., [5]Princeton Univ., Princeton, NJ

Abstract: Memory consolidation during sleep involves reactivation of memory traces. Targeting specific memories by presenting learning-related cues during sleep selectively enhances memory, but the mechanism behind this benefit is not fully understood. To better characterize the process of memory consolidation in humans, we tested whether multiple memories can be reactivated in parallel using a spatial-memory task. Results showed no differences between memory benefits for items in cued sets of one, two, or six items, which implies that reactivation resources are not divided between different memories. A compelling explanation for these findings is that a generalized context - and not individual memory traces - is reactivated during sleep. Intriguingly, sleep spindles and delta power modulations were sensitive to set-size and encode the extent of previous learning. Taken together, our results refute the notion that resource availability restricts the capacity of simultaneous sleep-reactivation and bring forward alternative and testable models for sleep-related consolidation.

Title: Updating the meaning of a word: Memory reactivation boosts integration into an existing memory trace

Authors: *L. KACZER[1], J. LAURINO[1], F. CHAVES[1], C. FORCATO[2], M. PEDREIRA[1]; [1]IFIBYNE CONICET, Buenos Aires, Argentina; [2]Unidad Ejecutora de Estudios de Neurociencias y Sistemas Complejos, CONICET, Univ. Nacional Arturo Jauretche, Hosp. de Alta Complejidad en Red El Cruce "Néstor Kirchner", Florencio Varela, Argentina., Buenos Aires, Argentina

Abstract: Words are extremely malleable memories, subject to updating and modification. However, the mechanisms that allow this plasticity remain unclear. While memory reconsolidation has been implied in memory updating, its role has not been addressed in the context of lexical-semantic learning. In this study we analyzed the contribution of memory reactivation to the process of a word's meaning updating. In four different experiments (N=128), native speakers of Spanish (19-35 years) learned either familiar or low-frequency words within their native language (Spanish), with their corresponding definitions (List 1). The following day, Reactivation groups were exposed to a reminder, consisting of the list of words they learnt the previous day, but with no chance of giving a response (thus increasing the prediction error). No Reactivation groups, on the other hand, did not receive a reminder. After this, all participants learned a new list of unrelated meanings for the words learned the previous day (List 2). Finally, memory retention was evaluated 48 hours or 7 days after training, using two procedures: a cued-recall test, and a semantic judgement task. Results were analyzed using a linear mixed-model. In the explicit recall task, our data show that memory for updated meanings is marginally enhanced by the reminder presentation one week after training. In the priming task, a significant enhancement of semantic recognition speed is revealed in the Reactivation group. Thus, memory reactivation might be one of the mechanisms that allow the rebuilding of the mental lexicon.

Title: Evidence that anterograde learning interference arises from an interaction of memories in different learning stages

Authors: *R. NING[1], B. A. WRIGHT[1,2,3];
[1]Communication Sci. and Disorders, [2]Knowles Hearing Ctr., [3]Northwestern Univ. Inst. for Neurosci., Northwestern Univ., Evanston, IL

Abstract: Training induces learning on many tasks. However, learning on one task can be disrupted by training on another. Retrograde learning interference, in which learning on the first task is prevented by practicing the second task, is typically attributed to a disruption of consolidation. In contrast, the nature of anterograde learning interference, in which learning on the second task is disrupted by practicing the first task, is unknown. One possibility is that anterograde interference occurs because an influence of training on the first task lingers in the encoding stage, altering the encoding of the second task. If so, alternating training between the two tasks, while both are still being encoded, should also disrupt the learning. Here we tested this prediction using a perceptual-learning paradigm in order to take advantage of a previous observation that learning on an interaural-level-difference (ILD) discrimination task (L) was disrupted by training on an interaural-time-difference (ITD) discrimination task (T) in the anterograde [T-L], but not retrograde [L-T], direction. Given this case of isolated anterograde interference, we assessed whether interference also occurs when T and L are interleaved. Specifically, we examined learning on L between a training session (300-360 trials per task) and a testing session the next day (300 trials), following one of four training regimens: L alone, T before L, and T alternating with L at two different rates. Results showed that practicing only L (two-interval-forced choice; standard: 4 kHz, 0 dB ILD) generated across-day learning on L (n=13). This learning was disrupted when practice on T (standard: 0.5 kHz, 0 microsecond ITD) was completed before practicing L (anterograde interference) (n= 11), but not when practice alternated between T and L every 60 trials (n=10). Decreasing the alternation rate to every 180 trials led to a partial release from the interference (n=10). Similar patterns were observed in within-session learning and off-line gain. Thus, contrary to the prediction, the anterograde interference induced by blocked training on two tasks was alleviated by interleaved training. This outcome suggests that anterograde interference does not occur simply because the influence of the training on the first task lingers in the encoding stage. Rather, it appears that the training on

the first task must enter the consolidation stage, by sufficient training, to be disruptive to the encoding of the second task. The implication is that the initially encoded form of learning on the first task is modified during consolidation into another form and it is this consolidated form that is disruptive to learning on the second task.

Title: Memory reactivation: A mechanism underlying enhanced persistence of emotional memories

Authors: *N. HERZ[1], Y. BAR-HAIM[1], H. SHARON[2], E. HOLMES[3], N. CENSOR[1];
[1]Sch. of Psychological Sciences, Sagol Sch. of Neurosci., Tel-Aviv Univ., Tel Aviv, Israel; [2]Tel Aviv Sourasky Med. Ctr., Tel-Aviv, Israel; [3]Dept. of Clin. Neurosci., Karolinska Institutet, Solna, Sweden

Abstract: Memories of negative emotional events tend to persist over time relative to memories for neutral information. Such memory persistence has been mainly attributed to heightened encoding and consolidation processes. However, reactivation of the encoded information may also lead to memory enhancement through reconsolidation. We first tested the hypothesis that spontaneous reactivations of stressful events function as part of a mechanism enhancing persistence of visual emotional memory. 18 participants watched a film containing eight scenes of aversive material and their visual recognition memory of the film content was then immediately tested. In the following five days, participants recorded any spontaneously reactivated intrusive memories of the film using a digitized online diary, and the corresponding scene from which the content of their intrusive memories emerged was noted. At the end of the 5-day period, participants' visual recognition memory for the film content was retested. Results indicated that persistence of memory for scenes that intruded was enhanced relative to memory for scenes that did not intrude, suggesting that spontaneously reactivated intrusive memories reduce normative visual emotional memory decay. We then tested whether synchronizing lab-induced memory reactivations with inhibitory 1 Hz repetitive Transcranial Magnetic Stimulation (rTMS) would impair the intensity of intrusive memories. 40 participants watched a trauma film

and were requested to record their intrusive memories in a digital diary in the following 5 days. One day following film watching participants' memory of the film was reactivated by brief reminders, followed by rTMS over primary visual cortex (V1, in light of previous results showing that the vividness of mental images is coupled with early visual cortex activity, n=19) or over a control site (Vertex, n=21). Preliminary results indicate that V1-rTMS alleviated the distress of memory intrusions. Our findings point to a reactivation mechanism through which negative emotional memories gain their stabilization over time, and to potential interventions to downregulate their intensity.

Title: The impact of predictability on memory representations

Authors: *M. KUMAR[1], N. B. TURK-BROWNE[2], K. A. NORMAN[1];
[1]Princeton Univ., Princeton, NJ; [2]Psychology, Yale Univ., New Haven, CT

Abstract: Our memory representations are shaped by our interactions with the world. What is not well understood is the exact nature of the mechanisms that cause memory representations to integrate (become more similar) or differentiate (become more distinct) over time. Recent work from our group has explored the implications of the non-monotonic plasticity hypothesis (NMPH) for integration and differentiation. According to the NMPH, moderate activation of memories causes synaptic weakening and higher activation cause synaptic strengthening. Applied to distributed patterns, the NMPH predicts a U-shaped function relating memory activation to changes in neural representations: If a memory does not activate, it is not changed;

if a memory activates moderately, it is differentiated from other, highly-active memories (due to weakening of connections to those memories); and if a memory activates strongly, it is integrated with other, highly-activated memories (due to strengthening of connections to those memories). To test these predictions, we ran an fMRI study using a statistical learning paradigm in which scene pairs (A-B) were embedded in a continuous stream of scenes; transition probability (i.e., the probability of B appearing after A) was varied in a parametric fashion across pairs, at eight levels ranging from 12.5% to 100%, in order to manipulate predictive activation strength. Extending prior work by Schapiro et al. (2012), we expected that intermediate transition probabilities would be sufficient to trigger prediction and moderate activation of B upon presentation of A, but this prediction would frequently be violated, leaving the activation moderate and leading to differentiation of B from A (which was presented and therefore strongly activated). Furthermore, we expected that higher transition probabilities would trigger stronger activation of B (including because the prediction was less likely to be violated), leading to integration of B with (also strongly activated) A. The advantage of this design is that it allows us to parametrically track levels of memory activation and the resulting changes in neural similarity between B and A, with the goal of showing a smooth transition from no learning to differentiation to integration as a function of memory activation. Preliminary results indicate prediction effects in the hippocampus, which we are now relating to changes in representational similarity.

Title: Twisting your memory: How the brain rewrites memories as the understanding of the past changes

Authors: *A. ZADBOOD[1], S. A. NASTASE[1], J. CHEN[2], K. NORMAN[1], U. HASSON[1]; [1]Princeton Univ., Princeton, NJ; [2]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: The brain actively re-shapes its past memories in light of new incoming information. In the current study, we used fMRI to track how neural representations are updated during naturalistic recall. Participants watched a movie (“The Sixth Sense”) in the scanner and -- at the end of the movie -- were exposed to a dramatic “twist” that changed the interpretation of the

previously encoded movie. Next, participants were asked to verbally recall the events in the scanner, while taking the new information into account. Most participants updated their recall to incorporate the twist. Two control groups recalled the movie without the need to update their memories during recall: one group never saw the twist, and thus recalled the original movie as-is; the second group was exposed to the twist prior to the beginning of the movie, which enforced encoding and recall of the same "twist" version of the movie. Our results show that providing participants with information about the twist beforehand (spoiled condition) altered the neural response patterns during the encoding phase (movie-viewing). Moreover, providing participants with information about the twist after the end of the encoding phase (post-viewing) transformed the neural representation of the encoded information during recall. The similarity between activation patterns during encoding and recall was attenuated in participants who better updated their recall to accommodate the new information. This suggests that neural representations of our past can be dynamically molded and integrated with new information that reshapes our memories.

Title: Anticipation of temporally structured events in the brain

Authors: *C. LEE, M. ALY, C. BALDASSANO;
Psychology, Columbia Univ., New York, NY

Abstract: Higher-order regions in the brain play a role in organizing perceptual input into semantically-meaningful schematic representations, and they do so at differing timescales up the cortical hierarchy (Baldassano et al., 2017, 2018). Such integration in higher-order regions, such as the posterior medial network, critically depends on the availability of temporal structure over long timescales (Aly, Chen, Turk-Browne, & Hasson, 2018; Hasson, Chen, & Honey, 2015). The ability to extract temporal structure is particularly adaptive because it enables the generation of predictions about upcoming events. How does the brain use repeated experience in structured environments to anticipate what is likely to come next? In the present work, we examine how the brain can anticipate event boundaries in familiar sequences of actions.
Critically, we used a naturalistic stimulus (a movie), in which regularities are present at multiple timescales, enabling us to identify multiple timescales of prediction in the brain. We hypothesized that the timescale of neural prediction would vary continuously, with progressively

higher-order regions (e.g., prefrontal cortex) predicting further in the future than lower-order regions (e.g., visual cortex). To test this, we examined brain activity with fMRI while individuals watched a 90-second clip from the movie *The Grand Budapest Hotel* , six times. To uncover neural anticipation, we used a searchlight approach in which, for each region of interest, we fit a Hidden Markov Model to identify temporal shifts between multivariate activity patterns evoked by the first viewing of the movie clip compared to repeated viewings. We found temporal shifts in event patterns throughout the brain, up to 12 seconds prior to event onset. The scale of prediction varied hierarchically in an anterior (more prediction) to posterior (less prediction) fashion. Together, these results demonstrate that prediction is ubiquitous in the brain, but the amount of prediction varies across the cortical hierarchy.

Title: A neural network model of naturalistic schema learning with computer-generated poetry

Authors: *M. E. SIEGELMAN, N. KRIEGESKORTE, C. BALDASSANO;
Psychology, Columbia Univ., New York, NY

Abstract: Naturalistic narrative stimuli such as movies and stories have proven to be a valuable tool for investigating how perception and memory are shaped by semantic and temporal structure in the environment. Studying and modeling the process of learning naturalistic structure is challenging, since it requires incorporating artificial experimental associations into naturalistic stimuli. We propose a novel text corpus generation method that can automatically construct a virtually unlimited number of natural-text stimuli with a pre-specified semantic structure. Specifically, we have designed a rhyming iambic pentameter poetry generator that writes poems progressing through ten distinct themes, with each four-line stanza in each poem embodying a single theme (e.g. *nature*, *music*, *warfare*). We have also developed a novel trial-and-error-based learning paradigm in which subjects must continuously select the correct next stanza (theme) from several competing options.
A pilot study of N=17 human subjects demonstrated that 76% subjects could achieve complete learning of the topic sequence (defined as the ability to correctly select the next stanza on twenty consecutive trials) after a short learning session ranging from 15-60 minutes. All subjects who performed at ceiling were able to correctly recall the full thematic sequence from memory following a short debriefing session in lab. These results demonstrate the feasibility of using computer-generated natural text stimuli for studying how abstract schematic sequences are

learned. Planned fMRI experiments will assess how responses in the language and semantic systems vary before and after learning when listening to the same set of poetry.
Since an arbitrarily large corpus of poetry can be generated using this approach, complex machine-learning models such as recurrent neural networks (RNNs) can also be fit to this same learning task. We found that a family of LSTM (Long short-term memory) models were able to achieve a word-level perplexity of 12.50 on this corpus, indicating that the model successfully captured iambic pentameter, rhyme-scheme, and critically, the thematic sequence. Temporal features of the model such as the timecourse of internal state changes (e.g. representing topic shifts) and the predictability of upcoming words can then be compared directly to fMRI responses for the same set of poetry.

Title: Prediction errors at event boundaries drive episodic memory reconsolidation

Authors: *A. H. SINCLAIR[1], G. M. MANALILI[2], M. D. BARENSE[2];
[1]Ctr. for Cognitive Neurosci., Duke Univ., Durham, NC; [2]Dept. of Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Through the process of *reconsolidation*, memories can be destabilized and distorted. Recent research has proposed that *prediction error*, or surprise, is a critical prerequisite for reconsolidation. Yet, the neural mechanisms of this process remain elusive, particularly with regards to naturalistic episodic memories. In our novel fMRI paradigm, we demonstrated that prediction error drives episodic memory reconsolidation. On Day 1, the Experimental group (N=24) viewed 70 narrative videos, each depicting an action-outcome event. During the Day 2 fMRI session, we reactivated memories by presenting the videos again. Critically, we elicited surprise by interrupting half of the videos to violate the action-outcome contingency. On Day 3, we assessed memory for the videos. Control group participants (N=24) completed the memory test on Day 2, preventing the hours-long reconsolidation process. Behaviorally, we found that interrupting videos during reactivation significantly increased false memories in the Experimental group. The Control group exhibited fewer false memories and was not influenced by prediction error. Using a text-based similarity analysis, we demonstrated that semantic

interference among the videos was associated with false memories. In an event-related design, we examined neural activity after video offset, and found distributed post-event activity in the hippocampus, striatum, cingulate, and lateral parietal cortex. Relative to full-length videos, interrupted videos elicited less hippocampal activity, and greater activity in the angular gyrus, precuneus, and TPJ. Lastly, we related trial-wise hippocampal and striatal activity to subsequent false memories. Surprising interruptions may have disrupted episodic binding by attenuating the hippocampal response after an event boundary. For the first time, we demonstrate that prediction error allows naturalistic episodic memories to be altered, and implicate the neural correlates of memory destabilization.

Title: Transient memory loss in humans 1-3 hours after training

Authors: *B. A. WRIGHT, A. E. CLAIN, R. NING;
Northwestern Univ., Evanston, IL

Abstract: During learning, memories are transformed from a fragile to a stable state through a process of consolidation. It has been proposed that this process involves multiple memory phases that each have different molecular requirements and distinct time courses. One behavioral pattern that is consistent with this proposal is the ‘Kamin effect,’ in which learning that is demonstrated soon after training is temporarily lost and then returns; the idea is that this transient memory lapse reflects a transition period between two memory phases. There have been numerous demonstrations of these memory lapses in animal models, but only a few in humans. Here we report two examples of a memory lapse in humans occurring 1-3 hours after training on a perceptual-discrimination task. We trained human young adults on an auditory interaural-level-difference (ILD) discrimination task (two-interval-forced choice; standard: 4 kHz, 0 dB ILD) for 300 trials and then tested performance on the trained task (learning), or on an untrained task--interaural-time-difference (ITD) discrimination (standard: 0.5 kHz, 0 μs ITD) (generalization)--at a variety of time points 30 minutes to 10 hours after training. Different groups completed each tested-task/time-point combination. We also assessed naïve performance on each task. Discrimination performance was non-monotonic over the post-training period, with a memory lapse at 1-3 hours revealed by a statistical trend toward a learning decrement for the trained task

(ILD discrimination) and a significant decrement for the untrained task (ITD discrimination) during that time period. After training on ILD discrimination, thresholds on that task were ~1.4 dB lower (better) than the starting thresholds at 30 minutes (n=11) and 6-10 hours (n=20) post-training, but only ~0.9 dB lower at 1-3 hours (n=17) post-training. Similarly, after training on ILD discrimination, thresholds on the untrained ITD-discrimination task were ~28 μs lower (better) than for a naïve control group (n=60) at 0 minutes (n=16), 30 minutes (n=38) and 10 hours (n=16) post-training, but were ~6 μs higher than naive performance at 1 hour (n=8) post-training. These results thus illustrate memory lapses in human perceptual learning 1-3 hours after training and demonstrate that these lapses can occur both in learning and generalization. To the extent that these lapses reflect transitions between different memory phases, these data suggest that the form of perceptual memories undergoes a marked shift in the first few post-training hours.

Title: A neural marker of declarative memory maintenance

Authors: *M. KWON[1], S.-H. LEE[1,2];
[1]Dept. of Bio and Brain Engin., [2]Program of Brain and Cognitive Engin., KAIST, Daejeon, Korea, Republic of

Abstract: The hippocampus has been thought to be critical for the formation of declarative memory. Prior memory studies suggest that the changes in neural activation and synaptic strength in the hippocampus underlie the consolidation and maintenance of declarative memory. However, it remains unclear whether the change of neural response patterns in the hippocampus during learning determines the maintenance of declarative memory in human subjects. Here, we performed an event-related functional magnetic resonance imaging (fMRI) experiment to investigate whether subsequent memory can be predicted from changes in neural response patterns during learning. In the experiment, participants were asked to conduct a memory task, consisting of separate learning, 1-day retrieval and 4-week retrieval sessions. During the learning session, the participants were trained to memorize pairs of images (object or building images) and person's names inside the scanner while the cortical activity was monitored. While each image-name association was learned individually, an object image and a building image were

associated with a common name. During the 1-day or 4-week retrieval session, the participants were asked to indicate whether the presented two images were associated. Using trial-by-trial similarity analysis, we found that memory performance at the 4-week retrieval session could be predicted from the change of the between-stimulus pattern similarity for the associated object-building pairs in the CA3/DG region of the hippocampus. This prediction was not available from the change of the neural pattern similarity for the non-associated pairs. These results showed that changes of neural pattern similarity in the hippocampus during learning can be used as a neural marker for the maintenance of declarative memory.

Title: How memory-based decisions evolve over time

Authors: *P. M. KRAEMER, S. GLUTH;
Dept. of Psychology, Univ. of Basel, Basel, Switzerland

Abstract: Human decision making often relies on information which is retrieved from episodic memory. Those memory-based decisions are composed of at least two cognitive processes: a) memory retrieval which gathers information from an episodic memory store, and b) preferential choice which weighs choice options against each other, contributing to action selection. Despite growing interest in the interaction of these processes (e.g. Shadlen & Shohamy, 2016, Neuron) it is still unclear how they interact on the neural level. In particular, the temporal characteristics of the interaction are unknown. To investigate the temporal emergence of these processes, we developed an EEG experiment in which participants performed a remember-and-decide task. During an encoding period, they associated peripherally presented food snack items with centrally presented abstract symbols. During a decision period, only the symbol was presented. The participants had to retrieve the associated snack and make a preferential choice between the snack and a fixed money amount by pressing a button with the left vs. right index finger. The experiment was designed to find hemisphere-specific neural events which can be attributed to a) the peripheral encoding of snack items or b) the lateralization of motor responses. Adopting contralateral-control methods (Gratton, 1998, Psychophysiology) allowed us to identify neural

signatures for memory and decision-making processes. We performed a time-frequency analysis on the obtained data. During decision periods, we found early stimulus-locked alpha- and beta activity in central and parietal electrode clusters. Furthermore, our analysis indicated that a cluster of centro-parietal electrodes shows signs of memory and decision-making processes in the beta-band activity, prior to response initiation. Our findings contribute to the understanding of the neural underpinnings of memory-based decision making. Furthermore, based on the results, we discuss the development of a cognitive process model that accounts for the temporal relationship of memory retrieval and decision making.

Title: Exploring the evolving geometric structure of experiences and memories

Authors: *P. C. FITZPATRICK, A. C. HEUSSER, J. R. MANNING;
Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Each event we experience in our day-to-day lives undergoes a series of transformations as it is encoded and maintained in memory. Our brains' distributed representations of memories by their contextual features gives rise to a framework in which temporally distant events may be recognized as related, and into which subsequent memories may be incorporated. In turn, existing memories within this framework influence how we process and remember future experiences. We recently developed an approach that models experiences and their corresponding recollections as "thought trajectories"—geometric shapes that unfold in a high-dimensional space defined by the experience's content (Heusser et al., 2018). Here, we build upon that approach to characterize how these thought trajectories are altered by the passage of time and the contextual congruence of existing memories. Participants viewed the pilot episode of a popular TV show (*Atlanta*), verbally recalled its content, and predicted how the next episode would unfold. A week later, they again recalled the pilot before viewing and recounting either the show's second episode or the pilot of a different show (*Arrested Development*). We examine how participants' memories are morphed over the intervening week, and how successful recall of the second week's episode is influenced by that of the first. We then draw upon a model of distributed neural semantic representations (Huth et al., 2016) and a massive online database of neuroimaging studies (Yarkoni et al., 2011) to map

these trajectories and their distortions onto the human cerebral cortex. This enables us to examine how the neural representation of an experience's content influences its inherent memorability.

Abstract: Meta-memory is the subjective judgement and monitoring of one’s own memory. Although it has been associated with the prefrontal cortex (PFC), it is unclear whether meta-memory and actual memory accuracy have dissociable neural signatures. In this study, we began addressing this issue by identifying PFC activity related to meta-memory judgments using a portable, versatile high-density functional near infrared spectroscopy(fNIRS) system.
Healthy adults(n=8) watched various animations of objects moving one-by-one into baskets. After a delay, subjects were shown the target video or a lure video and were asked whether they recognized the video as one that they had seen before. To measure meta-memory, subjects were asked to rate the confidence of their recognition judgment and the amount of details that they remembered. To assess memory accuracy, subjects were prompted to recreate the original video by clicking with the mouse the objects and baskets in the correct sequence.
Overall, subjects had 81% accuracy in active recollection and 69% accuracy in recognition. Subjects reported higher confidence on correctly recognized trials than on incorrect trials ($t(82)=-2.89$, $p=.005$). Analysis of fNIRS activity showed that, consistent with previous studies, right lateral PFC activity was associated with subjective uncertainty of memory during recall (r=-

0.72, p=.067 for confidence of recognition, r=-0.76, p=.048 for reported amount of detail) while left lateral PFC activity was associated with the higher meta-memory (r=0.71, p=.076). Moreover, different neural signals during encoding were predictive of subjective and objective recollection. Higher activation of the right PFC during encoding predicted later reporting of more details in subjective recollection. In contrast, higher frontopolar cortex activation during encoding predicted higher accuracy during recollection (right: r=0.79, p=.033, left: r=0.87, p=.010). Though it had been previously shown that the rPFC is associated with subjective recollection and that the frontopolar cortex is associated with episodic memory retrieval, their involvement in encoding has not been widely reported. One possible explanation is that the rPFC's monitoring of new episodic information during encoding contributes to better performance during recollection.
In conclusion, we observed multiple signals from the PFC that correlate with subjective/objective memory and revealed that these predictive activations may be specific to the encoding or retrieval. Such measurements provided by a portable fNIRS system could have wide applications for assessing meta-memory in various clinical and educational settings.

Title: REM sleep enhances emotion-relevant recapitulation

Authors: ***R. M. BOTTARY**[1], S. M. KARK[1], R. T. DALEY[1], J. D. PAYNE[2], E. A. KENSINGER[1];
[1]Psychology, Boston Col., Chestnut Hill, MA; [2]Psychology, Univ. of Notre Dame Dept. of Psychology, Notre Dame, IN

Abstract: Episodic memory retrieval is enhanced when brain regions engaged during memory encoding become reactivated at the time of retrieval, a phenomenon termed recapitulation. Additionally, slow wave sleep (SWS) is implicated in memory consolidation and rapid eye-movement (REM) sleep in emotional memory processing. Here, we investigate the links between individual differences in the spatial extent of emotionally-enhanced recapitulation and REM and SWS. Twenty-two healthy adults (11F, 11M; age: 19-29 years) underwent fMRI scanning during an incidental encoding task and a surprise recognition memory task following a 24-hr delay that included overnight, polysomnographically-recorded sleep. During encoding, participants viewed

line drawings of negative, neutral and positive images, each followed by their full-colored photo. At recognition, participants distinguished new from encoded line drawings, and rated the vividness of their memories. For each valence (negative, neutral, positive), recapitulation was defined as the whole-brain encoding-to-retrieval spatial overlap (i.e., conjunction of Encoding Hits > Misses ∩ Recognition Hits > Misses). We then calculated the spatial extent of valence-specific recapitulation processes (recap%) for each participant by dividing the total number of voxels observed in the Encoding ∩ Recognition maps by the total number of voxels observed in their corresponding encoding maps. To calculate emotion-specific recapitulation, we subtracted neutral recap% from negative and positive recap% separately, creating two summary values (neg-neu recap%; pos-neu recap%). Correlations between recap%, sleep metrics, and memory performance were conducted using Pearson coefficients or Spearman's Rho. REM sleep percentage was positively associated with neg-neu recap% ($r=.440$, $p=.041$) and pos-neu recap% ($r=.444$, $p=.039$). SWS percentage did not correlate with these metrics (ps > 0.5). Neutral recap% was positively associated with neutral memory ($r=.526$, $p=0.012$) and positive recap% was positively associated with positive memory at a trend level ($r=.397$, $p=.067$). The relation between negative recap% and negative memory did not reach significance. Individuals who spent a greater proportion of time in REM sleep were better at re-engaging encoding-related brain regions during the retrieval of emotional vs. neutral memories. This effect of REM sleep may provide a mechanistic explanation for why REM sleep is linked to enhanced emotional memory performance.

Title: Cortical thickness predicts recall improvement due to noninvasive stimulation targeting the hippocampal-cortical network in older adults

Authors: *Y. LAGOUTINA[1], A. S. NILAKANTAN[2], M. A. NIASARI[4], L. WANG[5], J. L. VOSS[3];

Abstract: Aging is associated with cortical atrophy, as well as with long-term episodic memory decline. Previous findings have suggested that it may be possible to alter function of the hippocampal-cortical network using transcranial magnetic stimulation (TMS), leading to memory improvement. The present experiment aimed to evaluate whether age-related cortical atrophy may predict the amount of memory improvement caused by TMS targeting the hippocampal-cortical network. A sample of 16 participants, aged 60-81, and 31 participants, aged 18-35, received TMS targeting the hippocampal-cortical network for 5 consecutive daily sessions. Effects of stimulation on memory were tested using an object-location paired-associates task administered before and after stimulation, as well as before and after a sham stimulation condition. Cortical thickness regions of interest (ROIs) were identified and evaluated using FreeSurfer software. We identified a canonical pattern of cortical thinning by comparing thickness values for younger versus older adults in our sample. Regions with thinner cortex for older versus younger adults included the default mode network (DMN), as well as several other regions that have shown aging-related atrophy in previous studies. Reduced cortical thickness in these regions predicted greater improvement in object-location recall memory ($R^2 = .25$) in the older participants, such that older adults with thinner cortex had relatively greater recall improvements. These findings suggest that memory gains due to the manipulation of hippocampal function via TMS are more salient for older adults with greater levels of cortical atrophy. This may be due to reduced compensatory mechanisms that are normally supported by the cortex in these individuals, causing them to be more dependent on hippocampal contributions to memory.

Title: Conformance of mental events to a group timeline during movie-viewing reflects cognitive ability

Authors: *J. TSENG[1], J. POPPENK[2];
[1]Ctr. for Neurosci. Studies, [2]Dept. of Psychology, Queen's Univ., Kingston, ON, Canada

Abstract: Movies induce similar brain activity across individuals. This organization can be found not only in perceptual cortices, but also higher-order brain areas, perhaps driven by semantic content. We recently validated procedures for deriving mental events from whole brain activity and found that these events, too, were organized by movies. However, the degree to which mental events conformed to the group timeline (i.e., conformity) differed across individuals. Do these individual differences reflect noise or something meaningful about those individuals?

To answer this question, we developed and validated a method to quantify the degree of shared structure, then investigated its neuroanatomical and behavioural correlates. Behavioural studies have shown that the tendency to identify the same conceptual boundaries in movie timelines as others is predictive of memory and general cognitive ability; thus, we hypothesized a positive correlation between conformity and cognitive ability. Also, because previous studies have found hippocampal activation at conceptual boundaries during movies, we hypothesized that properties of the hippocampus would predict conformity.

We conducted our analysis on 184 healthy participants (age: 22-35 years) from the Human Connectome Project dataset. Each participant had four 15-min movie-viewing functional MRI runs. Previously, we developed a method to obtain a timeline of network meta-state changes, which we determined to correspond to mental events, for each participant and movie run (*step distance vector*; Tseng & Poppenk, 2019). After applying this method, we calculated each participant's conformity by correlating the log of the participant's step distance vector to the log of the corresponding median group step distance vector. Because we found conformity to be internally stable across runs gathered on different days (mean $r = 0.50$), we averaged conformity values within participant to obtain a maximally stable trait estimate.

Our final step was to assess the relationship between conformity and recollection ability, cognitive function scores, and hippocampal volume. Higher conformity was correlated to higher Total Cognition Composite scores, driven by performance on the Picture Vocabulary subtest. Conformity was also correlated to better recollection memory and larger anterior/smaller posterior hippocampal volume. We conclude that conformity does not just reflect random statistical variation, but arises due to cognitive and neural characteristics of individuals. Our results further suggest that semantic knowledge helps to parse and encode streams of new information.

Title: Familiar movies are less effective at aligning viewers' cognitions

Authors: *Y. LU[1], J. TSENG[2], J. POPPENK[1];
[1]Psychology, [2]Neurosci., Queen's Univ., Kingston, ON, Canada

Abstract: What is different when we watch a movie for the second time? It is well established that novel stimuli better grab our attention, and that familiar stimuli are processed more efficiently. But what does this mean for our mental experience of movie-viewing? To address this question, we examined the impact of novelty on the tendency of movies to align participants' mental events. We have previously established (Tseng & Poppenk, 2019) that movie stimuli exert a powerful organizing quality over the timing of large-scale network transitions, and linked these transition points to mental events (apparently reflecting a shift to a new thought). Here we examined the possibility that novel movies are particularly effective at affecting such alignment due to greater stimulus control over cognition, and examined neural correlates of this phenomenon. As the anterior temporal lobe is known to play an important role in novelty processing, we focused our neural analysis on this region.
To this end, we analyzed fMRI data from 184 participants in the 7T Human Connectome Project dataset. Participants watched the same 82-second movie clip during four different scanning sessions. We distinguished between the first viewing (novel stimulus) and subsequent viewings (familiar stimulus). To identify mental events, we used procedures developed by Tseng and Poppenk to isolate large-scale brain network transitions. We then computed the group alignment representing how each individual's thought trajectory was in synchrony with that of the group as a whole, and the rate of underlying transitions. Finally, we regressed transition rate and group alignment with the hippocampus and amygdala volumes.
We found that group alignment for familiar runs was significantly lower than the alignment for the initial run and the transition rate for familiar runs was lower than the transition rate for the initial run. With respect to hippocampal and amygdala predictors, we found that a larger left and right hippocampal head, as well as a larger left and right amygdala, predicted more group alignment and fewer transitions for the initial run. However, these effects were weakened in the

familiar runs. These findings suggest that familiar stimuli are less effective at organizing our thoughts, likely because they become more idiosyncratic and less stimulus-driven. The implication of the hippocampus and amygdala is also consistent with their known role in novelty processing. We conclude that watching a movie for the second time really is different - not only do viewers know what's coming, but a director's ability to command their viewers' thoughts is diminished.

Title: Relatively large posterior hippocampal volumes predict greater memory precision in movie timeline task

Authors: *S. W. GORLICK, J. POPPENK;
Psychology, Queen's Univ., Kingston, ON, Canada

Abstract: Observations of anatomical and functional differences along the long axis of the hippocampus (HPC) have drawn attention to the nature of specializations of its anterior and posterior segments. More specifically, it has been proposed that gist-like episodic memory representations reside in the anterior portion, whereas more detailed episodic memory representations lie in the posterior portion. Here we sought to test this idea by evaluating memory for a movie narrative using tasks designed to measure both accuracy and precision. We conducted our analysis on data from 66 healthy participants between the ages of 22 and 35 years. Each participant first completed an ultra-high-resolution T2w image of their medial temporal lobe (0.5 mm isotropic) and a lower-resolution T1w whole-brain scan (0.7mm isotropic) to calculate hippocampal volume and the volumes of proximal structures. We corrected these values for intracranial volume. Participants then viewed a 20-minute movie, *Bang! You're Dead*, prior to completing memory tests assessing detail and gist memory for the

film. These included a timeline test, in which participants moved still movie frames to their location within the movie timeline; and a movie sequence task, in which participants rearranged three still movie frames into the order in which they occurred. Finally, the movie exam contained multiple choice and fill-in-the-blank questions about the film. Scores from each test were correlated with results from structural scans to assess whether individual differences in hippocampal volume predicted memory performance.
We found that a larger right anterior, but not posterior hippocampus predicted significantly more errors and lower precision on the timeline task. By contrast, in both hemispheres, a larger posterior hippocampus predicted smaller numeric errors in quantitative exam questions. Finally, larger right posterior hippocampus volumes predicted better relative ordering of stimuli in the sequence task.
These results support the notion that the anterior hippocampus plays a role in more approximate memory, whereas the posterior hippocampus features more precise ones. More broadly, it reinforces findings that distinguish between the volumetric properties of anterior and posterior hippocampal segments as predictors of memory.

Title: Emdr is not "special": De-arousal effects reflect domain-general memory-weakening phenomena

Authors: *J. POPPENK, D. WILSON;
Queen's Univ., Kingston, ON, Canada

Abstract: Arousal associated with aversive memories can be attenuated using the eye-movement desensitization and reprocessing (EMDR) technique, which typically requires participants to visualize the target memory while tracking a stimulus bilaterally. Such "de-arousal" can, however, also be obtained using substitute tasks for stimulus tracking, which is interpreted as evidence that it is mental visualization that lies at the core of EMDR's effects. In the current

study, we explored the possibility that visualization, too, is immaterial, as would be predicted by proposals that it is partial memory reactivation in general that underlies memory weakening, rather than a particular procedure for memory retrieval. We further explored whether neural characteristics might offer further clues into the specificity of the underlying mechanism. 65 participants completed a word-scene encoding task in which words described crimes that putatively occurred in the scenes. In an emotional appraisal task, participants then rated the scenes as more arousing than others. They next tracked a moving dot while scenes were presented behind the viewing area. In another emotional appraisal after dot-tracking, arousal for reactivated scenes returned to baseline, whereas arousal for non-reactivated scenes did not. We found this de-arousal could be predicted by patterns of structural and functional connectivity involving the anterior hippocampus, posterior hippocampus and corpus callosum. This pattern was most consistent with the idea that it was incomplete memory reactivation that contributed to weakening effects. Because neither stimulus oscillation nor mental visualization appear necessary to obtain EMDR-like effects, we argue EMDR is not distinctive among paradigms that induce memory-weakening, and that its effects can be parsimoniously explained using the non-monotonic plasticity hypothesis. Our findings also offer the first evidence that theoretically meaningful biological predictors can be used to predict which individuals will find memory weakening procedures most effective. In a health context, memory-weakening mental health treatments could one day be calibrated based upon neural inputs; in other contexts (such as eyewitness memory), the findings could one day reveal which individuals are most susceptible to memory-weakening.

Title: Sequential reactivation during offline periods in humans

Authors: *M. PETZKA[1], G. BALANOS[2], B. P. STARESINA[1];
[1]Sch. of Psychology and Ctr. for Human Brain Hlth., [2]Sch. of Sport, Exercise and Rehabil. Sci., Univ. of Birmingham, Birmingham, United Kingdom

Abstract: Our ability to remember past events relies on the re-emergence of learning patterns during sleep, a process referred to as memory reactivation. Memory reactivation has been linked to sleep spindles (10-16Hz), an oscillatory pattern thought to mediate the re-emergence and,

hence, strengthening of previously learned associations. In humans, previous studies focused on simple paired-associate learning (e.g. learning of word-picture associations), although episodic memories tend to contain multiple, sequentially experienced elements. Indeed, animal studies have provided evidence for reactivation of learning sequences ('replay') and suggest that sequential reactivation occurs in a compressed and forward manner. However, little is known about the temporal dynamics of sequential reactivation during offline periods in humans. Here, we applied targeted memory reactivation (TMR) to cue previously learned sequences of object-face-scene triplets during a post-learning nap (N = 19) or a matched post-learning wake period (N = 21) using high-density Electroencephalography (EEG). Memory cueing was performed during NREM sleep, presenting previously learned sounds (semantically linked with 50% of the objects) and control sounds (without any semantic content). Behavioural results confirm that triplets were indeed encoded as a sequence, as the conditional probability to correctly retrieve a face without remembering the following scene was higher than correctly retrieving a scene without remembering the preceding face ($p < .001$). Importantly, memory performance for sequences that were cued during the nap was higher compared to sequences not cued ($p = .014$), establishing that TMR for sequences was successful. On an electrophysiological level, both target and control cues elicited an evoked response (k-complex) and a significant increase relative to a pre-cue baseline in a broad frequency range (5-20Hz) roughly 1 second after cue onset ($p < .05$). Most interestingly, target cues elicited a stronger response compared to control cues in the sleep spindle frequency range between 1 - 2.5 seconds post cue ($p < .05$). Together, our data propose that sequential memories benefit from TMR and that cue-triggered spindles are likely to ignite the sequential reactivation of a memory trace.

Title: Post-learning sleep oscillations track learning networks as revealed via human electrocorticography

Authors: *H.-V. V. NGO[1], Y. Y. CHEN[2], D. YOSHOR[3], B. L. FOSTER[2], B. STARESINA[1]; [1]Univ. of Birmingham, Birmingham, United Kingdom; [2]Dept. of Neurosurg., Baylor Col. of Med., Houston, TX; [3]Baylor Col. Med., Houston, TX

Abstract: Memory consolidation, the transformation of labile memory traces into stable long-term representations, is facilitated by post-learning sleep. Computational and biophysical models suggest that cortical slow waves and thalamo-cortical sleep spindles play a key mechanistic role in the service of consolidation. In particular, by gating molecular signal cascades, these oscillations are thought to ignite structural changes at cortical learning sites. Here we tested the prediction that slow wave/spindle patterns are enhanced specifically over learning-related cortical areas. Six patients implanted with intracranial grid/strip arrays performed an associative word-image learning task in the evening prior to sleep. For half of the recording sessions, words were paired with images of objects and for the other half, paired with images of scenes. Memory was tested prior to sleep (PM) and again next morning (AM). Intracranial data was recorded during memory tests and intervening sleep. On the PM test, participants recalled the correct target image for 51% trials (SEM=5%), indicated the wrong target image on 20% (SEM=3%) and forgot the target on 25% (SEM=5%). On the AM test, the corresponding proportions were 41% (SEM=4%), 23% (SEM=3%) and 31 % (SEM=6%), pointing to moderate overnight forgetting rates. To identify cortical sites tuned to the learned image category, a separate visual localizer session was employed. Here, participants processed various image categories (objects, scenes, faces, body parts, numbers and words) and category-specific tuning was defined as a selective gamma band (50-150 Hz) increase for the target category (objects or scenes) relative to all other categories. Across participants, we recorded from 720 cortical sites, with 95 contacts (13%) showing object- or scene-specific tuning. Slow wave and spindle activity was algorithmically detected for non-rapid-eye-movement (NREM) sleep during the first half of the night. Intriguingly, both slow wave and spindle amplitudes were significantly increased at cortical sites selectively tuned to the learned image category as compared to non-target sites ($P < .01$). These results are consistent with the notion that slow wave and spindle activity track learning networks and thereby facilitate memory consolidation.

Title: Differential contributions of sleep oscillations to item- and associative memory consolidation

Authors: *T. SCHREINER, B. P. STARESINA;
Sch. of Psychology and Ctr. for Human Brain Hlth., Univ. of Birmingham, Birmingham, United Kingdom

Abstract: Post-learning sleep bolsters the stabilization of newly formed episodic memories. At the scalp level, the two oscillatory sleep signatures most consistently linked to memory processes are neocortical slow oscillations (SOs, < 1 Hz) and thalamocortical spindles (10-16 Hz). In particular, SOs are thought to orchestrate the intricate interplay of spindles with hippocampal ripples, the latter presumably reflecting reactivation of recent memory traces. A key prediction emerging from this framework is that SOs specifically mediate the consolidation of hippocampus-dependent memories, e.g. associative memories as opposed to non-associative item memories.Here we set out to elucidate the precise contributions of SOs to the consolidation of different expressions of declarative memory. Prior to sleep, participants (n = 17) encoded word-picture associations. During subsequent retrieval, participants first performed old/new judgments on previously presented ('old') and novel ('lures') words (item memory), followed by recall of the associated image (associative memory). Importantly, half of the stimuli were tested immediately after learning and half after an afternoon nap, ~2h later. The difference between post-sleep and pre-sleep performance indexed the extent of memory consolidation. Throughout the experiment, brain activity was recorded using electroencephalography (EEG). To elucidate the impact of SOs on the consolidation of item and associative memory, we detected SOs during non-rapid eye movement (NREM) sleep and correlated their density (number/minute) at fronto-central sensors with memory performance (difference in retrieval performance before and after sleep).Behavioural results revealed that participants recognized 73.6 ± 2.7% of the presented old words (HITs) during the initial memory test, out of which 65.2 ± 3.7% of the associated images were retrieved. After the sleep interval participants still recognized 64.1 ± 2.7% of the items and remembered 56.9 ± 4.5% of the targets. On a neuronal level, SO density positively correlated with memory consolidation across participants. Critically though, this was only the case for associative memory performance ($r = 0.38$, $P = 0.02$), while no such correlation was found for item memory ($r = 0.11$, $P = 0.51$). These results suggest that SOs are preferentially engaged in the consolidation of associative memories, consistent with a role in orchestrating a hippocampal-neocortical dialogue in service of episodic memory formation.

Title: Structural brain integrity of patients with medial temporal lobe resection in relation with episodic memory

Authors: *W. JEONG[1,2], J. KIM[3], C. CHUNG[2,4];
[1]Neurosci. Res. Inst., Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of; [2]Neurosurg., Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of; [3]Res. Inst. of Basic Sci., [4]Dept. of Brain and Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Purpose: The neural mechanisms of episodic memory in the absence of one medial temporal lobe (MTL) structures has recently started to be investigated. It has been suggested that increased functional connectivity of distributed brain areas, including the hippocampus contralateral to the resection, is the supporting mechanism for normal range of episodic memory function in patients with MTL resection (MTLR). However, regardless of its close relationship between function, behavior, and structure, structural substrates of memory reserve after MTLR has not been well characterized. In the present study, we aim to understand structural characteristics of MTLR brain and its relationship with episodic memory function. **Methods**: We studied 35 adult patients who underwent unilateral MTLR for the treatment of medically intractable epilepsy (17 left, 18 right) and 21 healthy controls (median age 32 years). All participants underwent diffusion-weighted imaging (3T). Group differences in white matter integrity, which were assessed via fractional anisotropy (FA), was investigated by applying tract-based spatial statistics. Finally, FA values were compared with memory capacity which was assessed by a standardized neuropsychological test. Additionally, we assessed the axial diffusivity (AD), the radial diffusivity (RD), and the mean diffusivity (MD). **Results**: All subject groups exhibited normal range of memory capacity. As for the white matter integrity, while HCs showed higher FA values in the tracts near the resection cavity, both patient groups showed higher FA values within ipsi-lesional superior corona radiata ($p<0.05$, corrected). The mean values for FA, AD, RD, and MD were extracted by using the cluster showing higher FA values in patients as a mask. Compared to the HC, both patient groups showed lower RD and higher AD values ($p<0.05$). For the relationship with memory function, all these values showed no significant correlation with any memory scores. **Conclusions**: Both reduced and increased microstructural integrity in similar tracts with our observation have also been reported in previous postoperative studies, which were often interpreted as reflecting cognitive impairment of patients. Given that our patients had a normal range of memory capacity and white matter integrity had no correlation with memory scores, altered integrity in our patients may reflect pathological condition rather than memory function. In the future, more sophisticated analysis methods (e.g., tractography started from hippocampus contralateral to the resection) should be adopted in order to reveal the structural substrates of normal episodic memory function without MTL.

Title: Training related suppression of EEG signals complexity

Authors: *U. MALINOWSKA[1], J. WOJCIECHOWSKI[2], M. WALIGÓRA[1], J. ROGALA[1]; [1]Nencki Inst. of Exptl. Biol., Warsaw, Poland; [2]World Hearing Ctr. of Inst. of Physiol. and Pathology of Hearing, Warsaw/Kajetany, Poland

Abstract: Learning processes associated with multiple task repetitions are deemed to affect brain plasticity via postsynaptic potentiation leading to long term changes in functional connectivity. These changes may cause increased or reduced activation of existing neural architecture. In this study, we examined the effect of three repetitions of delayed match-to-sample task on changes in the EEG signal complexity and spectral components. We modified the original task by adding control trials that did not require engagement of attention and memory. These additional trials allowed us to compare impact of attended versus passive conditions. We exanimated 14 subjects with the two types of trials in three sessions performed within 10-20 days. Scalp EEG was collected with 21 electrodes in the 10-20 system. For each electrode channel and trial of the correct response, we selected three 1-second long windows in different time points across a trial. For the selected signals we analyzed power in consecutive frequency bands <40 Hz and signals complexity measures such as sample entropy, Shannon entropy and Higuchi fractal dimension (HFD). Measures of signal entropy, as well as HFD, revealed gradual suppression of signal complexity in the consecutive sessions. The effect was significant in all examined windows extracted across a trial. Moreover, the changes were observed for both groups of tasks - for attentional and passive trials. We found also that the signal complexity remains always higher for the attentional trials. Comparison of spectral analysis for the group of subjects after the three sessions showed an increase in alpha power in frontal and parietal electrodes and in low beta activity (13-20 Hz) in central channels during the control trials. For the attentional trials, the alpha increase was observed only in a few frontal electrodes and in one parietal channel for a low beta activity. No significant changes were found for theta and high beta power in both conditions. However, we did not observe significant improvement of the test performance during the three sessions, the results of EEG analysis indicated changes in neuronal network manifested by the modified EEG signals. While in the case of passive trials, the suppression of the signal complexity may reflect increase of power in lower frequencies associated with inhibition of unnecessary attention and memory processes, confirmed by increase of the alpha power, the

changes observed in attentional trials, not accompanied by broad spectral changes, suggest rather learning related synchronization and reconfiguration of the network activity, potentially reflecting optimization of the underlying cortical processing networks.

Title: Evolutionary conserved role of neural cell adhesion molecule-1 (NCAM1) in memory

Authors: *P. MASTRANDREAS[1], V. VUKOJEVIC[1], F. PETER[1], I. KOLASSA[2], T. ELBERT[3], D. J. DE QUERVAIN[1], A. PAPASSOTIROPOULOS[1], A. STETAK[1];

Abstract: The neural cell adhesion molecule 1 (NCAM1) is involved in several brain-related biological processes, including neuronal migration, axonal branching, fasciculation, and synaptogenesis, with a pivotal role in synaptic plasticity. Here, we investigated the evolutionary conserved role of NCAM1 in learning and memory. Olfactory conditioning induced sustained changes in *ncam-1* expression in up to 24 hours after training. Loss of *ncam-1* function selectively impaired associative long-term memory, without causing acquisition, sensory, motor or short-term memory deficits. Expression of *C. elegans* or human NCAM1 fully reversed the memory loss of *ncam-1(lf)* worms, suggesting a conserved role of NCAM1 for learning and memory. In two independent healthy Swiss cohorts, DNA methylation of the NCAM1 promoter was associated with memory performance. In two independent Sub-Saharan populations of conflict zone survivors who had faced severe trauma, DNA methylation at an alternative promoter of the NCAM1 gene was associated with traumatic memories. Taken together, our results support a role of NCAM1 in associative memory in nematodes and humans.

Title: An fMRI investigation of medial prefrontal network dynamics during a context-dependent rule learning task

Authors: *W. MA[1,2], T. M. MORIN[3,2,1], A. E. CHANG[2,1], C. E. STERN[2,1];

Abstract: The purpose of this study was to investigate how functional interactions between brain networks support human context-dependent rule learning. In the task, healthy naive participants (N = 30) learned a series of context-dependent rules through trial and error during an fMRI scan. Our analysis examined changes in functional connectivity across the transition from learning to learned rule behavior. We first applied a community detection algorithm to examine changes in functional connectivity between brain regions across time (Bassett et al. 2011, PNAS). Flexibility was defined to be the number of times a node changed its community allegiance normalized by the number of possible changes. We found that flexibility was higher in anterior cingulate cortex and orbitofrontal cortex during learning compared to after learning. We used these same regions to perform a difference of correlation analysis. Results indicated that both anterior cingulate cortex and orbitofrontal cortex were more strongly connected with regions in the ventral attention network during learning compared to after learning. These results suggest that anterior cingulate cortex and orbitofrontal cortex are affiliated with different networks during learning compared to after learning.

Title: Cortical contributions to perceptual and symbolic reasoning using a one-dimensional raven's progressive matrices task

Authors: *T. M. MORIN[1,2,3], A. E. CHANG[2,3], C. E. STERN[2,3];
[1]Grad. Program for Neurosci., [2]Ctr. for Systems Neurosci., [3]Cognitive Neuroimaging Ctr., Boston Univ., Boston, MA

Abstract: The goal of this study was to investigate brain activity that underlies abstract reasoning of discrete symbolic and continuous texture stimuli. We developed a simplified, one-dimensional version of the Raven's Progressive Matrices task suitable for testing during an fMRI scan. During the task, participants (N = 27) viewed patterns composed of either discrete symbols or detailed continuous textures. Symbols or textures either varied from left to right according to a sequential rule or remained uniform throughout. Subjects were required to deduce and apply a sequence-rule to determine which of two answer choices correctly fit into a blank white square covering part of the stimulus. Participants were instructed on a paper version of the task outside of the scanner and completed 384 trials of the task during fMRI scanning. Participants exhibited high levels of accuracy and similar response times for all conditions. For both discrete symbolic and continuous texture stimuli, stimuli that required correctly deducing and applying a sequence rule resulted in increased BOLD signal in the frontoparietal control network (FPCN). Notably, regions of the FPCN strongly connected with the Default Network exhibited stronger activity when subjects were reasoning about a symbolic sequence, whereas regions of FPCN that were strongly connected with the Dorsal Attention Network showed greater activity when subjects were reasoning about a texture sequence. Increased BOLD signal in ventral visual regions was also associated with reasoning about a texture sequence. Our preliminary results suggest differential frontoparietal, dorsal attention, and default network contributions to reasoning about discrete symbolic and continuous texture stimuli.

Title: Overlapping frontal network mediates task-related connectivity changes between intrinsic cognitive control networks

Authors: *S. L. COOKSON, M. D'ESPOSITO;
Univ. of California, Berkeley, Berkeley, CA

Abstract: Regions of the lateral frontal cortex (LFC) are part of two separate intrinsic networks - the fronto-parietal (FP) and the cingulo-opercular (CO) - that are proposed to support distinct cognitive control processes (Dosenbach 2008). The FP and CO networks become more integrated during tasks versus rest, thought to indicate increased between-network communication (Cohen & D'Esposito 2014); however, it is yet unclear what drives this integration. Recently, using a mixed membership algorithm to parcellate resting fMRI data into overlapping intrinsic networks, we found a previously unidentified network that spans the majority of frontal cortex, overlapping with and containing LFC regions from the otherwise distinct FP and CO networks. The LFC regions in this intrinsic frontal network also form a hierarchically connected, task-related network proposed to implement cognitive control via top-down selection processes (Badre 2008). We have hypothesized that FP-CO integration may be facilitated by the frontal network via these overlapping connections. To test this hypothesis, we analyzed previously published fMRI data from our lab during which subjects performed a task that orthogonally manipulated two factors, each thought to engage the processing of distinct regions of the frontal network (Nee & D'Esposito 2016). In the original study, rostral LFC regions showed increased top-down influence as they were recruited by the task demands in each condition. In this analysis, we extended these results by assessing how integration between the frontal network and the FP and CO networks changed with different cognitive control demands. We assessed integration between the FP and CO networks and the frontal network by measuring beta series correlations between the regions unique to each network for each combination of task factors. We found that integration between the frontal and FP/CO networks depended simultaneously on both task factors; that is, the frontal network became more integrated with both the FP and CO networks when the task required processes supported by both networks. These results suggest that integration between the FP and CO networks is mediated by a third overlapping network, and may suggest ways to relate regional hierarchical interactions to network integration.

Title: Cognitive control networks balance domain generality and specificity in representing task rule information across multiple cognitive domains

Authors: *D. H. SCHULTZ[1], T. ITO[2], M. W. COLE[2];
[1]Ctr. for Brain, Biol. & Behavior, Univ. of Nebraska, Lincoln, Lincoln, NE; [2]Rutgers The State Univ. of New Jersey, Newark, NJ

Abstract: Cognitive control is a set of processes that allow for flexible information processing and behavior based on current goals. Some evidence suggests that cognitive control processes are domain general, reflecting general processes that are engaged regardless of context or modality. Other results have suggested that cognitive control can be better explained by a number of domain specific processes that are engaged in specific contexts or modalities (e.g. working memory, attention, visual stimuli, auditory stimuli, etc.). We hypothesized that activity patterns within regions of the brain would contain information regarding task rules, and more specifically, that cognitive control networks would contain information across a number of different contexts and modalities reflecting domain general processes consistent with the concept of "mixed selectivity" information coding. This would reflect the ability of these networks to integrate domain specific representations so they can be coordinated for task performance when different rules are encountered in novel situations. We also hypothesized that some brain regions would exhibit more specific information content (pertaining to a specific context or modality), reflecting the need for the brain to balance domain general, and domain specific representation. We tested this hypothesis in a large dataset (100 young adults) in which participants completed a flexible control task called the Concrete Permuted Rule Operations (C-PRO) paradigm in the scanner (fMRI). The C-PRO paradigm consists of three rule domains (Logic, Sensory, Motor) with four variants within each domain. When all of the rules are permuted it results in 64 unique rule combinations. This task design allowed us to compare task rule information content across three different modalities (Logic, Sensory, Motor) while controlling for attention, arousal, sensory input, and motor output across tasks. We examined multivariate patterns of activity across 360 cortical parcels. Information estimates were measured using representational similarity analysis, quantified as similarity of the activation pattern elicited by tasks with a common rule relative to tasks not sharing a rule. Consistent with our hypothesis, we found that cingulo-opercular, frontoparietal, and dorsal attention cognitive control networks contained domain general information, while portions of these networks also showed a preference for specific domains. These results suggest that cognitive control networks contain domain general information, but portions of these networks still maintain some level of domain specificity.

Title: Impulsivity and cognitive control in human intracranial and extracranial EEG

Authors: *E. H. SMITH, B. KUNDU, B. PHILIP, T. DAVIS, J. D. ROLSTON;
Neurosurg., Univ. of Utah, Salt Lake City, UT

Abstract: Impulsive choice refers to the tendency to favor immediate, small rewards over delayed, large rewards, is a component of many psychiatric disorders, particularly substance use disorder. Impulsive choice may initially predispose individuals to substance abuse, and has been shown to be essential in relapse. Neuroimaging studies of impulsive choice broadly highlight brain areas involved in decision making, suggesting that no single anatomical area is implicated as causing impulsivity. Here we seek to assess the extent to which impulsivity reflects a failure of cognitive control over decision making or a failure to incorporate a model of the task into decision making circuitry. In order to address these questions, we examined intracranial LFP and scalp EEG from neurosurgical patients undergoing monitoring for refractory epilepsy who performed a task that induced impulsivity for anticipated rewards: the balloon analog risk task (BART). Overall seven patients carried out 222.9 ± 10.8 trials of BART with an accuracy of 84.9 ± 5.8%. There was a bimodal distribution of overall impulsive behavior across patients, determined by the Kullback-Leibler divergence between successful active trials, in which subjects successfully ceased balloon inflation, and passive trials, in which balloons were inflated to their maximum size while subjects watched. Three subjects (43%) exhibited overall impulsivity using this metric. In order to gauge neural representations of an internalized task model, we examined broadband high frequency LFP (70-200 Hz; BHF) responses to increasing risk, reward, and uncertainty during balloon inflation (linear mixed effects model in Wilkinson notation: balloon size ~ 1 + BHF + (1 + BHF | trial)). We found that electrodes in the dorsolateral prefrontal and anterior lateral temporal cortices significantly tracked these variables (family-wise error corrected $p < 0.05$ for each electrode). In order to gauge intracranial correlates of canonical cognitive control signals, we examined differences in BHF in response to BART outcomes (wins, losses; point acquisition, balloon pops) using cluster corrected permutation tests, accounting for adjacent intracranial electrodes. We found significant differences following outcomes in the anterior cingulate, orbitofrontal cortex, and amygdala. These BHF responses correlated in time and amplitude with frontal midline theta recorded on the Fz scalp EEG contact across trials. These results address the neural mechanisms of control over impulsive decisions.

Title: Effect of heart rate reserve on prefrontal cortical activation in healthy older adults while dual-task walking

Authors: *A. BISHNOI[1], G. CHAPARRO[2], M. HERNANDEZ[1];
[1]Kinesiology and Community Hlth., Univ. of Illinois At Urbana-Champaign, Urbana-Champaign, IL; [2]California State Univ. Dominguez Hills, Carson, CA

Abstract: Heart rate reserve (HRR) has been shown to be associated with cardiovascular function in older adults, but much is still unknown how the heart rate reserve level affects cognitive control while dual-task walking. In this study, we aim to determine the relationship between heart rate reserve level and change in prefrontal cortical (PFC) activation patterns evaluated by functional near-infrared spectroscopy (fNIRS) between low HRR group (LHRR) and high HRR group (HHRR) while dual-task walking. This is a cross-sectional study design. Twenty-three older adults were divided into two groups: LHRR (N=9, age=74.8±7.2, 0 females) and HHRR (N=14, age: 63.3±9, 5 females), based on heart rate reserve cut off of 55, which was calculated by the difference of maximum heart rate and resting heart rate. Participants completed baseline cognitive and motor testing before starting the dual task paradigm on the treadmill. In the paradigm, participants completed a single task walking and dual-task walking with Modified Stroop Color and Word test (MSCWT). This condition was completed in order of easiest to most difficult (Neutral, Congruent, Incongruent, Switching). The results of the linear mixed model analysis revealed that the older adults with LHRR are limited in the recruitment of PFC resources in increasingly challenging cognitive tasks while walking, compared to older adults with HHRR (Figure 1, $p < .001$), while controlling for age and gender differences. These findings provide evidence that HRR in older adults is related to cognitive function. This study is the first to investigate the effect of HRR on brain activation changes in healthy older adults and provides a potential link between low HRR and cognitive impairments in older adults. Keyword(s): fNIRS, Prefrontal cortical activation, HRR

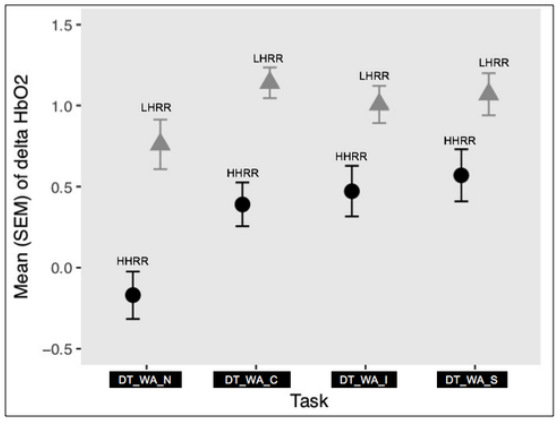

Figure 1: Mean (SEM) increase of the delta PFC (Dual task HbO2- Single task HbO2 level) in two groups (LHRR vs HHRR) with increasing difficulty of dual task walking condition (Neutral (DT_WA_N), Congruent (DT_WA_C), Incongruent (DT_WA_I), Switching (DT_WA_S)).

Title: The lateralization of mirror neurons in theinferior frontal gyrus during motion observation and execution

Authors: *F. ZHANG[1], S. IWAKI[2];
[1]Natl. Inst. of Advanced Industrial Sci., Tsukuba, Japan; [2]Natl. Inst. Adv Indust Sci. & Tech., Tsukuba, Japan

Abstract: Mirror neurons, which first reported in the macaque monkey, fire both during observation and the execution of similar action. However, the existence of mirror neuron system (MNS) in humans is not clear. The significant clusters responding to both observation and action have been reported in Brodmann area 44 that located in the inferior frontal gyrus (IFG), but the activation of neural system represents the common neural code or overlapping but distinct populations is still in debate. The purpose of our study is to investigate the presence and the role

of mirror neurons for motion observation and execution. We conducted a functional magnetic resonance imaging adaptation paradigm with separate left or right hand movement to define the presence and lateralization of MNS activation. In the further study, we applied the representational similarity analysis in MNS to analyze the response patterns with representational dissimilarity matrix (RDM). Our result revealed the right lateralization, not left lateralization of MNS in IFG. Furthermore, the result of RDM showed the similar brain activity patterns when participants were required to execute the hand movement with the ipsilateral or contralateral hand after they observed the video. This result suggested that when the MNS was activated by motion observation, the activity was right lateralized no matter whether the subsequent motion is completely agree with the observed motion. The result from RDM provided the supplemental evidence for the right lateralization of motor components of MNS in IFG.

Title: Frontostriatal connectivity during abstract sequential control

Authors: *T. H. MCKIM[1], T. M. DESROCHERS[2];
[1]Neurosci., [2]Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: The everyday goal of making coffee intimately intertwines the reward (drinking the perfect cup of coffee) and guiding sequential tasks (e.g., add water and coffee). A change in reward (different coffee) may change your performance of these task sequences. Several fMRI studies using abstract sequential tasks have demonstrated that activity in the rostrolateral prefrontal cortex (RLPFC) is increasingly engaged (ramps up) and is necessary during abstract sequential control (Desrochers et al., 2015; 2019). Ramping dynamics have also been found in the frontal cortex of animals (Donnelly et al., 2015), and dopamine concentration ramping in the striatum scales based on reward magnitude (Howe et al., 2013). Whether reward modulates the ramping signal within the RLPFC and throughout the brain during sequential tasks, and whether frontostriatal circuit connectivity changes as a result during sequential control in humans are

outstanding questions. We tested the hypothesis that progress towards a goal underlies RLPFC ramping, and changes in the associated network by manipulating the value of learned task sequences. Participants kept track of repeated four-item sequences of images that were associated with either high or low reward during fMRI scanning. On each trial, participants indicated whether the image was in or out of a pre-determined order. The sequential task included conditions whereall stimuli were visible (Vis), or all but the last stimulus in the block was occluded by a placeholder image (Occ), requiring sequence monitoring from memory. Elevated reaction times (RTs) at the first position within the sequence demonstrated that participants monitored the presented images as sequences (n = 25; Pos1>Pos2,3,4; $F_{1,24}$=16.097,p<0.001). We observed a trend that sequence value modified performance by decreasing RTs for high value sequences ($F_{1,24}$= 3.38, p=0.078). We found that RLPFC activity ramps up during sequence monitoring, replicating previous results. Preliminary task-based functional connectivity results showed increased connectivity between bilateral lateral prefrontal cortex in the frontoparietal control network, which overlaps with the RLPFC, and the caudate nucleus of the striatum when contrasting high versus low value sequences. We also found decreased connectivity between the specific ramping RLPFC cluster and the nucleus accumbens for the high versus low sequences. Our findings suggest a link between abstract sequential control and reward processing in frontostriatal circuits with similar neural signal dynamics across species that may represent goal-directed behavior.

Title: Continuous tracking of error-related negativity via electrocorticography in humans

Authors: *E. AHN[1], J. PLASS[1], D. BRANG[2];
[1]Univ. of Michigan, Ann Arbor, MI; [2]Univ. of Michian, Ann Arbor, MI

Abstract: The error-related negativity (ERN) is thought to be a neural-based performance monitoring mechanism used to identify and correct potential errors. The ERN takes the form of a negative deflection in the ERP response, reaching its peak within 100 ms after an error occurs. While a strong emphasis on the accuracy of one's performance can enhance this ERP response, some studies have reported detection of the ERN even in the absence of any conscious awareness of an error, suggesting that this mechanism is a highly integrated and graded response that our

brain relies on for everyday performance monitoring. The ERN has been detected using a variety cognitive and perceptual tasks, ranging from sentence verification to more complicated motor paradigms. However, research has largely been restricted to non-invasive recordings, limiting our understanding of the neural mechanisms of the ERN. Moreover, previous studies using invasive electrocorticography (ECoG) recordings examined the ERN resulting from single trial-based and discretely time-locked responses using highly artificial tasks like the go/no-go paradigm. Here we sought to study the ERN using ECoG while subjects completed a continuous performance monitoring task using the popular game Flappy Bird, in which subjects adjust the vertical position of a bird to navigate it through a series of pipes to avoid crashing. Using this paradigm in 4 patients, we demonstrate that the ERN can be observed during continuous performance monitoring of errors in a more natural context, localized to the anterior insula and the anterior cingulate cortex, replicating and extending the results of earlier intracranial studies. Additionally, the design of our current study allows continuous monitoring of participants' ERN responses by examining high-gamma activity (indicative of population spiking rates) as the bird moves closer or further from the pipes, reflecting graded changes in the potential for error through changes in crash probabilities. By tracking neural activity during this task, we will identify whether the ERN monitors errors in a continuous manner, reflecting the probability of an error at any given time point, or in a more discrete manner, only when a crash occurs.

Title: Surprise modulates orienting-related but not strategic post-error processing

Authors: *Y. GUAN, J. R. WESSEL;
Dept. of Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: Error processing may involve both non-specific, orienting-related processes, as well as error-specific, strategic processes (Wessel, 2018). Recent behavioral findings indicate that motor slowing after errors may be associated with the surprise of the error. For example, Parmentier et al. (2018) found an interaction between surprise processing and post-error slowing in a speeded auditory-visual reaction time task in which (in)correct responses were followed by (un)expected sounds, suggesting surprise as a common underlying mechanism. Here, we test whether surprise differentially affects processes *immediately after error commission* (*N* = 36; *M*

= 19.41 years; 15 males), which should be orienting-related and/or *immediately prior to the execution of the subsequent response* (*N* = 36; *M* = 19.77 years; 11 males), which should be strategic. Using an adapted version of Parmentier et al.'s oddball paradigm, we found the same interaction as Parmentier et al.'s study between the type of trial (post-correct vs. post-error) and the type of tone (standard vs. surprise) when a surprising sound was presented 100ms after the response, but *not* when the sound was presented 100ms following the next stimulus after an error. Since past EEG studies have shown that fronto-central EEG activity during both time periods predicts post-error slowing, we then conducted an EEG study to explore whether error-related signatures are differentially modulated by surprise at the two different time points. Preliminary analyses of a sample of *N* = 10 using time-frequency decomposition showed increased power in fronto-central theta band (4-8 Hz) within 200ms *immediately after the error commission* when a surprise tone was present (Fig. 1), but *not* when the surprising tone was present *immediately prior to the execution of the subsequent response*. These results provide empirical support for theories purporting that error processing entails both orienting and strategic processes, which are differentially related to the neural processing of surprise.

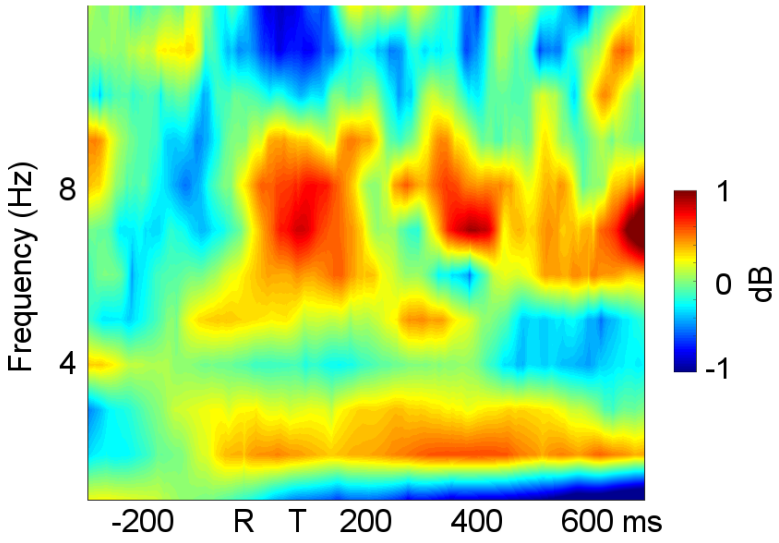

Fig. 1 Grand mean (N = 10) time-frequency plane showing power values at fronto-central sensors relative to a pre-response baseline in the setting where tone presented 100ms post-response onset. Power values were obtained via subtracting power in correct trials from error trials in the suprise tone condtion and the standard tone condition respectively and then subtract the latter from the former. Note the increased power at the theta band (4-8 Hz), which suggests surprise modulates orienting-related post-error processing.

[1]Kinesiology, Univ. of Waterloo, Waterloo, ON, Canada; [2]Kinesiology, Univ. Waterloo, Waterloo, ON, Canada

Abstract: Chronic aerobic exercise may facilitate plasticity in frontal brain regions associated with executive functions. Evidence suggests that more active individuals generally perform better on tasks of inhibitory control; perhaps due to enhanced top-down cognitive control and conflict monitoring occurring pre and post-error. In the present research, we therefore aimed to determine whether chronic aerobic exercise improves the efficacy of top-down cognitive control in response to differing levels of conflict. We hypothesized that enhanced cognitive control and pre-response conflict detection; reflected by a larger N2 ERP component would result in less post-error conflict; reflected by a smaller error-related negativity (ERN) amplitude. Furthermore, more active individuals were expected to respond more accurately and more quickly than non-active controls. 20 participants aged 18-25 were divided into the chronic aerobic exercise (CAE) group or the non-active group based on their responses to the International Physical Activity Questionnaire (2002). To be eligible for the CAE group, participants must be classified as high (>3000 METs); the non-active group was classified as low (<600 METs). Participants then performed a modified arrow-based Flanker task in which conflict was modulated by the distance of the distractors from the target (close or far) and congruency of arrows (incongruent or congruent). EEG was collected while participants performed 800 trials over 4 blocks; 80% of trials were congruent and 20% were incongruent, 50% were close and 50% were far. The ERN and error positivity (Pe) were extracted by subtracting response locked correct from error trials. The N2 was extracted by subtracting stimulus locked congruent from incongruent trials. There was no significant difference between the CAE group and the non-active group in terms of error frequency, reaction time or ERN amplitude. Mixed model ANOVAs with groups (between) and conflict level (within) as factors were used for analysis of ERP components (ERN, Pe, N2). The CAE group showed a significantly larger Pe amplitude ($F_{1,16}$=6.57, p=0.021) compared to the non-active group. Furthermore, close trials (more conflict) elicited a significantly larger N2 amplitude than far trials in the CAE group, but not the non-active group ($F_{1,16}$=9.67, p=0.007). These findings suggest that CAE confers some cognitive benefit regarding the endogenous

processing involved in pre-response conflict detection and the post-error response. These benefits may include enhanced adaptability in the allocation of cortical resources depending on task demands and more efficient evaluation of performance post-error.

Title: Task invariant and task dependent neural processes of conflict resolution during cognitive control

Authors: *Y. XIAO[1], H.-Y. YU[3,4], C.-C. CHOU[3], Y.-C. SHIH[3,4], J. MADSEN[5], D. WEISHOLTZ[6], I. M. REUCROFT[7], N. E. CRONE[8], W. ANDERSON[9], G. Abstract: Cognitive control involves simultaneously and flexibly combining multiple sensory inputs with task-dependent goals for decision making. Several tasks have been proposed to examine the mechanisms underlying cognitive control including the Stroop task, the Eriksen flanker task, the multi-source interference task, among many others. Because these tasks have been studied independently, it remains unclear whether any of the neural signatures that correlate with cognitive control reported to date reflect true control mechanisms or whether they are linked to specific sensory or behavioral peculiarities of each task. To address this question, here we directly compared the three tasks against each other in a single session, thereby allowing us to disentangle which neural mechanisms are specific to a given task and which mechanisms reflect task-independent control signals. We examined intracranial field potential recordings from 1196 electrodes in 10 subjects with pharmacologically intractable epilepsy. The behavioral results demonstrated that reaction time for the incongruent condition was significantly longer than that for congruent condition in all three tasks. Consistent with previous work (Tang et al, eLife 2016), we found conflict-selective electrodes that showed distinct gamma activity patterns for congruent

versus incongruent conditions. Interestingly, some electrodes showed task dependent correlates of conflict (i.e. differences between congruent and incongruent trials for some but not all tasks), whereas other electrodes showed task invariant correlates of conflict. These results provide initial steps to dissociate invariant cognitive control mechanisms from task specific sensory and decision processes.

Title: A novel training method of frontal lobe functions - An application of Wisconsin card sorting test and effects on colour stroop task

Authors: *M. SUGANAMI[1], S. ABE[1], K. KOBAYASHI[1], K. IMAMURA[1], M. KOMATSU[2]; [1]Wako Rehabil. Hosp., Saitama, Japan; [2]RIKEN Ctr. For Brain Sci., Saitama, Japan

Abstract: The functions of prefrontal area are often measured by Wisconsin Card Sorting Test (WCST), and the patient with prefrontal area damage usually fails WCST. WCST requires two functions: 1) set shifting among different rules and 2) guessing a hidden rule with partial information. To improve these functions, we have developed the Training of Set Shift (TSS) as an application of WCST. This training is applied as a part of cognitive rehabilitation by a speech therapist (ST), in conjunction with other training methods and with physio therapy and occupational therapy. We have experienced three cases with the prefrontal area lesion with variety of causes, with whom it was possible to conduct TSS. All of them exhibited improvements in the prefrontal area functions. TSS is divided into four parts: 1) pairing, 2) categorising, 3) conjecting and correction (CC), and 4) conjecting and identification (CI). These have different level of cognitive demand and the paring task is the least challenging whereas the CI task is the most demanding. With TSS, just like WCST, subjects are asked to sort a sequence of cards into four piles either in accordance with colour, form, or number, whereas sorting rules are pre-determined by ST. In the pairing task and the categorising task, sorting rules are explicitly shown. Subjects were asked to shift among the different sorting rules passively in the paring task, and actively in the categorising task. With the CC task and the CI task, pre-determined sorting rules are not shown. In these tasks, subjects are asked to guess which sorting rules are used from the feed backs they are given by ST. Cognitive rehabilitation sessions are started from the pairing task and gradually progressed to more demanding tasks. When we

conducted TSS, we administered a colour Stroop task, which is used to assess the prefrontal area function, before and after the TSS. With all three cases, in the first three days, the total reaction time of the colour Stroop task was significantly shortened after TSS ($P<0.05$). Then after several months of training, all three of them exhibited improvement in the Behavioural Assessment of the Dysexecutive Syndrome. One of them was even able to pass the WCST S-F version. These results suggest that, in a convalescent period of prefrontal area damage, TSS might be one of the effective trainings as a part of cognitive rehabilitation.

Title: Using independent components analysis to better understand the electrophysiology of error processing

Authors: S. M. WESTERLAND, M. M. LORTIE, S. J. BECKER, S. D. DORTCH, ***D. S. LELAND**;
Psychology, Univ. of Wisconsin-Eau Claire, Eau Claire, WI

Abstract: In two studies of error processing, participants completed a flanker task during EEG recording to invoke response errors and corresponding event-related potential (ERP) components: the error-related negativity (ERN) and error positivity (Pe). The scalp distribution for activity from 125-325 ms suggests that the neural activity that appears as a canonical Pe at posterior electrode sites may also show up as a negative deflection at anterior sites. Other studies have found similar inversions, although usually not as large (e.g. Buzzell et al., 2017; Lo et al., 2015; Schoenberg et al., 2014; Matthewson et al., 2005; Themanson et al., 2006). The inversion could reflect a single dipole (or set of dipoles) whose projections to scalp electrodes yield an anterior negativity together with a posterior positivity (shared dipole hypothesis). Alternatively, the canonical and inverted deflections could have distinct neural generators (distinct dipoles hypothesis). To address this question we have been using independent components analysis (ICA), a mathematical means of separating EEG signals into spatiotemporal components. Finding a common set of ICA components corresponding to both deflections would support the shared dipole hypothesis, while separate sets of ICA components for each deflection would support the distinct dipoles hypothesis. Preliminary findings with a single subject reveal two ICA

components with spatial distributions and peak timings consistent with the Pe. Each of these ICA components includes both anterior and posterior activations, with opposite polarity, in line with the shared dipoles hypothesis. Evidence thus far suggests that the anterior negativity in the Pe time window may be a reflection of the same neural event as the canonical Pe and that it may be a viable added measure for the electrophysiology of error processing.

Title: Effect of exogenous melatonin on cognitive functions

Authors: *J. SANCHEZ-BETANCOURT[1], M. AVILA-COSTA[2], C. HERRERA-VERDUGO[3], M. HUERTA-JAUREGUI[3], R. MUÑOZ-JIMENEZ[3], F. CARRILLO-GARCIA[3], M. OLMEDO-LICEA[3], A. MEZA-AMAYA[3];

Abstract: The use of exogenous melatonin has generally been found to successfully treat sleep disturbances. In recent years it has regained interest due to its favorable effects on learning and memory. In this sense, the benefits of melatonin on other types of processes such as abstract thinking have not been explored. The objective of the present investigation was to determine the effect of melatonin consumption during 2 months on these processes in young adults with an average age of 23.5 years. The sample consisted of 30 participants who were divided into a control group and an experimental group. The experimental group consumed 10 mg of melatonin daily for 2 months. Every three weeks, both groups were evaluated with computerized Wisconsin card tests. The results showed that melatonin had a significant improvement over abstract thinking but not about response times.

Abstract: In the aftermath of a terrorist attack, some people move forward while others remain deeply traumatized, continuously reliving a haunting and intrusive past that they cannot get rid of. Such intrusive memories are widely acknowledged as central to the expression and maintenance of PTSD. Here, we examine using fMRI whether the preservation of the neural functions supporting the ability to voluntarily control and suppress memory retrieval contribute to positive adaptation in the aftermath of Paris November 13 terrorist attack.

fMRI activity was recorded while 55 trauma-exposed participants with PTSD (PTSD; 26 males; 36.5y ± 8.4), 47 trauma-exposed participants without PTSD (non-PTSD; 30 males; 36.5y ± 7.1) and 73 non-exposed healthy participants (35 males; 33.5y ± 11.5) attempt to suppress unwanted memories of previously learnt word-object pairs. Participants self-reported the presence or absence of memory intrusion at the end of each trial, allowing to isolate the conditions that triggered inhibitory control. Functional connectivity between the right anterior medial frontal gyrus, a core node of the inhibitory control system, and memory target ROIs, was investigated using context-dependent psychophysiological interactions. The statistical results were corrected for multiple comparisons using the False Discovery Rate ($P_{\text{-FDR}} < .05$).

Attempt to prevent the unwanted emergence of intrusive memory into consciousness (compared to non-intrusive reminders) was associated with a significant increase in down-regulation for non-PTSD compared to PTSD group in the right rostral hippocampus ($t(100) = -1.9$), and the bilateral parahippocampal cortex ($t(100) < -2.2$), fusiform gyrus ($t(100) < -2.3$) and precuneus ($t(100) < -2.69$). A mixed pattern of findings was observed for the non-exposed group, showing intermediate effects between non-PTSD and PTSD groups. Finally, regression models showed that participants without PTSD who were more effective at downregulating the right rostral hippocampus and right precuneus in response to intrusions had lower intensity of reexperiencing symptoms at the clinical level (Beta = 0.30, [.13 .56] and 0.41, [.11 .82], respectively; bootstrapped 98.6% CI corrected for multiple comparisons).

Our findings highlight the presence of a central dysfunction in the ability to control and regulate unwanted intrusive memory in PTSD. The preservation of inhibitory control capacity to countermand the recollection in the hippocampus of unbidden intrusive memory contributes to a positive adaptation in the aftermath of traumatic experiences and to a good mental health outcome.

Title: Frontostriatal interactions during cognitive control

Authors: *D. A. VOGELSANG[1], J. RIDDLE[2], M. DESPOSITO[3];
[1]D'Esposito Lab., Berkeley, CA; [2]Psychiatry, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [3]Helen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA

Abstract: The prefrontal cortex is necessary for cognitive control. Specifically, it has been proposed that higher level abstract information is processed in rostrolateral frontal regions whereas more concrete lower level information is processed in caudolateral frontal regions. Recent research has suggested that a rostral-caudal gradient for abstraction may also exist in the striatum, in which the striatum gates relevant contexts into the frontal cortex. Here, we tested whether we could obtain evidence for rostral-caudal fronto-striatal interactions in a task that varied in dimensions of cognitive control. Twenty participants were scanned during functional magnetic resonance imaging (fMRI) while performing a cognitive control task that varied in two dimensions: the level of abstraction and the number of rules that had to be maintained. We found increased activation in a rostral frontal region (left middle frontal gyrus; BA 45) with increased abstraction of the task, replicating earlier findings. Additionally, when the number of rules was increased, we observed increased activation in the inferior frontal sulcus (BA 44) and the dorsal premotor cortex (BA 6). To assess fronto-striatal connectivity during cognitive control demands, we performed an analysis of generalized psychophysiological interaction (gPPI) for the cognitive control dimensions of our task. Our analysis revealed that the inferior frontal sulcus was coupled with the middle portion (body) of the striatum when the number of rules were increased; and middle frontal gyrus was coupled with the head of the caudate, but not the tail, as the abstraction of the task increased. These results demonstrate that frontal-striatal interactions are organized along a rostral-caudal axis of cognitive control.

Title: Neural dynamics across human prefrontal cortex supporting different levels of abstraction

Authors: *D. M. CLEVELAND[1], J. M. PHILLIPS[1], S. CHEN[2], L. WANG[3], Y. B. SAALMANN[4];
[1]Psychology, Univ. of Wisconsin-Madison, Madison, WI; [2]Chinese Acad. of Sci., Beijing, China; [3]Inst. of Psychology, Chinese Acad. of Sci., Beijing, China; [4]Univ. of Wisconsin - Madison, Madison, WI

Abstract: Task abstraction refers to the hierarchical nesting of processes, from those relating to abstract goals through to specific actions. Abstraction can take a number of forms, such as temporal, relational, or rule abstraction. Neural underpinnings of task abstraction critically involve the lateral prefrontal cortex (PFC), where abstract information is thought to be represented in anterior areas and concrete information in posterior areas, forming a rostral-caudal hierarchy. However, different views have emerged over the apex of this hierarchy, with original accounts placing the frontal pole at the apex and more recent accounts placing the mid-dorsolateral PFC at the apex. Because recent work in macaques suggests that beta rhythms (13-30Hz) and gamma rhythms (>30Hz) respectively support abstract and concrete rule processing, such neural signatures for rule abstraction may better characterize the rostro-caudal hierarchy. We analyzed electrocorticography recordings from epilepsy patients performing a rule abstraction task with a hierarchical structure. Patients needed to integrate abstract rules (specifying the relevant dimension of forthcoming cues and its associated concrete rule set) and concrete rules (mapping features to actions), to respond correctly. Depth electrodes were located across the rostro-caudal axis of the PFC, with regional designation based on the Automated Anatomical Labeling Atlas. After artifact and epileptiform activity removal, we re-referenced data using a bipolar derivation from sequential channels, and applied the Hilbert transform to the bandpass filtered data to calculate power spectra. Preliminary results suggest complex oscillatory patterns emerge across the PFC during rule processing. Orbitofrontal frontal cortex, and rostral PFC more generally, showed beta and lower frequency activity after the onset of the abstract rule cue, which persisted until the behavioral response was executed. Similarly, superior frontal cortex showed strong beta activity after the abstract cue onset. In comparison, the middle frontal gyrus showed greater gamma activity, especially in response to the concrete rule cue. Inferior frontal cortex similarly showed increased gamma activity. Selectivity for particular abstract or

concrete rules was evident in high gamma activity across much of lateral PFC. Our data suggest a link between rule processing and beta activity in rostral and superior PFC and gamma activity in caudal and inferior PFC. This is consistent with a rough topography of rule representations across the entire lateral PFC, and distinct roles for beta and gamma activity in rule abstraction.

Title: Accelerometer-measured physical activity is positively related to functional connectivity of the dorsal attention network in young adults

Authors: *D. M. PINDUS[1], C. E. ZWILLING[2], J. S. JARRETT[2], T. TALUKDAR[3], H. S. SCHWARB[4], C. H. HILLMAN[6], N. J. COHEN[5], A. F. KRAMER[6], A. K. BARBEY[4]; [1]Dept. of Kinesiology and Community Hlth., [2]Beckman Inst. for Advanced Sci. and Technology,, Univ. of Illinois at Urbana-Champaign, Urbana, IL; [3]Beckman Inst. for Advanced Sci. and Technol., Univ. of Illinois at Urbana-Champaign, Champaign, IL; [4]Beckman Inst. for Advanced Sci. and Technol., [5]Dept. of Psychology, Univ. of Illinois at Urbana-Champaign, Urbana, IL; [6]Dept. of Psychology, Northeastern Univ., Boston, MA

Abstract: Physically active young adults efficiently modulate attentional control, showing task-related increase in the activation in frontal and parietal brain regions. In older adults, physical activity (PA) interventions can enhance resting state functional connectivity globally and in cognitively salient brain networks. Whether daily PA may benefit functional connectivity in resting state brain networks in young adults has not been explored. We evaluated the associations between accelerometer-measured PA and graph theory measures of global and local efficiency of 7 intrinsic functional connectivity networks (ICNs; default mode (DMN), frontal-parietal (FPN), dorsal attention (DAN), ventral attention, limbic (LN), somatomotor and visual). We hypothesized that higher levels of moderate-to-vigorous PA (MVPA; min/day) will be related to greater efficiency of information transfer locally in cognitively salient ICNs (DMN, FPN and DAN) and globally, between these and all other networks. We used baseline data from 201 subjects (M_{age}=24.5 ±5.6 yrs, 106 females) from the INSIGHT trial (NCT02780739). Following

preprocessing, the mean fMRI BOLD time series were extracted from subjects' grey matter voxels using the Craddock parcellated brain atlas as a mask. A subject-wise functional connectivity matrix reflecting pairwise Pearson correlations between the mean BOLD time series signals obtained from nodes defined by the Craddock's atlas was computed, Fisher's Z-transformed and standardized to Z-scores. Z-scores associated with significant positive correlations within each subject's whole brain functional connectivity matrix (Bonferroni corrected thresholds) were re-scaled to represent connection weights ranging from 0 to 1. Based on these weights, weighted connectivity matrices representing functional connectivity between nodes of 7 ICNs were computed and measures of global (an inverse of an average path length of neighboring nodes within the network) and local efficiency (average efficiency within the network) were derived. After accounting for age, sex, education and aerobic fitness, greater PA volume (accelerometer counts/day) and more daily MVPA were related to *greater* local efficiency in the DAN, while greater PA volume was related to *lower* local efficiency in the LN. Our results suggest that more physically active young adults show more efficient transfer of information within DAN at rest, which supports effortful control. Decreased local efficiency in the LN further suggests that PA may preferentially bias resting state functional connectivity in support of goal directed, compared to automatic and reward driven, cognitive processing.

Abstract: Mental fatigue after mild traumatic brain injury (TBI-MF) and in patients with exhaustion disorder (ED) is characterized by pronounced decline in cognitive performance after moderate cognitive activity. In this study, we investigated brain activity in the frontal cortex during prolonged mental activity in TBI-MF patients (n=20), ED patients (n=20) and controls (n=20). We chose a test-retest design of six neuropsychological tests in conjunction with fNIRS to study brain activation changes in the frontal cortex during prolonged cognitive activity. The TBI-MF group performed comparatively worse than the controls during the Stroop-Simon test and did not improve as much as the controls on Digit Symbol Coding (DSC). ED patients felt subjectively more fatigued during the procedure and performed worse in the mental control task PASMO compared to controls. For fNIRS imaging, a Stroop-Simon test showed no change over time, but the controls had more activity in larger parts of the frontal cortex compared to TBI-MF and ED patients. For the Symbol Search and DSC, the TBI-MF group had more frontal brain activation than controls. ED patients activated the PFC more in the sustained attention task OPATUS-CPTA. In the Symbol Search the ED patients had higher activity in left PFC and in the Digit Symbol Coding more activation in the right frontal cortex. As the TBI-MF subjects were studied more than 5 months after injury and ED subjects were diagnosed more than 3 years earlier, our data indicate that the problems persist longer after initial diagnosis than previously known.

Title: Prospective and retrospective metacognitive judgments: Neural evidence that when a judgment is made determines the type of information used

Authors: *T. KELLEY[1], M. J. SERRA[1], B. D. ENGLAND[2], T. DAVIS[1];
[1]Texas Tech. Univ., Lubbock, TX; [2]Missouri Western State Univ., Saint Joseph, MO

Abstract: How do you think you will perform on the test tomorrow? How did you perform on the test yesterday? The information that we use to make metacognitive judgments can vary depending on subtle differences in perspective. If asked to judge future performance, we may attempt to retrieve information we know will be on the test or attempt to practice some of the material. If asked to judge past performance, we may use our sense of fluency for the test questions or our subjective sense of how easy the test was. The current study used neuroimaging to test how the brain supports prospective and retrospective metacognitive judgments.

Participants completed a probabilistic category learning task in which they learned to classify Gabor patches into two categories based on their spatial frequency. In between learning runs, they made prospective and retrospective judgments of whether they would classify specific Gabor patches correctly. In the prospective trials, they would see a Gabor patch, rate their likelihood of correctly categorizing it, and then categorize the stimulus. In the retrospective trials they would categorize the stimulus and then rate it. During prospective judgments, activation in the hippocampus and right rostrotrolateral PFC (rlPFC) tracked the objective uncertainty in the task. This result indicates that prospective judgments more attuned to the actual uncertainty associated with each Gabor patch. During retrospective judgments, the ventral striatum and right rlPFC were active and tracked participants' subjective confidence ratings. TThese results suggest that both types of judgment rely (at least partly) on similar metacognitive processes, but may use different sources of information to inform that process. Prospective judgments may rely on information from more intrinsic factors such as the objective uncertainty of the Gabor patches while retrospective judgments may rely on more internal, subjective cues.

Title: A two component model of human intelligence within the lateral frontal cortex

Authors: *W. R. TRENDER[1], R. BRAGA[2], A. HAMPSHIRE[1];
[1]Imperial Col. London, London, United Kingdom; [2]Stanford, Palo Alto, CA

Abstract: Human intelligence has been the topic of intense research since the late 1800s. One of the ways in which this research has manifested itself is in the investigation into variability between individuals' abilities to perform cognitive tasks. This is important because this variability may provide insight into the mechanisms by which our brains perform higher cognitive functions. Furthermore, although we are likely far from the truth, in the future this insight could provide a framework with which we can better understand intellectual disability and improve overall cognitive function.
In the present study we have investigated concepts of intelligence in the context of functional connectivity (FC) within the lateral frontal cortex (LFC). The LFC is known to be important in many aspects of cognition such as working memory, attention and response inhibition. However, we do not know how changes in activation and FC within the LFC relate to differences in cognitive ability.
To attempt to answer some of these questions we have used functional magnetic resonance

imaging (fMRI) and cognitive task data from 402 subjects in the Human Connectome Project (HCP). Correlations between different LFC regions time courses (TCs) were used as response variables to predict variability within the behavioural task data. A separate, seed based, whole brain analysis was performed using correlations between and within functional connectivity maps for each LFC region as response variables in a partial least squares (PLS) model to predict variation in the behavioural task data.
We found that, using the local LFC connections, the individual differences in cognitive ability could be represented by two components which explained 2.45% and 2.7% of the variability in the data respectively. No significant components were extracted from the whole brain within network coherence analysis. One significant component was extracted from the whole brain between network coupling analysis, explaining 1.21% of the variance in the behavioral data. These results provide evidence for a model of intelligence that contains distinct functional networks that work together to produce behavioural outcomes.

Title: Single neurons in human medial frontal cortex signal conflict post-action

Authors: *Z. FU[1], C. M. REED[2], J. M. CHUNG[2], A. N. MAMELAK[3], R. ADOLPHS[1], U. RUTISHAUSER[4];
[1]Caltech, Pasadena, CA; [2]Neurol., [3]Neurosurg., Cedars Sinai Med. Ctr., Los Angeles, CA; [4]Dept. of Neurosurg., Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: Goal-directed behaviors require monitoring of on-going actions and evaluating action outcomes. The medial frontal cortex (MFC) is crucially involved such evaluative processes and plays a pivotal role in learning the target and amount of cognitive control to be exerted based on monitored outcomes. A prominent example is conflict monitoring, in which case the MFC is thought to monitor conflict between co-activated neural representations of competing actions or goals. Such monitoring signal is assumed to have an early onset before an eventual action is committed, since competition of representations should ensue as soon as processing of goal-relevant stimulus information starts. However, given the prominence of evaluative signals in the MFC, it is likely that conflict levels can also be represented after an action has been completed.

The temporal smoothing of BOLD signal obfuscates the exact timing of conflict monitoring and dissociation of pre- and post-action thus requires techniques with high spatial and temporal resolution. We report single neurons in human dorsal anterior cingulate cortex (dACC) and pre-supplementary motor area (pre-SMA) that signal conflicts after action execution. We recorded single neuron activity from epilepsy surgical candidates. We investigate such post-action conflict signals with two tasks: the color-word Stroop task and the Multi-source Interference Task (MSIT). Since a subset of patients performed both tasks in the same session, a direct comparison of single-neuron activity in both tasks is thus possible. We confirmed the existence of conflict signals triggered by stimulus onset in both tasks as previously reported. In addition, we found a significant proportion of MFC neurons that signaled conflict immediately before action onset. However, the post-action conflict neurons constitute a different class of neurons than these two types of conflict neurons with pre-action activation. The post-action conflict signal could not be explained simply by continuation of stimulus-onset-triggered or pre-action conflict. Importantly, despite their similar timings and overall dynamics, post-action conflict signals in Stroop and MSIT are carried by two separate populations of neurons, which highlights the disparate nature of these signals. In addition, we also found correlation between the spike rates of these neurons and behavioral measures in the tasks. The post-action conflict signals could represent a metacognitive mechanism that evaluates difficulty encountered during action performance and enables learning and optimization of such actions.

Title: Stroop interference and 5HTTLPR polymorphism between heavy smokers

Authors: *H. AGUILAR-ZAVALA, J. NEGRETE-DIAZ, D. VARGAS-QUINTANA, F. SOTO;
Enfermería Clínica, Univ. De Guanajuato, Guanajuato, Mexico

Abstract: Introduction: Seven millions of people in the world dead to cause of smoker's habits. Smokers dead earlier, although world effort to limit the tobacco's use, the nicotine dependence is stronger. The genetic factors can explicate about dependence mechanism. The 5HTTLPR polymorphisms give risk to drugs use and abuse, in addition was related with cognitive disturbance, but there are few studies about link between 5HTTLPR polymorphism and smoker's habits. Objective: The main of this study was to compare the polymorphisms 5HTTLPR,

psychologic factors and attention skills between heavy smokers and no smokers. Methods: 55 subject adults were included, 28 heavy smokers and 27 no smokers. General data, family income and perceived stress were asked and the attentional skills from Stroop Colors Word test was evaluated. Blood sample was collected (10 ml) for DNA extraction and genotype classification of 5HTT gen polymorphisms. The subjects were grouping by allelic variants "S" (44pb deletion) (59 subjects) and "L" (528pb) (51 subjects). Results: Subjects with S allele show higher scores in attention ($\tilde{X}$=6.11) than subjects with L allele ($\tilde{X}$=6.11) (Z=0.012,p<0.02); In addition, 48% of smokers with S allele show lower age of initiation to tobacco habit (Z=-2.26,p<0.03). Furthermore, this results only keep similar in women with S allele. Conclusion: Subjects with S allele are better in resistance of interference Stroop, but begin to smoke early than others with allele L. The S allele only has effect in women.

Title: Inter personal functional connectivity in low beta band is associated with emotional convergence during watching movie

Authors: *H. KIM[1], P. SEO[1], S. HER[1], S. CHOI[1], J. CHOI[2], K.-H. KIM[1];
[1]Biomed. Engin., Yonsei Univ., Wonju, Korea, Republic of; [2]Neurosurg., UCLA, Los Angeles, CA

Abstract: Introduction: Recent studies demonstrated that physiological responses of interacting individuals become synchronized. However, it is unknown how the neural activities of individuals are synchronized and whether this inter-personal neural synchrony occurs from task similarity or emotional convergence. Here we tried to investigate the relationship between inter-personal neural synchrony and emotional convergence level during watching affective movies individually or simultaneously.

Methods: Fifteen subjects (22.8±1.66 years old, 10 males) watched affective movie clips individually in the first experiment, and sixteen pairs of healthy subjects with same sex (22.5±1.65 years old, 8 male pairs) watched the movie clips simultaneously in the second experiment. 62-channel EEGs were recorded. Immediately after watching each video clip, the subjects reported their emotional responses as valence levels in 9-point Likert scale. Emotional convergence scores were calculated as the inverse of absolute value of the difference between the self-ratings of the two subjects in a pair. Source current densities were estimated on cortical surface using weighted minimum norm estimation from surface EEGs. Inter-personal functional connectivity was quantified by the phase-locking values (PLVs). The association between PLV and emotional convergence score was investigated by Spearman correlation for the 16 pairs. The distribution of correlation from randomly-shuffled pairs was generated from 1,000 surrogate data in order to verify the significance of the association between PLV and emotional convergence.
Results: The Spearman correlation was significantly higher than zero for alpha- and beta-bands. This implies that the interpersonal functional connectivity is significantly correlated with emotional convergence, even when the two subjects did not watch the movie simultaneously. Comparing the first and second experiments, however, the second experiment, i.e. simultaneous watching, resulted in significantly higher correlation. The association between PLV and emotional convergence was concentrated in frontal, left temporal, paracentral, and occipital areas, in low beta-band.
Discussion: The results showed that shared emotional experience during simultaneous watching condition enhances the functional connectivity of cortical activities of two persons in low-beta band, probably due to the activity of mirror neuron system.

Title: Changes in event-related potential due to vigilance reduction by long-term driving

Authors: *P. SEO[1], H. KIM[1], S. HER[1], S. CHOI[1], J. CHOI[2], K.-H. KIM[1];
[1]Yonsei Univ., Wonju, Korea, Republic of; [2]Neurosurg., UCLA, Los Angeles, CA

Abstract: Our purpose was to investigate the changes in event-related potentials (ERPs) due to the vigilance reduction during long-term driving. Twenty undergraduate and graduate students participated in the experiment (18 males, 2 females, age: 23.9±1.4 years, average driving experience: 5.1±1.4 years). The participants took enough sleep (> 8 hours) in the night before the experiment, and did not take caffeine, nicotine, or other drugs on the day of the experiment. Experiments were conducted at 7:00 pm, after normal daytime activities of typical undergraduate students.
The participants were instructed to keep lane during driving on the straight road with two lanes. Two kinds of unexpected situation occurred randomly every 30±0.0764 seconds: sudden stopping of preceding vehicle, and sudden secession from the lane. 64 channel EEG were recorded along with steering wheel angle, acceleration/brake pedal operation, and driver's vehicle position in the lane.
The EEG signals were segmented according to the onsets of the unexpected events and classified into high or low vigilance conditions according to the response time (RT) (high vigilance: short RT, low vigilance: long RT, compared to the average RT). The ERP waveforms were obtained by averaging single-trial EEG waveforms, and major ERP components were defined according to the polarity and latency of peaks in the waveforms. The amplitudes and latencies of each component were statistically compared between high and low vigilance conditions.
Two ERP components were identified characterizing significant differences between high and low vigilance. The first one was at 300 ms after the unexpected event onset, representing the perceptual performance reduction due to the fatigue of long-term driving. Despite the huge differences between the two types of unexpected events, the characteristics of neural activity changes according to the vigilance level were not essentially different. Another ERP component was identified, which showed amplitude reduction for lower vigilance condition during a broad interval from 400 to 700 ms in parietal-occipital area. This corresponds to P300, which is recognized to show amplitude decrease for inattentive state. It is expected that cumulative fatigue of long-term driving causes attentional dysfunction as well as impaired sensory perception.

Hosp. at Gangdong, Seoul, Korea, Republic of; [6]Dept. of Neurol., Ajou Univ. Sch. of Medicine, Ajou Univ. Med. Ctr., Suwon, Korea, Republic of

Abstract: Idiopathic REM sleep behavior disorder (IRBD) is a sleep disorder which is characterized by dream enactment behavior and the loss of muscle atonia during REM sleep, and known to be associated with high risk of developing neurodegenerative diseases. Many IRBD patients are suffering from cognitive impairments, particularly visual perception, visuospatial abilities, attention, and executive function. However, neurophysiological mechanism of these cognitive impairments has not yet been identified. We investigated the oscillatory cortical activities of IRBD patients during attentional task, and tried to identify the spatiotemporal characteristics of abnormality compared to normal controls using machine learning. 15 IRBD patients and 17 healthy control subjects performed attentional network test while 60 channel EEGs were recorded. The subjects were requested to respond as quickly as possible to press a direction key corresponding to the middle arrow direction of the target stimulus. Source current densities on the cortical surface were estimated using weighted minimum norm estimate method. We tried to investigate the differences in single-trial cortical activities between IRBD patients and normal controls using a pattern classifier based on deep neural network (DNN). In addition, the critical information for the pattern classification was obtained by applying layer-wise relevance propagation (LRP) method to the trained DNN. The DNN consisted of four fully-connected layers of the units with rectified linear activation function. The time-series of single-trial event-related current densities at 100 cortical vertices formed the input to the DNN. The relevance score, i.e. the contribution of each input unit to the classifier's decision, was obtained by LRP method, which yielded the information on the time and location showing major difference between IRBD and control. The classification accuracy was as high as 73.8±1.3% (sensitivity: 70.4±2.9%, specificity: 76.8±2.7%). The activities of visual areas within 150-250 ms epoch were found to be the most critical for the classification of the two groups. This is in accordance with our previous ERP studies using Posner cueing task. Another important feature was the right frontal activity within 250-300 ms, which is judged to represent visuoperceptual dysfunction IRBD patients, due to top-down processing of frontal area. This is in line with previous studies which showed cortical thickness reduction in frontal area and lingual/fusiform gyri in IRBD.

Title: Higher flexibility in functional connectivity dynamics is associated with higher creativity and lower inhibition

Authors: ***H. XIE**[1], S. JAHANIKIA[1], C. GENIESSE[1], R. BEATY[2], N. SONALKAR[1], M. SAGGAR[1];
[1]Stanford Univ., Palo Alto, CA; [2]Pennsylvania State Univ., University Park, PA

Abstract: Creative thinking is crucial to scientific and technological innovation. While many studies approach creativity as either a divergent or convergent construct, we adopted a novel paradigm - creative foraging task (CFT; Hart et al., 2017) - to study the neurobehavioral relation between creativity and exploration/exploitation. Functional MRI data (N=29) were acquired while the participants were engaged in the CFT, where participants reorganized ten connected squares into unique and interesting solutions (Fig. 1). After preprocessing (fMRIprep v1.2.8), dynamic functional connectivity (FC) was estimated and the multi-slice community detection was used to quantify flexibility in FC. High FC flexibility implies higher rate of brain regions switching community memberships and has been linked with memory performance and learning. Here, we tested whether FC flexibility during CFT is related with creativity (using Alternate Uses Task and CFT performance) and executive functioning. Although no significant relation was observed between CFT performance (e.g., number of shapes created) and FC flexibility, a significant positive relation between FC flexibility during CFT and AUT fluency was observed (rho = 0.47, p = 0.025). Further, a negative relation between FC flexibility during CFT and cognitive inhibition (rho = -0.44, p = 0.035) was observed. In sum, our preliminary results suggest higher variation in brain dynamics is associated with higher creativity and lower inhibition.

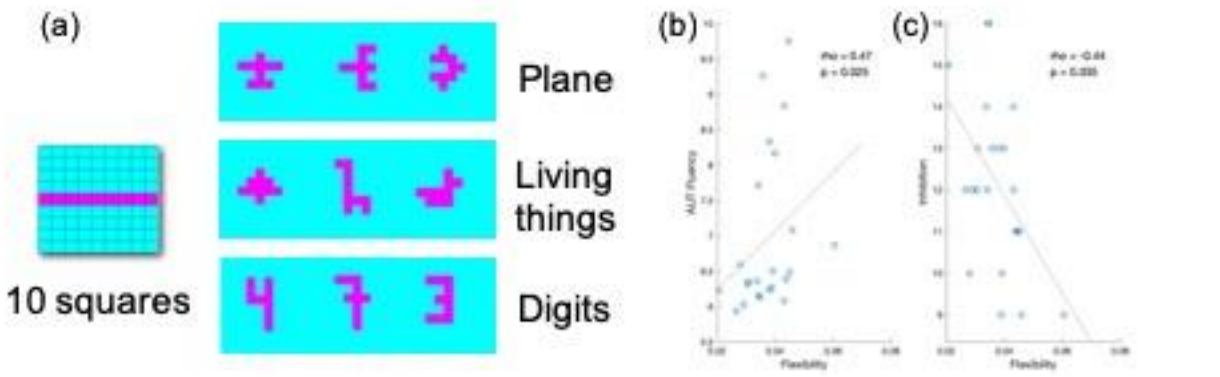

Figure1: (a) Creative foraging task. Subjects used a mouse to reorganize ten squares within a ten by ten space, with the only rule being all squares must be connected (diagonal connection not allowed). A total number of 36,446 unique solutions exists and our participants created 2,149 unique shapes during the 10 minutes' task. (b) AUT fluency vs FC flexibility. (c) Cognitive inhibition vs FC flexibility.

Title: In search of the extinction network: A multi-center study

Authors: *C. GOMES[1], F. LABRENZ[2], H. QUICK[2], D. TIMMANN-BRAUN[2], N. AXMACHER[1];
[1]Ruhr Univ. Bochum, Bochum, Germany; [2]Univ. of Duisburg-Essen, Essen, Germany

Abstract: Extinction learning is defined as the gradual decrease in the conditioned response with continuous presentation of the conditioned stimulus in the absence of the aversive stimulus. Converging behavioural and physiological evidence indicate that extinction is a new type of learning. However, the neural mechanism subserving this new learning process is far from understood. Indeed, although a few studies suggest that the extinction of learned fear responses involve changes in brain connectivity within an extended neural network, the exact brain structures that define this network remain largely elusive. In this ongoing project, we have

collected over two-hundred resting-state fMRI and diffusion weighted data shortly before participants engaged in various extinction learning paradigms. Our initial aim is to find structural and functional connectivity patterns that relate to the extinction learning network. Second, we intend to test whether structural and functional connectivity patterns predict inter-individual variations in the extinction efficacy. Finally, we also compare different preprocessing pipelines, both in-house as well as existing automatic implementations. Preliminary findings reveal correlations among several regions, including the hippocampus, amygdala, ventro-medial prefrontal cortex, anterior cingulate gyrus and cerebellum. These regions have been previously associated with the extinction learning network. Current work is in place to measure other types of connectivity, in particular Granger causality and spectral dynamic causal modelling, which will provide information about causal links within this network. Furthermore, we also aim to model behavioural and electrodermal activity responses during extinction learning, which will be used as indicators of learning efficacy.

Title: Episodic past, future, and counterfactual thinking in relapsing-remitting multiple sclerosis patients

Authors: *F. DE BRIGARD[1], O. AYALA[2], D. BANTA[1], L. DUARTE[2], A. LOZANO[2], J. GARCIA[3], P. MONTAÑÉS[2], S. W. DAVIS[4];
[1]Duke Univ., Durham, NC; [2]Univ. Nacional de Colombia, Bogota, Colombia; [3]Clinica Marly, Bogota, Colombia; [4]Duke Univ. Med. Ctr., Durham, NC

Abstract: Multiple sclerosis (MS) is a progressive disease characterized by widespread white matter lesions in the brain and spinal cord. In addition to well-characterized motor deficits, MS results in cognitive impairments in several domains, including attention, working memory, executive functions and, critically, episodic memory. Recent studies have also revealed that patients with MS exhibit deficits in episodic future thinking, i.e., our capacity to imagine possible events that may occur in our personal future. Both episodic memory and episodic future thinking have been shown to share cognitive and neural mechanisms with a related kind of hypothetical simulation known as *episodic counterfactual thinking*: our capacity to imagine alternative ways in which past personal events could have occurred but did not. However, the extent to which episodic counterfactual thinking is affected in MS is still unknown. The current

study sought to explore this issue by comparing performance in mental simulation tasks involving either past, future or counterfactual thoughts in 22 non-depressed relapsing-remitting MS patients and 22 matched controls. All participants underwent MRI structural imaging, and a thorough neuropsychological assessment prior to engaging in a mental simulation task. This task consisted in randomly generating episodic past, future and counterfactual thoughts in response to prompts. The contents of the mental simulations for all participants were assessed using an adapted version of the autobiographical interview. We found that, relative to controls, patients showed mark reductions in the number of internal details across all mental simulations. However, they show no differences in the number of external and semantic-based details, suggesting that the deficit is more specific to episodic than to semantic memory. Additionally, diffusion-weighted imaging tractography was used to estimate the integrity of several canonical fiber pathways. While we found that declines in fractional anisotropy in all white matter tracts—including primary motor (i.e., corticospinal tract) as well as retrieval-related pathways (i.e., uncinate fasciculus, corpus callosum)—correlated with deficits in tests of executive function, working, and episodic memory, tractography measures of streamline values for the superior longitudinal fasciculus correlated with more detailed counterfactual simulations in MS patients relative to controls. These findings further illuminate the brain basis of hypothetical simulation deficits in MS.

Title: Frontal asymmetry in ADHD and its modulation by TMS treatment

Authors: A. AVNIT, U. ALYAGON, *A. ZANGEN;
Life Sci., Ben-Gurion Univ. of the Negev, Beer-Sheva, Israel

Abstract: Abnormal functional brain asymmetry and interhemispheric coherence have been previously implicated in attention deficit hyperactivity disorder (ADHD). However, as current evidence for adult ADHD is scarce and inconclusive, it is not clear whether these neuromarkers proceed into adulthood. We investigated these abnormalities in adults ADHD by comparing a cohort of 99 ADHD and 78 non-clinical individuals. By combining TMS with EEG, we additionally examined right-frontal cortical excitability, indicated by TMS-evoked potential

(TEP), and interhemispheric connectivity, reversely indicated by right-to-left interhemispheric signal propagation (ISP). Moreover, we examined the relation between aberrant frontal asymmetry and a response inhibition deficiency in ADHD, measured as stop-signal reaction time and the N200 ERP components. The modulation of the above measures by a clinically effective multi-session TMS treatment was also examined. We found that, compared to controls, the ADHD group demonstrated elongated SSRT, reduced N200 right-frontal-asymmetry, weaker TEP, and stronger ISP. Moreover, in the ADHD group, N200 right-frontal-asymmetry positively correlated with SSRT and with TEP. Additionally, the effective TMS treatment decreased interhemispheric Alpha-power coherence, while its clinical effect was predicted by spontaneous low-frequency right-asymmetry measured at baseline. However, no differences between the ADHD and control groups in spontaneous resting-state asymmetry or in interhemispheric functional connectivity were observed. We conclude that: (1) In adult ADHD, frontal asymmetry abnormalities are apparent during response inhibition performance, but not for spontaneous brain oscillations; (2) Frontal interhemispheric connectivity abnormalities, previously observed in ADHD children, may normalize with age; (3) Abnormal frontal asymmetry is related to a key cognitive deficit in ADHD and to the clinical effect of TMS treatment, and may originate from reduced right-frontal excitability; (4) An effective TMS treatment might improve executive cognitive functioning, as indicated by decreasing interhemispheric Alpha coherence.

Title: Functional reorganization for executive functions in deaf individuals

Authors: *B. MANINI[1,3], V. VINOGRADOVA[1], B. WOLL[3], M. EIMER[4], D. CAMERON[2], J. SAADA[5], V. CARDIN[3,1];
[1]Sch. of Psychology, [2]Norwich Med. Sch., Univ. of East Anglia, Norwich, United Kingdom; [3]Deafness Cognition and Language Res. Ctr., Univ. Col. London, London, United Kingdom; [4]Birkbeck Univ. of London, London, United Kingdom; [5]Norwich and Norfolk Univ. Hosp., Norwich, United Kingdom

Abstract: Recent studies have described the functional reorganization of working memory networks in deaf individuals (Cardin et al., 2017; Ding et al., 2015). Specifically, the posterior superior temporal cortex, involved in auditory processing in hearing individuals, is recruited for Visual Working Memory (VWM) tasks in deaf participants. Furthermore, hearing and deaf participants show different functional connectivity profiles between temporal and frontoparietal regions. These results suggest that early auditory experience may impact the neural profile underlying cognitive processing. It is still unclear if this reorganization is ascribable to some specific aspects of VWM (namely, visual information storage) or if a broader functional reorganization occurs in the brain circuits involved in executive functions as a consequence of deafness. To address this, we studied brain regions involved in executive function in congenitally or early deaf and hearing individuals. We hypothesized reorganization of executive function networks as a consequence of early sensory loss.
Profoundly or severely deaf individuals and hearing control participants underwent MRI while performing tasks tapping into four executive functions: working memory, inhibition, task-switching, and planning. Images were realigned, co-registered, normalized, and smoothed (8 mm FWHM Gaussian kernel) following standard pre-processing procedures in SPM12.
Our results showed different functional profiles of activation between the groups. Specifically, there were differences in the extent of activation of temporal and frontoparietal regions between the two groups. These results suggest that neural plasticity and early auditory deprivation may reshape the cortical networks underlying higher-order cognitive functions.

Title: Hyperactivation of inferior frontal gyrus inhibits hyperactivity in ADHD: A quantitative EEG study

Authors: *T. BATABYAL[1], S. P. MUTHUKRISHNAN[1], C. LEON[1], R. SAGAR[2], P. TAYADE[1], R. SHARMA[1], S. KAUR[1];
[1]Physiol., [2]Psychiatry, All India Inst. of Med. Sciences, New Delhi, New Delhi, India

Abstract: Background:-Attention deficit hyperactivity disorder (ADHD) is the most common neurobehavioral disorder of childhood associated with impaired attention, excessive motor

activity and impulsivity.The neural signature of attentive mechanisms is largely dominated by alpha band oscillations and its inhibitory function has been recently suggested. Thus it is closely linked to two fundamental functions of attention (suppression and selection). Hence, we wanted to explore the pathophysiological relevance of cortical sources in the alpha band which are different between ADHD as compared to age-matched controls during resting state.
Methodology:- Resting state EEG data was acquired from 10 ADHD (mean age ± SD =11.1yrs ± 2.42, 9 males, 1 female) and age-matched controls (mean age ± SD =12 yrs ± 3.65, 8 males, 2 females) using 128 channel high density electrodes. Data was preprocessed in the frequency range of alpha (8 to 14 Hz) and source analysis was done using sLORETA algorithm. Statistical analysis of cortical source activity was performed using Statistical Non Parametric Mapping (SnPM) in sLORETA and cortical sources showing voxel activity above a statistically significant ($p<0.05$) with the critical threshold value of $t=3.772$ has been discussed.
Results:- Precentral gyri, superior frontal gyri, inferior frontal gyri and medial frontal gyri in frontal lobe and post central gyri in parietal lobe showed significantly higher activity in ADHD during resting. Maximum change was found to be localized at inferior frontal gyri in the frontal lobe (MNI coordinates 40,25,10; max $t = 4.656$, $p = 0.012$).
Discussion:- The motor cortical areas of pre-central and post-central gyri have shown higher activity in ADHD as compared to controls. This could be the neural basis for hyperactivity in ADHD. In order to overcome this behavioural symptom, inferior frontal gyrus has shown highest activity in ADHD which is known as a response inhibition centre. This could be one of the neural compensatory mechanism in ADHD wherein hyperactivity of inferior frontal gyrus in alpha frequency range causes inhibition of the motor cortical areas of pre-central and post-central gyri thereby suppressing hyperactive behaviour during resting state.

Title: Effects of repetitive head impacts on cognitive functions in collegiate contact sport athletes

Authors: *C. R. VUELVAS-OLMOS[1,2], N. Y. CORTÉS-ALVAREZ[1,3], P. J. FLORES-MORENO[1,2], A. VUELVAS-OLMOS[4], J. GUZMÁN-MUÑIZ[5,3], N. A. MOY-LÓPEZ[4,3], F. ROJAS-LARIOS[1,2];

[1]Sch. of Med., [2]Lab. of Ecology, [3]Lab. of Neurosciences, [4]Sch. of Psychology, Univ. of Colima, Colima, Mexico; [5]Sch. of Psychology, Univ. of Colima, Colima, México, Mexico

Abstract: Introduction: Contact sport practice has been rise worldwide. Contact sports are sports that emphasize or require physical contact between players. Currently soccer, football, rugby and box are the most practiced sport in the world, however, in these sports direct or indirect contact of the head are implicated. According previous studies, head impacts constant while playing contact sports may lead to a variety of worrisome outcomes, even, an increased the susceptibility to concussion, chronic traumatic encephalopathy risk, changes in the brain with just a season in a sport contact, even when the player is not outward signs of a concussion, including neurocognitive deficits and brain matter changes at magnetic resonance imaging.
Aim: To determine the effects of contact sport practice on cognitive performance in collegiate sport athletes.
Material and method: Participants were 20 collegiate soccer players and 20 noncontacts collegiate sport athletes, who practiced along 6 months uninterrupted and without record of TBI. All athletes were assessed using the CogState Battery, which consists of six cognitive tasks that measure control motor visual, associated peer learning, psychomotor function, attention, working memory and executive function.
Results: There no found significant differences between contact sport group compared to noncontact sport group, according to the sex, age and years of education. The contact sport athletes performed more poorly at two cognitive domains than noncontact sport athletes: Associated peer learning (contact group: accuracy (ACC) 1.39±0.22 vs noncontact group: ACC 1.78±0.18; p=0.001) and working memory (contact group: Movements per second (MPS) 1.47±0.3, correct moves (CMV): 45±6 vs noncontact group: MPS 1.60±0.24, CMV: 51±4; p=0.003). There not found significant differences in the others cognitive domains.
Results: Therefore, repetitive head impacts may negatively impact the associated peer learning and working memory functions in soccer players; even when there are no outward signs of an injury. Further studies are necessary, mainly because in Mexico it has not been issued or published in the declaration of the national health policy for the evaluation and management of the heads.

Title: Effects of cognitive-motor training on executive function and resting prefrontal cortex connectivity in preschool children: An fNIRS study

Authors: *C. ENG[1], M. POCSAI[1], F. FISHBURN[4], N. C. WILLIAMS[2], D. CALKOSZ[3], E. THIESSEN[1], A. FISHER[1];
[1]Psychology, [2]Logic and Computation, [3]Computer Sci., Carnegie Mellon Univ., Pittsburgh, PA; [4]Psychiatry, Univ. of Pittsburgh Med. Ctr., Pittsburgh, PA

Abstract: Studies utilizing functional near infrared spectroscopy (fNIRS) show that prefrontal cortex (PFC) connectivity at rest plays an important role in the development of executive functions (EF). Studies with older populations show that Exergames (concurrent cognitive and motor stimulation) improve EF. Yet, little is known about the effects of Exergame training on EF and the associated neural substrates in children below school age. This study investigated the effects of Exergame training on resting PFC connectivity and EF of 4 to 5 year olds. Participants were first blocked on sex, classroom, and age, and then were randomly assigned to either the Exergame or Control condition: 21 children formed the Exergame group (M = 5.06 ± .65 years; 8 females), while 20 children (M = 5.06 ± .64 years; 8 females) in the Control group engaged in typical classroom activities. The 1-week Exergame intervention included two 20-minute consecutive sessions. The Exergame was projected onto a wall with a connected nonslip game mat and children responded by stepping left or right on the game mat's arrows in accordance with the goals of the game. PFC resting connectivity, performance on 2 EF tasks (Flanker and Day-Night), and teacher ratings of EF (BRIEF) were collected before the intervention (pretest), after the intervention (posttest), and 1 month later (delay test). PFC connectivity was assessed using *Inscapes*: a movie paradigm of abstract shapes without a narrative that elicits patterns of resting connectivity, while mitigating fidgetiness. Teachers and researchers who administered the EF tasks were blind to condition assignment. Oxy-hemoglobin concentration was recorded using a 10-channel continuous wave fNIRS system (TechEN CW6, 8 detectors, 4 sources) on the PFC, and connectivity was computed between all channel pairs at pre, post, and delay tests. A repeated measures ANOVA on each of the Z-transformed connectivity values was conducted, correcting for multiple comparisons. Results indicate that Exergame training significantly increased PFC inter-hemispheric connectivity, increased intra-hemispheric connectivity in the left PFC, Flanker Task accuracy, Day-Night Task accuracy, and BRIEF scores from pre to posttest (all ps < .001), while no significant differences were found in the sex/classroom/age-matched control group in PFC connectivity or EF assessments from pre to posttest. These Exergame training induced changes in PFC connectivity correlated with improved EF skills. The improvements in EF persisted over a 1 month period. This study provides novel insights into the associations between Exergame training, PFC connectivity, and EF development in preschool children.

Title: A resting-state fNIRS study in early childhood and early adolescence

Authors: *S. EOM[1], **J. CHOI**[2], J.-M. KIM[2], M. LEE[3], D.-J. YI[4];
[1]Yonsei Univ. Col. of Med., Seoul, Korea, Republic of; [2]Optical Brain Electronics Lab., Seoul, Korea, Republic of; [3]Epilepsy Res. Inst., Seoul, Korea, Republic of; [4]Dept. of Psychology, Yonsei Univ., Sseoul, Korea, Republic of

Abstract: Resting-state functional near-infrared spectroscopy (fNIRS) is a potential technique for the study of brain functional connectivity (FC) and networks in children. The present study aimed to investigate functional brain activation patterns in network organization during development from early childhood to early adolescence using resting state functional Near Infrared Spectroscopy (rs-fNIRS).
This study enrolled 71 healthy normal participants, including 44 young children (7.7 ± 1.1 years, age range of 6.0-10.1 y; 17 boys) and 27 early adolescents (11.1 ± 0.8 years, age range of 11.1-13.0 y; 8 boys). Measurements were performed by NIRSIT (OBELAB Inc, Korea) which utilizes 24 lasers source and 32 photo detectors with multiple source-detector spacing. For representing individual distance matrix, density parameter is calculated after applying threshold value at the distance matrix. Moreover, relating neuropsychological tests for working memory and processing speed such as Digit Span, Coding, and Symbol Search from Wechsler Intelligence Scale for Children-fourth edition, and for executive function such as Children's Color Trails Test (CCTT) were performed. fNIRS data and behavioral measure were analyzed with normality test and independent t-test as an inter-group factor and correlation analysis was conducted among fNIRS, behavioral and neuropsychological data. Subjects were classified into two groups by their cognitive functional level as low- and high- group based on their scores in the neuropsychological tests. And then, we compared functional connectivity matrices of low- and high score groups at the level of cognitive function.
In terms of development, early adolescents showed significantly high level of density parameter in rs-fNIRS compared to early children in cognitively low function group, particularly in Coding ($p<0.05$), and CCTT interference ($p<0.01$). However, no significant differences on rs-fNIRS parameters were shown in high function level group between early children and early adolescents. Furthermore, significant discrimination in CCTT interference based on rs-fNIRS density between low and high function group was found ($P<0.01$) in early adolescents.

Our results suggest that re-fNIRS parameters are associated with different functional activation patterns in the frontal subregions based on not only cognitive level but also developmental aspects. fNIRS could be a potential measure as an effective tool to investigate the contributions of developmental prefontal function of executive functioning in early children and early adolescents.

Title: Working memory, inhibitory control, and set-shifting in an unmedicated ADHD cohort diagnosed in adulthood

Authors: *V. A. GRANE[1,2], A.-K. SOLBAKK[2,1,3], T. ENDESTAD[2,1];
[1]Dept. of Neuropsychology, Helgeland Hosp., Mosjøen, Norway; [2]Dept. of Psychology, Univ. of Oslo, Oslo, Norway; [3]Dept. of Neurosurg., Oslo Univ. Hosp. - Rikshospitalet, Oslo, Norway

Abstract: Objective: To examine whether core executive control functions are reduced in unmedicated adults with Attention Deficit Hyperactivity Disorder (ADHD) compared to match healthy controls. **Method:** Performance on tasks demanding memory span and working memory (Digit Span), interference control and response inhibition (Color Word Interference Test; CWIT-Inhibition), and set-shifting (Trail Making Test; TMT and CWIT-Switching) was assessed in newly diagnosed patients with ADHD (n=36) and in healthy controls (n=34). The associations of test scores to self-reported symptoms (Achenbach System of Empirically Based Assessment, ASEBA) and executive function in everyday life (Behavior Rating Inventory of Executive Function; BRIEF-A) were also examined. **Results:** The groups did not differ in immediate memory span, but the ADHD cohort performed significantly worse than controls when there was an additional demand on working memory. Statistically controlling for individual differences in information processing speed, using an independent simple reaction time measure, did not influence the result. The ADHD group performed inferiorly to the control group on the baseline psychomotor speed conditions of the TMT, but the most pronounced difference appeared on the set-shifting condition. Results on the interference control/response inhibition task (CWIT-Inhibition) did not distinguish the groups, but there was a tendency for the ADHD group to perform more poorly when a concurrent demand on attentional switching was introduced

(CWIT-Switching). For the ADHD group, prolonged CWIT-Switching task completion time was significantly associated with increased self-reported problems with behavioral regulation (BRIEF-A). **Conclusion:** ADHD-related reductions of attentional set-shifting and working memory capacity, but not inhibitory control, support the growing literature suggesting that adult ADHD may not be associated with an overall impairment in executive functioning, but rather with difficulty in specific aspects of executive function. Accordingly, clinical assessment should ideally span a wide range of executive control tests, including the fundamental control functions studied here.

Title: Time course of induced oscillatory neural activity during Stroop conflict in healthy adults and children

Authors: *C. L. DALE[1], L. B. HINKLEY[1], K. G. RANASINGHE[2], T. L. LUKS[1], A. M. FINDLAY[1], N. J. POJMAN[2], P. BUKSHPUN[2], T. THIEU[2], T. P. ROBERTS[3], P. MUKHERJEE[1], E. H. SHERR[2], S. S. NAGARAJAN[1];
[1]Radiology and Biomed. Imaging, [2]Neurol., Univ. of California San Francisco, San Francisco, CA; [3]Radiology, Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: A long history of research utilizing Stroop interference tasks has documented poorer performance when task-directed responses conflict with overlearned or automatic responses in healthy adults and youth. Electrophysiological and BOLD-derived cortical sources associated with conflict-related processing implicate frontal, parietal, and anterior cingulate areas, the latter occurring 400-450 ms post-stimulus. These evoked methods emphasize low frequency activity that is tightly coupled to stimulus onset, minimizing neural processes with higher temporal variability that may help describe the neural underpinnings of cognitive conflict. Given that efficiency of executive functions and fidelity of frontal regions are developing in youth, induced

spatiotemporal patterns of activity are of interest. Healthy adults (N = 54, 18-55 years) and typically-developing youth (N = 42, 7-17 years) underwent a cognitive assessment battery and whole-head magnetoencephalography recording (MEG, CTF Systems, Vancouver BC) during a Color Naming Stroop Task. Using adaptive spatial beamforming methods implemented in NUTMEG (bil.ucsf.edu/nutmeg), the difference between cortical oscillatory power induced by Incongruent versus Congruent stimuli was analyzed at each voxel over time within 5 frequency bands. Cortical power differences were submitted to within- and between-group SnPM analyses, as well as correlated with performance on both Stroop and cognitive assessment tasks. Typical Stroop performance decrements were obtained in each age group, with youth both slower and less accurate than adults. MEG results indicate a spatial sequence of frontal conflict-related activation in adults, predominately in theta and high gamma bands, initiated as early as 125 ms and continuing through the response. Patterns of high gamma activity indicate a more complex, re-entrant pattern of conflict activity in lateral and medial frontal areas, as well as inferior parietal lobe. Youth showed limited activation in lower frequency bands, but strong high gamma activity localized to medial frontal and cingulate areas from 200 ms through 475 ms. Overall, data reveal a spatiotemporal evolution of conflict-related neural activity in multiple frequency bands as executive functions mature.

Title: Neuropsychological assessment of executive functions in juvenile offenders

Authors: *P. ZARATE GONZALEZ, J. VAZQUEZ-RAMIREZ, N. SANDOVAL-FLORES, F. BENITES-SERRATOS, D. PAZ-TREJO, H. SANCHEZ-CASTILLO;
Applied Neurosci., Iberoamerican Society For Applied Neurosci. (NG, Mexico City, Mexico

Abstract: Different perspectives and theories in cognitive neuroscience have been tried to explain juvenile delinquency and risk behavior in adolescents, especially in those who committed homicide, kidnap, rape and extremely violent behavior. Nowadays two perspectives spread light through the issue. On the one hand, the arguments about cerebral immaturity bring us a closer look into the PFC, in which the role played by the density of gray and white matter is crucial in the process of decision making in a risky situation; on the other hand, the brain imbalance model provides a new paradigm that questions the adolescent's own immaturity,

placing the asynchrony between cortical and subcortical areas as an explanatory framework. In this study, we performed a neuropsychological assessment of the executive functions in juvenile offenders from the General office for juvenile offenders in Mexico City (DGTPA). The sample consisted of 30 male (mean 16 years old) and 6 female (mean 17 years old) adolescents (N=36) convicted mostly for homicide, robbery and kidnap. We employed a neuropsychological battery called BANFE (neuropsychological battery of executive functions and frontal lobes) that links prefrontal, orbitomedial and dorsolateral areas with specific executive functions. The results indicate alterations in a small group of participants in both, anatomical and functional areas and overall executive functioning, these results only showed significant differences between female and male in those executive functions related with orbitomedial and dorsolateral areas. The hypothesis of emotional valence is highly associated with risky behavior in adolescents as a mediator of decision making in almost all executive functions and displace the hypothesis of neurological immaturity in the commission of juvenile delinquency.

Title: Do different self-control skills in youth share a common neural substrate

Authors: *J. F. GUASSI MOREIRA[1], A. S. MENDEZ LEAL[1], Y. WAIZMAN[1], N. EMILIA[1], J. A. SILVERS[2];
[2]Dept. of Psychology, [1]UCLA, Los Angeles, CA

Abstract: The acquisition of self-control is an inherently developmental process that occurs over the course of decades. To date, much research has examined the neurodevelopmental bases of self-control across a range of contexts. However, virtually no work has addressed whether the neural bases of self-control across different contexts stem from a common neural substrate, or whether they are instantiated differently (i.e., marked by similar or disparate population coding). We address this issue in an ongoing study in which a sample of youth—exposed to varying degrees of stress—completed three tasks while undergoing functional magnetic resonance imaging (fMRI). Forty-three youth (age range: 10-22) completed two self-control tasks under affectively 'hot' conditions: a cognitive reappraisal task, which involved using a cognitive

strategy to regulate negative affect, and a driving simulation task, which involved weighing potential risks and rewards during decision making. After preprocessing and cleaning the data, we conducted a whole-brain multi-voxel pattern searchlight analysis (neighborhood size = 75 voxels, naïve Bayes classifier, leave-one-out cross validation) to reveal brain regions where the population codes could discriminate between tasks. The analysis identified clusters in the bilateral dorsolateral prefrontal cortex, dorsal anterior cingulate cortex, and bilateral superior parietal lobule. Importantly, clusters were not simply obtained due to chance, as they survived the 67% classification accuracy threshold (obtained using a binomial reference distribution). That activity from these regions—consistently implicated in self-control tasks such as those used here—were found to discriminate between tasks suggests that the neural code underlying the development of self-control varies across affective contexts. In other words, the neural basis of brain regions involved in self-control is not comprised of a common substrate and appears to vary as a function contextual demands. Future analyses will seek to identify instances where the opposite is true: where the neural code is indeed similar across different contexts of self-control.

Title: Neural approach for understanding event segmentation in early development

Authors: *T. S. YATES, L. J. SKALABAN, C. T. ELLIS, N. B. TURK-BROWNE; Psychology, Yale Univ., New Haven, CT

Abstract: In order to structure and scaffold experience, humans segment continuous input into discrete events. Much of the prior research on event segmentation has been in adults. Across individuals, there is consistency in where they identify boundaries during naturalistic experience, and these boundaries are reflected in state changes in neural activity patterns. Different parts of the cortical hierarchy segment experience at different timescales: for example, events tend to be relatively short in duration (i.e., more boundaries) in early visual areas and long in duration (i.e., fewer boundaries) in higher-order association cortex. Here we explore whether an analogous neural state approach can be used to study event segmentation in infants and toddlers who are pre-verbal or otherwise unable to perform behavioral event segmentation tasks. How young

children perceive and segment events is largely unknown, so if successful, this has potential to reveal fundamental insights about their experience of the world. For example, it is possible that infants have similar event structures to adults in early visual areas, reflecting similar sensory processing, but lack longer event structures in association cortex, which are thought to track memory, understanding, and narrative. Infants could also exhibit event boundaries at different time points or be less reliable than adults in what constitutes an event boundary. Our approach is to compare the fMRI activity of infants and adults watching the same short cartoon movie. Adult passive movie viewing data were obtained from a larger fMRI dataset collected from our lab. Consensus event boundaries were determined behaviorally by an independent sample of adults. Using a hidden Markov model, we replicated previous findings of a decrease in the optimal number of events higher in the cortical processing hierarchy, even in a considerably shorter narrative. We also found overlap in the timing of event boundaries between this neural approach and the boundaries identified behaviorally by others. Indeed, fMRI activity patterns were more correlated within vs. across behavioral events in the precuneus and posterior cingulate cortex. Having quantified neural event structure in adults, we are now investigating the fMRI activity of infants watching the same movie to determine at which timescales they segment events, how these boundaries compare to adults, and where in the brain they are represented.

Title: Association between lung function and neurocognitive assessments in urban minority children

Authors: *L. B. MENDEZ[1], H. J. ROSA-LOPEZ[1], N. G. MEDINA[2];
[1]Sch. of Sci. and Technol., [2]Sch. of Social and Human Sci., Univ. Ana G. Mendez, Carolina, PR

Abstract: Epidemiological studies have found associations between exposure to ambient particulate matter (PM) and adverse respiratory and neurocognitive outcomes. Children are particularly vulnerable to the effects of ambient PM since their CNS is still in development, especially in regions related to executive functions, which develop significantly between the ages of 6 to 10 years. It has been reported that children exposed to high levels of traffic related air pollutants (TRAP) had lower scores in attention and working memory. However, not much is

known about the relationship between cognitive changes and lung function in children. Therefore, the main goal of this research is to evaluate the relationship between lung function and neurocognition in Puerto Rican children living in urban areas with heavy traffic. We hypothesized that children with reduced lung capacity will score lower in cognitive tasks related to executive functions. To test this hypothesis, we conducted a secondary data analysis of previously collected respiratory and cognitive data of children ages 6 to 9 living near two main sources of traffic TRAP. For the analysis, we selected the days and participants for which lung function was measured prior the administration of the cognitive test (i.e. Cognitive Assessment System 2). Results showed significant associations between forced vital capacity and the planning construct ($r=0.881$, $p=0.03$), specifically in the connections subtest (a version of the trail-making test). Similar results were observed in a replicate study. Additional research is needed to understand the effects of pulmonary function on cognitive skills, especially in vulnerable populations such as children.

Title: Polygenic score of intelligence is more predictive of crystallized than fluid performance among children

Authors: *R. J. LOUGHNAN[1], C. E. PALMER[2], W. K. THOMPSON[3], A. M. DALE[4], T. L. JERNIGAN[6], C. CHIEH FAN[5];
[1]Dept. of Cognitive Sci., [2]Ctr. for Human Develop., [3]Div. of Biostatistics, Dept. of Family Med. and Publ. Hlth., [4]Neurosciences and Radiology, [5]Ctr. for Multimodal Imaging and Genet., UCSD, La Jolla, CA; [6]Ctr. for Human Develop., Univ. of California San Diego, La Jolla, CA

Abstract: Intelligence is a strong correlate of educational, occupational and health outcomes. Twin and Genome Wide Association Studies in adults have revealed genetic associations with intelligence to be moderately heritable and related to the neurobiology of the brain. We aimed to better understand these genetic associations with intelligence in the context of the developing brain. Specifically, we questioned if genetic associations of intelligence a) loaded on specific factors of cognition (i.e. fluid vs crystallized) and b) related to differences in cortical brain morphology measured using MRI scans. To do this we generated a genome-wide polygenic score of intelligence (GPSI) for the Adolescent Brain Cognitive Development (ABCD) baseline data, which consists of 11,875 nine and ten year olds across the US. We found that the GPSI was a highly significant predictor of estimates of both fluid ($t=7.1$, $p=1.2\times10^{-12}$) and crystallized

(t=15.0, $p=3.5x10^{-50}$) cognition, with greater predictive power for crystallized than fluid (z=4.9, $p=8.7x10^{-7}$). This indicates a stronger loading of GPSI on crystallized cognition. GPSI was significantly correlated with total cortical surface area (t=5.3, $p=1.4x10^{-7}$), but not mean thickness (t=0.25, p=0.8). Vertex-wise analyses showed that the surface area association is largely global across the cortex. The stronger association of GPSI with crystallized than fluid measures is consistent with recent findings that more culturally dependent measures of cognition are more heritable. These findings in children provide new evidence relevant to the developmental origins of previously observed cognitive loadings and brain morphology patterns associated with GPS of intelligence.

Title: Neurobehavioral trait and state signatures in child-victims of peer bullying

Authors: *I. SOLIS[1], Y. KIM[1], C. M. MCGINNIS[1], P. G. LESNIK[1], L. SERNA[2], K. T. REWIN CIESIELSKI[1,3];
[1]Dept. of Psychology, Pediatric Neurosci. Lab., Univ. of New Mexico, Albuquerque, NM; [2]Dept. of Special Education, Univ. of New Mexico, Albuquerque, NM; [3]Dept. of Radiology, MGH/MIT A. A. Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hospital, HMS, Boston, MA

Abstract: Introduction: Child-Victims (CVs) of peer bullying persistently exposed to physical and psychological victimization, and social exclusion present with low self-esteem, suicidal ideations, somatic and psychological disorders, reduced life achievements and violent acts of desperation, including school shootings. Early prevention is an urgent call and poses two major questions: (i) How early in childhood is bullying experienced, and therefore, when to begin the first preventive efforts, and (ii) What are the primary risks factors for victimization in CVs, and therefore what neurobehavioral phenomena must be targeted by preventive efforts. Searching for the answers we conducted two studies. **Methods:** *Study I:* Structural interviews comprising 50 questions in 18 local preschools with 20 instructors of children ages 4-6, that focused on the content of earliest episodes of child-peer bullying, and *Study II*: 34 CVs ages 6-17, with matched, non-involved, control-children (CC). Examination of a two-factorial model of neurobehavioral CVs characteristics was conducted: (i) *Trait Signatures* (TS), the crystalized, long-term neurobehavioral markers from early life; and (ii) *State Signatures* (SS), the psychological, somatic, and cognitive acute consequences of ongoing victimization. A neuropsychological

battery of tests, clinical parental interviews, and resting state brain EEG (reported elsewhere) were applied. **Results:** Among TS, CVs as compared to CC, displayed early life history of high anxiety, compulsive behaviors, visual-spatial perception/attention deficits, limited vocabulary and various diverse characteristics, such as exceptional high school performance, and extremes of physical attractiveness. Among SS, CVs displayed higher levels of ongoing depressive moods, low visual-spatial memory/conceptualization, and higher rates of ongoing traumatic experiences compared to CC. **Conclusion:** The cognitive-social-emotional profile of developmental Trait Signatures calls for translational programs of prevention with children at risk for bullying victimization at an early preschool age aiming to increase self-esteem and skills of social communication, ability for top-down inhibitory control of emotions and behaviors, and acceptance of diversity.

Title: Functional dynamics of the infant brain

Authors: *S. NAIK[1], D. BATTAGLIA[2], G. DEHAENE-LAMBERTZ[1];
[1]Developmental Neuroimaging Group, UNICOG, Neurospin, Paris-Saclay, France; [2]INS, Univ. Aix-Marseille, Marseille, France

Abstract: Compared to adults, infant visual Event Related Potentials (ERPs) are highly variable across trials in terms of latency of the known ERP components, making it difficult to interpret the subject-specific ERPs. While the traditional ERP studies focus on the mean activity--discarding the across-trial variability as noise-- this variability is important for improving our understanding of the maturation of functional dynamics in infants. Using multivariate topographic analysis on high-density EEG recordings, we explored the variability of responses to face stimuli in 2-6 month old infants (N=39, Mean age: 14.15 +/- 4.79 weeks) to understand how this variability is adjusted throughout the course of development. Specifically, we show that the latencies of the single trial events most resembling to known target ERP components (e.g. P1- or P400-like topographies) fluctuate from one trial to the next, but the **distributions** of these latencies gradually **concentrate in time and reduce their spread around the mean** throughout the age of maturation. Furthermore, using multivariate topographic analysis, we defined a

measure of dissimilarity across trials and observed the time-evolution of this measure to understand the stimulus driven differences (variability) across trials while the infants process lateralized face stimuli; passively looking at the fixation. We prove the existence of **durations of reduced inter-trial variance**– or Variability Quenching Events (VQE)– following stimulus presentation at this early age. We observe that the latencies of infant VQEs are later than those of the adults. Moreover, these VQE events align with the developing latencies of P1 and P400 response components, being possibly involved in their maturation dynamics. Furthermore, we observed **transient 'slowing down'** or intra-trial variance quenching **in single-trial,** onset of which briefly aligned in time with the onset of VQEs-- possibly suggesting the existence of stable temporal window for information integration. Interestingly, infants exhibited stable intra-trial patterns for longer durations than adults and overall sluggish dynamics, unlike in adults where the slowing down was concentrated around the peri-stimulus durations. In future, understanding the relationship between transiently stable dynamics and task-related responses may help unravel the role played by response variance in the emergence and development of ERP responses.

Title: Brain and cognitive sequelae of preterm birth: Baseline findings from the ABCD study

Authors: *F. HAIST, N. AKSHOOMOFF;
Psychiatry, UC San Diego, La Jolla, CA

Abstract: Children born preterm are at increased risk of disrupted perinatal brain development and subsequent neurodevelopmental impairments. Even "healthy preterm" children with a benign neonatal course and without focal brain injury show diffuse changes in white matter but little is known about how these affect cortical development and associated cognitive functions as children enter adolescence. Large scale studies may provide valuable information to address this. Here, we used data from 9 and 10 year-olds from in the Adolescent Brain Cognitive Development (ABCD) study (NDA Release 2.0) to evaluate major white matter tract integrity, regional subcortical gray and white matter volume, and cognitive test performance (NIH Toolbox Battery) across three birth groups: Full Term (FT; ≥ 37 wks gestation; Max N=10,099), Late Preterm (LPT; 33-36 wks; Max N=1262), and Very Preterm (VPT; 28-32 wks; Max

N=341). We used general linear model univariate and multivariate tests that controlled for age and sex. In terms of mean diffusivity (MD) within select white matter tracts, we found significant birth term group effects within the corpus callosum, bilateral fornix, bilateral anterior thalamic radiations, and right hemisphere cingulate. Within each of these regions, the preterm groups (LPT & VPT) had lower MD values than FT children, suggesting that reduced white matter integrity is present in most children born preterm. The exception was in the left hemisphere cingulate, with no significant group differences. There were significant volumetric differences, where both preterm groups had significantly enlarged lateral ventricles and reduced brainstem volume than the FT group. The VPT group had significantly reduced whole brain volume, cerebellar white matter, cerebral white matter, and thalamic volume than both the LPT and FT groups. On the NIH Toolbox, the VPT group scored significantly lower than the FT group for both the Crystalized (verbal) and Fluid (performance) composite measures, while the LPT scored significantly lower only on the Crystalized measure. The large sample afforded by the ABCD cohort provides a unique opportunity to explore the long-term sequelae of preterm birth.

Title: ASD and ADHD motor neurodevelopmental disorders

Authors: *J. V. JOSE[1], J. I. NURNBERGER, Jr.[2], M. H. PLAWECKI[3], A. PHADNIS[4], K. DOCTOR[5];
[1]Physics and Stark Neurosci., Indiana Univ., Bloomington, IN; [2]Inst. of Psychiatry, Indiana Univ., Indiana University, Indianapolis, IN; [3]Inst. of Psychiatry, Indiana Univesity, Indiana University, Indianapolis, IN; [4]Physics, Indiana Univesity, Indiana University, Bloomington, IN; [5]Computer Sci., Univ. of Massachusetts Amherst, UMass Amherst, MA

Abstract: From childhood to adulthood our brains keep changing as we learn. Neurodevelopmental disorders in children refer to deficits or delays in the developmental process. An important example is Autism Spectrum Disorders (ASD). Despite its high prevalence, most clinical diagnoses of ASD remain subjective in nature. Similarly, Attention Deficit Hyperactive Disorders (ADHD) involve developmental deficiencies. There are no general and effective treatments for this psychiatric Neurodevelopmental Disorders (NND).

There is a significant need to find objective NDD assessments biomarkers. In our previous work, we introduced a quantitative biomarker (s-Peaks) based on a statistical analysis of natural motions at millisecond time scales (Wu et al 2018). We used these biomarker in ASD subgroups that have idiophatic origins. The biomarker provides a precise screening tool for ASD severity with unprecedented accuracy. It also provided a quantitative connection between the way individuals move and to their psychiatric scores (Wu et al. 2018). This connection suggest that the motor feature we found in ASD may be a core element characterizing generally NDDs. Here we have extended our ASD biomarker studies to ADHD individuals. Recently DSM-5 noted that there are a number of co-morbidities between ASD and ADHD. They did not include, however, motor deficiencies. Here we compare ASD against ADHD to find how they are different or similar in terms of our s-Spikes movement biomarker (Wu et al. 2018). We also included Typically Developing (TD) individuals as controls o compare to ASD and ADHD. We developed a battery of movement protocols by using bleu tooth sensors that can capture motions with high frequency (www.xsens.com & http:apdm.com). These sensors are mounted on the subject's bodies (i.e. gloves, torso suits including up to six sensors). The subjects considered have developing or already developed motor skills. The ASD-ADHD and TD individuals followed motor protocols, like normal reaching or walking. These motions provide the necessary kinematic information to extract the statistical properties to extract the statistical properties characterizing in ASD and ADHD individuals. We will present detailed statistical analyses of the results found.

Title: Mental abacus skilled kindergarteners have enhanced attentional and spatial abilities

Authors: *D. CHENG[1], X. ZHOU[2];
[1]Capital Inst. of Pediatrics, Beijing, China; [2]State Key Lab. of Cognitive Neurosci. and Learning, Beijing Normal Univ., Beijing, China

Abstract: In China and other Asian countries, it is popular for children to learn mental abacus skills. Mental abacus skilled children or adults can perform fast and accurate calculation based on mental image of an abacus. Studies consistently show that mental abacus learning can promote arithmetic abilities and numerical processing abilities. However, ti is controversial that whether there is transfer effects of mental abacus learning on general cognitive abilities. The

current investigation examined the group differences between mental abacus skilled kindergarteners and controls in general cognitive abilities. A total of 442 kindergarteners participated in the investigation, half being mental abacus skilled (passing the Test for Level 7 on the Standard Mental Abacus) and the other half being without any experience of abacus and mental abacus. The results showed that mental abacus skilled kindergarteners performed better in continuous geometric form searching task and two-dimensional mental rotation task, and the group differences still existed after controlling for other cognitive abilities (i.e., intelligence, reaction and decision speed, and precision of approximate number system). The findings suggest that mental abacus skilled kindergarteners have enhanced attentional and spatial abilities, and mental abacus learning before formal schooling could effectively promote the development of children's attentional and spatial abilities.

Title: Combined analysis of cortical surface area and cortical thickness in adolescent anorexia nervosa

Authors: *P. M. ASLAKSEN[1], A. D. MYRVANG[2], J. H. ROSENVINGE[2], T. ENDESTAD[3], K. STEDAL[4], Ø. RØ[4], T. R. VANGBERG[2];

Norway; [4]Regional Dept. for Eating Disorders, Div. of Mental Hlth. and Addiction, Oslo Univ. Hosp., Oslo, Norway

Abstract: The aim of the present study was to test whether cortical surface area (CSa) and cortical thickness (CTh) were significantly different in girls with anorexia nervosa (AN) compared to healthy controls (HC). Previous studies have separately suggested that AN is accompanied by reductions in CTh and cortical surface architecture. To our knowledge, no previous study has concomitantly tested how CTh and CSa is affected in patients with AN. 30 inpatients with restrictive AN and 28 age matched healthy controls participated in the study. The mean age of the AN patients was 15.8 years and 16.2 for the HC group. MR scanning was performed in two 3T-scanners (Siemens Skyra and Phillips Achieva), with voxel sizes of 1x1x1mm and slice thickness of 1mm in both scanners. The AN patients were scanned approximately 4 weeks after admission. The Freesurfer 6.0 software was used to preprocess MR data for CTh and CSa. The Permutation Analysis of Linear Models (PALM) was used to perform statistical analysis of the data. The statistical analyses were performed with threshold free cluster enhancement, FWER-corrections across modalities (CTh and CSa) and contrasts, and 1000 permutations with tail-approximations. The results showed that both CTh and CSa separately were significantly reduced in AN patients compared to the HC group when controlling for age and scanner-type. The reductions in CTh were widespread across the cortical surface, but most pronounced in the superior frontal and the cingulate cortices. A non-parametric combination analysis (Fisher) performed with PALM showed that the reduction of CTh and CSa in AN patients compared to the HC was strongest in the superior temporal, the precuneus and the posterior cingulate cortices. In sum, the present study suggests that cortical thickness and cortical surface area are differentially affected in patients with AN.

Title: Investigation of intergroup bias in two neuromaturationally distinct age cohorts: An ERP study

Authors: *R. M. HANNA[1,2], T. J. BOSCH[3,1], K. A. FERCHO[4,1], L. A. BAUGH[3,1]; [1]Ctr. for Brain and Behavior Res., Vermillion, SD; [2]South Dakota State Univ., Brookings, SD; [3]Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD; [4]Aviation Safety, AAM-510, FAA Civil Aerospace Med. Inst., Oklahoma City, OK

Abstract: It is well established that humans are a social species. Not only are we social, when compared to other primate species we are superlative in measures of reciprocal and non-reciprocal altruism, complexity and breadth of our social networks, and empathy towards conspecifics and heterospecifics alike. However, our prosocial nature is not without boundaries. Like many of our primate cousins (e.g., Rhesus Macaques, Chimpanzees, &c.) we subdivide our social world into ingroups and outgroups. Ingroups are continually updated and play a significant role for us across the lifespan. At no other time in life is the importance of the ingroup more acutely felt or observed than during adolescence/young adulthood. Between the ages of 12 and 25 peer salience, along with risk-taking, reward seeking, and novelty seeking increases. The developmental mismatch hypothesis of the dual systems model of brain development posits that these adolescent typical behaviors result from earlier maturing subcortical structures (NAcc and AMG) "overriding" phylogenetically newer structures of the PFC, specifically the dlPFC, dACC, and OFC. Many of the primary structures implicated in "the social brain." While studies (primarily fMRI) have been conducted to understand social cognition across the lifespan, few ERP studies explicitly investigate intergroup bias from a developmental mismatch perspective. The present study does exactly this. Using notional groups based upon each subjects' political affiliation with non-noxious initiation we investigated the temporal differences in ingroup vs. outgroup processing. Following a separate behavioral training session, subjects were asked to view images of ingroup members or novel outgroup (that held an opposing political ideology) members that were paired with congruent or incongruent conservative vs. liberal stereotype statements. Subjects needed to evaluate group affiliation, assess the statement and indicate the likelihood that the person pictured made the statement within 5000 ms. Results (maximal over frontocentral electrodes) replicate previous findings that show increased P2 amplitude for outgroup images and increased N2 amplitude for ingroup images, but only for the 30-35-year-old age cohort. For both congruency and group conditions, these results were reversed in the 18-19 year-old age cohort. These findings support increased early categorization of ingroup peers in adolescents. However, because these trends are from a pilot study with low sample sizes (18-19 n=16; 30-35 n=4) further investigation is necessary.

Title: Brain maturity: The structural connectome and its relationship with psychiatric symptoms in youth

Authors: *A. LUNA[1], C. JIOOK[2,1], J. POSNER[2,1];
[1]Columbia Univ. Med. Ctr., New York, NY; [2]New York State Psychiatric Inst., New York, NY

Abstract: Evidence for the role of abnormal neuromaturation in psychiatric disorders is emerging and warrants further investigation. Accurate measurement of neuromaturation can be used to characterize psychiatric disorders. We present a multimodal age prediction model using stacked ensemble machine learning (SEML). We evaluate the utility of brain predicted age differences (BrainPAD) in characterizing the relationship between abnormal neuromaturation and psychiatric symptoms in youth (ages 5-18). Using the Child Behavioral Checklist (CBCL) to assess symptoms, we hypothesized that subjects with greater symptoms would have greater BrainPAD.

T1-weighted structural and diffusion MRI from the Healthy Brain Network (N=498) were used to estimate morphometry (Freesurfer v6.0) and white matter (WM) structural connectomes (MRtrix3). A machine learning framework (H2O), was used to predict brain age based on connectomic and morphometric features. BrainPAD was defined as predicted age minus chronological age. Participants with a CBCL Total score in the normal range (T-score < 60; N=263) were used for model development (train/test = 80%/20%). 5-fold cross validation was performed to train, validate, and optimize the model, followed by testing on the hold-out set (20%). The model was then used to predict brain age in participants with a CBCL Total score in the borderline/clinical range (CBCL Total T-score > 59, N=235).

Mean absolute errors (MAE) for each SEML model were 1.653 (morphometry), 1.395 (connectome), and 1.162 years (morphometry + connectome). Generalized linear modeling (GLM) (y = all brainPAD scores), adjusted for age, sex, and race, revealed a negative association with CBCL Total raw score [t(234) = -2.10, p=0.03]. GLM with only negative brainPAD values (< -1.162) revealed a negative relationship with thought problems [t(72)= -3.09, p=0.003], externalizing [t(69)= -2.48, p=0.016], and total scores [t(69)= -2.24, p=0.028). ANOVA revealed group differences in internalizing [F(2, 280)=4.052, p = 0.01], and withdrawn/depressed raw scores [F(2, 280)=5.628, p = 0.006]. Post hoc Tukey HSD revealed higher mean internalizing (p-adj=0.013) and withdrawn/depressed scores (p-adj = 0.015) for Negative vs Normal brainPAD.

The most accurate age prediction in youths was achieved using both the WM structural connectomes and morphometry. The significant association between negative brainPAD and neuropsychiatric symptoms suggests that aberrant behavior in youth may be rooted in delayed neuromaturation. Future research could examine whether brainPAD predicts onset of psychiatric disorders, as well as factors that contribute to alterations of brain age.

Title: Developmental increase in 1/f slope in EEG oscillatory power

Authors: *D. CELLIER[1], J. RIDDLE[2], K. HWANG[1];
[1]Univ. of Iowa, Iowa City, IA; [2]Psychiatry, Univ. of North Carolina, Chapel Hill, Chapel Hill, NC

Abstract: Differences in neural electrophysiology across development have been hypothesized as a potential correlate of neurocognitive abilities and biomarkers of psychiatric or neurodevelopmental disorders. Results from prior EEG studies have found age- or disease-related differences in the amplitude of theta- or alpha-band oscillations, as well as the ratio of theta- vs beta-band power (theta-beta ratio; Arns et al., 2011). However, prior research has not taken into account the 1/*f* background signal that is ubiquitous in electrophysiological recordings. The 1/*f* background signal in EEG is thought to reflect the excitation-inhibition balance in spontaneous neural activity (Peterson et al., 2018), and changes in the slope of 1/*f* background signal have been associated with a decline in cognitive performance in aging adults (Voytek et al., 2015). The developmental change in 1/*f* signal, however, has not been addressed. In the present study, we analyzed a high-density resting-state EEG dataset from the Child Mind Institute (Langer et al., 2017) which consists of 40 healthy subjects between the ages of 9 and 25 years. We first defined EEG electrode clusters of interest in the frontal cortex and the parietal-occipital cortex. We then calculated the power spectral density of canonical frequency bands (theta: 4-8 Hz, alpha: 8-12 Hz, and beta: 18-25 Hz). Next, we used the FOOOF toolbox (Peterson et al. 2018) to calculate the 1/*f* background signal. We were interested in whether 1/*f* background signal would serve as a better predictor of age than the theta-beta ratio. In a multiple regression model, we found that the slope of the 1/*f* background noise was negatively associated with age (beta = -2.71; p = 0.046), indicating that 1/*f* slope becomes steeper with age. Importantly, the amplitude of alpha-, theta-, and beta-band did not significantly correlate with age after accounting for age-related differences in 1/*f* slope, nor did the theta-beta ratio. Therefore, our results suggest that, compared to conventional band-limited measures, accounting the contribution from 1/*f* slope is a more parsimonious and informative approach to tracking both typical and atypical development of intrinsic neural oscillations.

Title: White matter microstructure and childhood head injury: Results from the adolescent brain cognitive development (ABCD) study

Authors: *C. SHETH[1], R. HUBER[1], E. MCGLADE[1], P. RENSHAW[2], D. A. YURGELUN-TODD[2];
[1]Psychiatry, [2]Univ. of Utah, Salt Lake City, UT

Abstract: Adolescence is an important period in human development characterized by rapid brain maturation. The Adolescent Brain Cognitive Development (ABCD) study is a longitudinal, multi-site study that has recruited nine-ten year old children with the goal of investigating factors that influence the developmental trajectories across childhood and adolescence. Over the last decade, there has been increasing concern about the potential sequelae of concussion and head injury in children. Studies have indicated that head injuries may increase risk for physical and mental health-related problems. Furthermore, injury to the developing brain may alter subsequent maturation and impact neurobehavioral and cognitive development. Advanced magnetic resonance (MR) neuroimaging techniques such as diffusion tensor imaging (DTI) and restriction spectrum imaging (RSI) have been increasingly used to characterize underlying brain changes that correlate with patterns of behavioral change associated with head injury. Previous DTI studies of childhood head injury have concluded that forces of acceleration and deceleration lead to vulnerability of white matter tracts within fronto-temporal, limbic, and projection fibers. We examined data from the ABCD study from 3818 participants (first data release) to investigate whether presence of a head injury was associated with white matter abnormalities. Head injury was assessed by the Modified Ohio Traumatic Brain Injury Screen instrument completed by the parent. Five hundred and four parents reported a head injury that caused their child to be evaluated in the emergency room and 3314 parents endorsed no head injury. Results from DTI and RSI analyses showed lower fractional anisotropy (FA) (p=0.03) and neurite density (ND) (p=0.04) in the sub-adjacent white matter associated with the left rostral anterior cingulate cortex (rACC) in participants with head injury. Both reductions in FA and ND are thought to reflect compromised white matter integrity. ND is driven primarily by myelinated axons and the observed lower ND may be associated with decreased density or smaller average caliber of myelinated axons and thus may be related to changes in myelin integrity. DTI provides a measure of white matter tract orientation however RSI is more resistant to signal contamination by crossing fibers. The FA and ND results converge to suggest white matter abnormalities in the left rACC are associated with head injury in this age group. Alterations of white matter integrity may be related to reported changes in emotional and cognitive domains after head injury given that the ACC is a central hub for emotion regulation and cognition.

Title: Identifying behavioral and neural predictors of caffeinated soda intake in childhood using a large database from the ABCD study

Authors: *M. KWON[1], ***H. KIM**[1], J. YANG[1], J. HUR[1], T.-H. LEE[3], W.-Y. AHN[2]; [2]Dept. of Psychology, [1]Seoul Natl. Univ., Seoul, Korea, Republic of; [3]Virginia Polytechnic Inst. and State Univ., Blacksburg, VA

Abstract: Caffeine is the most frequently used substance among children, and caffeinated soda is the most preferred routes of caffeine administration. Even though early caffeine overdose is known to have long-term negative effects in youth including higher vulnerability to a Substance Use Disorder (SUD) in adolescence and adulthood, the effects of soda consumption on cognitive and neural functions in childhood remain largely elusive. Here, we examined the behavioral and neural correlates of regular soda consumption on reward processing, impulsivity, and working memory, which are well-known to be associated with SUDs. We used a large database (N = 2001, age = approximately 10-11 years old) from the Adolescent Brain and Cognitive Development (ABCD) Study, which is a 10 years longitudinal cohort study in the US measuring comprehensive predictors and outcomes related to mental and physical health across childhood and adolescence. We classified participants into the soda drinking group and the control group (no soda consumption at all) and compared their behavior and fMRI patterns. Hierarchical linear regression approaches were used to identify measures with significant group differences, and machine learning approaches (LASSO and elastic net) were used to identify the multivariate patterns of behavioral and neural predictors for caffeinated soda intake. Preliminary results suggest that (1) frequent caffeinated soda drinking is associated with higher impulsivity and impaired working memory performance, and (2) the frequency of soda drinking was associated with increased activation in the hippocampus, amygdala, and dorsolateral prefrontal cortex during the emotional N-back task. These patterns were only found in males whose average soda intake was higher than females. In sum, our results revealed specific behavioral and neural predictors of caffeinated soda intake using a large database, and suggest that regular caffeinated soda intake in childhood is associated with impaired cognitive functions.

Title: Topological abnormal load in ADHD functional brain network

Authors: *Z. GRACIA TABUENCA, J. DIAZ-PATIÑO, I. ARELIO, S. ALCAUTER;
Univ. Nacional Autónoma de México, Querétaro, Mexico

Abstract: Attention Deficit Hyperactivity Disorder (ADHD) is a developmental disorder characterized with difficulty to control the own behavior. Its symptoms have been associated with lower fronto-parietal functional connectivity (Elton et al., 2013), however many questions remain at the hierarchical brain network level. This study focuses on analyzing the ADHD functional brain network as a topological space.
Sample consisted of 81 control (38 male, age: 7.2 - 18.0 years old) and 99 (78 male, age: 7.2 - 17.6 years old) from the ADHD200 dataset (Milham et al., 2012), who underwent a resting-state fMRI scan (3Tesla, TR = 2s, 180 volumes). After standard preprocessing and spatial normalization to a standard space, average fMRI time series were extracted from 264 anatomical regions of interest (ROI) and a Pearson's cross-correlation (r) matrix was calculated. These ROIs can be divided into 14 functional networks. Based on the connectivity distance (1-r), the gradual process to connect every isolated ROI (1-r = 0) into a one single component in the 264 shorted steps was calculated. This process is called Rips filtration. The whole set of distances was sum up for each dataset, which can be interpreted as a connectivity rate at the brain network level. Group inference was assessed with a logistic regression including sex, age, and average head-motion as confounding variables. Results were corrected for multiple comparison with a False Discovery Rate (FDR $q < 0.05$).
Rips filtration sum showed higher scores in the ADHD group ($z = -3.02$, $p = 0.0025$) at the whole brain level. This pattern was also found between subcortical and auditory ($z = -3.36$, $p = 7.92e-04$) and salience ($z = -3.44$, $p = 5.71e-04$) networks.
Results showed higher functional connectivity in the ADHD group, contrary to previous studies (Tomasi et al., 2012; Elton et al., 2013), however these works only measured bivariate relationships between brain regions, instead of taking into account the brain network as a topological space. These results showed different topological properties in the ADHD brain network that could not been addressed by the standard functional connectivity methods, and can contribute to the better understanding of the physiopathology of this neurodevelopmental disorder.

Title: The evolution of narrative processing during development

Authors: *S. S. COHEN, C. BALDASSANO;
Psychology, Columbia Univ., New York, NY

Abstract: Development is marked by an increase in the proficiency with the variable domain of day to day life. This knowledge growth may create more coherent neural representations of life experiences, and a more abstract and semantic organization of the events within them. Here we look at the changes in neural processing with age in the Healthy Brain Network (HBN) dataset. Functional magnetic resonance imaging (fMRI) data was recorded from 233 children (80 female) whose ages ranged from 5 to 21 while they viewed two video animations. Videos were used because they allow for the assessment of brain dynamics evoked by multidimensional stimuli in which each moment dynamically depends on what preceded it. In order to assess changes in narrative processing in a data-driven way (without an explicit stimulus model), we explore how both inter-subject correlation (ISC) and stable event patterns change with maturation and other phenotypic variables. Preliminary results indicate that ISC increases with age in the auditory cortex (from 0.51 to 0.60, p = 5e-4), intraoccipital sulcus (from 0.45 to 0.52, p = 0.003), fusiform gyrus (from 0.50 to 0.57, p = 0.002), and posterior middle temporal gyrus (from 0.43 to 0.50, p = 0.005). These results indicate that age, and the increase in life experiences that accompany it, induce more coherent neural responses in both sensory and higher-level processing regions.

Title: Parietal hyper-connectivity is associated with low math performance during adolescence

Authors: *R. A. ABREU-MENDOZA[1], M. PINCUS[1], Y. CHAMORRO[2], E. MATUTE[2], M. J. ROSENBERG-LEE[1];
[1]Rutgers Univ., Newark, NJ; [2]Inst. de Neurociencias, Univ. de Guadalajara, Guadalajara, Mexico

Abstract: In childhood, hyper-connectivity of the intraparietal sulcus (IPS) with frontal, parietal and temporal-occipital regions has been associated with poor math achievement in both rest (Jolles et al., 2016) and task (Rosenberg-Lee et al., 2015). However, no research to date has examined whether this same connectivity pattern is observed in later stages of development. Furthermore, most research has focused on comparing the lower end of the math ability spectrum to the middle; thus, little is known about the brain connectivity patterns of individuals with very high math performance.

This study aimed to determine whether whole-brain functional connectivity of the bilateral IPS, during rest, was modulated by math performance in adolescence. We collected task-free fMRI data of 42 adolescents (21 females, mean age = 16.42 years, SD = 0.78) with a wide range of math performance levels (1st - 99th percentile), as measured by the Math Computation subtest from the WRAT-4 (Wilkinson & Robertson, 2006). All participants had an IQ ≥ 80 on a short form of the WISC-IV (Wechsler, 2007), a reading speed score above the 10th percentile in the Reading a Text Aloud subtest from the Neuropsychological Assessment for Children (ENI; Matute et al., 2007) and did not meet the diagnostic criteria for Attention-Deficit/Hyperactivity Disorder. To conduct the connectivity analysis, we used as seed regions the right and left IPS, defined by combining the right and left hIP1, hIP2, and hIP3 from the Jüelich histological atlas. Math performance was strongly correlated with IQ (r = .68), thus we used residualized math scores as our covariate of interest. Our main prediction was that lower math performance scores would be associated with higher connectivity between the IPS and other math-relevant brain regions.

Consistent with previous research, low math performance was correlated with higher connectivity from left IPS to a set of frontal (supplementary motor area, SMA), parietal (superior parietal lobule), and visual areas (inferior occipital gyrus and lingual gyrus). While connectivity from the right IPS to the right SMA was also associated with worse math performance, connectivity of this seed to left inferior parietal lobule was positively correlated with better math performance. Overall, these results suggest that across childhood and adolescence, hyper-connectivity of IPS may be a biomarker of low mathematical abilities.

Title: Using EEG to evaluate an early childhood intervention

Authors: *K. J. YE[1], A. SAMEK[3], K. J. YODER[2], J. DECETY[2], A. HORTACSU[1], J. A. LIST[1]; [1]Econ., [2]Psychology, Univ. of Chicago, Chicago, IL; [3]Econ., USC, Los Angeles, CA

Abstract: Early childhood interventions — such as preschool — are now observed to have a large impact on academic skills and Kindergarten readiness of disadvantaged children. While researchers and policymakers have argued for expanded preschool access, exactly *why* and *how* preschool works has remained a black box. This paper provides the first evidence that a large-scale early childhood intervention can change an important biological input to the education production function, children's executive function brain activity. We take advantage of the Chicago Heights Early Childhood Center (CHECC) RCT that randomized children to a free preschool or to a control group for a year. Following the intervention, we collected electroencephalogram (EEG) measures to assess the children's brain activity as a complement to ongoing behavioral assessments. We recorded event-related potentials (ERPs) from 72 4- to 6-year-old children (36 treated, 36 control; 33 female, 39 male) who participated in CHECC while they completed an academic and an executive function task, a modified Peabody Picture Vocabulary Test (PPVT) and Animal Go-Nogo (AGNG), respectively. Our main outcome measures are academic and executive function ERP components: N4, which measures language processing, and N2 and P3, which measure attention and effort. We find evidence that the CHECC preschool had an impact on executive function brain activity during AGNG: compared to children in the control group, the treated children had lower N2 mean amplitude ($p<0.05$) measured at the Cz electrode. Furthermore, the N2 mean amplitude is predictive of longer-term executive function skills. Three years after the end of the CHECC intervention (and after the EEG data collection), we recruited children from our EEG sample to participate in a behavioral follow-up assessment of their academic and executive function skills. We find that our EEG measures collected are predictive of children's scores in the three-year follow-up, above and beyond the predictive power of baseline abilities. All results use linear regressions with gender, age, race, and baseline ability controls.

Title: Understanding the role of cortico-cerebellar circuits in supporting cognitive control

Authors: *M. AVERY[1], B. CAMPBELL[2], N. MATTHEWS[2], A. G. MACHADO[3], K. B. BAKER[4];
[1]Case Western Reserve Univ., Cleveland, OH; [2]Cleveland Clin. Lerner Col. of Med., Cleveland, OH; [3]Ctr. Neurolog. Restoration, [4]Dept. of Neurosci., Cleveland Clin., Cleveland, OH

Abstract: The cerebellum is thought to play an important role in movement and cognition through its widespread interactions with cerebral cortical and subcortical structures (Romer et al. 2018). We have shown previously that chronic stimulation of the dentate nucleus (DN), a major ascending output pathway of the cerebellum, can modulate cortical excitability and lead to improvements in stroke recovery through enhanced functional reorganization of motor circuitry (Baker et al. 2010). That work is currently being translated to humans, with chronic, post-stroke patients undergo unilateral implantation of an eight-channel deep brain stimulation (DBS) lead in the DN contralateral to the affected cerebral hemisphere. As part of that procedure, the proximal end of the lead is externalized for a period of time post-surgery, which allows for the recording of DN local field potentials in conjunction with scalp EEG. Here, we present data addressing how communication between the cerebellum and cortex is coordinated in order to facilitate cognitive control. Patients performed an anti-saccade task in which they had to saccade towards or away from a visually-presented cue. Saccading away from the cue is thought to actuate cognitive control mechanisms partially mediated by frontal cortex and cortico-cerebellar circuits. DN LFP and scalp EEG data were time-locked to task events. Our results suggest that patients exhibit deficits in the anti-saccade task, marked by slowed reaction time and errors in voluntary but not involuntary saccadic movements. Electrophysiological recordings from the DN and EEG surface electrodes showed task-mediated modulation of activity in both the DN and frontal cortex during anti-saccade trials. Specifically, we saw frequency-specific alterations in the beta band during anti-saccade trials. This suggests that stimulation within the beta frequency may be able to promote improvement in certain aspects of cognition. Future experiments will incorporate stimulation of the DN at various frequencies to assess frequency-specific improvements or impairments in performance.

Title: Does layer 5 of the cortex project to the thalamic reticular nucleus? Implications for core and matrix thalamocortical circuits and sleep spindles

Authors: A. YAZDANBAKHSH, ***B. ZIKOPOULOS**;
Boston Univ., Boston, MA

Abstract: Two distinct thalamocortical (TC) circuits with reciprocal components can be identified in mammals: The core TC circuit, prevalent in sensory thalamus, drives activity focally in the middle cortical layers. In turn, these core thalamic neurons are innervated by small 'modulatory' cortical axon terminals from pyramidal neurons in layer 6 (L6). The matrix TC circuit, prevalent in high-order thalamus, has a complementary organization: large axon terminals from cortical layer 5 (L5) pyramidal neurons drive activity of matrix thalamic neurons that, in turn, innervate broadly and modulate the superficial cortical layers. Situated strategically between the thalamus and cortex, the inhibitory thalamic reticular nucleus (TRN) intercepts all TC communication. Projections from sensory or motor cortices to TRN terminate exclusively as small boutons and originate from L6, akin to core TC circuits. No studies have shown direct projections to TRN from cortical neurons in L5 that participate in matrix circuits. However, in comparison with other cortices, prefrontal cortices issue substantial projections to the thalamus from L5 and send similar driver-like projections to TRN, which terminate as large boutons and could potentially originate from L5. These large prefrontal axon terminals are similar to cortical boutons in the caudate nucleus and the amygdala, which originate mainly from L5. Based on this indirect evidence we tested the hypothesis that cortical L5 neurons project to TRN in matrix networks, by constructing a computational TC circuit that included core and matrix components with an optional cortical L5 to TRN projection (L5-TRN ON/OFF). Based on the features of TC circuits, our model was able to simulate relay and filtering of signals, and could initiate and propagate spindle oscillations. Activation of TRN neurons with L5-TRN ON in our model initiated spindle generation with different powers, depending on the level of cortical feedback and involvement of model core vs. matrix. Our preliminary findings are in agreement with hypotheses that spindles can be classified in core-generated, matrix-generated or mixed types, depending on the pathways involved in their generation, but only if L5-TRN is ON. Simulation

results indicate a more diffuse nature of spindles in matrix compared to core, with the mix type showing intermediate properties, suggesting that shifts in the engagement of distinct TRN, core, and matrix circuits may underlie typical sleep spindle generation and states of vigilance. Disruption of TC-TRN circuit balance may underlie seizures, atypical sensory reactivity, and deficits in sleep and attentional gating seen in autism and schizophrenia.

Title: Motor inhibition and motor-based response conflict share a common neural mechanism involving the subthalamic nucleus

Authors: *D. A. WALLER[1], A. SINGH[2], A. ESPINOZA[2], N. S. NARAYANAN[2], J. R. WESSEL[1];
[1]Psychology, Univ. of Iowa, Iowa City, IA; [2]Neurol., Univ. of Iowa Col. of Med., Iowa City, IA

Abstract: Recent research suggests that the same neural circuit underlying outright motor inhibition may also be involved during motoric response-conflict, induced by paradigms like the Simon task. This circuit, implemented in a fronto-basal ganglia network, relies on the subthalamic nucleus (STN) and internal segment of the globus pallidus (GPi) in the basal ganglia to implement inhibitory control. So far, the differential contributions of these two regions to motor inhibition and the resolution of response-conflict are unclear. The current study aimed to illuminate the causal role of both regions in motor inhibition and response conflict using deep brain stimulation (DBS). Eighteen patients with DBS implanted bilaterally in the STN (N = 9) or GPi (N = 9) completed a stop-signal and Simon task in both the DBS ON and DBS OFF states. Control samples of young, healthy adults (N = 21) and Parkinson's (PD) patients with no DBS (N = 20) were collected. Scalp EEG data was also collected from all subjects. Stop-signal reaction time (SSRT), a measure of outright stopping in the stop-signal task, was longer on average for PD patient controls (264ms) than healthy controls (223ms). Though DBS patients had SSRTs longer than both control groups, SSRTs for the ON state (307ms) were closer to both control groups than OFF state SSRTs (338ms), and therefore closer to the healthy baseline. SSRT was faster in the ON compared to the OFF state in both GPi ($t(8) = 2.17$, $p = 0.03$) and

STN patients ($t(8) = 1.80$, $p = 0.055$), which is in line with prior literature. In contrast, DBS only reduced the Simon reaction-time effect, a measure of response conflict, in STN patients ($t(8) = 2.62$, $p = 0.015$). The degree of response conflict in the Simon task was calculated by subtracting congruent trial RT from incongruent trial RT and dividing by congruent RT to yield a normalized difference score. These Simon effect scores with DBS ON (.079) more closely resembled Simon effect scores of healthy participants (.086), while DBS OFF scores (.095) were closer to scores of PD controls (.098). The Simon effect scores and SSRTs for STN patients with DBS on were positively correlated ($R^2 = 0.66$, $p = .008$): subjects with shorter SSRTs also yielded less conflict interference. These results indicate a common mechanism shared by outright motor inhibition and resolution of motor-based response conflict, which appears to rely on the STN and not the GPi. This aligns with theories that DBS as treatment for movement disorders may work by interrupting a pathologically overactive inhibitory basal-ganglia pathway, restoring it to a closer-to-baseline state.

Title: Hippocampal connectivity with sensorimotor cortex during volitional finger movements: Evidence for volitional control

Authors: *D. D. BURMAN, B. PETROVIC, J. MEYER;
Northshore Univ. Healthsystem, Evanston, IL

Abstract: Cognitive control refers to brain processes involved in regulating behavior according to internal goals or plans. This study examines whether hippocampal connectivity with sensorimotor cortex during paced movements shows a pattern of spatial and temporal selectivity required for cognitive control. Functional magnetic resonance imaging activity was recorded from thirteen right-handed subjects during a paced, non-mnemonic (repetitive tapping) motor task. Connectivity was examined from psychophysiological interactions in hippocampal activity during two analyses: the first identified motor interactions relative to rest, whereas the second identified differential motor activity between adjacent fingers. Connectivity was observed in both pre- and postcentral gyrus, but only postcentral connectivity was topographical, coincident with finger representations identified in a previous study. Differences in the magnitude of connectivity were observed between finger representations, representing spatial selectivity for the target of movements; the postcentral representation of the moving finger invariably showed

greater connectivity than adjacent fingers. Furthermore, the magnitude of connectivity within a pre- or postcentral finger representation was largest when its finger moved, representing temporal selectivity for movement. While the hippocampus is known to be sensitive to spatial and temporal features of the environment, consistent with its role in learning and memory, the pattern of spatial and temporal selectivity of hippocampal connectivity observed in this study occurred during volitional movements in the absence of motor learning or recall. Spatial and temporal selectivity of connectivity during volitional movements meets the criteria for cognitive control adapted from oculomotor studies, suggesting a role for the hippocampus in motor control.

Title: Characterizing higher-order thalamo-cortical projection patterns in humans

Authors: *A. M. HOWELL[1], S. WARRINGTON[2], J. JI[1], B. ADKINSON[1], C. FONTENEAU[1], S. N. SOTIROPOULOS[2], J. D. MURRAY[1], A. ANTICEVIC[1];
[1]Div. of Neurocognition, Neurocomputation, & Neurogenetics (N3), Yale Univ., New Haven, CT; [2]Univ. of Nottingham, Nottingham, United Kingdom

Abstract: Thalamic systems form the nexus of virtually all brain-wide information flow. Specifically, higher-order thalamic systems, such as the mediodorsal nucleus of the thalamus (MDThal), exhibits extensive projections to prefrontal cortex (PFC), which support higher-order executive computations and behavior. However, higher order thalamo-cortical projections in humans remain understudied. Recent non-human primate work in rhesus macaques has demonstrated an organized pattern of MDThal-PFC projections whereby most PFC regions display topographically-ordered projections to MDThal sectors. However, one PFC area - namely cingulate area 24 (CA24) - exhibits a unique projection pattern, which spans all of MDThal. This type of anatomical mapping has not been characterized in humans, which is critical to inform functional mechanisms of how MDThal-to-PFC projection may subserve higher cognition. The current study tests if MDThal-PFC projection patterns established in rhesus macaques generalize to humans. Using diffusion weighted imaging (DWI) we computed a whole-brain probabilistic tractography (wbPT) (Behrens et al., 2007) solution, from which we quantified MDThal-PFC projections using Human Connectome Project data (n=337 unrelated; HCP-1200 release). We leveraged recently-developed neuroanatomically informed constraints on the DWI wbPT solution to more specifically examine MDThal-PFC diffusivity. In turn, we

tested if CA24-to-MDThal tractography exhibits a focal or diffuse projection patterns in humans. This thalamic tractography result provides key constraints for interpreting how higher order PFC-to-thalamus functional interactions may be shaped in humans, which are shaped across neurodevelopment and profoundly altered by mental illness. Ultimately, establishing a unified multi-modal cortico-thalamic topography in humans is vital to inform how brain-wide information flow shapes complex behavior.

Title: Neurocognitive processes associated with reduced top-down control of prepotent eye movements in autism spectrum disorder

Authors: *S. E. KELLY[1,2,3], L. M. SCHMITT[4], J. A. SWEENEY[5], M. W. MOSCONI[1,2,3]; [1]Clin. Child Psychology, The Univ. of Kansas, Lawrence, KS; [2]Schiefelbusch Inst. for Life Span Studies, [3]Kansas Ctr. for Autism Res. and Training (KCART), Univ. of Kansas, Lawrence, KS; [4]Div. of Developmental and Behavioral Pediatrics, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [5]Psychiatry and Behavioral Neurosci., Univ. of Cincinnati, Cincinnati, OH

Abstract: Impairments in inhibitory control (IC), or the ability to suppress a dominant behavioral response, are common in individuals with autism spectrum disorder (ASD). Multiple psychological and neurophysiological processes contribute to successful IC, though the extent to which these distinct processes are affected in ASD is not known. We previously have documented that individuals with ASD show a reduced ability to proactively delay response onset during a manual stop-signal task which contributes to failures inhibiting contextually inappropriate responses. Relative to manual movements, eye movements are highly automated, more difficult to inhibit, and more closely linked to discrete neurophysiological processes. Characterizing IC of eye movements in ASD may provide key insights into spared and affected psychological and neurophysiological processes. Sixty individuals with ASD aged 5-29 years and 63 age- and gender-matched typically developing controls completed an oculomotor stop-

signal task (i.e., countermanding). During this task, the majority of trials were GO trials, on which participants made rapid eye movements (i.e., saccades) toward peripheral targets (12 degrees to the left or right of center). The remaining trials were STOP trials, on which a stop signal appeared at variable intervals following the peripheral target (i.e., stop signal delays) to cue the participant to inhibit the saccade. Stopping accuracy (i.e., the percent of STOP trials successfully inhibited), estimated reaction time of the stopping process (SSRT), and reaction time slowing on GO trials (RT slowing) compared to a baseline RT task were examined. Individuals with ASD exhibited reduced stopping accuracy and RT slowing and faster SSRTs compared to controls. For both groups, stopping accuracy was positively related to RT slowing and not related to SSRT. Increased age was associated with higher stopping accuracy and RT slowing, and these relationships did not differ across groups. The results indicate that individuals with ASD show a reduced ability to inhibit and proactively delay prepotent eye movements, while reactive stopping abilities are unaffected. Impaired IC was strongly and selectively associated with deficits in their ability to strategically delay response onset rather than reactively inhibit responses. These findings implicate reduced top-down control via fronto-striatal inhibition of brainstem circuitry in ASD, provide new targets for addressing clinical issues of IC, and suggest that tests of proactive control of eye movements may be useful for testing treatment efficacy and clarifying neurophysiological mechanisms of key clinical outcomes in ASD.

Program, [4]Dept. of Psychology, Yale Univ., New Haven, CT; [5]Dept. of Psychology, Univ. of Ljubljana, Ljubljana, Slovenia; [6]Dept. of Psychiatry, Vanderbilt Univ. Sch. of Medicine,, Nashville, TN

Abstract: Brain networks linking cortex to thalamus are critical for cognitive, sensory, and motor function. Dysruption of thalamocortical networks has been implicated in the pathophysiology of neurodevelopmental disorders, including psychosis, and mechanisms of clinical phenotypes, especially cognitive impairment. More specifically, patients with schizophrenia and bipolar disorder consistently show a combination of thalamic hypo-connectivity with the prefrontal cortex and thalamic hyper-connectivity with the sensorimotor cortex. However, critical knowledge gaps remain with respect to the normal developmental trajectory of thalamocortical networks and onset of thalamocortical disturbances in psychosis. In addition, very little is known about how individual differences in thalamocortical connectivity relate to cognitive impairment in individuals expressing psychosis spectrum symptoms. With this in mind, the aim of our study was to characterize the thalamocortical network development across the mental health spectra. Using multi-modal neuroimaging data, we assessed the functional and structural connectivity in healthy and at-risk participants from several available large-scale cross-sectional datasets (Philadelphia Neurodevelopmental Cohort (n=1601, ages 8-21); Cambridge Center for Ageing and Neuroscience (n=656, ages 18-88); Nathan Kline Institute-Rockland Sample (n=932, ages 6-85); Pediatric Imaging, Neurocognition, and Genetics dataset (PING: N=1239, ages 3-20)). Furthermore, our study also characterized the association between individual differences in thalamocortical connectivity and executive functions, in order to put forth a mechanistic model of normal variation in cognitive function and cognitive impairment in youth with psychosis spectrum symptoms. In particular, we focused on the medial-dorsal nucleus of the thalamus known to play a critical role in executive functions. Identifying the neural correlates of psychosis spectrum symptomatology may provide intervention targets for improving outcomes in youth with psychosis spectrum symptoms, biomarkers for stratifying at-risk individuals, and inform etiological and dimensional models of psychosis.

Title: A 20-minute single-bout of aerobic exercise optimizes psychological arousal and improves executive function

Authors: *N. AYALA, M. D. HEATH;
Univ. of Western Ontario, London, ON, Canada

Abstract: A single-bout of aerobic and/or resistance training provides a short-term 'boost' to executive function. This improvement has been linked to increased regional cerebral blood flow and a concomitant increase in task-dependent activity within frontoparietal networks. It is, however, possible that the observed post-exercise benefit is additionally related to a general enhancement in psychological arousal; that is, the improvement is attributed to both low- and high-level executive benefits. To address this issue, we employed pupillometry to examine whether psychological arousal contributes to an exercise-induced improvement in executive function. Notably, changes in pupil size during a goal-directed saccade task have been reliably shown to reflect overall arousal (i.e. tonic locus ceruleus neural activity) as well as task-dependent neural activation (i.e. phasic neural activity) within the superior colliculus (SC)- a region providing retinotopic coordinates for saccades and mediated via direct projections from frontal executive networks. In the present study, participants (N=20) completed a 20-minute aerobic exercise session (via cycle ergometer at 80% HR_{max}). Pre- and post-exercise oculomotor performance and pupil dynamics were assessed via pro- and antisaccades. Prosaccades are a stimulus-driven response requiring a saccade to veridical target location, whereas antisaccades entail a response mirror-symmetrical to target location and are mediated via an extensive frontoparietal executive network. Results showed: (1) a pre- to post- exercise decrease in pro- and antisaccade reaction times ($p=0.041$), (2) decreased post-exercise tonic pupil size ($p<0.001$), and (3) increased task-dependent phasic pupil dilations ($p=0.045$). Accordingly, the results demonstrate that saccadic performance is associated with a decrease in arousal- closer to an optimal level of arousal for task engagement- and augmented phasic recruitment of neural resources following aerobic exercise. Accordingly, we propose that improved post-exercise executive function is- in part- related to enhanced psychological arousal.

Title: Neuromodulatory brainstem activity predicts intrinsic co-fluctuations in cortical activity

Authors: *R. L. VAN DEN BRINK[1], O. COLIZOLI[1], J. W. DE GEE[2], T. H. DONNER[1]; [2]Neurophysiol. und Pathophysiology, [1]Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: The ascending arousal systems of the brainstem send widespread projections to the cortex, from which they release modulatory neurotransmitters that alter the dynamics of their cortical target circuits. As such, these brainstem systems are ideally situated to induce coordinated state change across widespread cortical regions. Here, we used fMRI in humans to examine co-fluctuations between cortex-wide activity and multiple neuromodulatory brainstem nuclei: the basal forebrain (BF), ventral tegmental area (VTA), substantia nigra (SN), dorsal raphe (DR), and locus coeruleus (LC). We characterized co-fluctuations between these nuclei themselves, their relationship with pupillary indices of arousal, and examined their contribution to cortical activity fluctuations in two datasets and behavioral contexts: (i) trial-to-trial fluctuations of rapid responses evoked by a challenging perceptual choice task (2AFC random dot motion discrimination, N=15); and (ii) ongoing fluctuations during fixation of an otherwise blank screen ('rest', N=24). We used anatomical atlases to delineate brainstem nuclei, physiological noise regression to suppress respiratory and cardiac artifacts, and seed-based partial correlation analysis to evaluate co-fluctuations (with pupil or cortical dynamics) unique to each brainstem nucleus.We found positive partial correlations between pupil diameter and VTA and DR (task), SN (rest), LC and BF (task and rest). In both behavioral contexts, activity in most brainstem nuclei co-varied with activity in other brainstem nuclei and in widespread cortical regions. Task-evoked responses in all nuclei showed exclusively positive correlations with the cortex, with the strongest correlations for BF and LC. Evoked responses in the VTA and SN showed small correlations when locked to stimulus onset but more widespread correlations when locked to performance feedback. Remarkably, correlations between DR and cortex dissociated between behavioral contexts: positive correlations during task, but negative correlations during rest. Our findings suggest that neuromodulatory brainstem arousal systems control widespread cortical state changes on different timescales. We delineate, for the first time, the unique contribution of individual neuromodulatory systems to such changes. Our results also indicate that brainstem activity is an important factor shaping intrinsic co-fluctuations in cortical activity, which are often interpreted as expressions of intra-cortical network interactions.

Title: Parasympathetic arousal related cortical activity is associated with attention during cognitive task performance

Authors: *A. D. BARBER[1], M. JOHN[2], P. DEROSSE[1], M. L. BIRNBAUM[1], T. LENCZ[1], A. K. MALHOTRA[1];
[1]Feinstein Inst. for Med. Res., Manhasset, NY; [2]Mathematics, Hofstra Univ., Hempstead, NY

Abstract: Parasympathetic arousal is associated with states of heightened attention and well-being. Arousal may affect widespread cortical and subcortical systems across the brain, however, little is known about its influence on cognitive task processing and performance. Healthy adult participants (n=20) underwent multi-band echo-planar imaging (TR = 0.72 seconds) with simultaneous pulse oximetry recordings during the performance of the Multi Source Interference Task (MSIT), the Oddball Task (OBT), and during rest. Processing speed on both tasks was robustly related to heart rate. Participants with slower heart rate responded faster on both the MSIT (33% variance explained) and the OBT (25% variance explained). Within all participants, trial-to-trial fluctuations in processing speed were robustly related to the heartbeat-stimulus interval, a metric that is dependent both on the concurrent heart rate and the stimulus timing with respect to the heartbeat. Models examining the cardiac-BOLD response revealed that a distributed set of regions showed arousal-related activity that was distinct for different task conditions. Across these cortical regions, activity increased with slower heart rate. Arousal-related activity was distinct from task-evoked activity and it was robust to the inclusion of additional physiological nuisance regressors into the models. For the MSIT, such arousal-related activity occurred across visual and dorsal attention network regions. For the OBT, this activity occurred within fronto-parietal regions. For rest, arousal-related activity also occurred, but was confined to occipital regions. The pulvinar nucleus of the thalamus showed arousal-related activity during all three task conditions. Widespread cortical activity, associated with increased parasympathetic arousal, may be propagated by thalamic circuits and contributes to improved attention. This activity is distinct from task-evoked activity, but affects cognitive performance and therefore should be incorporated into neurobiological models of cognition and clinical disorders.

Title: The neural basis of inter individual differences in episodic memory performance

Authors: *L. GEISSMANN, D. COYNEL, D. J. DE QUERVAIN;
Univ. of Basel, Basel, Switzerland

Abstract: Background. Group-based fMRI activation studies have revealed several brain regions related to episodic memory (EM) by showing voxel clusters that are more active during encoding of subsequently remembered vs. not remembered items. However, much less is known about the neural basis of the substantial variability in EM performance across subjects. Here, we investigated inter-individual differences in EM performance using a conventional voxel-based approach and a network-based approach. The latter approach might be particularly well-suited as cognition stems from networks of interacting brain regions, rather than from isolated brain regions.
Methods. In an fMRI task, healthy young subjects (n = 1434) encoded 72 pictures and were asked to freely recalled them after 10 min. First, the fMRI data were decomposed using a group-based ICA (d = 60 components [ICs]) to extract task-based functional connectivity networks. This decomposition was conducted in two separate subsamples (n = 590 and n = 580) to test for the ICA solution's stability. Time-courses for all 60 ICs were extracted for each subject with dual regression and used to estimate the individual responsivity of the networks to the presented stimuli, by means of linear models. We then calculated responsivity scores for each subject, each IC, and each voxel, to correlate them with EM (brain behavior correlation). Responsivity scores were based on encoding-specific first-level contrast estimates and available for all voxels throughout the brain (voxel-based approach) and all 60 ICs (network-based approach). Individual responsivities were then correlated with EM performance (*FWE*-corrected).
Results. The voxel-based approach revealed brain behavior correlations in the left precuneus/PCC, OFC, SFC, left cerebellum, and bilateral hippocampal formation. The network-based approach revealed brain behavior correlations in 6 FCNs. These FCNs partly match well-known resting-state networks, such as the default mode network and executive control network, and were reproducible in both subsamples (r > |.7|).

Conclusions. This study reports a neural basis of inter-individual differences in EM performance using two different approaches. Compared to the voxel-based approach, the network-based approach revealed additional brain behavior correlates of EM. EM relies on sensory processing and cognitive integration during encoding. This fits with brain regions covered by the 6 FCN.

Title: Hierarchical bayesian analyses reveal individual differences in the neural dynamics of response inhibition

Authors: *M. F. MOLLOY, G. BAHG, Z.-L. LU, B. M. TURNER;
Psychology, The Ohio State Univ., Columbus, OH

Abstract: Response inhibition is widely used to examine differences in executive functioning between different groups, often comparing stopping abilities between clinical populations and healthy controls. However, individual variability has been found to be intrinsic to cognitive control tasks. Hence, an examination of response inhibition would ideally involve an accurate estimation of both group- and individual-level effects. Hierarchical Bayesian analyses account for individual differences by simultaneously estimating group and individual factors and compensate for sparse data by pooling information across subjects. Hierarchical Bayesian models are thus an ideal tool for studying response inhibition, especially when analyzing neural data. We constructed hierarchical Bayesian models of the functional magnetic resonance imaging (fMRI) neural time series, constructing hierarchies across conditions, subjects, and regions of interest (ROIs). In previous work, we demonstrated that in models of the BOLD time series data, constructing a hierarchy across conditions and subjects provided the best balance between model fit, generalizability, and constraint. The hierarchical structure constructed across ROIs provides additional information about functional connectivity. Here, we applied this modeling technique to response inhibition to explore the sources and prevalence of individual differences within the neural dynamics of response inhibition. First, we ran a simulation study to compare our hierarchical Bayesian models to a conventional GLM. We found that the models we constructed out-performed a standard analysis in separating signal from noise in fMRI data, especially when accounting for individual and trial-to-trial variability. Second, we applied our model to go/no-go and stop-signal fMRI data from eleven participants (mean age = 24.6 years; 5 females and 6 males). The simultaneous group and individual estimates revealed the different dynamics in going, not going, and stopping on a group level while preserving individuality. Finally, analyses

of coactivation between ROIs estimated by the models demonstrated the prevalence of individual differences within functional connectivity across the two tasks. The ubiquity of individual differences in neuroscience and cognitive processes is becoming clear. We demonstrate the utility of hierarchical Bayesian modeling in not only accounting for these differences, but using these differences to help us further understand cognition.

Title: Partitioning heritability analalysis unveils the genetic architecture of human brain functional connectivity patterns

Authors: *J. FENG, G. XUE;
State Key Lab. of Cognitive Neurosci. and, Beijing, China

Abstract: Resting state functional connectivity profile has been increasingly shown as an important endophenotype that is tightly linked to human cognitive functions and psychiatric diseases, yet the genetic architecture of this multidimensional trait is barely understood. Using a unique sample of 1534 unrelated, young and healthy Chinese Han individuals, we revealed significant heritability of functional connectivity patterns in the whole brain and different subnetworks. We further proposed a partitioned heritability analysis for multidimensional functional connectivity patterns, which revealed the common and unique enrichment patterns of genetic contribution to brain connectivity patterns for several gene sets linked to brain functions. In particular, we found that genes linked to functional connectivity (FC) or expressed preferentially in the central nervous system (CNS) showed enriched contribution to heritability in almost all significantly heritable networks, whereas the SNPs associated with intelligence (IQ) or educational attainment (EA) showed enrichment primarily in cognitive control networks including medial frontal network, frontoparietal network and their combinations. Interestingly, gene sets associated with different psychiatric conditions, including autism (ASD), attention deficit hyperactivity disorder (ADHD), and schizophrenia (SCZ), showed both common and

unique patterns of enrichment. SCZ-associated SNPs only showed enrichment in the medial frontal network, ASD and ADHD-associated SNPs both were enriched in the frontoparietal network, additionally, ASD-associated SNPs were enriched in the executive control network (the combination of medial frontal and frontoparietal networks). This novel knowledge of the genomic architecture of neuroimaging endophenotypes provides new insight to link genes, brain and behaviors, which will allow us to better understand the genetic and cognitive mechanisms underlying various psychiatric conditions, and eventually guide the developmental of effective diagnoses and treatments.

Title: Mixed handedness predicts academic achievement of university students

Authors: *G. PLUCK[1], P. BRAVO MANCERO[2];
[1]Univ. San Francisco De Quito, Quito, Ecuador; [2]Univ. Nacional de Chimborazo, Riobamba, Ecuador

Abstract: Hand preference is linked to cerebral hemisphere dominance. This is seen, for example, in language lateralization. People with a preference for their right hand are highly likely to have language lateralized to the left hemisphere. For people with a preference for their left hand, language lateralization on the right hemisphere is much more common. However, the implications of variation in hemisphere dominance and lateralization are poorly understood. In children, having no hand preference, i.e. being at the 'hemispheric indecision point', appears to have a negative impact on cognitive processes, as reflected in lower school grades. In contrast, laboratory studies with adults have shown that mixed handedness, i.e. not showing a strong preference for either left or right hands, is associated with better declarative memory. We studied the association of mixed handedness with academic grades in a sample of 120 undergraduate students (60 engineering and 60 psychology). All were assessed with the Edinburgh Handedness Inventory, a self-report measure of hand preference which provides a continuous measure of mixed handedness, and measures of intelligence (Matrix Matching Test) and psychological distress (General Health Questionnaire-28). The latter were included as both tend to correlate with academic grades and may mask associations between handedness and academic achievement. Sex was covaried due to the differences between the groups. The results confirmed that intelligence was positively correlated ($r = .154$, $p < .05$) and psychological distress was negatively correlated with academic grades ($r = -.159$, $p < .05$). There was a positive but non-

significant correlation between mixed handedness scores and academic grades. However, with intelligence and psychological distress scores covaried, the partial correlation between mixed handedness and grades was significant ($r = .204$, $p < .05$). The correlation of greater mixed handedness associated with higher academic grades appears to be independent of the material studied as it is similar in magnitude in both the Engineer ($r = .193$) and Psychology ($r = .203$) groups. Although a relatively weak association, and only revealed with potential confounders controlled for, the results suggest a benefit to mixed handedness. This association is likely therefore to be a consequence of low hemispheric dominance, which seems to provide some small advantage in educational achievement. This could possibly act through more efficient cognitive processing. Nevertheless, further research is needed to replicate the current finding and identify mechanisms through which mixed handedness may provide an advantage in higher education.

Title: Inter-subject representational similarity analysis reveals phenotype-specific patterns of brain activity during movie watching

Authors: *E. S. FINN[1], A. KHOJANDI[1], D. A. HANDWERKER[1], P. J. MOLFESE[1], *P. BANDETTINI[2];
[2]Section on Functional Imaging Methods, [1]NIMH-NIH, Bethesda, MD

Abstract: Naturalistic tasks, such movie watching, are an ecologically valid way to study brain function in human neuroimaging experiments. Such stimuli evoke patterns of brain activity that are, by and large, highly consistent across subjects, yet there exist meaningful individual differences atop this shared variance. Here, we use inter-subject representational similarity analysis to determine if and how similarity of brain activity during movie watching is related to similarity of behavioral phenotypes. Subjects (n = 89 unrelated; Human Connectome Project) underwent fMRI scanning (~60min, 7T, voxel size = 1.6 mm^3, TR = 1s) while viewing a series of video clips from documentary or Hollywood-style films. Subjects also completed several behavioral measures outside the scanner. We calculated inter-subject correlation (ISC) for each of 268 nodes in a whole-brain atlas (brain similarity), and related this to behavioral similarity for various traits modeled using two different distance functions (Fig 1, left column). Results

showed widespread representational similarity between brain responses and phenotypes, the nature of which differed by trait (Fig. 1). For some traits, this relationship was best modeled by a Euclidean distance function, in which subjects look most similar to their nearest neighbors, regardless of absolute score—e.g., subjects with more similar responses on the NEO Five-Factor Personality Inventory had more similar brain responses in several regions, irrespective of their absolute trait scores (extraversion, openness, etc.). For other traits, similarity scaled monotonically (increasing or decreasing) with absolute score, such that, for example, pairs of subjects with faster reaction times on an emotion recognition task showed higher ISC than pairs of subjects with slower reaction times across much of the brain. We conclude that inter-subject similarity of brain responses during movie watching shows nuanced relationships with phenotypes, suggesting the potential for a movie-based "stress test" to draw out individual variation of interest.

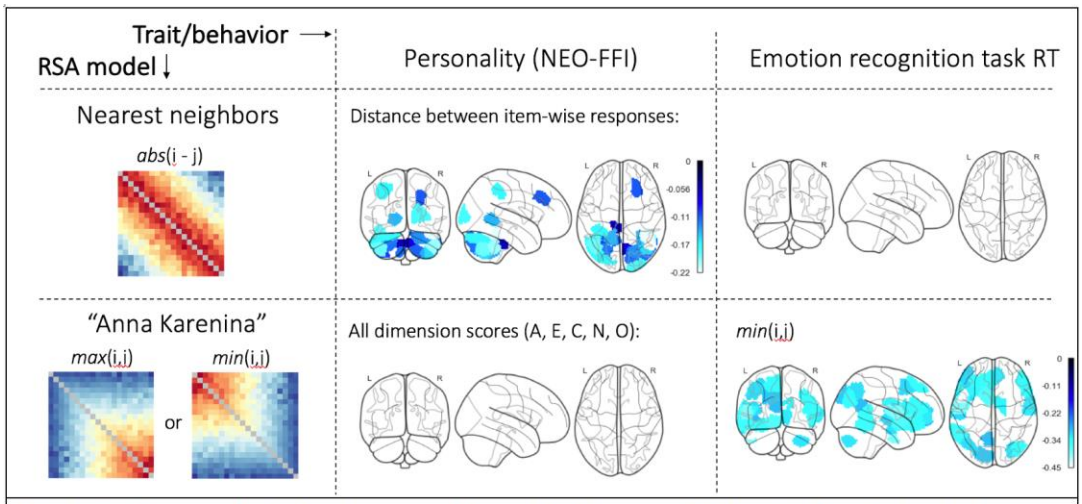

Fig. 1. Capturing relationships between inter-subject brain and behavioral similarity. Left column: simulated inter-subject correlation matrices, where each row (*i*) and column (*j*) corresponds to a subject, and subjects are ordered by score on a behavioral phenotype. Warm (cool) colors denote higher (lower) predicted similarity of brain response for two different potential RSA models ("nearest neighbors" and "Anna Karenina"). Some traits (e.g., personality) are better modeled by a "nearest neighbors" distance function (middle panel, top row; cool colors reflect the expected inverse relationship between Euclidean distance and brain similarity), while other traits or behaviors (e.g., reaction time on an emotion recognition task) are better modeled by an "Anna Karenina" distance function, in which all fast responders are alike, while all low responders are less similar (again, cool colors reflect the expected inverse relationship, such that subject pairs with a lower minimum reaction time show more similar brain responses). All results calculated based on a 268-node whole-brain atlas, with nodewise representational similarity p-values determined via permutation test (n = 10,000) and displayed at $p < 0.05$, FDR corrected.

Title: Predictive utility of functional connectivity vs. voxel activation

Authors: *C. G. HABECK, Q. R. RAZLIGHI, Y. STERN;
Cognitive Neurosci. Div., Columbia Univ., New York, NY

Abstract: Functional connectivity has become a major focus of cognitive neuroimaging research in the last 1.5 decades, for both resting-state as well as task-related imaging. Given the abundance of task-related data, empirical comparisons of the predictive utility of voxel activation vs. functional connectivity are easy to undertake and enable rigorous apples-to-apples comparison in identical held-out data. We investigated the differential predictive utility of both modalities, for different ages and cognitive outcomes. Two hundred and forty six participants aged 20 to 77 underwent fMRI for 12 cognitive tasks, pertaining to 4 cognitive domains: episodic memory (MEM), fluid reasoning (FLUID), perceptual speed (SPEED), and vocabulary (VOCAB) (Habeck, Gazes et al. 2016, Habeck, Eich et al. 2018). Functional connectomes were computed after scrubbing and motion-confound regression to arrive at 264 x 264 task-and-subject connectivity matrices (Power, Cohen et al. 2011, Power, Barnes et al. 2012, Carp 2013). Standard first-level time-series modeling was performed with FSL to derive task-and-subject maps. Data for each cognitive domain were stacked, resulting in 246*3=738 task-and-subject observations. We then performed extensive split-sample simulations to probe quasi-replication with 1000 iterations, for which 240 observations were randomly sampled as a training data set, and 60 different observations were randomly picked as the test set, repeatedly. Training and test sets are independent within, but not across, iterations. We ran a simple PCA-regression to estimate a regression model which could then be applied to the held-out data to venture a prediction of the cognitive outcome of interest. The predictive utility in the held-out data was quantified with the Predicted Residual Sum Of Squares (PRESS) statistic between predicted and actual outcomes. Apart from the single-modality predictions, a combined average ("vote") was considered too. We found that connectivity only showed superior predictive utility for select cognitive outcomes and age groups considered in this study, and thus did not prove superior across the board. The results confirm the continued importance of voxel activation data, at least for empirical success of brain-behavior prediction. Further, regardless of data modality, out-of-sample prediction showed better success for younger than older participants, suggesting that both

task-related activation and connectivity determine task performance in older participants to a lesser degree than in younger participants.

Title: Physiological and cognitive factors underlying perceptual variability in a sensory system

Authors: M. MANTEL, C. MANESSE, A. FOURNEL, C. ROUBY, C. FERDENZI, ***M. BENSAFI**;
Ctr. De Recherche En Neurosciences De Lyon, Bron, France

Abstract: Perceptual variability is a characteristic of sensory experience: the same environmental stimulus can lead to distinct behavioral responses in different individuals. An issue raised and not yet clearly elucidated in behavioral and cognitive neuroscience concerns the role of physiological and cognitive factors in this variability. What is the weight of age, gender, culture, motivation, etc. in this perceptual diversity? The present study attempted to answer this question in a sensory system where variability is the rule, namely olfaction. The study of perceptual variability raises two methodological challenges: the first deals with sample size, and the second with the representativeness of the used stimulations. Here, we considered these 2 challenges by setting up a large-scale study in more than 5000 individuals who were asked to rate 8 representative odors (i.e food, non-food, pleasant, unpleasant odors, etc.) in an online psychophysical experiment. Participants were asked to identify and rate the odorants along several perceptual dimensions (intensity, familiarity, pleasantness, irritation and edibility). A large number of factors that could potentially influence olfaction were also collected, including sex, age, BMI, cultural background, culinary habits, smoking habits, sensory diseases, etc. Preliminary analysis showed than 77% of the variance in perceptual ratings could be explained by two main factors. The first one was highly correlated to odor hedonics and edibility. The second factor was highly correlated to irritation evoked by the odors. This reinforces the idea that both olfactory and trigeminal dimensions intervene perception of smell. We also found some sources of variability in the individual space: identification performances were higher among women and correlated to neophilia scores. Moreover, age, a variable known to highly influence olfactory abilities, was not related to identification abilities but was rather correlated to the perceptual experience of odors, as they were more pleasant, but also less intense and irritating as

the participants got older. These preliminary results contribute to draw a portrait of olfactory perception and its diversity among a large population.

Title: The brain network of personality traits and cognition

Authors: L. PIRETTI[1], T. CERNI[1], D. CHECCHI[2], R. JOB[1], ***R. RUMIATI**[3];
[1]Dept. of Psychology and Cognitive Sci., Univ. of Trento, Trento, Italy; [2]Dept. di Economia, Mgmt. e Metodi Quantitativi, Univ. degli Studi di Milano, Milano, Italy; [3]Area of Neurosci., SISSA, Trieste, Italy

Abstract: Personality plays an important role in determining individual differences in academic and life outcomes[1]. However, the mapping between personality-related brain areas and cognition is still poorly understood. Here we investigated whether the grey matter (GM) of personality-related brain areas might correlate with cognitive skills. 83 participants underwent t1-weighted structural magnetic resonance imaging and were administered the Big Five Inventory[2]. Literacy and numeracy were also assessed in a participants' subset. First, voxel-based morphometry (VBM) was performed to investigate the brain areas associated with each personality trait. Results showed that local GM concentration in the occipital cortex bilaterally, right supramarginal gyrus and left dorsolateral prefrontal cortex (dlPFC) inversely correlated with neuroticism. Openness directly correlated with the local GM in right medial orbitofrontal cortex and left cerebellum, and inversely with right amygdala and hippocampus. Moreover, GM inversely correlated with agreeableness in the occipital cortex bilaterally, and conscientiousness within left postcentral gyrus. By extracting from each peak of activation the average GM concentration within an 8mm sphere. Second, to test eventual links between personality-brain areas and cognitive skills, the region of interest (ROI) derived from VBM analysis was correlated with 43 participants' literacy and numeracy scores. Among the clusters associated with neuroticism, only the local GM concentration in the left dlPFC (r = -0.31, p < .05) inversely correlated with the numeracy score. In addition, grey matter concentration in right amygdala and hippocampus, that inversely correlated with openness, also inversely correlated with both numeracy (r = -0.32, p < .05) and literacy scores (r = -0.37, p < .05). Our results suggest that GM of specific brain areas is associated with specific personality traits which, in turn, are linked to participants' cognition.

Title: Tracking gray matter footprints of neurally distributed cognitive functions

Authors: E. AKPAN, G. E. KOCH, *M. N. COUTANCHE;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The gray matter volume of particular brain regions can reflect a person's cognitive and affective functioning, as well as their experience. Anatomical metrics from neuroimaging scans have been successfully related to individual differences in navigational experience, anxiety, developmental IQ, prior physical activity, and more. When a cognitive function of interest is closely linked to a specific brain region, an anatomical analysis can target a particular region-of-interest. In cases where cognitive functions are represented across widely distributed brain regions, however, a whole-brain exploratory approach is the most frequently used method. This method has a number of limitations, particularly the strong multiple-comparison correction required, which limits its potential for detecting brain-to-behavior relationships. We report the development of a novel method that leverages a massive synthesis of functional results to measure the distributed "gray matter footprint" (GMF) underlying a cognitive function. This approach is both data and hypothesis driven, as it draws on a synthesis of thousands of studies to identify distributed voxels that are associated with a particular cognitive function. Specifically, Neurosynth, an automated meta-analytical online resource that synthesizes functional imaging data from thousands of studies, is combined with a participant's segmented gray matter map to measure the volume of gray matter associated with a cognitive function. We provide a proof-of-concept by predicting individuals' reported semantic memory usage from their semantic-memory GMFs. A leave-one-subject-out support vector regression trained on subjects' GMF can predict the semantic memory scores of untrained participants, supporting the method's predictive potential.

Title: Assessment of individual differences in navigation by diffusion MRI connectometry

Authors: *J. M. SMITH, E. R. CHRASTIL;
UCSB, Santa Barbara, CA

Abstract: Navigation is arguably one of the most important behaviors associated with survival. Although a common, optimized strategy among individuals within a species could be advantageous, in reality, navigation has an incredible degree of variability, both between individuals and between groups. This variability is poorly understood, largely due to the complexity of the systems involved and lack of methods for studying individual differences in cognition.The current study is part of a multi-modal imaging approach to assess individual differences in navigation. Subjects explored an unfamiliar virtual maze environment and were tasked with remembering the location of objects throughout the maze. To assess performance, subjects were asked to start at one object and navigate to a target object on each trial. During this phase, all of the objects were replaced with identical red spheres, thus, a memory of the environment is required to successfully navigate to the correct object. Diffusion spectrum imaging was conducted just prior to the navigational task (139 directions, TR=4300, TE=100.2ms, b-max=4990). After scanning, the diffusion images were preprocessed with QSIPrep and analyzed with the connectometry toolbox software DSI Studio. Connectometry is a permutation based approach that provides higher reliability and replicability with less false positives than standard diffusion imaging analysis. Preliminary analysis on a subset (n=48) of our subject pool found extremely apparent tracks associated with high task performance that project from the middle of the brain into the cerebellum ($P = 0.002$, $t > 3.00$, $FDR < 0.05$). An alternative fiber bundle, which appears to terminate in the same cerebellar region, is negatively correlated, suggesting an alternative pathways in those who performed poorly. Previous findings of cerebellar activity suggests its role in navigation is related to self-motion information processing. The results of our current study provide evidence that the cerebellum is one of the key brain regions responsible for differences in navigational capability. These findings suggest promise for diffusion connectometry as a useful toolbox in analyzing individual differences in cognition.

Title: Genes to memory: Multi-level omics data integration of quantitative trait loci linked to memory in two independent samples

Authors: *V. VUKOJEVIC[1], V. FREYTAG[1], A. MILNIK[1], A. PAPASSOTIROPOULOS[1], D. J. DE QUERVAIN[2];

Abstract: A large amount of phenotypic variability of complex traits, e.g. cognitive performance, is driven by the underlying genetic architecture. Therefore, understanding the genetic basis of the quantitative trait variation, e.g. quantitative trait loci (QTL), is one of the major challenges in current biology of complex cognitive traits. In the present study we performed a genome wide analysis of DNA methylation and expression cis-QTLs (meQTLs and eQTLs, respectively) in a European sample of healthy young adults (N = 533). We validated our findings in an independent sample of similar size and origin (N = 319), and further investigated the association of the significant loci with episodic and working memory performance across two samples. Finally, we extended our analysis with the metabolomics data in both samples, and identified those QTLs that share conserved effects on cognitive traits from DNA to metabolite level. The cross-investigation of cis-meQTLs in the discovery and replication sample revealed 154'135 unique meQTLs (corrected for 1.4×10^{11} tests; 448'243 CpGs, 313'505 SNPs). These meQTLs were significantly associated to 19'929 unique CpGs, targeting a total of 8'599 genes (FDR of 5%). The same set of SNPs was additionally enriched in eQTLs: 37'721 SNPs associated to 6'578 transcripts (4'330 genes, 67% concordance with meQTLs overlapping genes; FDR of 5%). Data integration with the metabolome data assessed in the same samples (771 metabolites, 54'619 metabQTLs; FDR of 5%) revealed a significant proportion of QTLs shared from "genes to metabolites" (3'692 shared QTLs, 945 unique genes; targeting 89% of the measured metabolites). A second level analysis revealed that these shared QTL CpGs were also related to cognitive phenotypes across two investigated European samples (255 SNPs/42 metabolites and 172 SNPs/25 metabolites, for episodic and working memory respectively). Our findings suggest that there a significant proportion of multi-level omics QTLs that also show an enrichment of significant hits in association analyses with complex traits, like cognitive performance. This is of special importance for studies that rely on proxy tissues, like in the case of cognition and psychiatric disorders, and might provide novel biomarkers or drug targets.

Title: Heritability of individual variant sub-types in functional brain networks

Authors: ***B. A. SEITZMAN**[1], C. N. LESSOV-SCHLAGGAR[2], B. ADEYEMO[1], A. DWORETSKY[3], B. T. KRAUS[5], S. E. PETERSEN[1,3,4,8,9], C. GRATTON[5,6,7];

Abstract: Many recent research efforts have focused on uncovering individual differences in functional brain networks measured with fMRI data. We have recently demonstrated the presence of stable localized regions of the brain where individuals differ from the typical group-average network organization - regions we call network variants. Evidence suggests that network variants are systematically organized; they appear in characteristic regions of the brain and tend to associate with particular functional networks. Moreover, the distribution of network variants across individuals clusters into at least two distinct clusters or subgroups in multiple datasets. Given these trait-like properties, here we investigated the heritability of network variants. We exploited the familial design of the Human Connectome Project, analyzing resting-state fMRI data from monozygotic (85 pairs) and dizygotic twins (46 pairs), non-twin siblings (64 pairs), and unrelated individuals (N = 362). We only included individuals with greater than 45 minutes of high-quality, low-motion data to ensure within-subject reliability of network variants (variant stability issues are discussed extensively in an accompanying abstract). From these data, we identified variant locations and functional network memberships by comparing individual-specific data to a group-average of 120 typical young-adults. Then, we clustered individuals into network variant sub-types on the basis of the distribution of their variants.
As has been described previously, overall network structure shows significant heritability.

Interestingly, network variant sub-types also showed significant heritability: monozygotic twin pairs were significantly more likely to have the same sub-type of variant distribution than any other relationship pairing. This may suggest that some network structure heritability derives from common patterns of individual differences.
Overall, our results suggest that network variant sub-types may be partially affected by genetic influences. In addition, the results point to strong environmental contributions to distributions of network variants.

Title: Stability of individual variations in functional connectivity across states

Authors: *B. KRAUS[1], B. A. SEITZMAN[3], A. DWORETSKY[4], S. E. PETERSEN[5], C. GRATTON[2];
[1]Psychology, [2]Psychology, Neurology, Northwestern Univ. Interdepartmental Neurosci. Program, Northwestern Univ., Evanston, IL; [3]Neurol., [4]Radiology, [5]Neurology, Psychological and Brain Sciences, Radiology, Neuroscience, Biomed. Engin., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Precision imaging is a technique utilizing large amounts of data to obtain reliable functional connectivity (FC) MRI measures of large-scale networks at the individual level. With this method it is possible to examine brain regions where an individual's network patterns deviate from group averages, which we call network variants. Network variants may prove to be valuable substrates for understanding individual differences in brain organization and how they relate to individual differences in behavior. We recently demonstrated that network variants are consistent within resting-state sessions of an individual with >40 minutes of artifact free data. However, one disadvantage of this method is that many current datasets do not have enough resting-state FC data to reach high reliability. If network variants are trait-like markers of individual differences in brain organization, it is possible that they will also be identifiable during task periods as well as rest (i.e., exhibiting stability across states) - opening up additional datasets for variant analysis.
Here we test this hypothesis by asking whether network variants identified from task fMRI data show a high degree of similarity to those seen during resting-state. In order to quantify variant similarity across states, we measured network variants during both task and rest in the Midnight

Scan Club dataset and measured the similarity in their locations via Dice overlap. As a comparison, we also examined the degree of variant overlap across individuals as well as within a given state (task or rest) across independent runs. We found that network variants showed a high degree of overlap across states (Dice = 0.62). This overlap was much higher than that seen across participants ($t(8) = 25.7$, $p < .001$, $d = 8.58$). However, network variant overlap across-states was still significantly lower than overlap within states (Dice = 0.73; $t(8) = 8.5$, $p < .001$, $d = 2.85$), although the effect was smaller. Overall, these findings indicate that network variants are fairly stable across task and rest states within participants relative to what would be expected across participants. However, a systematic difference is still present across states.
These findings suggest that variants are relatively more trait-like in their stability within individuals, but still carry some state-sensitivity. Our results suggest that it is feasible to measure individual differences, in the form of network variants, in a task-state, with the caveat that there are some systematic differences with resting-state FC. Future work will examine interactions between task state and individual differences on FC to better understand their sources.

Title: Probabilistic mapping of human functional brain networks identifies regions of high inter-subject consensus

Authors: *A. DWORETSKY[1], B. A. SEITZMAN[2], B. ADEYEMO[2], M. NETA[6], R. S. COALSON[1,2], S. E. PETERSEN[1,2,3,4,5], C. GRATTON[7,8,9];

Abstract: While considerable headway has been made in advancing our understanding of functional network organization in the human brain, most studies have focused on representing data averaged across groups of individuals. However, recent work has demonstrated that individual differences in functional network organization are common and widespread, and that averaging across subjects may conceal such differences. These findings, therefore, warrant a re-examination of past group studies in light of individual variation. To this end, we produce a

probabilistic representation of 14 canonical brain networks that leverages information on both group consensus and individual specificity. Further, we present a set of publicly available tools derived from this representation that will enable researchers to apply information about individual variability and consistency across a variety of experimental contexts.
Specifically, voxelwise templates were created for each of 14 canonical brain networks. These templates were applied to each of 69 high-data individual subjects, producing 69 individual network maps. These maps were then overlaid to produce a voxelwise representation of network probability across subjects for each cortical location, both in volume and on the cortical surface. The resulting map shows separable "core" regions of very high reliability (consistent network assignments across >90% of individuals), and regions of high variability between the cores. Individual networks vary in the size of their core and in the extent of their surrounding higher variability components. Further, we show that regions with high variability validate previous findings on the distribution of regions with high inter-subject network variability and with a high occurrence of topological network variants.
Along with a nuanced exploration of reliability and variability, this probabilistic representation allows for novel methods of exploring other functional datasets and experiments. First, a set of high-probability network sensitive regions of interest (ROIs) are generated, which can be applied to group datasets to analyze the most consistent core regions of each network. Second, a voxelwise point-and-click probability tool is created which allows researchers using Connectome Workbench to explore the network membership probability of individual locations in their own data in task, structural, or resting-state studies.

Title: Neural oscillations and nursery rhymes (an EEG study into individual differences in infant language development)

Authors: *A. ATTAHERI[1], A. NI CHOISDEALBHA[1], P. BRUSINI[1,2], S. ROCHA-THOMAS[1], S. FLANAGAN[1], N. MEAD[1], P. BOUTRIS[1], S. GIBBON[1], H. SCOTT[1], H. AHMED[1], I. WILLIAMS[1], U. GOSWAMI[1];

Abstract: The synchronisation of cortical oscillations with different patterns of temporal information in the speech signal may be key in how the brain processes language. Our current research focuses on individual differences between infants in the entrainment of low frequency neural oscillations (delta band, ~2Hz, and theta band, ~5 Hz) in early development to both speech and non-speech inputs. In spoken language, a 2Hz rhythm reflects the production of stressed syllables, which are produced approximately twice a second across languages. Modulation energy in the delta band (0.9 - 2.5 Hz) is increased in infant directed speech (IDS) compared to adult directed speech (ADS), and across languages lullabies and nursery rhymes also converge on a 2 Hz beat rate. Our hypothesis is that accurate entrainment to a 2 Hz "beat" may provide a foundational entrainment rate across languages, offering a rhythmic skeleton upon which other language units (words, syllables, rhyme, phonemes) may be scaffolded. To test this, we are conducting a longitudinal assessment of infants from 2 months to 2.5 years of age. Our primary measures use EEG to measure oscillatory entrainment to different inputs (simple drum beat, rhythmic repetition of syllable 'ta' and phrasal prosody via nursery rhymes). We focus on the entrainment of these low frequency EEG oscillations to features from the language stimulus, across the first year of life (2-11 months). Infants are followed up between 12 and 30 months, using a range of phonological, morphological and vocabulary assessments. We report preliminary findings suggesting individual differences in the EEG responses to audio visually presented nursery rhymes at 4, 7 and 11 months. We first report individual differences in stimulus envelope reconstruction using a linear modeling technique (mTRF toolbox), with early indications that this entrainment correlates to language comprehension by infants. Secondly, we show phase amplitude coupling (PAC) in response to nursery rhymes and how this changes longitudinally during the first year of life. By tracking longitudinal measures through infant development, these results show the potential importance of individual differences in neural entrainment in predicting later language outcomes.

Title: Local DTI patterns predict fMRI language task activation with group-level precision

Authors: *D. G. ELLIS, M. R. AIZENBERG;
Neurosurg., Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: A fundamental assumption of neuroscience is that brain function is determined by brain structure. Even in healthy populations, both brain structure and brain function vary between individuals and groups. We hypothesize that individual and group differences in functional brain activation can be predicted by localized structural patterns of diffusivity. To this aim, we trained a convolutional neural network (CNN) to predict language task-fMRI (tfMRI) activation maps using only the maps of local mean diffusivity and fractional anisotropy as measured by the diffusion tensor model. The model reads in a 64mm x 64mm x 64mm image centered on a vertex on the pial surface. The model then predicts the language activation at that vertex. After training on 595 subjects, the model was used to predict the language activation maps for a validation group of 300 (128 male) subjects. To assess the model's ability to accurately predict variations between groups of subjects, a linear support vector machine (SVM) was trained to predict gender based on the parcellated actual fMRI language responses of the training group. The SVM was then used to predict the gender of the validation group using only the CNN predicted fMRI language data. The predicted fMRI data was able to predict gender with an area under (AUC) the receiver operating characteristic (ROC) curve of 0.69, which is significantly greater than chance ($p < 0.01$). This study demonstrates that local structural patterns are predictive of group-level variations in language task activation. Future research could utilize local DTI patterns in combination with fMRI data to provide functional mappings that are more robust to noise. From a clinical perspective, DTI patterns could be used to estimate functional activation in patients that have not undergone functional mapping.

Title: Cortical networks associated with the human anterior medial temporal lobe estimated within the individual using intrinsic functional connectivity

Authors: *D. REZNIK[1], L. M. DINICOLA[1], R. M. BRAGA[1,2], P. ANGELI[1], R. L. BUCKNER[1,3,4];
[1]Harvard Univ., Cambridge, MA; [2]Stanford Univ., Stanford, CA; [3]Massachusetts Gen. Hosp., Boston, MA; [4]Harvard Med. Sch., Boston, MA

Abstract: Monkey anatomical tract-tracing studies indicate entorhinal, perirhinal and parahippocampal cortices are connected with multiple cortical regions in a manner that is characterized by both distinct and similar topography. Human functional connectivity studies have recapitulated several of these features (Greicius et al., 2004 *PNAS*; Vincent et al., 2006 *JNeurophys*; Kahn et al., 2008 *JNeurophys*). Recently, human explorations have revealed that canonical distributed networks defined using group-averaged data are divisible into two or more spatially distinct networks when estimated with individuals. More specifically, it was demonstrated that the canonical default network (DN) can be divided into at least two distinct networks, DN-A and DN-B, and that DN-A (but not DN-B) includes the posterior MTL (parahippocampal cortex; Braga & Buckner, 2017 *Neuron;* Braga et al., 2019 *JNeurophys*). Although imaging the anterior MTL is a challenge due to its sensitivity to magnetic susceptibility artifacts, here we examined this region in detail and explored the hypothesis that anterior portions of the MTL might associate with distinct cortical networks that have been hidden in prior analyses. We estimated the organizational properties of networks associated with entorhinal, perirhinal and parahippocampal cortices from resting-state data in eight densely sampled individuals (fixation data collected during 54.6 to 430.5 minutes). Consistent with previous findings, whole-brain correlation maps with seed regions placed in posterior parahippocampal cortex pointed to DN-A. Whole-brain correlation maps with seed regions placed in entorhinal and perirhinal cortices provided initial evidence for distinct distributed networks. Interestingly, inspired by these preliminary findings, examination of publicly available resting-state fMRI data from 4181 individuals released by the UK Biobank (a large-scale population based study) with seed regions placed in the group entorhinal and perirhinal cortices pointed to networks that reflect the topography we observed in individual subjects. These results provide further insight into the neuroanatomical organization of the human MTL.

Title: Fast temporal characterization of distributed association networks within the individual using intracranial recording and repeated sampling functional MRI

Authors: *R. M. BRAGA[1], C. A. SAVA-SEGAL[1], R. A. POLDRACK[2], J. PARVIZI[1]; [1]Neurol. and Neurolog. Sci., Stanford Univ., Stanford, CA; [2]Psychology, 450 Serra Mall Bldg. 420, Stanford, CA

Abstract: The cerebral association cortex is organized into networks that are distributed across frontal, parietal, temporal and midline association zones. Analysis of functional MRI (fMRI) data from repeatedly sampled individuals reveals that canonical networks, such as the default network, comprise two or more networks when defined within the individual (Braga and Buckner 2017). The distinction between networks has been replicated across multiple individuals and analysis methods (Braga et al. 2019). However, questions remain regarding to what extent the network distinctions correspond to differences in local neural activity, as well as long-distance coupling at faster frequencies. Further, it is unclear whether neighboring networks engage in cross-talk over short timescales and/or at frequencies that are not detectable by conventional fMRI.

To address these questions, we delineated the distributed networks with precision in an individual with intractable epilepsy who was scheduled for intracranial monitoring with stereo-electroencephalography as part of their routine presurgical evaluation. A primary aim was to establish that repeated sampling fMRI could in principle be performed, and the previously observed network distinctions be reproduced, in this population.

In a presurgical MR session, fMRI data (2.4 mm, 1.0 sec TR) were acquired during three runs of a fixation task, each lasting 7 min 2 sec. The patient was compliant, though complained of sleepiness at the end of the session. Several steps were taken to minimize movement, and the patient provided good quality data (mean and maximum framewise displacement range: 0.122–0.142 mm and 0.543–0.586 mm). Data were processed using the 'iProc' pipeline (Braga et al. 2019), which is optimized for individual-subject registration, and includes upsampling to 1mm resolution. Data were smoothed at 3 mm FWHM.

Initial analyses confirmed that the default network could be separated into two parallel networks

within this patient as previously reported in non-clinical subjects (Braga and Buckner 2017). Registration of the MRI data to the patient's CT image, containing the location of implanted electrodes, was performed using the iELVis pipeline. In the posteromedial and dorsal prefrontal cortices, side-by-side regions belonging to the two networks overlapped with implanted electrodes, suggesting that neighboring and distant regions of the two networks were being sampled. This work provides proof-of-principle that precision mapping is viable in presurgical epilepsy patients. Ongoing work is characterizing the networks at high temporal frequency and optimizing the data collection protocol for future patients.

Title: Proof-of-concept longitudinal tracking of brain change within individual patients using repeated acquisitions of rapid structural scans

Authors: *L. C. HANFORD[1], J. A. NIELSEN[2], R. W. MAIR[1,3], J. A. COLLINS[3,4], M. QUIMBY[3,4], M. C. ELDAIEF[3,4], B. C. DICKERSON[3,4], R. L. BUCKNER[1,3,4];
[1]Harvard Univ., Cambridge, MA; [2]Brigham Young Univ., Provo, UT; [3]Massachusetts Gen. Hosp., Charlestown, MA; [4]Harvard Med. Sch., Boston, MA

Abstract: A major limitation of translational neuroimaging is reliability and sensitivity to change within the individual. To overcome this limitation, we explored estimating longitudinal change in structural brain images by collecting numerous repetitions of rapid acquisitions at each timepoint (Nielsen et al., 2019, *bioRxiv*). Individuals with expected increases in brain volumes (patients with Major Depressive Disorder receiving treatment) and expected decreases in brain volumes (patients with neurodegenerative disease including semantic dementia and posterior cortical atrophy) were enrolled. At each timepoint, a total of 4 sessions of 8 or 9 Multi-Echo MPRAGE T1-weighted images were acquired with vNAV to track within-acquisition motion (2.2mins, resolution:1.2mm, see Mair et al., 2012, *ISMRM*; Holmes et al., 2015, *Sci Data;* Nielsen et al. 2019). Sessions were spread out across two separate days. Subjects were tracked across 3 timepoints over 6 months, totaling 96 to 108 independent scans per subject. Despite the large number of scans, participants found this burden low and manageable, largely owing to the time in the scanner being brief. Images were processed using Freesurfer v6.0. Metrics were motion- and scan-order adjusted. Patients with MDD following TMS treatment showed increased total brain volume (0.49%, 1.54% annualized increase), and maintained or increased

hippocampal volume (0.01%, 0.68%). Patients with neurodegenerative disease showed decreased total brain volume (-2.46% to -1.11% annualized decrease), as well as hippocampal volume reductions (-4.37% to -2.46%). Estimated total intracranial volume, used as a control measure given its stability, changed minimally. Measurement error, estimated as the absolute difference in measurements for acquisitions across days within the same timepoint, was below 0.2% for eTIV and below or near 1.0% for cortical and hippocampal measures. These results provide support for adopting rapid, repeat scanning methods to achieve measurement stability within individuals in longitudinal designs. We discuss these results as well as ways to further improve sensitivity and reduce measurement error. Scan time can be further reduced by adopting even faster wave-CAIPI or compressed-sensing MPRAGE variants (able to achieve 1.0 mm scans in a minute, or sub-mm scans in a few min). Through repeated sampling, we can further interrogate sources of noise such as head position, and local B0 inhomogeneities. The goal of this work is to provide tools to measure clinically-relevant brain change in individuals or small groups as would be enrolled in targeted clinical research studies or early-stage clinical trials.

Title: Human structural connectomes are heritable

Authors: J. CHUNG, B. D. PEDIGO, C. PRIEBE, *J. T. VOGELSTEIN;
Johns Hopkins Univ., Baltimore, MD

Abstract: Understanding heritability, or the extent to which genes and environment determines human brain connectivity and structure, is important for improving our understanding of brain function and diseases. Current methodologies study connectomes estimated from neuroimaging data, such as diffusion and functional MRI, by computing graphs features, such as small

worldness, modularity, etc, which are difficult to interpret. This study leverages a statistically principled procedure for studying a population of connectomes, and show that the structural connectomes are heritable and strongly related to familial relationship.
Using the Human Connectome Project Young Adult S1200 dataset (n=985, age=22-37), structural connectomes are obtained from diffusion MRI (dMRI) via deterministic diffusion tractography. Flood-filled Desikan-Killiany atlas (83 region of interest (ROIs)) was used to parcellate the brain. Each connectome is embedded into *d* dimensions using adjacency spectral embedding (ASE) to obtain latent variables for each ROI. Distances between connectomes are obtained by computing the Procrustes distance of a pair of embeddings for all pairs of monozygotic (MZ, n=125 pairs), dizygotic (DZ, n=130 pairs), siblings (SIB, n=712 pairs), and unrelated (UN, n=1000 pairs) individuals. Unrelated pairs, defined as two individuals not sharing a mother or father, were sampled such that the distribution of difference in age were identical to that of SIB in order to control for age effects.
Distances between MZ connectomes were stochastically smaller than those of DZ, SIB, and UN, while the distances between UN connectomes were stochastically larger than those of MZ, DZ, and UN. The distances of DZ were stochastically larger than that of MZ, but smaller than that of SIB. This stochastic ordering suggest that the distance between a pair of connectomes is highly related to the genetic similarity between the individuals. Furthermore, order of DZ and SIB suggest age or environmental influences on brain structure since they share similar genetic variance. This claim is validated via two-sample Kolmogrov-Smirnoff (KS) test of distributions. The null hypothesis state that a pair of distance distributions are the same, and the alternate hypothesis is that one distribution stochastically larger than the other. Alternate hypothesis were formed for all six pairs of distributions while maintaining the stochastic order. (MZ < DZ, MZ < SIB, MZ < UN, DZ < SIB, DZ < UN, SIB < UN). Using a significance level of 0.05, KS tests find that there is a statistically significant difference in distributions for all tests.

Title: cBRAIN: Tracking all individuals and marking their brain activity for the study of collective brain research

Authors: *C. KIM[1,2], J. KIM[1,3], W. YOUM[4], S. LEE[4], J. CHOI[1,2];
[1]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [2]Univ. of Sci. and Technol., Seoul, Korea, Republic of; [3]Korea Univ., Seoul, Korea, Republic of; [4]Electronics and Telecommunications Res. Inst., Daejeon, Korea, Republic of

Abstract: Understanding the neural mechanisms underlying the collective behaviors in a group is limited by the ability to track each individual and monitor its neural activity at the same time. Traditional neural recording systems send information over wires restraining the animals' habitat or behavior, whilst recently introduced innovative approach using telemetry still has limited capacity in simultaneous measurement of multiple individuals in a group. Here, we describe a novel method, cBRAIN (collective brain research aided by instant neurodisplay), which was developed for the purpose of tracking the position and certain neural activity of all naturally behaving individuals in a group. Basically, the cBRAIN is composed of its hardware and algorithm. Firstly, the cBRAIN hardware includes a headstage, CCD camera, and data logger. The 3.5-g weighted headstage is a telemetry featuring recording and data transmission, and blue and red LED lights indicating the position and the occurrence of user-set neural activity, respectively. Also, the headstage contains an internal counter to sync between headstages and a programmable log array for LED trigger working in a recognition scheme to detect the moment when the neural activity of interests occurs. The data logger records raw data up to eight headstages with sampling rate which is tunable up to 20 kHz. The CCD camera records the optical signals with 10~170 Hz sampling rate and a resolution of 2048 x 1088. Secondly, the cBRAIN algorithm has three main purposes: (i) tracking the position of individual mouse, (ii) detecting the moment of red LED on and merging it into the position data, and (iii) statistical mapping such as space occupancy and location map of neural activities of interest, and presentation of inter-agent proximity for the study of collective motion of a group. Finally, we demonstrate a study of social hierarchy in a group using cBRAIN. A classification algorithm for identifying social behaviors such as fighting, chasing, sniffing, and huddling, built based on the tracking data, will be introduced. Lastly, the cBRAIN system therefore provides a promising ground for studying dynamic interplay between social and neural activities from naturally behaving individuals living in a group, and further associating the neural activities with collective behaviors of a group of mice.

Title: Resting state EEG in patient with completely locked in syndrome

Authors: *M. KHALILI ARDALI[1], U. CHAUDHARY[1], N. BIRBAUMER[2];
[1]Inst. For Med. Psychology and Behavioural N, Tuebingen, Germany; [2]Wyss Ctr. for Bio and Neuroengineering, Geneve, Switzerland

Abstract: Different studies have reported conflicting results on the cognitive capacity of Individuals in locked-In state (LIS), due to amyotrophic lateral sclerosis (ALS), ranging from degrading to intact cognitive capacity. While on the other hand, there is no information available on the cognitive capacity of Individuals in completely locked-In state (CLIS), due to amyotrophic lateral sclerosis (ALS), who are left without any means of communication. There has been a significant advancement in determining the capacity of consciousness of patients with disorders of consciousness (DoC) by employing information integration theory (IIT) based indexes and global workspace network (GWN). Despite these advances it is still both difficult and challenging to apply such methods to estimate the level of consciousness for Individuals in CLIS. Even before we could determine the level of consciousness of Individuals in CLIS, in this study we propose to investigate the basic neurophysiological properties using electroencephalogram (EEG) acquired from CLIS patients during the resting state. High density EEG signal acquired from 5 individuals in CLIS will be investigated to elucidate the time domain and spectral features, as well as connectivity metrics of EEG signal of individuals in CLIS, which will be compared which healthy population. Initial analysis of EEG of individuals in CLIS shows shift in the spectral features towards the lower frequency bands immediately after the transition to CLIS as well as significant decrease in the amplitude. In depth analysis as proposed in this study will be performed to explicate the neurophysiological properties underlying the resting state brain activity of individuals in CLIS. Such an analysis might prove to be the first step towards the goal to estimate the metrics for the capacity of consciousness of Individuals in CLIS.

Title: Human age is predicted by a strong multidimensional association of brain networks and behavioral factors

Authors: *B. MCPHERSON[1], F. PESTILLI[2];
[1]Psychological and Brain Sci., Indiana Univ. Bloomington, Bloomington, IN; [2]Psychology, Neuroscience, Cognitive Sci. and Network Sci., Indiana Univ., Bloomington, IN

Abstract: Human behavior and cognitive performance change across the lifespan. Behavioral and cognitive performance improves in many domains during early development and peaks shortly after adolescence. Brain network connectivity also peaks shortly after adolescence. The degree to which these two lifespan trajectories map onto each other is unclear. Further, researchers have only recently attempted to link brain network connectivity to specific behavioral and cognitive domains with human chronological age. We used a multivariate approach to simultaneously model multiple behavioral and brain network factors. Our analyses demonstrate a strong association between the brain network properties and performance in a variety of behavioral domains. To test the association between brain networks, behavioral domains, and age (CCA; Smith et al., 2015). We estimated the association between measures of performance from 334 behavioral tasks across seven domains with a 376 node network estimate of brain connectivity measured in 594 human individuals across the lifespan (18-88 years). We processed the raw data and generated multiple brain network measures using diffusion-weighted and anatomical MRI data from the Cambridge Center for Aging Neuroscience (Taylor et al., 2014) and the cloud computing platform brainlife.io (Avesani et al., in press). Brain networks were built using multi-shell diffusion models, probabilistic tractography to trace candidate fibers between brain regions (Takemura et al., 2016; Smith et al., 2014), and brain atlas (Glasser et al., 2017). We found that a single dimension of covariation strongly associates (r=0.86) measures of performance across seven behavioral domains. This single dimension of covariation predicted the held-out age of the individuals in the sample (r=0.66). This is the first study to report a single, strong association between performance across behaviors and brain networks predicting age. The results suggest that human age can be predicted by the synchronous degradation of structural brain networks and behavioral performance.

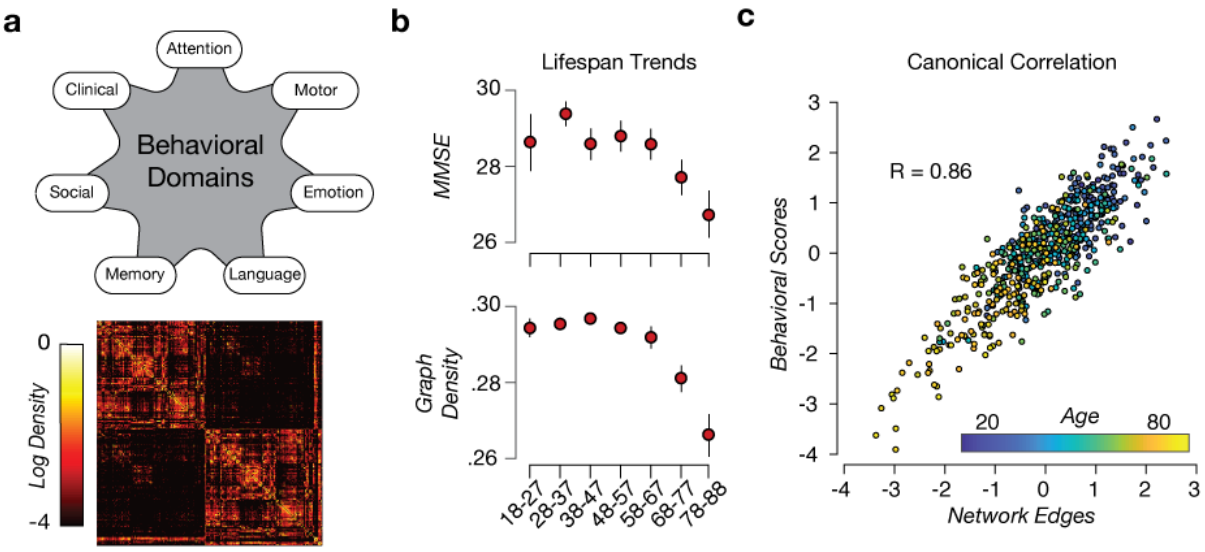

Figure 1. Covariation of behavior and brain networks across the lifespan. (a) *(top)* A diagram showing the behavioral domains used in the analysis. *(bottom)* One representative structural brain network reconstructed using tractography methods on brainlife.io. **(b)** *(top)* A representative example of the established lifespan trends reproduced in the Can-CAM dataset for one behavioral domain. The Mini-Mental State Examination (MMSE) shows declining cognitive ability across the lifespan. **(b)** *(bottom)* A representative example of the established lifespan trends observed in a brain network property. **(c)** Positive-negative single association axis linking behavior and brain networks using a canonical correlation analysis (R=0.86). Individual points in the plot are color-coded using each subject's age. The correlation between each subject's location in the association axis and the held-out age of the individual in the plot is high (R=0.66, not shown).

Title: Neurotrophic and antioxidant effects of risperidone improve dendritic spine dynamics in the prefrontal cortex of rats with neonatal ventral hippocampus lesion

Authors: *H. TENDILLA[1,2,3,4], R. A. VAZQUEZ-ROQUE[2], A. J. VÁZQUEZ-HERNÁNDEZ[2], D. MARTÍN-HERNÁNDEZ[3,4,5,6], K. MACDOWELL[3,4,5,6], L. GARCÉS-RAMÍREZ[1], J. LEZA[3,4,5,6], G. FLORES[2];

Abstract: Schizophrenia is a mental disorder whose etiology and mechanisms underlie neurodevelopmental disruptions. Psychosis, social isolation and cognitive deficits observed in schizophrenia has been related to prefrontal cortex (PFC) dysfunction, since gray matter loss and lack of dendritic spines has been described in this brain region. Second generation antipsychotics are the drugs of choice for schizophrenia. Apart from their dopamine/serotonin antagonism activity, some of these substances ameliorate the symptoms by other mechanisms such as anti-inflammatory, antioxidant, neurotrophic and neuroprotective effects. Neonatal ventral hippocampus lesion (NVHL) in the rat is considered a developmental schizophrenia-related model. Adult rats NVHL had decreased spine density and a reduction of mature spines in the PFC, associated with the disruption of the brain-derived neurotrophic factor/tyrosine kinase B (BDNF/TrkB) pathway. Also, reduced brain levels of nuclear factor (erythroid-derived 2)-like 2 (Nrf2), which promotes the synthesis of antioxidant enzymes, as well as increased protein levels of cyclooxygenase-2 (COX-2), a potent pro-inflammatory mediator, in the brain and periphery was observed in NVHL animals. The abovementioned settles oxidative/nitrosative stress in the PFC in the NVHL, that was evidenced by the increased lipid peroxidation. The atypical antipsychotic risperidone (RISP) restored the BDNF/TrkB pathway and reduced the oxidative/nitrosative stress in the PFC and periphery of NVHL rats, that is associated with the enhancement of the mature spine population. Thus, our data show the neurotrophic and antioxidant effect of RISP and its impact on dendritic spine remodeling in this rodent model, which highlight the link between brain development and immune response in order to understand mechanisms related to the schizophrenia pathophysiology.

Title: The effect of neonatal GSK3 inhibition on the regulation of behavioral deficits and neuromorphological alterations in AKT1 mutant mouse model of schizophrenia

Authors: *S.-C. WAN[1], T.-Y. JEN[2], W.-S. LAI[1,3,4];
[1]Dept. of Psychology, Natl. Taiwan Univ., Taipei, Taiwan; [2]Dept. of Life Science, Natl. Taiwan Univ., Taipei, Taiwan; [3]Grad. Inst. of Brain and Mind Sciences, Natl. Taiwan Univ., Taipei, Taiwan; [4]Neurobio. and Cognitive Sci. Center, Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Schizophrenia is considered as a neurodevelopmental disorder that leads to behavioral, neuronal, and biochemical abnormalities. Accumulating evidence suggests that *AKT1* (protein kinase Bα) contributes to susceptibility to schizophrenia and the AKT-GSK3 signaling pathway is involved in the pathogenesis of schizophrenia. GSK3, a key kinase modulating the development of the nervous system, is largely regulated by one of its upstream targets- AKT. Convergent evidence indicates a decrease in AKT1 protein levels and levels of phosphorylation of GSK3β in the peripheral lymphocytes and brains of individuals with schizophrenia. Furthermore, it has been found that direct inhibition of active GSK3 by GSK3 inhibitors alleviated the schizophrenia-like behaviors in adult *Akt1*$^{-/-}$ mice. Given the involvement of AKT-GSK3 signaling pathway in schizophrenia, here, we aim to investigate whether direct inhibition of GSK3 during early developmental period could rescue the behavioral deficits and neuromorphological alterations in adult *Akt1*-deficient mice. SB216763 (GSK3 inhibitor) was selected and administrated to both male and female *Akt1*$^{+/-}$ mice and their wild-type littermates every other day during postnatal day 7 to 27 (P7-27). Compared to vehicle controls, the administration of SB216763 resulted in a significant enhancement of phosphorylated GSK3α/β in the prefrontal cortex and hippocampus of *Akt1*$^{+/-}$ mice at P27. At 3 months of age, a battery of behavioral tasks was performed in these mice to evaluate their behavioral phenotypes, including the acoustic prepulse inhibition (for sensorimotor gating function), puzzle box (for problem solving), and fear conditioning (for associative learning and memory). Consistent with previous findings, our preliminary results indicate that *Akt1*$^{+/-}$ female mice displayed significant abnormality of prepulse inhibition, and *Akt1*$^{+/-}$ male mice exhibited potentially impaired performance on contextual fear conditioning. Both sexes of *Akt1*$^{+/-}$ mice also revealed different types of behavioral impairments in the puzzle box. Intriguingly, the neonatal administration of SB216763 seemed to somehow rescue observed behavioral deficits in these Akt1 mutant mice. Based on behavioral findings, we further analyze neuromorphological alterations in the prefrontal cortex and hippocampus using Thy1-GFP-M transgenic mice. The morphometric analysis is still in progress. Collectively, our findings suggest the involvement of AKT1-GSK3 signaling pathway in the pathogenesis of schizophrenia-related phenotypes and the early developmental inhibition of GSK3 in the treatment of schizophrenia, especially during neonatal stage.

Title: Investigating the role of the pre and postnatal maternal environments on offspring behavioural deficits in a rodent model of maternal immune activation

Authors: *H. G. POTTER, G. REVILL, R. M. WOODS, J. D. GLAZIER, J. C. NEILL, R. HAGER;
Fac. of Biology, Med. and Hlth., Univ. of Manchester, Manchester, United Kingdom

Abstract: Converging evidence from epidemiological studies and animal models has implicated maternal immune activation (mIA) as a risk factor for neurodevelopmental disorders such as schizophrenia. The transient increase in maternal pro-inflammatory cytokines, such as tumour necrosis factor-alpha (TNF-α), elicited following mIA is thought to perturb fetal neurodevelopment and results in cognitive deficits. Here, we employed a split-litter cross-fostering design to investigate how the prenatal (maternal cytokine response) and postnatal (maternal care) environments interact to predict offspring cognitive deficits in a rodent model of mIA. 22 female Wistar rats were timed-mated and treated with a single intraperitoneal injection of 10mg/kg bodyweight polyinosinic-polycytidylic acid (poly I:C; low-molecular weight, InvivoGen) or vehicle (endotoxin-free 0.9% saline) on GD15. A tail vein blood sample was taken 3h post-treatment to measure maternal cytokine concentration. Offspring were culled to 10 pups/litter on postnatal day 1 (PD1) and either crossed to a dam in the opposite treatment group or remained in their home litter. Offspring ultrasonic vocalisations (USVs) were recorded on PD6, 10, and 14 and analysed using the open-source MATLAB script MUPET. Offspring were tested on the attentional set-shifting task (ASST) in adulthood. Statistical analysis was carried out in SPSS using General Linear Models (GLM) and General Linear Mixed Models (GLMM). Prenatal exposure to poly I:C, independent of postnatal maternal effects, significantly increased the number of syllables emitted by female ($F_{(1,295)}$=16.65, $p<0.001$) and male ($F_{(1,298)}$=13.05, $p<0.001$) pups across all time-points. Cross-fostering had no effect on the number of syllables emitted by female ($F_{(1,295)}$=0.23, p=0.631) or male ($F_{(1,293)}$=0.91, p=0.341) pups. In adult female offspring, poly I:C caused an increase in the number of trials taken in the ASST ($F_{(1,11)}$=10.14, p=0.009). Furthermore, the concentration of the maternal TNF-α response predicted a more severe set-shifting deficit ($F_{(1,11)}$=5.70, p=0.036). Poly I:C induced a rise in maternal TNF-α concentration. Neonatal and adult offspring from poly I:C treated dams exhibited a range of behavioural and cognitive deficits. Prenatal exposure to maternal pro-inflammatory cytokines,

but not the postnatal maternal environment, affected USVs in male and female offspring. Our data suggests that the prenatal environment, specifically the maternal inflammatory cytokine response, is an important predictor of later life cognitive deficits and contributes to the pathogenesis of cognitive dysfunction.

Title: MicroRNA-206 signaling in cerebellar Purkinje cells regulates avoidance behaviors and sensorimotor gating

Authors: *M. P. HEYER[1], M. ISHIKAWA[1], G. FENG[2], P. J. KENNY[1];
[1]Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: The cerebellum is primarily known for its roles in motor learning and coordination. Emerging evidence suggests that the cerebellum also regulates more complex behaviors related to cognition, affect, and reward, and dysfunction in this brain structure may contribute to schizophrenia and other neurodevelopment disorders. The cerebellum shares extensive reciprocal connectivity with the neocortex, basal ganglia and hindbrain nuclei, and is thought to convey sensory experiences that shape cortical development and function. Nevertheless, the genes, cells, and circuits that govern cerebellar interactions with higher-order brain systems are poorly understood. Using brain-wide *in situ* hybridization, we find that the schizophrenia-associated microRNA, miR-206, is specifically enriched in cerebellar Purkinje cells. Mice with a targeted deletion of miR-206 exhibit impaired pre-pulse inhibition, an endophenotype of schizophrenia, increased innate fear-related and avoidance behaviors, and sex-dependent cognitive deficits. Pre-pulse inhibition impairments were recapitulated by conditional deletion of miR-206 in parvalbumin-expressing cells, including Purkinje cells, suggesting that altered cerebellar output may contribute to these behavioral abnormalities. Consistent with this possibility, the spontaneous firing frequency of Purkinje cells was increased in miR-206 null mice. Together,

these findings suggest that miR-206 regulates the function of cerebellar Purkinje cells and that this action controls cognitive, affective, and reward-related behaviors that are relevant to schizophrenia.

Title: Prenatal exposure to environmental factors affects protein expression of rat brain and increases risk of developing schizophrenia

Authors: H. LEE, H.-K. KIM, J.-T. KWON, *H.-J. KIM;
Clin. Pharmacol., Soonchunhyang University, Col. of Med., Cheonan / Chungcheongnam-Do, Korea, Republic of

Abstract: Exposing a pregnant female of early life to some environmental components (heavy metal and stress) may contribute to development of schizophrenia in adult offspring. We constructed an animal model of schizophrenia, which was induced by two environmental factor, low level of lead (lead acetate, 0.2% in drinking water) during pregnancy and lactation periods and a repeated-variable stress paradigm during the last week of gestation. Subsequently, our study aimed to investigate whether prenatally-stressed with lead (PNS-L) could affect behavioral impairment and expression level of protein associated with neurodevelopment. Behavioral and proteomic analyses were conducted in PNS-L adult offspring and controls. Many parameters changed in the offspring rats with environmental changes compared to those in non-exposed offspring in open-field, social interaction, and prepulse inhibition tests. Changes in the proteome of a brain tissue were detected by two-dimensional electrophoresis, and the 13 proteins exhibiting differential expression were identified by matrix-assisted laser desorption/ionizationetime-of-flight mass spectrometry. Down-regulation of two of these proteins, Pebp1 (phosphatidylethanolamine binding protein 1) and Prdx2 (peroxiredoxin 2), in PNS-L rat was confirmed by western blotting analyses. Our results suggest that Pebp1 and Prdx2 might be associated with environmental changes of early life and, thus, might be involved in the pathophysiology of schizophrenia.

Title: Neuronal avalanches in a developmental mouse model for schizophrenia

Authors: *S. R. MILLER[1,2], S. SENGUPTA[2], D. PLENZ[2];
[1]Univ. of Maryland Col. Park, College Park, MD; [2]Sect Critical Brain Dynamics, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: The healthy neural state in mammalian cortex is characterized by scale-invariant dynamics balanced between excitatory (glutamatergic) and inhibitory (GABAergic) contributions to cortical activity. Recent research has pointed to NMDA and GABAergic signaling dysfunction as causes of positive and negative symptoms in schizophrenia. However, the specific population-level manifestations of pathological cortical activity patterns are unknown. A common method of eliciting schizophrenia-like symptoms in rodents, perinatal exposure to the NMDA receptor antagonist phencyclidine (PCP), has revealed altered neuronal avalanche characteristics in adolescent rats. We hypothesize that changes in neural ensemble dynamics in excitatory and inhibitory cell populations in cortex may explain behavioral deficits in PCP-treated mice. By leveraging transgenic mouse lines and two-photon calcium imaging, we confirm our previous results in rats (Seshadri et al., 2018) which show power laws that fulfill scaling criteria in both normal and PCP treated groups.

Title: Impact of maternal immune activation and adolescent cannabinoid exposure on auditory mismatch responses in awake, freely-moving rats

Authors: A. DUNN[1], J. JALEWA[1], J. TODD[1], D. HODGSON[1], P. T. MICHIE[1], ***L. R. HARMS**[2];
[1]Univ. of Newcastle, Callaghan, Australia; [2]The Univ. of Newcastle, Callaghan, Australia

Abstract: Mismatch Negativity (MMN) is an auditory change detection response that is consistently found to be reduced in schizophrenia. This MMN impairment correlates with functional impairment in diagnosed individuals and is related to the cognitive impairments observed in the disorder, also of marked functional significance. For the past 10 years, strong evidence has emerged than mismatch responses, similar to human MMN, can be observed in rodents, particularly in rats. In this study, we aim to use mismatch responses as an outcome measure to examine a "two-hit" animal model of schizophrenia. We examined repetition suppression and prediction error, two elements of the mismatch response, believed to reflect simple neuronal adaptation processes and more complex predictive coding, respectively, in male and female rats exposed to maternal immune activation (MIA; 5mg/kg Poly I:C at gestational day 19), adolescent cannabinoid exposure (ACE; 0.075-0.1mg/kg/day HU-210 from postnatal day 35-48), neither exposure or both exposures. We also investigated whether these rats exhibited expected human-like attenuation and facilitation of the mismatch response in response to changing contingencies, such as increased difference between the expected and surprising auditory stimuli, and reduced probability of the surprising stimulus. Rats exposed to the two schizophrenia risk factors exhibited schizophrenia-like reductions in the mismatch response relative to controls and those exposed to either factor alone, which were due to reduced repetition suppression. All rats exhibited expected changes in mismatch response amplitude in line with shifts in experimental contingencies. These data indicate that rodent measures of MMN in general, and mismatch responses in our "two-hit" animal model, specifically, may provide a good platform for future preclinical drug development studies.

Title: Blocking PirB to grow new dendritic spines in the prefrontal cortex; a potential novel treatment for the cognitive deficits in schizophrenia

Authors: *H. MACNEIL[1], W. INOUE[2], B. L. ALLMAN[3], R. RAJAKUMAR[4];
[1]Neurosci., [3]Anat. and Cell Biol., [2]Univ. of Western Ontario, London, ON, Canada; [4]Anat. & Cell Biol., Univ. Western Ontario, London, ON, Canada

Abstract: Schizophrenia is a psychotic disorder consisting of positive, negative and cognitive symptoms. While the positive and negative symptoms of schizophrenia have relatively high treatment effectiveness, the cognitive deficits remain largely untreated, causing difficulties for many schizophrenia patients. The quantity of spines present within a set area along a dendrite (spine density) in the prefrontal cortex (PFC) is thought to underlie the complex neuronal structure of cognition. A marked reduction of dendritic spines on layer II/III pyramidal neurons in the PFC is a consistent pathological indicator of schizophrenia. Due to the role of the PFC in executive function, this loss of dendritic spines in schizophrenia may be associated with the well-established decline in cognition.
Studies have identified a role of a receptor called PirB in inhibiting spine growth in adulthood. PirB has been manipulated in a variety of animal models both by genetic deletion and by pharmacological intervention. Blocking the activity of PirB in the visual cortex past the critical period of cortical plasticity by introducing a PirB ectodomain has been shown to increase dendritic spine density and functional recovery from long-term monocular deprivation. Furthermore, blocking PirB in aged mice has shown to increase cognitive and motor functions typically associated with aging. Taken together, these results provide exciting insight into the ability to re-open the critical period of cortical plasticity by blocking PirB in adulthood.
In this study, PirB will be blocked in the PFC of an adult rodent model of schizophrenia with the aim of recovering dendritic spine density and in turn cognitive function. All experiments will be conducted on 4 groups of animals. Two groups of animals will possess the schizophrenia symptoms while the other two groups will receive not. One group of animals from each of these two groups will receive infusion of a PirB ectodomain with a TAT sequence (for cellular penetration) while the other group from each of the surgery conditions will receive a control infusion. If the predicted results are obtained, this research will provide a next step towards developing a successful treatment for the cognitive deficits of schizophrenia.

Title: Developmental NMDA receptor ablation in a subset of interneurons confers circuit-wide aberrant gene expression and schizophrenia-like impairments

Authors: *V. MAHADEVAN[1], R. CHITTAJALLU[1], A. PELTEKIAN[1], K. A. PELKEY[1], C. ESNAULT[2], Y. ZHANG[3], M. DRAGAN[4], X. YUAN[1], S. HUNT[1], D. ABEBE[1], R. DALE[2], T. J. PETROS[3], C. J. MCBAIN[1];

Abstract: Medial ganglionic eminence (MGE)-derived forebrain GABAergic interneurons comprise several classes of interneurons namely, the parvalbumin, somatostatin, and neurogliaform / ivy cells that critically regulate cortical circuit maturation and refinement. NMDA-receptor (NMDAR) complexes within MGE interneurons mediate their development, physiology, and recruitment during network activity and plasticity. NMDARs provide a crucial source of calcium entry into neurons, and their signaling is a dominant convergence point for cell-intrinsic excitation-transcription (E-T) coupling. However, a comprehensive understanding of NMDAR-mediated E-T coupling in distinct interneuron classes is currently lacking, although interneuronal NMDAR-hypofunction is well known to underlie network and cognitive abnormalities in neurodevelopmental disorders, notably schizophrenia (SCZ). Here, we conditionally ablated the requisite GRIN1 subunit of NMDARs in the MGE-derived interneurons throughout development and examined its impact on cell-type specific gene expression, and behavioral abnormalities. Combined single-cell RNA sequencing and MGE-specific translating RNA sequencing analyses revealed a dramatic reduction in the expression of the neuron-specific inducible-transcription factor NPAS4 and its target BTG2 in the GRIN1-ablated cortical interneurons. Moreover, we observed a robust increase in the expressions of synapse regulators NTNG1, NORBIN, and KCNH2 in GRIN1-ablated hippocampal interneurons. Surprisingly, we observed non- cell-autonomous gene expression changes in pyramidal neurons and non-neurons, indirectly as a result of GRIN1-ablated MGE-interneuron impairment. In particular, we observed a robust increase in the pyramidal-neuron expressed immediate early genes, NPTX2, BDNF, and ARC, indicating aberrant pyramidal neuron hyperactivity; and a marked decrease in the microglia-expressed CX3CR1, IGF2. Importantly, several aberrantly expressed genes we identified are established human schizophrenia risk genes. Moreover, these animals exhibit novelty-induced hyperlocomotion, social anxiety and motor abnormalities reminiscent of SCZ-like impairments. Together, our study establishes that developmental NMDAR dysregulation initiated in a subset of GABAergic interneurons promotes circuit-wide gene expression abnormalities resembling those associated with SCZ etiology.

Title: Role of delayed maturation of $GABA_A$ receptor function in schizophrenia

Authors: *G. LEE[1], N. RAJAKUMAR[2], W. INOUE[3];
[2]Anat. & Cell Biology, Schulich Sch. of Med. & Dent., [3]Physiol. & Pharmacology, Schulich Sch. of Med. & Dent., [1]Western Univ., London, ON, Canada

Abstract: Unlike positive and negative symptoms of schizophrenia, cognitive abnormalities of this disorder are manifested very early and are present in the prodromal period in preadolescent children. An imbalance in excitatory/inhibitory transmission in the prefrontal cortex (PFC) unrelated to synaptic pruning may underlie this preadolescent manifestation of cognitive deficits. In the normal brain, GABA binding to $GABA_A$ receptors cause depolarization during early development and then becomes hyperpolarizing owing to the changes in KCC2 and NKCC1 expression and function. Interestingly, premature ablation of the subplate (SP) layer of the developing visual cortex resulted in delayed upregulation of KCC2 causing a continued depolarizing effect of GABA in the cerebral cortex. Our laboratory described that neonatal ablation of the SP layer of the PFC results in multiple behavioral and neuropathological abnormalities of schizophrenia. In order to study the effects of a delayed GABA functional switch on cognitive function and PFC pathology of schizophrenia, we sought to ablate the SP layer of the developing PFC in postnatal day 1-old mice. Lesioned and sham-operated pups were sacrificed at different time points between P2 and P14, and coronal sections through the PFC were processed for immunohistochemical labeling of GAD67, VGluT2, KCC2, NKCC1, and $GABA_A$ receptor subunits. Immunohistochemical findings will be correlated to future patch-clamp electrophysiological investigations.

Title: Consequences of Arc/Arg3.1 deletion during development on schizophrenia-endophenotypes in the adult mouse

Authors: *X. GAO[1], J. GRENDEL[1], M. MUHIA[2], S. CASTRO-GOMEZ[1], D. ISBRANDT[3], M. KNEUSSEL[2], D. KUHL[1], O. OHANA[1];

Abstract: Arc/Arg3.1, an activity regulated immediate early gene, is essential for learning and memory and for consolidation of synaptic plasticity. Expression of Arc/Arg3.1 during early postnatal development is essential for proper development of spatial cognition and hippocampal activity, whereas aberrant Arc/Arg3.1 expression had been linked to neurodevelopmental disorders such as autism and Fragile X syndrome. Recent studies on schizophrenia patients implicated Arc/Arg3.1 as a molecular hub in synaptic gene-networks whose abnormalities possibly play a significant role in the pathogenesis of schizophrenia. However, whether Arc/Arg3.1 deletion or misregulation by itself can lead to schizophrenia-like phenotypes remains questionable. To address this question, we generated constitutive and conditional Arc/Arg3.1 KO mice in which the Arc/Arg3.1 gene was deleted at different time points of development. We used behavioral, biochemical and *in vivo* electrophysiological methods to investigate the presence of schizophrenia endophenotypes in adult mice. Our data shows that loss of Arc/Arg3.1 during early development does not cause schizophrenia-like behavior, but can alter network activity in schizophrenia-relevant brain regions. Our results differ from previous reports and highlight a novel mechanism of Arc/Arg3.1 in neurodevelopmental disease.

Title: Chronic early-life lead exposure disrupts behavior and neuronal systems relevant to mental disorders and substance abuse

Authors: *D. ALBORES-GARCIA[1], J. L. MCGLOTHAN DZIEDZIC[1], D. R. BROOKS[1], K. H. STANSFIELD[2], T. R. GUILARTE[1];
[1]Envrn. Hlth. Sci., Florida Intl. Univ., Miami, FL; [2]Envrn. Hlth. Sci., Columbia Univ., New York, NY

Abstract: Environmental factors have been associated with psychiatric disorders and recent epidemiological studies suggest an association between prenatal lead (Pb^{2+}) exposure and schizophrenia (SZ). Preclinical studies show that developmental Pb^{2+} exposure recapitulates specific neuropathological and dopaminergic system changes present in SZ. Given the high comorbidity of substance abuse in SZ, we hypothesized that early life Pb^{2+}-exposure could sensitize neuronal systems relevant to both conditions. Male and female rats were developmentally exposed to Pb^{2+} using a validated experimental paradigm. This exposure paradigm results in blood lead levels averaging 0.6 ± 0.1 (control) or 22 ± 0.07 μg/dL (Pb^{2+}). Using this model, we investigated sensorimotor gating using pre-pulse inhibition of the acoustic startle (PPI) in early adolescence (postnatal day 28, PN28), late adolescence (PN50) or at adulthood (PN120). Chronic Pb^{2+} exposure did not have an effect in PN28 male rats, however, PPI deficits were present in PN50 male rats and were more pronounced in male adult rats (PN120), consistent with the age trajectory of PPI deficits in SZ. We found no effect of Pb^{2+} exposure on PPI in female rats at any age. To study sensitivity to psychostimulants, rats were administered saline, 5 or 15 mg/kg of cocaine-HCl before being placed in activity chambers. Cocaine locomotor activation was 78% higher in PN28 male Pb^{2+} rats ($p=0.027$) and 55% higher in PN28 female Pb^{2+} rats compared to controls ($p=0.008$). In PN50 rats, only Pb^{2+} males had increased cocaine-induced locomotor activity ($p=0.007$). These effects were abrogated by a D1-dopamine receptor (D1R) antagonist. We then measured D1R and mu opioid receptor (MOR) levels in relevant brain regions using autoradiography. In PN28 Pb^{2+} male rats, we found an increase of D1R in the striatum (STR), nucleus accumbens (NAC) and olfactory tubercle (OT) of rats relative to controls, the same in PN28 females, except for NAC. In PN50 Pb^{2+} male, but not female rats, there was an increase in D1R levels in OT only. MOR levels were increased in the STR, NAC, basolateral amygdala and several areas in the thalamus of male and female PN28

Pb^{2+} rats. Ongoing studies are determining MOR levels in PN 50 and PN120 animals and cocaine-induced locomotor activity and D1R at PN120. These studies show that chronic early life Pb^{2+}-exposure results in PPI inhibition, an endophenotype for SZ and produces changes in the dopaminergic and opioid systems that could sensitize and predispose the animal to substance abuse in an age and sex-dependent fashion. Our findings suggest the role of environmental factors, such as Pb^{2+}, as a risk factor for mental disorders and substance abuse.

Title: Glycogen synthase kinase 3 (GSK3) inhibition alleviates deficits in *in vivo* spike synchrony, gamma oscillation and cognitive impairment in a schizophrenia mouse model

Authors: *K. NAKAO[1,2], R. HUNTER[1], K. NAKAZAWA[1,2];
[1]Southern Res., Birmingham, AL; [2]Dept. of Psychiatry and Behavioral Neurobio., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Auditory steady-state responses (ASSRs), tone-evoked EEG oscillations at 40-Hz, is known to be compromised in patients with schizophrenia, although its underlying mechanism and functional outcome is poorly understood. Forty-Hz click train-evoked LFP (local field potential) activity in primary auditory (A1) cortex is also defective in a schizophrenia mutant model (Nakao and Nakazawa, 2014), in which Grin1 gene encoding the indispensable NMDA receptor subunit is deleted in ~50% off cortical and hippocampal GABA neurons in early postnatal development (Ppp1r2cre/Grin1 KO mice). Furthermore, we recently found that immunoreactivity (IR) against phospho-GSK3 (at Y216 in GSK3β), an auto-activated form of GSK3α/β, is augmented in the PV neurons (presumably Grin1-deleted), but not pyramidal neurons, of the mutant mPFC. The IR of GSK3β protein, but not GSK3α, in the PV neurons was also higher in Grin1 mutants. To assess the impact of predictive GSK3β over-activity on the *in vivo* action potential (AP) spike synchrony of cortical pyramidal neurons and *in vivo* tone-evoked LFP gamma oscillation, we took a pharmacological and genetic approach. First, we found that systemic pretreatment of TDZD-8 (nonselective GSK3 inhibitor, 2.5 mg/kg, IP) alleviates in vivo AP spike synchrony deficits (21 pairs, $p = 0.0004$, paired student's t-test) and diminished

tone-evoked gamma oscillations in the Grin1 mutant mice (6 channels, p=0.018). To determine which isoform of GSK3, GSK3α or GSK3β, elicits the impairment via over-activity, we used the GSK3β-paralog selective inhibitor, BRD3731 (30 mg/kg IP). BRD3731 alleviated the defective gamma oscillation in the Grin1 mutant mice (6 channels, p=0.009). To address whether GSK3β-specific inhibition in GABA neurons is sufficient to rescue the mutants' gamma oscillation deficits, we crossed a floxed-GSK3β strain (kindly provided by Dr. J. Woodgett) to the Ppp1r2cre/Grin1 KO mutant mice to generate the GABA neuron-selective GSK3β haploinsufficiency. Preliminary data showed that GSK3β haploinsufficiency reverses the *in vivo* AP spike synchrony deficits (P = 0.001, Grin1 KO (24 pairs) vs GSK3β haploinsufficiency (31 pairs), student's t-test). Finally, we assessed whether GSK3 inhibition restored the cognitive dysfunction in the Grin1 mutant mice. TDZD-8 restored the spontaneous alternation in Spatial Y-maze (n=6, $p < 0.05$) and paired-pulse inhibition (PPI) of the Grin1 mutant mice (n=12, p=0.05, two-way ANOVA). These results suggest GSK3β inhibition acting on cortical GABA neurons may ameliorate the cognitive dysfunction in schizophrenia presumably by the restoration of gamma synchronous activity.

Title: Neonatal ventral hippocampal lesions causes deficits in value-based decision making in adult rats

Authors: *N. PREM[1], L. T. RAO[1], J. P. JOHN[2], B. M. KUTTY[1];
[1]Dept. of Neurophysiology, Natl. Inst. of Mental Hlth. & Neurosciences, Bangalore, India;
[2]Dept. of Psychiatry, Natl. Inst. of Mental Hlth. & Neurosciences, Bangalore, India

Abstract: Cognitive deficits observed in schizophrenia patients have been recognized as the core feature of the disorder. Impairments in executive functions such as decision making is one of the cognitive domains that is affected. The neonatal ventral hippocampal lesion (NVHL) rodent model is a well-established neurodevelopmental model of schizophrenia. In the present study, we investigated the performance of NVHL animals in value-based decision-making task. Adult NVHL rats were subjected to test battery that consisted of the open field test (OFT), the direct interaction test (DIT) and the three-chambered social interaction test (SIT). NVHL animals exhibited hyperactivity in OFT, reduced social interaction and aggressive behavior in DIT and

impairment in social memory and deficits in preference for novel experiences when compared to control animals in SIT. Further, all animals were subsequently subjected to value-based decision-making task in the operant chamber using light cues. NVHL animals demonstrated impaired cue discrimination as they made more response error demonstrating inability to acquire stimulus-response associations. When subjected to unequal reward outcomes, NVHL animals developed preference for big reward more slowly. Cognitive flexibility was assessed by reversing the task rules and NVHL animals exhibited impairment in reversal learning as they were unable to track changes and made more incorrect responses when compared to control animals. Neonatal ventral hippocampal lesion leads to the disruption of normal development of the hippocampus and its efferents such as the prefrontal cortex. Therefore, the findings observed in this study encompass the notion that the cognitive deficits observed may be due to the compromised anatomical and functional integrity of the prefrontal cortex as a consequence of early developmental insult to ventral hippocampus.

Title: Interleukin-15/natural killer cell deficiency alters the effect of poly IC maternal immune activation on the offspring

Authors: *F. HADDAD[1], S. PATEL[2], C. DE OLIVEIRA[3], K. WIECZERZAK[1], B. ALLMAN[3], S. RENAUD[3], S. SCHMID[3];
[1]Grad. Neurosci. Program, [2]Physiol. and Pharmacol., [3]Anat. and Cell Biol., Univ. of Western Ontario, London, ON, Canada

Abstract: Maternal infection and its associated immune response during pregnancy are known risk factors for neurodevelopmental disorders such as autism spectrum disorder (ASD) and schizophrenia in the offspring. In rodents, maternal immune activation (MIA) by pathogen-free immune stimulants in pregnant mothers produces brain and behavioral deficits in the offspring. The contribution of different maternal immune cells to these deficits is still unclear. Natural Killer (NK) cells are innate immune cells whose maturation is dependent on Interleukin-15 (IL-15) and are involved in the response to infections, and previous studies have shown changes in peripheral NK cell phenotype in individuals with ASD and schizophrenia. Distinct uterine NK populations are also involved in establishing fetal blood supply and may be able to modulate the

immune signals that reach the fetus, and hence modulate the impact of MIA. We induced MIA using the viral mimic polyinosinic: polycytidylic (poly I:C) at gestation day 9.5 in homozygously bred wild type (+/+) or IL-15 knockout (-/-) rats and tested offspring in adolescence and adulthood. Our results indicate that IL-15 deficiency reduces offspring hearing threshold and signal latency in the auditory brainstem response and increases startle reactivity in adolescence regardless of exposure to MIA. On the other hand, poly I:C MIA increased male offspring body weight regardless of age or genotype and reduced open field exploration in both +/+ and -/- offspring. Moreover, poly I:C differentially affected offspring prepulse inhibition (PPI), startle reactivity and open field exploration in an age and genotype-dependent manner. For example, poly I:C MIA reduced baseline startle reactivity in adult +/+ but not -/- offspring. In contrast, poly I:C MIA reduced PPI in adolescent -/- but not +/+ offspring. Experiments in progress will use immunohistochemistry to search for molecular changes associated with the observed deficits. Our results point towards a role for IL15/NK cells in development of the auditory brainstem response and modulating MIA's effects on brain development. Further work will attempt to elucidate the contribution of fetal and uterine NK populations in this model.

Abstract: The human brain consists of billions of neurons, with one neuron forming more than 1000 synaptic connections with others. One crucial step to understand brain function is to construct neuronal connectomics at the synaptic resolution with cell-type specificity. Electron microscopy (EM), because of its unique nanometer resolution and excellent structural preservation, provides a powerful tool to build 3D reconstruction for neuronal connection network with increasing scale. However, conventional EM alone renders only gray scale images, lacking critical cell-type information most of the time. Genetically-encoded EM tags, such as APEX and miniSOG, could mark a few cell types a time, constraining our understanding of rules that may govern information flow from distinct cell-types. Here, we develop a series of new genetically-encoded EM tags by combining proteins that target distinct organelles with APEX2, which together creates different patterns under EM. We also exploit APEX with different activity or different copy number, to achieve different strength of electron density. Lastly, we also develop methods to control the sparseness of organelle tags. Importantly, these three labeling strategies are orthogonal to each other, thereby offering opportunities to combine them for generating combinatorial EM barcodes to uniquely label distinct cell types. We have validate the applicability of such multiplex EM tags in cultured cells and plan to apply them in more intact nervous systems, such as in flies or in mouse brains.

Title: Rapid automated serial block face SEM preparation of brain tissue

Authors: *S. L. GOODMAN[1,2], J. M. CAMPBELL[3], P. H. SMITH[3], E. K. BENSON[4], G. J. KIDD[4];
[1]Neurolog. Surgery & Pathobiological Sci., Univ. of Wisconsin, Madison, WI; [2]Microscopy Innovations, LLC, Marshfield, WI; [3]Dept. of Neurosci., Madison, WI; [4]Renovo Neural, Inc., Cleveland, OH

Abstract: Serial block-face electron microscopy (SBEM) provides powerful 3D insight into neurological structures for mapping and quantification. While image acquisition is now computer-controlled, SBEM sample preparation typically requires tedious circa week-long manual exchanges of toxic reagents.
We report herein an SBEM protocol for neurological tissue where all reagent exchanges are

automatically performed in one day using the programable mPrep ASP-1000 Automated Specimen Processor (ASP). The ASP enables high-speed preparation of biological tissues with rapid and repeated fluid exchanges that accelerate reagent diffusion into specimens, as shown for transmission electron microscopy (TEM) [1]. For SBEM, a circa 4-day manual preparative protocol [2] was reduced to 7.5 hours of automated processing, followed by overnight resin curing.
Adult rats were perfusion-fixed with cacodylate-buffered glutaraldehyde-paraformaldehyde. Cortex and corpus callosum specimens (1-3 mm) were oriented in mPrep/s capsules, loaded onto the ASP, and all preparative reagents were aliquoted into microwell plates on the ASP stage. The ASP executed the protocol by aspirating successive reagents into each capsule for the programmed time with agitation provided by gentle flow reversals every few seconds. Epoxy infiltrated specimens in the capsules were then removed from the ASP and cured overnight at 60C. An FEI Teneo VolumeScope imaged blocks at 2.0 kV, 0.1 nA under high vacuum with the T1 BSE detector. Imaged volumes were ~60 x 60 um by 20 um from 70 nm sections.
Specimens prepared with the 7.5 hour ASP protocol (plus resin curing) and with the 4-day manual protocol were compared from the same animal: Even myelin staining in both indicated good reagent penetration since lipid-rich myelin membranes are a dense target for metal staining and a barrier to diffusion. Synaptic vesicle clarity and discrimination of mitochondrial cristae against the dark mitochondrial matrix were also comparable. Neither ASP or manually-prepared specimens exhibited deficits characteristic of poor staining, dehydration, or infiltration. The reproducibility of automation, programmable control to optimize protocols for different tissue samples, and the potential inclusion of immuno-labeling, as demonstrated for TEM [3], are all benefits of programmable automated processing. Finally, since the ASP reduces reagent handling, and as it vents into or is contained in a fume hood, experimenter exposure to noxious reagents may also be reduced.

Title: Real consequences of improved histocompatibility: A TEM study of flexible organics vs standard rigid implants in mice and the effect on seizure onset

Authors: *S. SAFIEDDINE[1], E. RUSINA[1], R. POULKOURAS[1], F. MISSEY[1], B. BOTZANOWSKI[1], E. ACERBO[1], A. SLEIZA[1], M. DONAHUE[2], M. CARRÈRE[1], A. WILLIAMSON[1];
[1]Inst. de Neurosciences des Systèmes, Marseille, France; [2]Dept. of Bioelectronics, Ecole Nationale Supérieure des Mines, Gardanne, France

Abstract: Stimulating and recording the electrical activity of neurons *in vivo* are critical functions in contemporary biomedical research and in the treatment of patients with neurological disorders such as Epilepsy, Alzheimer and Parkinson Disease. The current widely used stimulation implants are inorganic and tend to exhibit shorter effective lifespans. This is due to the degradation of the signal transmission resulting from the tissue response at the electrode-brain interface, and the tissue damage from the limited charge storage capacity (CSC) of the electrodes due to the generation of Reactive Oxygen Species (ROS). To overcome these limitations, new electrodes are designed to minimize tissue response and to increase the charge storage capacity. Conducting polymers such as PEDOT:PSS (poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) allow a high CSC, avoiding the use of high voltages that could cause tissue damage. However, *in vivo* studies using such new materials for implants have been conducted on a limited sample size. The main focus was not on the histocompatibility of the devices tested, but on the aspect of the material. Here, we present the first detailed histocompatibility study of flexible organic implants and demonstrate the effect of implant type on the threshold for seizure onset. We report it on the cellular level and more particularly the mitochondrial size and number in the cells surrounding the inorganic rigid and organic flexible electrode. These were done in the hippocampus of mouse-model for one, four, seven or fifteen days using Transmission Electron Microscopy. At the same time, we focus on the evolution of the response of microglia, astrocytes and oligodentrocytes to the implants. In this poster we show that mitochondrial fission and number in the cells surrounding the flexible organic electrode are lower than the ones in a standard rigid electrode. Our results show negligible immune reaction of the flexible implants compared to standard rigid stimulators where the threshold for seizure onset is dramatically reduced.

Abstract: The ultimate realization of connectomics is to map the wiring of a whole brain but we lack reliable and scalable methods for staining whole brains for electron microscopy. We and others have found previously published methods for staining whole mouse brains to be difficult to reproduce prompting us to develop an alternative protocol. Here we describe a perfusion-based method for preparing whole brains for electron microscopy where, following aldehyde fixation, osmium tetroxide is transcardially delivered to the whole brain. We compare different osmium staining methods and show reduced osmium provides complete staining and ultrastructure preservation. We show that post-staining ultrathin sections with uranyl acetate and lead nitrate provide sufficient contrast from such perfusion approaches for algorithmic automatic segmentation. This method solves a major bottleneck in preparing whole brains for serial electron microscopy, staining entire brains, paving the way for large volume serial electron microscopy.

Title: Towards a partial connectome of hair and skin

Authors: *E. A. OLAPO[1], N. B. KASTHURI[3], J. AUSTIN, II[4], A. MASELLI[2];
[2]Dept. of Biol. Sci., [1]Chicago State Univ., Chicago, IL; [3]Dept. of Neurobio., [4]Advanced Electron Microscopy Facility, Univ. of Chicago, Chicago, IL

Abstract: The skin is the body’s largest sensory organ receiving tactile stimuli and transmitting pain. Despite it's obvious importance in normal brain functioning and its role in human pathology, little is known about how nerves innervate the skin. A three dimensional nanoscale model of skin and its innervation would significantly advance our understanding. We report here efforts to use automated serial electron microscopy -connectomics- using the ATUM (Automated Tape Collecting Ultramicrotome) to build a three dimensional model of the sensory apparatus

surrounding a hair follicle in mouse skin. We are optimizing sample preparation for electron microscopy including fixation with aldehydes, heavy metal staining, and plastic embedding tailored for nanoscale reconstructions of skin and hair. Initial results suggest that skin samples can be prepared with sufficient signal for large volume serial electron microscopy and long runs of serial sections can be collected with the ATUM. We will use our connectomic reconstructions of wild type skin from the mouse to compare across skin regions without hair follicles, across species, and in pathology.

Title: A quantitative ultrastructural readout of *in vivo* presynaptic activity for connectomics

Authors: *A. SIMON[1], A. ROTH[1], M. FISEK[1], V. MARRA[2], C. RACCA[3], K. STARAS[4], M. HAUSSER[1];
[1]Univ. Col. London, London, United Kingdom; [2]Univ. of Leicester, Leicester, United Kingdom; [3]Newcastle Univ., Newcastle-Upon-Tyne, United Kingdom; [4]Univ. of Sussex, Brighton, United Kingdom

Abstract: The patterns of synaptic input received by cortical neurons during behavior are not known. Ideally, they should be measured in the context of the wiring diagram of the circuit. How to quantitatively assess synaptic weights and synaptic activity is also an open problem for current connectomics approaches. Here we describe a strategy for measuring presynaptic activity and release probability during circuit function along with circuit connectivity at nanoscale resolution. The method relies on FM 1-43FX labelling and dye photoconversion as a marker of functionally recycled vesicles *in vivo*, permitting active terminals to be visualized using electron microscopy-based connectomics approaches.
FM 1-43FX was injected via a patch pipette into L2/3 of V1 in awake head-fixed mice running on treadmill. The FM bolus was monitored by 2-photon imaging while mice were shown a visual stimulus for 10 min. After transcardial perfusion fixation, the brain was postfixed overnight. Vibratome sections containing the dye-loaded presynaptic boutons were photoconverted and processed for EM. FIBSEM was chosen to acquire high-resolution 3D data (6.2 x 6.2 x 9.3 nm^3 voxels), allowing each synaptic vesicle to appear on 5-6 consecutive images. Two distinct

vesicle populations were found in presynaptic terminals (Fig. 1): i) dye-loaded, photoconverted (PC+) active vesicles with a dark lumen, ii) unloaded (PC-) vesicles with a clear lumen. Voxel classification using ilastik readily distinguished the two vesicle types.
A large majority of excitatory and inhibitory boutons contained PC+ vesicles, suggesting that most were active during visual stimulation. In active boutons, the fraction of vesicles classified as PC+ varied widely, indicating broad distributions of activity levels and presynaptic release probabilities. In summary, our method provides a powerful readout of presynaptic activity with ultrastructural context, enabling the organization of active synapses *in vivo* to be revealed for the first time. We anticipate our approach will provide a valuable new strategy for functional connectomics.

Title: The influence of the microbiome on the 'connectome' of the enteric nervous system

Authors: V. SAMPATHKUMAR[1], ***M. E. FRITH**[2,3], A. SHAHBAZI[5], N. PATEL[4], V. LEONE[3], E. B. CHANG[3], N. B. KASTHURI[1];

Abstract: The enteric nervous system (ENS) is a semi-autonomous collection of neurons and enteric glial cells critical for gastrointestinal function. Despite its importance, little is known about the circuitry of the ENS and how that circuitry is shaped by the nearby microbiome. In order to address this gap, we have developed a multi-scale, multi-modal imaging approach that combines synchrotron source x-ray microscopy (μXCT; 1-micron resolution over cm^3), automated large volume serial electron microscopy using the ATUM (EM; 10 nm resolution over mm^3), stimulated emission depletion (STED) and standard confocal microscopy, to map differences in the cellular, vascular, and the connectivity of the enteric neurons between conventionally raised (specific pathogen-free, SPF) and germ-free (GF) wildtype mice. We report that ENS neurons in both SPF and GF mice have less elaborated dendritic arbors compared to CNS neurons and receive approximately 40 inputs per cell, distributed over the soma and dendrites. ENS neurons in a specific ganglion receive the majority of their connections from neurons in other ganglia, and the same axons make multiple connections with single post-synaptic targets. In GF animals, we find large scale structural differences including altered composition of the gut wall musculature, decreased branching of the vasculature, and potential reductions in the number of synapses per enteric neuron. We report, for the first time, the basic principles of connectivity in the ENS and how connectivity changes in the absence of the microbiome.

Title: Segmentation of murine cervical vagus nerve fibers from transmission electron microscopy images using domain randomization and deep convolutional neural networks

Authors: *V. TÓTH, T. TSAAVA, E. H. CHANG, A. BORCA-TASCIUC, T. P. ZANOS; Inst. of Bioelectronic Med., Feinstein Inst. for Med. Res., Manhasset, NY

Abstract: Selective modulation specific fibers within peripheral nerves is a major goal of emerging bioelectronic medicine efforts. To achieve this goal, we need to understand the axon

distributions and features of the nerves that we record and stimulate. The vagus nerve (VN) is a primary interface target various bioelectronic medicine devices, however, the fiber composition within this nerve is not well understood. In transmission electron microscopy (TEM) images of this nerve, unmyelinated C-fibers that carry nociceptive signals are challenging to quantify due to their small diameter and lack of a myelin sheath. Manual segmentation labeling of C-fibers on TEM images is time-consuming while training state-of-the-art deep learning methods to segment and subsequently count the fibers demands a substantial amount of labeled images. One way to address these issues is to generate synthetic pre-labeled images that resemble real TEM images. These images can be subsequently used to train deep neural networks to segment and count fibers in TEM images. To this end, ultrathin cross-sections of the mouse cervical VN were prepared following glutaraldehyde-paraformaldehyde fixation, 1% osmium tetroxide, and uranyl acetate staining. Samples were acquired on a transmission electron microscope with the Gatan UltraScan 4000 imaging system. TEM images were acquired at 1200X magnification to assemble the real dataset. To further enrich the data beyond image augmentations of rotation and stretching, we applied domain randomization by automatically generating labeled image sets of neural fibers using a 2D physics engine. By assembling axons in physics simulations, we spawned diverse, morphed forms of both myelinated and unmyelinated fibers resembling the ones on the TEM images. The simulation engine provided exact labels of axons, myelin sheath and background pixels for the acquired dataset. A deep convolutional neural network was first trained to segment the automatically generated, randomized electron microscope images, then the same network was fine-tuned using labeled real images retrieved from the VN of mice. A control convolutional network was only trained on the real images. The model pre-trained on the synthetic images significantly outperformed the control neural network, demonstrating the benefit of using domain randomization for axon segmentation. Our developed methodology can be translated to fiber counting of nerves other than the cervical VN, where the distribution, size, and form of myelinated and unmyelinated fibers are different.

Title: Reconstruction of motor control circuits in adult *Drosophila* with automated transmission electron microscopy

Authors: *D. G. C. HILDEBRAND[1], J. T. MANIATES-SELVIN[1], B. J. GRAHAM[1], A. T. KUAN[1], L. A. THOMAS[1], B. L. SHANNY[1], W.-C. A. LEE[1,2];

Abstract: Animal behavior is ultimately controlled by populations of motor neurons integrating diverse synaptic inputs in the nervous system and innervating muscles in the periphery. Understanding networks and computations that orchestrate movement has been challenging due to the inaccessibility and complexity of the underlying circuitry. Here, we present reconstructions of the neuronal circuits supporting motor control in an adult female *Drosophila* ventral nerve cord (VNC) using a tape-based, reel-to-reel, large-scale electron microscopy (EM) pipeline. This method, called GridTape, combines automated serial sectioning with automated, high-throughput transmission EM to provide nanometer-resolution imaging with consistent sample collection, which accelerates imaging and analysis throughput for a fraction of the cost of alternative approaches. The resulting dataset affords the opportunity for comprehensive, unbiased mapping of circuits that coordinate walking and flight. To examine how the nervous system controls locomotor behavior, we reconstructed all the motor neurons innervating the front legs. To facilitate combined structural, functional, and genetic analyses, we registered the EM dataset with a light microscopy-based reference VNC atlas. Our analysis demonstrates functionally specific sensory feedback onto motor neurons and considerable bilateral symmetry. We provide open-access to the dataset, reconstructions, and GridTape instrumentation designs to fuel further discovery of network motifs supporting motor codes and to make EM-based connectomics more broadly accessible.

Title: Combined light and electron microscopy characterize microcircuits in an excitatory retinal amacrine cell

Authors: *K. FRIEDRICHSEN, J.-C. HSIANG, D. KERSCHENSTEINER, J. L. MORGAN; Ophthalmology & Visual Sci., Washington Univ. In St. Louis, Saint Louis, MO

Abstract: The Vesicular Glutamate 3-Expressing Amacrine Cell (VG3-AC) is a retinal amacrine cell which participates in multiple retinal circuits simultaneously. It receives input from both the ON and OFF visual pathways and provides ON, OFF, or ON/OFF output to multiple cell types using either excitatory (glutamatergic) or inhibitory (glycinergic) synapses. Calcium imaging has shown that light responses in the VG3-AC arbor are heterogenous, with some areas exhibiting only ON or OFF responses and others a combination. Because input and output synapses are interspersed throughout the arbor, the response heterogeneities may represent many distinct input/output pathways within a single neuron.How the synaptic connectivity and morphology of the arbor selectively mix and segregate synaptic inputs and direct them to appropriate outputs is unclear. We are combining calcium imaging with serial section scanning electron microscopy (SS-SEM) to reconstruct the connectome and ultrastructure of a functionally characterized VG3-AC, allowing us to better understand how synaptic inputs are combined or segregated to produce observed light responses and how this information is targeted to appropriate downstream neurons.We use calcium imaging to capture the responses to light stimuli of an excised live mouse retina expressing GcAMP-6F in VG3-ACs in a Cre-dependent manner. We then use an Automated Tape-Collecting Ultramicrotome (ATUM) to collect thousands of serial sections representing the full thickness of the retina. These are imaged at multiple resolutions, aligned, and annotated to reconstruct the structure and connectome (fig 1A) of the same VG3-ACs characterized by calcium imaging. Using this method, we can directly correlate the structure and connectivity of an arbor region with its functional responses to light stimuli (fig 1B).With this combined data set, we have begun identifying synaptic motifs in the connectivity of VG3-AC segments and correlating these microcircuit domains with their functional response patterns.

Title: Building and testing a system for neural ensemble recording from a subcortical bundled electrode

Authors: C. AYON-GARCIA, J. HARRINGTON, N. KUHLMANN, M. TCHERNOOKOV, ***M. A. WARACZYNSKI**, O. YAVUZCETIN, D. ZAMZOW;
Univ. of Wisconsin Whitewater, Whitewater, WI

Abstract: Neural ensemble recording affords a wealth of data that relate the activity of cell groups to behavioral phenomena observed in conscious, unrestrained animals. However, relatively little of this type of research has involved recording from neural groups located substantially below the cortex, given the difficulty of accurately implanting fine wire electrodes at depth. Here we present our work on developing a system for doing so by bundling electrodes and implanting them within a confining guide cannula. Bundling the electrodes presents an additional challenge: The KlustaKwick open source spike sorting software requires that the user know the bundle's adjacency graph, i.e., the position of each electrode tip relative to all others in the bundle. The user must also determine the amplifier channel input to which each electrode is connected. This adjacency information is lost as the wire bundle is twisted, a step necessary to give the bundle sufficient resilience to survive the implant process intact. We present novel software for determining that adjacency information based on delivering a known AC signal to each electrode in turn, and recording the received signal at each other electrode. These recordings allow us to generate a matrix of Fourier components corresponding to the frequency of the supplied signal. Based on the relative size of these components the software then iteratively assigns neighbors to the stimulated electrodes, producing a binary adjacency matrix. We present proof of concept data obtained by creating an adjacency graph for an electrode bundle that is not twisted, i.e., with known adjacency. We also present data testing the validity of our adjacency determination software, obtained by delivering known, artificial neural-like signals to an electrode bundle and comparing KlustaKwik's outputs to these known inputs. These data indicate that our system validly collects neural ensemble activity data.

Title: Dura penetration, deep insertion, and electrophysiological recording with cellular-scale microelectrodes using 3D-printed custom skull cap

Authors: *L. CHEN[1,2], J. HARTNER[2], T. DONG[1], P. R. PATEL[3], J. RICHIE[3], A. SHIH[1,3], C. A. CHESTEK[3], B. O. WATSON[4];
[1]Mechanical Engin., [2]Psychiatry, [3]Biomed. Engin., [4]Dept. of Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: Electrophysiological methods are a mature methodology for recording brain dynamics at millisecond timescales in either local or large spatial scales. Microelectrode arrays (MEAs) are a well-established tool for chronic recording of electrophysiological signals and have the advantage of minimal brain damage if constructed from microelectrodes with cellular-scale diameters (25um or less). However, further development of large cellular-scale MEAs is necessary for wide use by neuroscientists, especially for deep insertion cases. Efforts to reduce the size of microelectrodes and make them more flexible bring collateral difficulties due to buckling during penetration through membranes (dura/pia) and consequent inability to implant deeply into the brain. In this study, we investigated the insertion force of cellular-scale microelectrodes through pia and dura maters using a newly-developed cantilever-beam based force measurement system with flexible range (mN level) and resolution (sub-μN level). We also developed a custom skull cap with precision guide holes to stabilize the brain and membranes, provide sufficient support to microelectrode along the insertion path, and minimize the unsupported length of microelectrodes during dura/pia penetration and deeper insertion. Insertion force measurements found that both diameter reduction and tip sharpening reduce the rupture force during membrane penetration. Due to the decreasing unsupported length of the microelectrode and slow increase of friction force, buckling is less likely after membrane rupture for cellular-scale microelectrodes. Insertion tests through the skull cap showed that a 25 μm diameter tungsten microwire penetrated through the dura mater and was inserted over 10 mm into the brain without buckling and could be used for electrophysiological recordings. In comparison, without the cap or precision guide, insertion of the same microwire caused over 2

mm dimpling of the dura without penetration and finally led to electrode buckling. This study showed that with proper supporting mechanism above the membrane, it is feasible to insert cellular-scale microelectrodes deep into the brain through the dura mater without buckling. We are conducting in-vivo brain recording tests in freely behaving rats with cellular-scale microelectrodes through the skull cap to verify the feasibility and durability for both acute and chronic electrophysiological recordings.

Title: MRI compatible, 3D printed microdrive for chronic or acute neurophysiological recordings

Authors: R. SWADER[1], E. BAEG[2], H. LEE[3], A. ROSENBERG[4], ***B. KIM**[4];
[1]Mogridge Inst. for Res., Madison, WI; [2]CNIR, Inst. For Basic Sci. (IBS), Suwon, Korea, Republic of; [3]Mechanical Engin., Univ. of Wisconsin Madison, Madison, WI; [4]Neurosci., Univ. of Wisconsin - Madison, Madison, WI

Abstract: We present an MRI compatible 3D printed microdrive for conducting chronic or acute neurophysiological recordings. Testing results are presented using recordings from macaque monkeys. Major innovations 1. Construction of a microdrive with high resolution 3D printing. A microdrive requires miniature moving parts to carry various types of electrodes with micrometer accuracy. Cutting-edge 3D printing enables the printing of materials with such high resolution. Moreover, with 3D printing, the construction and modification of microdrive components are highly convenient and more cost effective than with conventional machining. 2. Novel and innovative design of a recording grid system that enables micro-drilling for introducing electrodes into the brain that eliminates the need for large craniotomies and debridement of dura matter. 3. Full MRI compatibility. All parts of the microdrive are constructed from MRI compatible plastics, except for the electrode actuating threads which are made from MRI compatible brass. The actuating threads are distal from the brain and introduce negligible MRI distortion. Since no craniotomy is performed, the system does not create an air-filled space on top of the dura that can introduce imaging artifacts. 4. Versatile microdrive for chronic or acute

neurophysiological recordings. Since all of the moving parts and recording grid are enclosed in the microdrive body, the system is naturally isolated from the external environment. The system further allows electrodes to be individually replaced without reinstalling the microdrive body. This design makes it suitable for both long-term chronic recordings as well as daily acute recordings with minimal maintenance.

Title: An open-source, interactive neuronavigation system for planning, simulating and performing surgeries

Authors: *S. SCHAFFELHOFER[1,2], W. ZARCO[1], R. PRÜCKL[2], W. FREIWALD[1];
[1]Lab. of Neural Systems, The Rockefeller Univ., New York, NY; [2]cortEXplore GmbH, Linz, Austria

Abstract: Accessing cortical and subcortical areas accurately and safely is crucial for most disciplines in neuroscience and medicine. Traditional navigation methods rely on operations in stereotaxic coordinates for which mechanical frames and arms are positioned to reach targets in the brain. The manual adjustment of these parts can cause cumulative positioning errors and lack in error-detection. Here, we report a low-cost neuronavigation system (NNS), which measures the position of surgical instruments directly via infrared cameras and transforms and visualizes their location into the medical images of a surgical subject at run-time and sub-voxel resolution. Preoperative, the introduced NNS can merge the medical scans of a subject, such as CT, MRI, and fMRI. Based on scan intensities, 3D iso-surfaces of multiple tissues, such as cortex, blood-vessels, and skull can be computed and merged in a multimodal image. Additionally, CAD files can be imported and merged with the biological structures. This way, implants, such as electrodes can be set virtually to optimize their position relative to the biological target and to define a surgical plan.
Intraoperative, the NNS connects to infrared cameras (NaturalPoint) to detect the position and orientation of surgical instruments via triangulation (6 degrees of freedom). At the beginning of a procedure, surgeons use a pointer to measure the location of multiple fiducial markers on the

subject's head in order to register them to their corresponding location in the medical images (point-set registration algorithm). These transforms are acquired once and can be afterwards accessed to transfer the instruments into the medical imaging space at sampling rates >60Hz. Thus, surgeons can see their instruments relative to the subject's anatomy on a computer screen to follow the preoperatively defined plan.
Our NNS was evaluated in-vitro (fiducial point detection on 3D printed head) and in-vivo (recording chamber in macaques) and reached positioning accuracies with errors of 430±202 µm (mean±sd, n=72) and 348µm respectively (mri resolutions =0.5mm isotropic). Additionally, six microelectrode arrays (Microprobes) were implanted successfully at sub-millimeter precision and provided functional spiking activity.
Together, our navigation platform leads to safe, fast and accurate interventions. The prospects in many other scenarios are significant not only for research, but also for eventual clinical translation. The software is provided open-source under the MIT-license: http://www.cortEXplore.com/Software/NeuronavigationSfN2019.zip

Title: Accelerated aging test of organic and inorganic packaging materials for implantable neural interface devices

Authors: *Y. GONG, W. YANG, W. LI, Q. FAN;
Electrical and Computer Engin., Michigan State Univ., East Lansing, MI

Abstract: Implantable neural interface devices have been widely used in neuroscience and clinical research to understand brain functions. Many implantable devices target long-term (>1 year) recording period in the host body. During chronic applications, the stability of an insulation layer is a critical factor to ensure the reliable performance of implantable neural devices. Typically an insulation layer is utilized to isolate unwanted noise, prevent cross-talking, protect electronics and metallic elements, as well as provide biocompatibility. Although Parylene-C has been widely used as a substrate and insulation material for many FDA-approved implantable devices, pinholes in Parylene-C thin films greatly limit their barrier performance. Inorganic thin films enable hermetic packaging performance but they are more mechanically rigid than polymers. To facilitate the design and development of packaging materials for neural implants,

we studied and compared the barrier performance of four different organic and inorganic thin films: Parylene-C, SiO_2, Si_3N_4, Al_2O_3. To prepare samples, tungsten microwires were coated with single- or multi-layer thin films of different materials under various thicknesses. The coating at the tip of the wire was precisely removed to expose electrode sites. The samples were aged in three solutions: phosphate-buffered saline (PBS), 30 mM and 150 mM H_2O_2 mixed with PBS, to mimic acute post-surgery inflammatory reaction. To accelerate the aging test, the solutions were heated at high temperatures of up to 60 °C. Electrochemical impedance spectroscopy (EIS) was used to monitor the changes in impedance over the course of soak testing, as an indication of degradation of the insulation coating. Mean-time-to-failure (MTTF) at body temperature of 37 °C was extrapolated using $Age_{37℃} = (Age_{60℃})*Q^{|Taa-Trt|/10}$, where Q_{10} is a 10 ℃ increase rate of the chemical reaction, T_{AA} is accelerated aging temperature and T_{RT} is recommended shelf temperature-body temperature. Scanning electron microscope (SEM) was used to identify signs of physical damages of the insulation coating and tungsten electrodes.

Title: Chronic *in-vivo* recording of rodent neural systems utilizing an updated affordable and open-sourced microdrive

Authors: A. RAMACHANDRAN, A. ALAVI, A. EL BANNA, ***G. M. MUIR**;
St. Olaf Col., Northfield, MN

Abstract: Among the many challenges of chronically recording neuronal activity from multiple cells is the cost of purchasing or producing drives that fit the functional and spatial requirements needed for individual recordings. These challenges are even greater when employing such technologies in the instruction of undergraduates or during research at under-funded institutions. We have created an updated customizable microdrive array that allows for the independent driving of 8 tetrodes (32 electrodes) with a drive body that is entirely 3D-printable using a standard 3D printer. This is assembled using cheap and open source materials, and it is compatible with the open-ephys system. The quick turn-around time and cheap cost of our microdrive allows for basic in-vivo electrophysiology to be feasible for undergraduate or teaching laboratories.

Title: Developing a 3D parylene-based multi-electrode array for large-scale recordings from the rat brain

Authors: *W. JIANG, H. XU, X. WANG, E. MENG, D. SONG;
USC, Los Angeles, CA

Abstract: Large-scale monitoring of resolvable neuronal activities from multiple brain regions of behaving animals provides valuable insights into complex brain mechanism at the cellular level. However, current state-of-the-art probes such as microwire or silicon electrodes are orders of magnitude stiffer than brain tissue, which largely increases the chance of inflammation and damage caused by chemical and mechanical interactions, and therefore makes difficult to consistently record high-quality signals over long period of time. Due to its biocompatibility and flexibility, parylene C is a promising alternative structural and insulation material for building neural probes with reduced mechanical mismatch between tissue and implants. In our previous work, a 64-channel parylene-based multi-electrode array with 8 shanks was developed and applied to chronic recording of multiple hippocampal sub-regions in behaving rats. In our current work, a novel 3D parylene-based probe consisting of 24 (3x8) shanks with a 250um spacing was developed. Each shank contains 8 platinum electrodes and thereby realizes a total of 192 electrodes for large-scale recordings of multiple brain regions in rat. To aid insertion, dissolvable polyethylene glycol (PEG) brace was employed to temporarily support the flexible probe, shorten the effective length of the shanks, and increase the critical buckling force. The PEG block is designed in a wedged shape to avoid unbalanced dissolving rates on the two sides. In the preliminary studies, after craniotomy and removal of dura mater and blood vessels, a sham 3D parylene array was successfully implanted to the full depth of 5.14mm in vivo. The depth of implantation was confirmed with micro-CT imaging. This result demonstrated the feasibility of implanting 3D flexible polymer probe to deep brain structures. In future, corresponding packages and data transmission system for functional 3D parylene array will be developed; the large-scale, high-density 3D parylene probe will be tested both acutely and chronically for recording from multiple brain regions in behaving rats.

Title: Transparent inkjet-printed ECoG electrode arrays integrated into polymer skulls for simultaneous whole cortex electro- and opto- physiological monitoring

Authors: ***P. DONALDSON**[1], Z. S. NAVABI[2], M. RYNES[2], L. GHANBARI[2], S. B. KODANDARAMAIAH[2,3], S. L. SWISHER[1];

Abstract: Considering the separate, yet complementary origins of electrophysiological and optophysiological (e.g. fluorescence from genetically encoded calcium indicators) recording techniques, a powerful approach to studying cortical dynamics would be to utilize a platform that combines high spatial resolution optical imaging with high temporal resolution electrical recording across a large swathe of the cortex. Recently, we have developed transparent polymer skulls consisting of a flexible and highly transparent PET film bonded into a 3D-printed frame. Here we demonstrate the integration of transparent and reconfigurable electrocorticography (ECoG) electrode arrays into these transparent skulls by patterning a conductive and transparent polymer (PEDOT:PSS) directly onto the PET film using an LP50 inkjet materials printer (Meyer-Burger Technologies). Outside of the imaging region, PEDOT:PSS traces connect to inkjet-printed silver traces that route signals to printed bond pads. The electrode arrays are encapsulated in the transparent insulating polymer Parylene, with openings over the electrodes and bond pads. The bond pads are bonded to a conventional PCB to interface the array with external electronics. Finally, the electrode arrays are bonded to 3D-printed frames and implanted, along with a titanium headplate which provides support for the PCB and locations to head-fix the mouse for imaging experiments. Printed PEDOT:PSS features show negligible optical absorption (less than 3% throughout the visible and NIR wavelengths). PEDOT:PSS electrodes with 300 μm diameters exhibit channel impedances of less than 10 kΩ at 100 Hz for up to 3 weeks in 37°C PBS. ECoG-integrated transparent skulls have been chronically implanted on C57/BL6 mice for over 6 weeks. Impedances of functional channels were found to be 203 ± 176 kΩ at 100 Hz for

the 6 week period. We are currently refining the implant design and performing experiments to measure stimulus evoked electrode potentials, and compatibility with epifluorescence and 2-Photon imaging of calcium activity. We believe this platform will enable novel neuroscience studies that can utilize the complementary benefits of electrical and optical neural sensing modalities to unravel the intricacies of cortical neurophysiology.

Title: Functional characterization of graphene microelectrodes on rat sensorimotor cortex

Authors: *F. T. DUVAN[1], D. VIANA[2], S. WALSTON[2], J. A. GARRIDO[2], B. GÜÇLÜ[1]; [1]Inst. of Biomed. Engin., Boğaziçi Univ., İstanbul, Turkey; [2]Catalan Inst. of Nanoscience and Nanotechnology – ICN2, Barcelona, Spain

Abstract: Neuroprostheses based on cortical implants are promising to provide partial sensorimotor function in severe neurological conditions such as spinal cord injuries and amyotrophic lateral sclerosis. One of the key components of these systems is the microelectrode array, which is used for recording brain activity to control a robotic limb and/or for stimulation to induce somatosensory feedback. Due to its unique electrical, mechanical, and biochemical properties, graphene exhibits a great potential as electrode material. We tested 64-channel flexible surface neural probes (site diameter: 25 μm) based on reduced graphene oxide thin film technology for functional characterization on rat sensorimotor cortex (SI). Evoked local field potentials were recorded epidurally at the hindpaw representation of SI in anesthetized Wistar albino rats. The vibrotactile stimuli were bursts of sinusoidal (5, 40, and 250 Hz) displacements (duration: 0.5 s, amplitude range: 19-270 μm) applied on the glabrous skin. Consistent with our previous results from platinum surface electrodes, robust evoked potentials could be observed shortly after the onset of contralateral stimuli. At low stimulus intensity, the evoked potential mostly lasted about 0.1-0.2 s, but frequency-following entrainment could be obtained for 5 Hz at higher intensities. Additionally, the stimulus onset caused large coherence changes among the channels. Ipsilateral vibrotactile stimuli usually did not produce evoked potentials, but they

sometimes changed the ECoG rhythm especially in the gamma and higher (30-150 Hz) bands due to interhemispheric networks. At different filter settings, small-medium amplitude (<80 μV) multi-unit spike activity, and sometimes single-unit spikes could be recorded. On the other hand, electrical stimulation (10 biphasic current pulses, 0.25 ms phase duration at 100 Hz) of the cortical surface resulted in twitch responses mostly at neck, face, and trunk muscles only at high current thresholds (~0.7 mA) above material and Shannon limits. Although generating a motor output at the lower leg seems to be not feasible by surface stimulation under anesthesia, graphene electrodes with small sites may be used to induce artificial sensation for somatosensory feedback during chronic experiments, in which much smaller currents (<0.1 mA) are applied.

Title: Simultaneous *in vivo* measurement of neural activity, extracellular glutamate and GABA concentrations using an MRI-compatible implantable microelectrode array

Authors: E. MITRICHEVA, R. KIMURA, L. PASCUAL MANSILLA, E. KRAMPE, A. OELTERMANN, N. K. LOGOTHETIS, ***H. R. NOORI**;

Abstract: Glutamate and γ-aminobutyric acid (GABA) are the most common neurotransmitters in the central nervous system, activating both ionotropic and metabotropic (modulatory) receptors. By exciting, inhibiting, and even modulating neural elements and microcircuits, these chemicals critically regulate brain information processing and energy metabolism at different spatiotemporal scales. Although a great deal of work has been done at the biophysical and cellular level, the exact relationship between the extracellular concentration of these molecules and emergence of specific patterns in neuronal ensemble activity remains elusive. Partly this is due to the fact that recording of the mean extracellular field potentials (mEFP) concurrently with a quantitative assessment of alterations in the concentration of such neurochemicals are currently unavailable. Here, we present a silicon-based implantable ultrafine microelectrode array (35 μm diameter and 50 μm thickness) composed of several iridium-stabilized electrochemical and electrophysiological contacts. The distance between each electrode channel is 250 μm. The electrophysiological electrodes have an average impedance of 0.5 MΩ at 1 kHz. The

amperometric electrochemical channels are divided into two groups of glutamate- and GABA-responsive electrodes with the former showing a sensitivity of 0.39 nA μM^{-1} for glutamate, while the adjacent channel has a sensitivity of 0.38 nA μM^{-1} for GABA. Both have a detection limit of 0.2 µM. This novel multimodal microelectrode was used to simultaneously monitor extracellular glutamate and GABA concentrations, spikes, multi-unit neuronal activity (MUA) and local field potentials (LFP) in the lateral geniculate nucleus (LGN) of anaesthetized, adult Wistar rats (n=5). Retinal stimulation with flickering monochromatic light, emphasizing the simplest form of feedforward processing in thalamus, induced neuronal response patterns in LGN that were highly correlated with the temporal alterations in glutamate concentrations. GABA responses, while similar in profile to MUA and LFP recordings, were found to be event-selective and uncorrelated with the overall range of neuronal activity, suggesting the involvement of network processes that require further investigation. Our findings suggest that this multimodal method may greatly contribute into our understanding of microcircuit organization, by reducing the inherent ambiguity in the mEFP through neurotransmitter-release-tracking. Understanding microcircuits and their interactions is the only hope to develop neural networks models that my underly the brain's function and dysfunction.

Abstract: In the field of neurotechnology, there has been a general trend towards miniaturization of implantable probes. Smaller probes allow for better integration with the surrounding tissue and ultimately promote improved longevity for chronic applications. Given the large amount of neurons in the brain (~86 billion), it lies close at hand that selective communication with individual neurons demands smaller electrode contacts for adequately resolving single unit activity. While miniaturization for stiff silicon probes has substantially advanced, there is still a

lack of flexible probes providing stimulation and recording at high density. We here present a Multisite Active Neuro-Technology Array (MANTArray) with 32 recording/stimulation sites at a pitch of 24 µm on polyimide (PI) to advance this trend also to polymer-based neural probes. The MANTArrays were fabricated with standard cleanroom lithographic technologies in a design employing multiple metal layers to increase packing density of recording and/or stimulating sites at a minimal device footprint: they are, in fact, only 78 µm wide and 12 µm thick. Connection tracks were embedded below the electrode sites and spread over four metal planes, separated by PI layers. The electrode contacts were coated with Iridium Oxide (IrOx), nanostructured platinum (nanoPt) or PEDOT/PSS to ensure low impedance for the microsized electrode contacts ($15x15\mu m^2$) and efficient charge injection. An impedance of $45.06 \pm 1.66k\Omega$ (at 1kHz) could be reached for the $15x15\mu m^2$ sites, suggesting excellent recording and stimulation properties. With the presented arrays, it is now possible to place all microelectrodes within e.g. the same layer of one cortical column and allow for neural recordings at exceptional spatial resolution. A large number of densely spaced single neurons can be followed with the MANTArrays even over long implantation times. The implementation of three-dimensional electrode materials, such as nanoPt and PEDOT/PSS, in addition, promotes high signal-to-noise recordings and makes MANTArrays suitable also for microstimulation.

Abstract: Simultaneous Neural recording Active Pixel Sensor technology (SiNAPS) is a modular circuit solution (Angotzi et al., 2019) to devise implantable active multielectrode array probes for simultaneous recording from hundreds to thousands of densely packed electrodes. Exploiting the modularity of SiNAPS technology, we were able to rapidly design and experimentally validate two different probe configurations, a single-shank and a four-shank probe. The former integrates 512 electrode-pixels (size 21x21µm, pitch 26µm in x direction, 28µm in z direction) arranged in 3 columns along a narrow (120 µm) and elongated (6.2mm) single shank; the latter integrates 1024 electrode-pixels (size 15x15µm, pitch 28µm) arranged on four distinct shanks (80µm wide x 5mm long; incorporating 256 contacts/shank covering 3.6mm; shank separation 560µm). Here we report the recording capabilities of these SiNAPS probes as evaluated *in vivo* in multiple labs and different animal models, including recordings from awake head-fixed mice, anesthetized rats, and anesthetized monkeys. Our SiNAPS probes acquired broad-band neural signals simultaneously from up to 1024 channels, with low noise, 7.5μV_{RMS} and 24.5 μV_{RMS} in the action potential and local field potential (LFP) bands, respectively. Noise levels measured in saline and *in vivo* were comparable, and in line with simulation results. The use of SiNAPS probes in rodents allowed us (1) to map LFPs across all layers of the cortex and down to the deeper hippocampal and thalamic regions (2) to track the propagation of neuronal activations across close-by electrodes and adjacent shanks and (3) to monitor the spiking activity of single units. In the monkey model, single shank probes were able to record the activity of the motor cortex with high spatiotemporal accuracy.

Title: A multi-channel capacitive coupled implantable system to restore natural sensory feedback

Authors: *P. KIELE, C. F. PASLUOSTA, T. STIEGLITZ;
Lab. for Biomed. Microtechnology, IMTEK-Dept Microsystems Eng, Univ. of Freiburg, Freiburg im Breisgau, Germany

Abstract: The loss of a limb severely restrains even simple activities of daily life. Prosthetic devices provide functional replacement of the missing limb but still lack of somatosensory perception, which is essential to restore proper object manipulation, the senses of embodiment and agency. Previous studies have demonstrated that natural sensory restoration is possible by electrically stimulating afferent nerves via implanted intrafascicular electrodes. However, assessing the remaining nerves after a limb amputation is usually difficult. Targeted Muscle Reinnervation (TMR) is a surgical intervention to re-route the remaining nerves from the stump to other part of the human body where they become more accessible. Thus, TMR presents as an excellent opportunity for restoring somatosensory feedback via electrical stimulation since sensory nerves also spread out while reinnervating the host muscles. This is specified as Targeted Sensory Reinnervation (TSR). We propose to take advantage of the natural branching of the reinnervated fibers to stimulate somatosensory pathways via an implanted system. Implanted stimulation electrodes are connected to a transcutaneous wireless coupling unit for the provision of energy and signals. A multichannel capacitive coupling approach is proposed for the transcutaneous coupling unit, consisting of extracorporeal electrodes placed on top of the skin and a subcutaneous counterpart. This approach unifies the beauty of eliminating failure due to complex implanted electronics and permanent skin trauma. Flexible and very thin implanted electrode arrays minimize the invasiveness of such a system and therefore foreign body reactions can be reduced. We evaluated the electrical crosstalk behavior of a ten channel coupling unit in an *ex vivo* study using healthy explanted human skin. Two different transfer strategies with and without direct contact of the metal part of the electrode and the skin tissue were evaluated. While the first provides additional resistive paths through the skin, the latter blocks these with a polymeric insulation layer. To integrate such system with lasting wearable devices (e.g., prostheses' socket), dry and reusable extracorporeal electrode arrays are required. Requirements on the implanted pickup electrodes are long-term stability and biocompatibility, which comprises thin and flexible arrays. The implication on resorting a selective natural sensory feedback with the proposed implantable system are further discussed.

Title: 3D-printed implants that facilitate chronic recordings and reuse of neuropixels probes in freely behaving rodents

Authors: *F. MICHON, C. AYDIN, R. VAN DAAL, H. DEN BAKKER, J.-J. SUN, S. HAESLER, F. KLOOSTERMAN;
NeuroElectronics Res. Flanders, Leuven, Belgium

Abstract: Studying the relationship between the activity of neuronal populations and behavior is critical to advance our understanding of brain function. Assays in which animals are unrestrained that promote naturalistic behaviors are better suited for the study of cognitive functions such as navigation or social interactions. Extracellular electrophysiological recordings provide the high temporal resolution to monitor single cells spiking activity as well as local field potentials. Recent technological advances have enhanced the sampling capabilities of neural probes. A single Neuropixels probe[1] enables recording from over 380 switchable electrodes distributed along the 10mm long probe shank. It offers the possibility to simultaneously record from several hundred cells from multiple brain regions in awake animals. Neuropixels probes have been successfully used in chronic preparations, with stable recordings over time and high cluster fidelity. However, at present little to no technical support exists to use these devices chronically in unrestrained behaving animals. In particular, current designs for chronic implants lack an efficient mechanism to recover the probes and do not support the integration of multiple probes in a single implant.
We have developed a 3D-printed implants for Neuropixels probes that facilitates the reliable use, and re-use, of probes chronically implanted in freely behaving rodents. The implants meet three key criteria: 1) it is lightweight and can be easily carried by rats and mice, 2) it enables chronic insertion of several Neuropixels probes at flexible coordinates, and 3) the neural probes are easily recovered and reused with high success rate. The 3D-printed implant has been successfully used to record from populations of cells over days in our lab. Overall, the system has the potential to facilitate and broaden the use of Neuropixels probes, and potentially similar devices, in chronic preparations for freely behaving animals.

Title: Continuous long-term tracking of neuronal clusters with ultraflexible oversampling electrode array

Authors: *H. ZHU[1], X. LI[1], Z. ZHAO[1], F. HE[1], X. WEI[1], L. LUAN[1], N. TRAN[2], C. XIE[1];

Abstract: The brain is formed by massively interconnected and constantly evolving networks of neurons that communicate in milliseconds. Therefore, the ability to reliably track gradual changes of local neural circuits with high temporal resolution longitudinally is crucial for the understanding brain functions. Conventional rigid extracellular electrode arrays provide simultaneous large scale neuronal recording. However, their capability to follow the same neurons over extended period of time remain elusive due to the gradual degradation of cell-electrode interface attributable to the chronic neuro-inflammatory response induced by the mechanical mismatch. Additionally, such mechanical mismatch under physiological micro-motions induces relative movements at the biotic-abiotic interface, which makes the same neurons difficult to track. Here we demonstrate semi-supervised mapping and tracking of neuronal ensembles over 30 days with ultraflexible electrode arrays [1] featuring oversampling contact densities. Ultraflexible electrode arrays with oversampling detection range were fabricated using our published method [1]. 32 channel probes were implanted in the mouse fore-limb sensory cortex. After two months of surgery recovery, tethered continuous recording was performed for 32 days. Recordings were segmented into overlapping one hour periods and sorted individually with MountainSort [2]. We sorted an average of 50.4580 ±5.9217 (n=1356) single units per time segment, or 2138.2 ± 150.3 (n=32) when pooled over all sessions per day. Units identified in each segment were compared against those detected on nearby sessions by waveform similarity and linked according to a binary split structured mutual nearest neighbor principle. After this step, units were grouped into 112.1250 ± 11.1782 distinct neurons. Within the same day, support vector machine based supervised tracking further merged the same units, which yielded 71.7813 ± 3.4895 uniquely tracked units per day. Across multiple days, similar semi-automatic procedure yielded 212 identified neurons, which could be tracked for 10.8349

±11.6153 days. Among these tracked neurons, 30 were identifiable every day. They moved, over this 32-day period, 13.8661 ± 10.1473 μm. We finally examined the waveforms of the 212 automatically tracked neurons visually and merged them into 90 final units. With ultraflexible electrode arrays, we demonstrate their capacity to reliably detect the same neurons longitudinally. References: [1] Luan, Lan (L.L.) Sci Adv, 2017, Vol 3, e1601966. [2] Jason E. Title: Using EEG as a translatable pharmacodynamic biomarker in non-human primates: Test case and reliability

Authors: *P. GARCES[1], M. POULIOT[2], S. AUTHIER[2], J. F. HIPP[1];
[1]Roche Pharma Res. Early Development. Neurosci. and Rare Diseases., Roche Innovation Ctr. Basel, Basel, Switzerland; [2]Citoxlab North America, Laval, QC, Canada

Abstract: Robust and reliable pharmacodynamic (PD) biomarkers are crucial for first in human studies. Modulation in the intensity of brain rhythms as measured with EEG (electroencephalography) can be used for this purpose, as shown in the benzodiazepines literature. However, identifying EEG biomarkers for clinical trials from preclinical experiments is challenging: EEG effects may not be translatable due to differences between species and experimental conditions. Here, we highlight the value of non-human primate EEG to inform clinical studies. We present a test case with diazepam and scopolamine in n=13 freely moving cynomolgus with EEG/EOG/EMG telemetry recordings (L04 transmitters, DSI). We opted for a freely moving telemetry setup rather than a constrained recording (with e.g. primate chair) which could be formally closer to a human resting state paradigm in order to allow for an extended EEG and behavioural evaluation (24h) while ensuring subjects' welfare and minimizing stress and emotional interference. Power spectra and power at classical frequency bands: delta (2-4Hz), theta (4-8Hz), alpha (8-13Hz), low beta (13-20Hz) and high beta (20-30Hz) were estimated with Morlet wavelet transforms for two EEG derivations: fronto-occipital (Fz-Oz) and frontal (Fz-F3). Only data without artifacts (visual and automated scoring) was used. Awake and asleep intervals (expert scoring) were considered separately. The statistical significance of drug effects relative to vehicle treatment was determined with linear mixed effects models. Significant modulations were observed for both drugs: decrease in theta power and increase in beta power with diazepam

(4 mg/kg p.o.) and increase in low frequency power with scopolamine (0.03 mg/kg i.m., all $p<0.001$). These patterns match the outcomes of previous human experiments. Notably, awake and asleep modulations, although qualitatively similar, differed in strength and variability. Additionally, the test-retest reliability of EEG power was estimated from two separate vehicle recordings (test-retest interval: 2-5 weeks) and was found excellent for all frequency bands (intraclass correlation coefficient > 0.9). Overall, the translatability of the EEG PD signatures for diazepam and scopolamine, along with an excellent test-retest reliability support the further use of this NHP EEG design to inform clinical studies

Abstract: Our group has developed carbon fiber electrode arrays that can record both electrophysiological and dopaminergic activity. These arrays can be implanted in a variety of brain regions at different depths. Previously, we used a glass cannula as an insertion guide to reach more ventral depths, but we noted that this would occasionally lead to heavy bleeding. To eliminate this problem the array was re-designed with carbon fibers secured within individual

silicon tines, or supports, that allow for a cannula-free insertion, while still maintaining functionality. The supports can be made to any desired length which has allowed us to record chronic dopamine (DA) in rat dorsal striatum as well as electrophysiology from rat motor and pre-frontal cortex (PFC). In three separate rats we have successfully implanted 8 channel arrays (pitch=160um), optimized for dopamine sensing, into dorsal striatum. In the first 2 rats, DA was detected intraoperatively on at least 6 of the 8 implanted channels after stimulation of the medial forebrain bundle (MFB). In a third rat, with a chronically implanted array, DA was detected on 6 of 7 active channels at day 12 after MFB stimulation. At day 16 in the same animal, DA was detected on all 7 active channels after an intraperitoneal (IP) injection of raclopride which came 20 minutes after an IP injection of cocaine.
To validate the ability of these array to detect electrophysiology we targeted two brain regions, motor cortex and PFC. In one animal we chronically implanted a 16 channel array (pitch=80um), functionalized with poly-3,4-ethylenedioxythiophene, into rat motor cortex. In this animal we detected unit activity out to 3 months. In a separate group of rats (n=9) we implanted an 8 channel variant (pitch=160um) into PFC and acutely detected activity from both excitatory and inhibitory neurons. In the latter group of animals we cemented the probes in place, perfused, and used our slice in place technique to isolate the probe tips within the tissue. Briefly, the skull, brain, and electrodes remain intact and soak in a solution that decalcifies the bone, which allows us to cryosection through all three at the same time. We can then identify cell types adjacent to our recording tips using antibody staining.
Taken together, these results point to the viability of this new platform to sense both electrophysiological and dopaminergic activity in various brain regions. We are developing automated fabrication methods to mechanically deposit and cut the carbon fibers to length to improve our device throughput and channel count. Increasing the electrode density and count will continue to provide more information about neural population dynamics.

Title: Fast functional imaging of neural networks with nanoelectrode arrays

Authors: *N. MUKUNDAN[1], H. YOON[2], A. KHAN[2], C. OWUSU-ANSAH[2];
[1]Neural Engin. Lab., Norfolk State Univ., Norfolk, VA; [2]Neural Engin. Lab., Norfolk State Univ., Yorktown, VA

Abstract: This research is to develop a fast electrical impedance tomography (fEIT) imaging system which can simultaneously image multiple areas of brain including deep brain structures on in behaving animals. This will enable chronic imaging of fast neural activity for deep brain structures and neuronal networks with high temporal resolution. This EIT imaging technology for fast neural activity could lead to radical advances in understanding brain function and enable quantitative mathematical modeling and analysis of neural systems. In this research, we fabricated vertically aligned IrOx/AuNW electrodes with low impedance values. For fEIT imaging of neural network, electrochemical properties of electrodes including impedance spectrum determines spatial and temporal resolution of imaging. We also developed an electronic system for effectively recording impedance changes during neuronal depolarization in the brain. Results from bench testing with various phantom samples to evaluate the EIT system functions and imaging algorithm will be presented.

Title: Highly flexible microelectrode arrays for intracortical single unit recording

Authors: *M. LEBER, A. HURLBUT, S. WIEBE, R. BHANDARI, S. NEGI;
Blackrock Microsystems, Salt Lake City, UT

Abstract: Implantable microelectrodes are indispensable in neuroscience research, offering the possibility to record and to stimulate extracellular potentials from single neurons, as well as multi-unit and local field potential recordings. Although rigid silicon based and metallic microwire electrode arrays have allowed intracortical recordings over the last decades, there has been continued interest to reduce the form factor of the microelectrodes. Smaller probe dimensions have the advantage being less damaging to the tissue, while flexible devices mitigate mechanical mismatch between the device and the surrounding tissue, leading to reduced foreign body response and therefore, improved signal quality and longevity of the device. Here we present MicroFlex Array (MFA), that unites all these favorable implant properties into a new robust and reliable microelectrode array solution. The MFA allows for a highly customizable layout of electrodes made of either platinum or iridium oxide. The electrodes are located on a 10

µm thin and 200 µm wide polyimide shaft, that can reach lengths of up to 80 mm (Figure 1 A). The MFA can be connected to a headstage through various connector types, such as Omnetics, pedestal, and Molex. Figure 1 B displays an assembly of 5 MFAs connected to a pedestal type connector. Using a minimally invasive process, the MFA can be implanted at various depths, avoiding the necessity of large craniotomies, or opening the dura during implantation. With a patent pending implantation technology, the MFA can record from single units during stereotaxic insertion. This allows the device to be implanted at the desired optimal depth in the tissue. We have achieved acute recording from hippocampus area with signal-to-noise ratios of over 20:1 and are currently pursuing our chronic experiments for several weeks. With the data recorded from the MFA up to date, the presented technology will mark a new milestone in electrophysiology and single unit recordings in neuroscientific research.

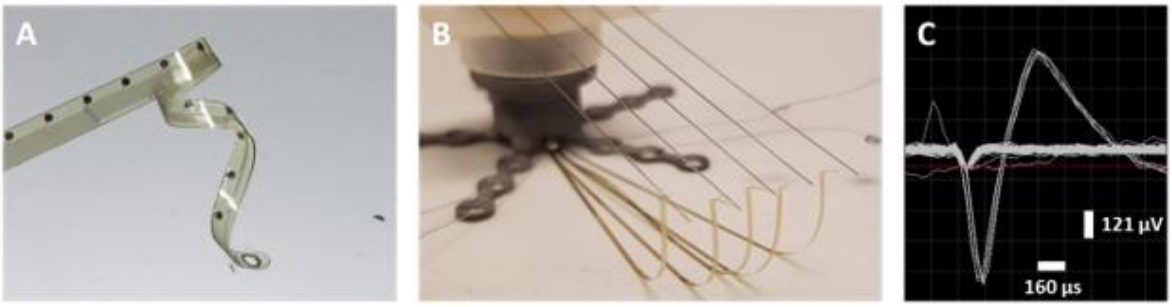

Figure 1: A) Flexible MFA shaft with electrodes. B) Assembly of 5 MFAs to pedestal with insertion needles. C) Recording of 2 single units in acute rodent experiment form same iridium oxide electrode (30 µm diameter).

Title: Ultra-sensitive measurement of *in vivo* brain penetration with microscale probes and live imaging

Authors: A. M. OBAID[1], *Y.-W. WU[2], M.-E. HANNA[4], J. B. DING[5], N. MELOSH[3]; [1]Stanford Univ., Stanford, CA; [2]Stanford Univ., Palo Alto, CA; [3]Materials Sci., Stanford Univ.,

Stanford, CA; [4]Mina-Elraheb Hanna, Stanford University, CA; [5]Neurosurg., Stanford Univ. Dept. of Neurosurg., Palo Alto, CA

Abstract: While penetrating microelectrodes have been used effectively in experimental neuroscience for decades, important quantifications of the force and work exerted on the brain tissue during insertion are not well described. The most critical theme of these microwire electrodes is to have the wires inserted into the brain without buckling but also have them small enough so that they can insert and reduce physiological damage. Mechanical measurements of single wire insertion into the brain are important quantifications of the force and work exerted on the brain tissue during insertion and may help identify lower-damage microelectrode designs and surgical procedures.Many aspects of the mechanics of insertion remain unknown, such as the effects of wire diameter and tip shape. To address the limitations of typical force transducers, we have devised a high-resolution mechanical measurement system to probe the ultra-compliant properties of the brain at much higher force and temporal resolution than previous measurements. We perform a systematic study of the insertion mechanics into traditional brain mimics, freshly removed murine brains (ex-vivo), and in-vivo for a series of different microwire diameters (7.5 um to 125 um) and tip geometries (flat, angled, and electrosharpened).Surprisingly, both penetration force and tissue compression scaled linearly with wire diameter, rather than cross-sectional area. Linear brain compression with wire diameter strongly suggests smaller probes will cause less tissue damage upon insertion, though unexpectedly no statistical difference was observed between angled and flat-tipped probes. The data from brain insertion was strikingly different from those in traditional brain mimics and excised tissue and provide the first clear view of how insertion mechanics depend on wire geometry.These ultra-sensitive force measurements were coupled with live 2-photon microscopy and epifluorescence imaging, providing a unique visualization of the insertion process with simultaneous force measurement. We found no disruption of microvasculature with wire diameters of 25 um or less, while damage is clearly observed with diameters greater than or equal to 50 µm. These first of their kind measurements provide a mechanical framework for designing effective microprobe geometries while limiting mechanical damage.

Title: Improved insertion of floating microelectrode arrays in brain with an ultrasonic vibration insertion system

Authors: *R. S. CLEMENT, N. N. TIRKO, J. K. GREASER, R. B. BAGWELL, M. L. MULVIHILL;
Actuated Med. Inc., Bellefonte, PA

Abstract: Penetrating microelectrode arrays have been a valuable research tool for neuroscientists to interface with and study brain circuits with both high temporal and spatial resolution. A common challenge with these devices is how to successfully implant them to a pre-determined cortical depth without excessive dimpling and trauma. Sub-optimal insertion mechanics can result in non-uniform shank insertion, increased risk of trauma, bleeding and inflammation at the implant site, and may accentuate the chronic foreign body response (FBR) leading to neural cell death, glial scaring, and device failure. These issues have limited the use of penetrating arrays in preclinical studies as well as clinical translation of these devices to applications such as brain-machine interfacing and cortical visual prostheses. We have previously shown that ultrasonic vibration of fixed microwire electrode arrays during insertion improves insertion accuracy and reduces insertion force and tissue dimpling, without interfering with electrode integrity or performance. Adapting the approach to floating arrays (FAs)—designed to float with the brain to reduce relative micromotion at the brain-implant interface—offers specific challenges related to effective coupling and non-perturbing post-insertion release. Here we present on our efforts to adapt our ultrasonic vibration technology (www.neuralglider.com) to several FA types, including NeuroNexus (H-series, Matrix) and Microprobes floating microwire arrays. Our implant insertion system incorporates a piezoelectric ultrasonic transducer, operated in an axial resonant mode, which transmits high frequency micro-vibrations to the FA. We developed several reversible coupling approaches to efficiently couple vibration between the insertion system and the FA, allowing for non-perturbing release of the FA following insertion. These have included temporary adhesive (e.g. polyethylene glycol) or mechanical gripping-based approaches. Approaches were evaluated in benchtop insertion studies in agar and *ex vivo* tissue models, as well as *in vivo* insertion studies in acute and chronic rat and pig models. Results (insertion video analysis, neural recordings, histology) support the feasibility and potential of the insertion system for improving insertion mechanics of a wide range of implant types.

Title: Suture-like braided microprobes for peripheral nerve interfaces and multi-sites and combinatorics for higher yields in neural recording

Authors: *T. KIM[1], K. A. SCHMIDT[3], S. F. GISZTER[2];
[2]Dept Neurobiol & Anat, [1]Drexel Univ. Col. of Med., Philadelphia, PA; [3]Drexel Univ., Philadelphia, PA

Abstract: The braided multi-electrode probe (BMEP) is a bundle of tubularly braided ultrafine microwires used as a neural probe to record neural signals or stimulate neural tissue with electrical current for neural interfaces. A BMEP has potential empty space due to the intrinsic tubular structure. Any material can form the core and occupy the lumen. Surgical sutures are one core material. We call long BMEPs with sutures, or without a suture core 'suture-like BMEPs' - they could be used as sutures. Peripheral nerve interfaces require a smaller size and greater mechanical flexibility due to the long thin form and freely moving conditions of peripheral nerves. We show comparisons of BMEPs consisting of 6 x 9.6um wires, with and without 10-0 suture cores with the LIFE electrode. The LIFE has the smallest footprint (35um diameter) as an intrafascicular peripheral nerve interfaces. Our suture-like BMEP not only has higher mechanical flexibility (albeit bigger diameter), but also 6 recording/stimulation channels. We suggest that the suture-like BMEP is ideal for some peripheral nerve interfaces. In addition, suture-like BMEPs support increased neural yield per wire in single unit electrophysiology using combinatoric probe designs. Combining individual wire sites in different locations can provide unique wire combinations with polytrode pickup capabilities at each location. These help to localize and separate units along the length of the probe. We have performed computational simulations under the condition that 9 wire probes arranged as multisite wires (4 sites per wire) in an iterated ${}_3C_2$ pattern with 5 seconds of 40Hz Poisson distributed spike trains from 4 neurons with unique spike shapes at 30KHz sampling rate. To extract mixed signals, ICA (Independent Component Analysis), a blind source separation algorithm was used. From simulation results, we found good combinatoric signal extraction (ICA separated each spatial site's activity nearly perfectly, with correlation values between the original site activity without noise added, and activity reconstructed via ICs averaging 0.9981 ± 0.0007). This result shows that the potential neural yields with this technique could be increased by a factor of 4. This technique can be used with

modified braid geometry by our second generation microbraiding machine in near future. The 6 wire suture-like BMEP described above can be arranged as a $_3C_2$ pattern of paired wires assembled in groups of 4 under this strategy. Supported by NIH NINDS NS054894 and NS072651

Title: Leveraging MRI, CAD, CAM and 3D printing to implant five microelectrode arrays in three nodes of the macaque frontoparietal grasp network

Authors: *R. N. TIEN, A. B. SCHWARTZ;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Comprehensive study of the neural basis of complex behaviors such as grasping and object interaction requires simultaneous electrophysiological recording in multiple cortical brain areas, some of which are located deep in sulci. Here, we present a novel method in which MRI, CAD, CAM and 3D printing were used to enable rapid, accurate and stable implantation of multiple microelectrode arrays into three brain areas. We used structural MRI to non-invasively image the brain and skull anatomy. We then segmented these MRI images and imported them into a 3D CAD model to plan the placement of five electrode arrays (four Microprobes FMA electrodes and one Blackrock Utah array) totaling 224 channels. This model was then used to generate a bespoke 3D printed insertion guide. Use of this guide reduced total surgery duration and ensured precise electrode array placements, resulting in high unit yield. Traditional computer-aided manufacturing techniques were leveraged to fabricate a custom titanium pedestal to house the FMA connectors for robust long-term recording. A 3D printed model of the subject's skull allowed for intuitive, hands-on planning of the incision, craniotomy, bone strap and pedestal placements. This method could easily be extended to streamline the implantation of a multitude of different probes in cortical or subcortical sites.

Title: A Utah Array based acute microelectrode array for intra-operative recordings from human cortex

Authors: *G. PALIS[1], R. BHANDARI[1], V. NGO[1], R. FRANKLIN[1], M. GERHARDT[1], F. SOLZBACHER[2];
[1]Blackrock Microsystems, Salt Lake City, UT; [2]Univ. of Utah, Salt Lake City, UT

Abstract: Research Focus: Tools and methods
Rationale: An increasing number of neurosurgeries (DBS implantation, epilepsy monitoring with SEEG) are completed with burr hole incisions instead of traditional craniotomies due to reduced surgical complications. Vast amounts of data could be collected from micro-electrodes during these surgeries.
Objective: Characterize a re-designed Utah Microelectrode Array's ability to record single unit activity and local field potentials intra-operatively through a burr hole.
Abstract:
The NeuroPort Electrode, the FDA cleared Utah Multi-Electrode Array, (UMEA) has served as the only FDA cleared cortical microelectrode and has provided significant volume of data invaluable to the neuroscience community. The UMEA has been most impactful in the fields of brain computer interface and motor prosthetics, however it has played a critical role in the study of learning, memory, sensation, and visual processing/prosthetics.
The UMEA is an invasive cortical electrode that requires a craniotomy for implantation. The surgical risk associated with craniotomy limits the volume of the research efforts with the UMEA. Due to reduced surgical complications when using burr holes instead of craniotomies, more and more common neurosurgeries, such as epileptic monitoring and placement of deep brain stimulation (DBS) leads, are completed with a burr hole only. As DBS devices are implanted more frequently for treatment of the motor symptoms of Parkinson's disease and are shown to be safe and effective treatments for additional neurological disorders the number of neurosurgeries completed with burr holes will continue to increase.
A UMEA adapted for acute recordings through a burr hole would allow collection of significant amounts of otherwise inaccessible single unit activity and local field potential (LFP) data, advancing the field of neuroscience without posing significant additional risk to patients undergoing said procedures.
The goal of this poster is to characterize the adapted UMEA, dubbed the Right-Angle Array, to demonstrate suitability for single unit and LFP recordings from cortex through a burr hole >4 cm

diameter. This poster will also present surgical experience and data collected by the first neurosurgeons to use the Right-Angle Array in human studies.
Conclusion: The Right Angle Array is a modified UMEA proposed for acute recordings during neurosurgery procedures, such as DBS implantation, for collection of otherwise inaccessible single unit and LFP data without posing additional surgical risk to patients.

Title: Tissue reaction to the neural probes implanted into the rat brain: A transcriptome analysis

Authors: *E. V. DIAS[1], J. D. MACHADO[1], R. PANEPUCCI[2], R. COVOLAN[1], F. CENDES[1], I. T. LOPES-CENDES[1], A. S. VIEIRA[1];
[1]State Univ. of Campinas - Unicamp, Campinas, Brazil; [2]CTI Renato Archer, Campinas, Brazil

Abstract: Brain probes are important tools for understanding the nervous system. They allow evaluating the electrical activity of single neurons and its relation with the subject behavior. Since neural probes need to be positioned within tens of micrometers of the neurons of interest, they are necessarily invasive devices. As it happens with any foreign material that is implanted into the body, the tissue reaction process starts with the attempt to clean up the site and eliminate the threat of the invader. If the threat persists, a chronic inflammatory process ensues, with the attempt to shield the affected area from the surrounding tissue. This shielding, which in the brain consists of a capsule formed predominantly by astrocytes, gradually decreases the quality of the recorded neuronal signals. This study evaluates tissue response to the neural probes designed and fabricated by the BRAINN research groups, comparing it with the tissue response to other recording devices implanted into the brain. Stereotaxic surgery for implantation of recording neural probes was performed in Fischer 344 male rats. Rats received recording neural probes developed in BRAINN projects, or commercial silicon probes, or stainless steel micro wires. Recording probes were implanted into the dentate gyrus of the hippocampus (AP -3.0; L ±2.0; V

-3.5). After a period of 2 or 28 days, rats were euthanized and the brains were removed. Laser microdissection of the regions proximal to probe implantation was carried out and the material was subjected to transcriptome analysis by RNA-seq using Illumina HiSeq platform. Neural tissue was also analyzed with immunofluorescence labeling for markers for foreign body reaction (GFAP and CD68), and for neuronal marker (NeuN). All procedures were approved by the Ethics Committee for Animal Research at the Unicamp (protocol 4438-1). Transcriptome analysis showed around 8000 differentially expressed genes among control and implanted groups. Between implanted groups, there are 748 differentially expressed genes in the tissue surrounding the BRAINN probe compared to the tissue surrounding the stainless steel micro wire. Two days after surgery, the tissue surrounding the probes is disorganized and immunostaining for CD68 around the probe sites reveals reactive microglia. Our preliminary data show that probes implanted into the brain lead to an acute reaction with drastic changes in gene expression. Furthermore, different probe materials induced different tissue responses.

Title: EXTRACT: Automated cell extraction for large-scale neural calcium imaging based on a framework of robust statistics

Authors: *H. INAN[1], T. TASCI[1], C. SCHMUCKERMAIR[1], B. AHANONU[2], O. HERNANDEZ[1], M. A. ERDOGDU[3], M. J. SCHNITZER[4];
[2]Dept. of Biol., [1]Stanford Univ., Stanford, CA; [3]Univ. of Toronto, Toronto, ON, Canada; [4]Depts. Biol. & Applied Physics, Stanford Univ. Dept. of Biol., Stanford, CA

Abstract: Fluorescence imaging of neural calcium activity enables studies that track the dynamics of large ensembles of individual cells in awake behaving animals. These experiments can extend across repeated imaging sessions, and due to recent advances in optical imaging technology, can sample thousands of cells per session. Thus, there is a major need for fast and accurate computational approaches that can extract the identities of individual neurons and their activity traces from large video datasets. Common computational challenges include nearby cells that share overlapping sets of video pixels, and non-stationary background fluorescence from neuropil activation. Past research has sought to address these challenges, but a general-purpose

framework that is applicable across a wide range of imaging modalities has not emerged. Here we present a computational platform, termed EXTRACT, for cell extraction based on the framework of robust statistical estimation. By testing our approach on simulated and experimental datasets, we found that this framework enables substantial improvements in the accuracy with which neural morphologies and activity traces can be estimated under realistic imaging conditions. EXTRACT is well suited to use on datasets exhibiting a broad range of signal and noise attributes, including those typical of recent one- and two-photon fluorescence imaging modalities for use in head-fixed and freely behaving animals. Efficient implementation of EXTRACT, including parallelization across multiple graphical processing units (GPUs), allows imaging datasets to be processed about ten-fold faster than the actual recording durations. We used EXTRACT to analyze data from several different calcium imaging experiments in behaving animals; the resulting neural activity traces enabled superior reconstructions of animal behavior than activity traces from other cell sorting algorithms. Overall, EXTRACT is a powerful, high-fidelity approach for automated analysis of large-scale calcium imaging datasets.

Title: Automatically delineating anatomic regions and mapping cell populations in mouse brain

Authors: *N. J. O'CONNOR[1], B. S. EASTWOOD[1], P. J. ANGSTMAN[1], N. D. LIESE[1], C. S. GERFEN[1], H. L. KESSLER[1], M. GULENKO[1], C. R. GERFEN[2], J. R. GLASER[1];
[1]MBF Biosci., Williston, VT; [2]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Advances in molecular neuroanatomical methods have expanded the ability to map connections of specific neuron subtypes in the context of behaviorally or pathologically driven patterns of neuronal activity. Analyses of connectivity and neuronal activity across whole mouse brains that have been registered to a reference atlas reveal details about the functional organization of brain circuits related to behavior and pathologies that can be compared across animals, experiments, and laboratories. Here we present novel advances to our previous work for automatically aligning and reconstructing images of mouse brain sections labeled with standard histochemical techniques into whole-brain 3D image volumes, registering these brain image

volumes to the Allen Mouse Brain Common Coordinate Framework (CCF), and subsequently automatically delineating anatomical brain regions in experimental tissue sections.
Sections containing brain regions with well-defined anatomic landmarks are registered to the CCF with a transform model that accounts for artifacts due to histological cutting, mounting, and fixation. This transform is propagated to other sections with linear and nonlinear refinements that preserve the histologic sectioning model. We compared atlas-based segmentation results using this method to the previous single-section approach using manual delineations of 15 anatomic regions.
Examples of whole brain analysis of connectivity using trans-synaptic rabies labeling of neurons providing inputs to Cre-expressing neuron subtypes and of analysis of behaviorally relevant brain circuits using fos labeling of activity in neurons correlated with specific behaviors. For analysis, coronal brain sections are reconstructed into a 3D volume, labeled neurons are automatically marked using a Laplacian of Gaussian algorithm, and brain sections and marked neurons are registered to the CCF. The number of labeled neurons in each of the 2500 brain structures in the CCF are tallied, allowing for comparative quantitative analysis between mice.

Title: Automatic segmentation and detection of neuronal cell types from serial-two photon obtained whole-brain mouse images using U-Net

Authors: *C. ELOWSKY[1], J. PALMER[2], K. UMADEVI VENKATARAJU[2];
[1]Cold Spring Harbor Lab., Cold Spring Harbor Laboratory, NY; [2]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Since the advancement in automated high-throughput whole brain imaging, there has been a large effort to identify the existence of diverse neuronal cell types. Manually tracing these cells is a tedious and time consuming process, and automated segmentation methods, such as traditional convolutional neural networks, have proven to be sub-optimal. U-Net, a generic deep-

learning-based model, designed as a modified convolution network architecture, has proven to achieve more precise cell detection and segmentation. Using special data-augmentation strategies, U-Net allows for accurate segmentation of large amounts of biological images, with only minimal training data needed. We propose the use of U-Net in our computational pipeline for detection and segmentation of both cytoplasmic and neuronal signal from fluorescently labeled whole-brain mouse images obtained via serial two-photon tomography.

Title: A neuronal dynamic clamp system for improving action potential recording in human stem cell derived neurons

Authors: *M. W. NOWAK[1], B. K. PANAMA[2,1], B. FRANKS[1], L. KORBEL[1], R. L. RASMUSSON[2,1], G. C. L. BETT[2,1];
[1]Cytocybernetics Inc., North Tonawanda, NY; [2]SUNY Buffalo, Buffalo, NY

Abstract: Human stem-cell derived (hiPSC) neurons are a model system for studying the electrophysiological properties of native neurons. A significant limitation of the neuronal hiPSCs is the decreased/lack of expression of background K^+ currents (e.g. TASK, TWIK, TREK) resulting in depolarized resting membrane potentials (RMPs) and the inability to evoke stable action potentials (APs). We have overcome this limitation by using a neuronal dynamic clamp system to electronically express in real-time tunable K+ current-voltage relationships to hyperpolarize the RMP. iCell hiPSC GABANeurons (Fujifilm Cellular Dynamics, WI) were cultured according to the manufacturer's instructions and used 7-27 days after plating. Standard electrophysiology voltage clamp with the whole-cell ruptured configuration was used, and APs were triggered by stimulating with 0.5-1.0 nA pulses for 0.3-1.5 ms at 0.5 Hz. Background K^+ currents were electronically expressed using a real-time dynamic clamp system (Cytocybernetics, NY).
The resting membrane potentials (RMP) of the neuronal hiPSCs were highly depolarized (31±1 mV, n=72) with distorted evoked APs (Amp. = 60±3 mV, after-hyperpolarization (AHP) at -45±2 mV). We tuned the RMP to -65 mV via injection of a constant current (I_{const}) and the electronic expression of a background outwardly rectifying K^+ current (I_{GHK}). Injection of a constant current resulted in unstable RMPs (σ=2; n=8) while electronic expression of I_{GHK} had a

more stable RMP (σ=0.7 mV, n=10). There were differences in AP morphology. With expression of I_{GHK} the amplitude showed a decrease as compared to constant current injection (I_{GHK}: 112±4 mV, I_{const}=123±4 mV, n=8, $p<0.05$).
To examine the effects of background conductance on excitability we extended the electronic expression of I_{GHK} to allow tuning of RMP to hyperpolarized potentials (-55 to -65 mV) resulting in the recording of evoked APs with a characteristic after-hyperpolarization (for RMP= 55 mV: Amp.= 95±4 mV, AHP at 62±1 mV, n=25). In a subset of hiPSC neurons, we also observed RMP-dependent spontaneous firing.
Taken together, we have shown that electronic addition of background K+ currents during electrophysiological recording in hiPSC neurons allows the tuning of RMPs to physiological levels improving the measurement of functional responses (action potential morphology, phasic firing, post synaptic summation, after-hyperpolarization and long-term potentiation).

Title: Connectivity analysis of multielectrode data from simulated CPG and real neural systems using a stochastic framework

Authors: M. ABOLFATH-BEYGI[1], T. D. SANGER[2], ***S. F. GISZTER**[3];
[1]Dept. of Biomed. Engin., [2]Biomed. Engin., USC, Los Angeles, CA; [3]Neurobio., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: We have developed a new methodology for connectivity analysis using a stochastic model. This may also be combined with neural perturbation. The method is based on stochastic dynamic operators (SDO) used in order to quantify the peripheral effects in EMG and limb state and the internal inter-relations of neural dynamics. Our goal has been to develop a methodology for discovering structural connectivity maps with stimulation of fewer neurons in the network. The SDO framework quantifies uncertainty in the dynamics, and we aim to use this framework for discovering effects and connectivity in the presence of uncertainty and without any averaging or dimensionality reduction in the high-level network behavior. SDO allows for quantifying the dynamic effects of both individual and ensemble of neuronal populations on outputs and activity of other populations. By learning these dynamic effects, we can predict the output or bias control in the network. The framework goals are understanding neural connectivity, and developing predictive models suitable for neuroprostheses. The advantages of the SDO framework over current neural analysis and predictive models include: 1) ability to describe state-based probabilistic dynamic effects of neurons, 2) methodologies to embed nonlinear dynamics in a linear framework in the probability domain, and 3) capacity to extend pair-wise neural analysis to multi-neural analysis through linear superpositions in probability. In the SDO framework, each spike triggers a Markov operator mapping probability of current state of movement variables to the probability of next state. An SDO thus represents both sensory (current state) and motor (mapping to the next state) effects in the neuron. We use both real neural data collected in spinal frogs, and artificial data from a simulated spinal network as a 'ground truth' network of known connectivity and hierarchy, driven by Hodgkin-Huxley dynamics, as developed by Rybak, Shevtsova, and Markin for spinal cord simulation of populations of pattern generation neurons. The 'fictive' simulated network generates rhythms, deletions, and motor pool spiking which can be integrated to simulate electromyographic (EMG) recordings. Previous tests validated the use of SDO-based predictive models of EMG as well as interneuron firing activities. We have assembled the framework into two analysis packages in MATLAB which are now under beta testing by users before broader distribution. In conclusion, the SDO framework shows significant promise as a new mathematical model for understanding, interacting with and controlling neural activity in BMI and prosthetics.

Title: Rigbox: An open-source toolbox for probing neurons and behavior

Authors: *J. BHAGAT[1], M. J. WELLS[1], A. J. PETERS[1], K. D. HARRIS[1], M. CARANDINI[1], C. P. BURGESS[2];
[1]Univ. Col. London, London, United Kingdom; [2]Deepmind, London, United Kingdom

Abstract: Setting up a behavioral neuroscience experiment is a complex process that is often managed with ad hoc solutions. To streamline this process, we developed Rigbox, a high-performance, open-source software toolbox for managing experiments. Rigbox simplifies hardware/software interfacing, synchronizes data streams from multiple sources, manages experimental data via communication with a remote database, and creates an environment where experimental parameters can be easily monitored and manipulated. The toolbox's object-oriented paradigm facilitates a modular approach to designing experiments.
The main submodule of Rigbox, Signals, allows straightforward programming of behavioral experiments. Signals is built around the paradigm of functional reactive programming: an experiment is represented as a reactive network whose nodes represent experimental parameters which evolve over time through mutual interactions. The input nodes to this network represent time, experiment epochs, and hardware input sensors. This framework allows an experimenter to concisely describe an experiment as a set of transformations on the input nodes that update as the experiment unfolds.
Rigbox runs in MATLAB, with some Java components to handle network communication, and a C library to boost performance. Rigbox requires two computers, referred to as the "Master Computer" (MC) and "Stimulus/Slave Computer" (SC). MC is responsible for selecting, parameterizing, starting and monitoring an experiment via a MATLAB GUI. SC is responsible for running an experiment on a rig and interacting with that rig's hardware during runtime. MC can control multiple SCs simultaneously. MC and SC communicate during runtime via Java WebSockets using TCP/IP. Precise hardware requirements depend on the complexity and number of experiments run concurrently. For most experiments, typical modern desktop computers running Windows will suffice. Rigbox is available open-source at https://github.com/cortex-lab/Rigbox.

Abstract: A fundamental goal of systems neuroscience is to understand the relationship between neural activity and behavior. Behavior has traditionally been characterized by task-related variables such as movement speed or response times. More recently, there has been a growing interest in analyzing video data collected during experiments. One approach is the supervised tracking of body parts [Mathis et al. 2018, Pereira et al., 2019, Graving et al. 2019], though this requires user effort to label training images and may not capture all of the useful information in the image. Fully-unsupervised linear dimensionality reduction methods have been used to represent behavioral videos directly [Musall et al. 2019, Stringer et al. 2019], but these require a large number of dimensions to represent behavioral videos, hampering downstream analyses. Here we introduce a probabilistic framework for the unsupervised analysis of behavioral video and neural activity, building upon previous work [Wiltschko et al. 2015, Johnson et al. 2016, Gao et al. 2016, Markowitz et al. 2018]. This framework provides tools for compression, segmentation, generation, and decoding of behavioral videos. Compression is performed using convolutional autoencoders (CAEs), which yield a low-dimensional, continuous representation of behavior that requires fewer dimensions than linear methods (e.g., PCA) to obtain the same video reconstruction error. We then use an autoregressive hidden Markov model (ARHMM) to segment the CAE representation into discrete "behavioral syllables" and find that many syllables correspond to interpretable behaviors (e.g. grooming, rearing). The resulting generative model can be used to simulate behavioral video data. Finally, we fit decoders which take in neural activity and output estimates of the full-resolution behavioral video. These analyses allow us to explore how behavior is represented across different brain regions.
We demonstrate the use of this framework using a wide range of experimental paradigms and behavioral and neural recording technologies: video and neuropixel recordings from freely behaving head-fixed mice [Steinmetz et al. 2018], video and widefield imaging from task-engaged head-fixed mice [Musall et al. 2019], and 3D depth imaging and microendoscopic calcium imaging from freely moving mice exploring an open field environment [Markowitz et al. 2018].

Title: Localized semi-nonnegative matrix factorization (LocaNMF) for widefield calcium imaging data

Authors: *S. SAXENA[1], I. KINSELLA[1], S. MUSALL[5], J. MESZAROS[2], D. N. THIBODEAUX[3], S. H. KIM[2], J. P. CUNNINGHAM[1], E. M. HILLMAN[4], A. K. CHURCHLAND[5], L. M. PANINSKI[2];

Abstract: Widefield calcium imaging is a high-throughput approach for recording large-scale neural activity across dorsal cortex. In order to examine the relationship of these neural signals to the resulting behavior, it is helpful to compress, denoise, and demix the videos into meaningful spatial and temporal components that can be decoded and compared across different behavioral sessions and experimental conditions. Mapping the inferred components onto well-defined brain regions provides an interpretable, stable decomposition. Although existing brain atlases define detailed maps of the cortical structures for an average mouse, no current tools satisfactorily extract the activity of the different brain regions in individual mice in a data-driven manner, while taking into account mouse-specific and preparation-specific differences.
Here, we introduce a variant of Nonnegative Matrix Factorization (NMF), termed Localized semi-NMF (LocaNMF), that efficiently decomposes widefield video data and allows us to directly compare activity across multiple mice by outputting mouse-specific localized functional regions. LocaNMF uses a fast low-rank version of Hierarchical Alternating Least Squares (HALS), and outputs components that are significantly more interpretable than more traditional NMF or SVD-based techniques. Specifically, while representing a user-defined fraction of the variance in denoised data (usually chosen to be 99%), it also outputs spatial components that are soft-assigned to atlas-defined regions, thus easily enabling comparison across animals.

Moreover, it provides a natural subspace to directly compare correlation maps and neural dynamics across different mice, and enables identification of task- and movement-related brain regions. In experimental data from mice expressing different calcium indicators and exhibiting a variety of behaviors, we find that (a) functional regions are consistent across different sessions in the same mouse, (b) correlation maps across these regions are consistent across different sessions in the same mouse and even across some mice, (c) the frontal areas of cortex are consistently useful in decoding the direction of licks in a spatial discrimination task, and (d) the parietal areas of cortex are useful in decoding the movements of the paws during the same task, as tracked using DeepLabCut. Thus, the LocaNMF decomposition provides a useful framework when analyzing widefield calcium imaging activity across mice.

Title: Cortex-wide activity during task learning reveals increasing engagement of parietal and frontal areas during decision-making

Authors: *S. MUSALL, S. GLUF, H. MOHAN, X. AN, Z. HUANG, A. K. CHURCHLAND; Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Multiple cortical areas are involved in learning and execution of complex behaviors. During learning, neural activity within local cortical circuits undergoes significant changes, such as enhanced representation of task-related sensory stimuli or decision variables. However, how cortex-wide activity patterns change with task-learning and how they relate to changes in animal behavior is unknown. Further, it is not known whether different types of excitatory, cortical neurons may represent distinct functional circuits that contribute differently to decision-making. To address these questions, we trained GCaMP6f-expressing, transgenic mice on a delayed, audio-tactile rate discrimination task and recorded neural activity across the dorsal cortex using widefield calcium imaging. Mice were imaged continuously over 4-5 months while learning

increasingly complex task stages. The total variance and dimensionality of cortical activity was similar across all sessions, indicating that large-scale cortical activity remains largely stable over longer time periods. In addition, we used video cameras and behavioral sensors to record animal movements and quantify long-term changes in animal behavior. Using a multivariate-regression model, we found that cortical activity in all sessions was mostly related to animal movements. Over several weeks of training, animal movements became less variable and their predictive power decreased while the importance of task variables increased. To isolate task-related activity, we then trained a logistic regression model to predict sensory stimuli and upcoming animal choices. Choices were well-predicted by activity in frontal cortical areas while sensory stimuli were most represented in primary sensory, parietal and secondary motor cortices. These results were confirmed by optogenetically inactivating parietal or frontal cortex. In both areas, inactivation strongly impaired task performance, with parietal effects being stronger during stimulus presentation and frontal effects being stronger during a subsequent delay. Lastly, we collected imaging data from transgenic mice that expressed GCaMP6f in excitatory neurons, either projecting to the striatum or other subcortical regions. Here, we found that corticostriatal projection neurons in parietal cortex reliably encoded auditory stimulus information while subcortical projection neurons in frontal cortex reflected animal's upcoming choices. Our results offer a detailed quantification of long-term changes in cortical activity and animal behavior and highlight the importance of parietal and frontal cortices for decision-making.

Title: From artificial to biological neural networks: How machine learning facilitates simulation of nonlinear synaptic dynamics in large-scale models

Authors: *D.-T. J. PHAM[1], J.-M. C. BOUTEILLER[2], G. J. YU[3], D. SONG[2], T. W. BERGER[2]; [1]Biomed. Engin., USC, Los Angeles California, CA; [2]Biomed. Engin., [3]USC, Los Angeles, CA

Abstract: Accurately capturing synaptic dynamics using computational models may prove important in identifying neuron- and network-level emergent properties. Existing detailed kinetic models can replicate complex synaptic nonlinear dynamics, but they are not practical in large-scale models due to the computational complexity associated with the number of differential equations that need to be solved at every timestep. This motivates the development of a more parsimonious model capable of maintaining biological accuracy while keeping computational load to a minimum. Previously, we have developed the Laguerre-Volterra Input-Output (LV-IO) Synapse model and its successor, the Laguerre-Volterra Network (LVN) as means for accurately predicting the synaptic dynamics while circumventing the complexity of the kinetic models. Using these models resulted in significant reduction in computational load. In the present study, we introduce two new models and associated methodologies. The first is the Laguerre-Volterra Network using Artificial Neural Networks (LVN-ANN) which implements the LVN model within the Keras deep learning framework. The second is the Laguerre-Volterra Network Look-Up Table (LVN-LUT) in which specific waveforms are stored in a pre-computed look-up table thereby replacing costly operations with computationally fast memory access. The results we obtained indicate that the LVN-ANN is capable of significantly reducing model training time by a factor of 40 when compared to the previous LVN model implementation, while also slightly improving accuracy. Additionally, the LVN-LUT model further reduces simulation time, offering over 10-fold speed increase over our previously fastest model, while yielding similar accuracy levels. Here, we present our results and demonstrate how using such methodologies enable us to extend simulations to large-scale network-level models that include a very large number of synapses, all while maintaining biologically realistic accuracy and efficient runtimes.

Title: A numerical approach to calculating LFPs in multi-scale neural network models

Authors: C. S. BINGHAM[1], C. GIRARD[2], J. PAKNAHAD[3], D. SONG[1], ***J.-M. C. BOUTEILLER**[4], G. LAZZI[3], T. W. BERGER[1];

[1]Biomed. Engin., USC, Los Angeles, CA; [2]Electrical Engin., USC, University of Southern California, CA; [3]Electrical Engin., [4]Dept. of Biomed. Engin., USC, Los Angeles, CA

Abstract: Significant progress has been made toward model-based prediction of hippocampal activation in response to extracellular electrical stimulation, but challenges remain in the accurate and efficient estimation of local field potentials (LFP). Analytical methods of estimating electric fields are a first-order approximation that may be suitable for model validation but they are computationally expensive and cannot accurately capture boundary conditions in heterogeneous tissue. While there exist many appropriate numerical methods of solving electric fields in neural tissue models, there isn't an established standard for mesh geometry nor a well-known rule for handling any mismatch in spatial resolution or alignment between current sources and mesh nodes in a finite-element or resistor-network method volume conduction model. Therefore, using a previously published and validated multi-scale model of the hippocampus, the authors have formulated an algorithm for bidirectional communication between Admittance Method (AM) volume conduction models and biologically detailed neural circuit models constructed in NEURON. Development of this algorithm required that we assess meshes of (i) unstructured tetrahedral and grid-based hexahedral geometries as well as (ii) differing approaches for managing the spatial misalignment of current sources and mesh nodes. The resulting algorithm is validated through the comparison of AM-predicted evoked potentials with analytically estimated LFPs. Establishing this method is a critical step toward closed-loop integration of the AM and NEURON models that could lead to substantial improvement of the predictive power of multi-scale models of cortical tissue. These models may be used to deepen our understanding of hippocampal pathologies and the identification of efficacious electroceutical treatments.

Title: Towards synaptic plasticity in a computational, large-scale network of hippocampus: An investigation of spike-timing dependent plasticity models

Authors: *Z. Z. CHOU[1], G. J. YU[1], T. W. BERGER[2];
[2]Biomed. Engin., [1]USC, Los Angeles, CA

Abstract: The function of the hippocampus is definitively implicated with memory and requires synaptic plasticity to achieve this function. However, the exact role of the hippocampus with respect to memory is still unknown. We have been developing a computational platform with which a large-scale, spiking neuronal network model of a hippocampus can be simulated, and previous work has focused on the construction of the topographic connectivity that would provide the neural architecture of a hippocampal network. This previous work did not include synaptic plasticity. In the present work, we compare different methods for implementing spike-timing dependent plasticity (STDP) in a large-scale CA3 network consisting of an associational system and entorhinal and dentate inputs. Three different STDP rules, developed by other groups, were investigated: additive, multiplicative, and log-normal STDP. Additive STDP uses an update rule in which the synaptic weight is updated with an addition or subtraction amount that is dependent on the timing difference between presynaptic and postsynaptic spikes. Multiplicative STDP modifies the update by multiplying the current synaptic weight by a factor. Finally, log-normal STDP implements a customized update function, based on the Fokker-Planck equation, that produces a long-tail distribution of synaptic weights, with a small number of synapses having very large weights. It has already been shown that these three different rules have trade-offs in the stability of weights and synaptic competition (Gilson and Fukai, 2011). Here, we investigate further by exploring how the evolution and convergence of synaptic weights under different rules affect the spatio-temporal dynamics of a large-scale network. In combination with the previously developed large-scale model of rat hippocampus, the present work with synaptic plasticity will result in a computational platform through which the effects of synaptic plasticity, and its interaction with other properties of the hippocampus, on learning and memory can be investigated.

Title: Computational modeling of somatic calcium release due to cholinergic modulation in CA1 pyramidal cells

Authors: *A. MERGENTHAL, J.-M. BOUTEILLER, T. BERGER;
Biomed. Engin., USC, Los Angeles, CA

Abstract: Cells throughout the hippocampus are subject to cholinergic modulation. Depending on the cell type, the result of this modulation can vary depending on the receptor types expressed. In the CA1, the pyramidal cells express M_1 and M_3 muscarinic acetylcholine receptors (mAChRs). The activation of M_1/M_3 mAChRs initiates two chain reactions which modulate cell excitability. These reactions include an inhibition of ion channels that depolarize the cell membrane and the release of calcium from intracellular stores. These effects are well documented, but how these translate into changes in overall network activity is still poorly understood. Yet, these network-level effects are important as they may shed some light on a variety of disorders associated with the widespread dysregulation of cholinergic modulation (e.g. Alzheimer's disease). To this effect, we have been working toward developing a network model of the CA1 region by implementing single cell models of multiple cell types. We herein discuss our efforts aimed at modeling the release of calcium from intracellular stores in the somatic region of pyramidal neurons. We detail the steps taken to tune this model and demonstrate the model's ability to faithfully replicate dynamics observed in in-vitro experiments. Among the behaviors replicated are the ability for acetylcholine to inhibit spiking due to activation of calcium-gated potassium (SK) channels, intracellular store depletion after repeated activation, and increased calcium concentrations following action potentials restocking intracellular stores. We discuss our results, list future steps, and elaborate on the overall perspectives of this effort.

Title: A large-scale neuronal network model of the trisynaptic pathway of rat hippocampus

Authors: *G. J. YU, J.-M. C. BOUTEILLER, D. SONG, T. W. BERGER;
Biomed. Engin., USC, Los Angeles, CA

Abstract: The axonal projections between neural populations are often anatomically organized resulting in ordered topographic maps that determine the connectivity of the neural system. They are seldom, if at all, connected uniformly random or all-to-all. The hippocampus is a system that

clearly demonstrates a higher-level organization as described by the trisynaptic circuit in which activity predominantly propagates in a feedforward manner through the three hippocampal subfields. In addition, each projection exhibits its own distinct topography. However, there have been few studies that investigate how the individual topographies affect the dynamics of each subfield and the activity transformations that each subfield performs.
We have developed a computational platform for simulating the full-scale, in terms of numbers of neurons and synapses and the geometric volume, of a rat hippocampus. Using this platform, we have constructed a neuronal network using the NEURON simulation environment which incorporates the unique topographies of the perforant path projection, the mossy fiber projection, the CA3 associational system, and the Schaffer collaterals. In this work, we created a network composed of 112 000 entorhinal cortical cells, 120 000 granule cells, 25 000 CA3 pyramidal cells, and 38 000 CA1 pyramidal cells that include basket cells for each subfield. The geometric area for the axon terminal fields for each projection were constrained based on anatomical studies of the respective axonal distributions. The initial perforant path projection was shown to organize random Poisson activity into finite regions of spatially and temporally dense spiking activity that we called clusters. These clusters persisted throughout the trisynaptic pathway in various forms as they were propagated through the network. Topography was ultimately found to determine the spatial extent of the clusters, predominantly along the longitudinal axis of the hippocampus. This was further quantified as the longitudinal distance at which neuronal spiking could be correlated.
The results of this work demonstrate a clear role for topography in determining the spatio-temporal dynamics of a neural system. The work also establishes a neuronal network model that can be used to investigate the trisynaptic pathway at a scale that encompasses the entire rat hippocampus.

Title: NTracer2: An ImageJ/Fiji plug-in for multispectral neuronal tracing and annotation in densely labeled brains

Authors: ***L. A. WALKER**[1], H. CHENG[2], A. DIZAJI[2], F. Y. SHEN[3], Y. LI[2], M. CHEN[2], D. CAI[2,1,3];

Abstract: Techniques for neural tracing and reconstruction plays an important role in our understanding of nervous system development. Multispectral labeling techniques, such as Brainbow [Livet, et. al, Nature 2007; Cai, et. al, Nat. Methods 2013], allow the tracing of densely-labeled neurons by expressing different, random combinations of fluorescent proteins in each cell. These sample can then be imaged with, for example, a confocal or lightsheet fluorescence microscope. While many automated techniques exist for the reconstruction of sparsely labeled neurons from optical microscopy data, no automated approach is currently capable of properly handling the multichannel nature of the Brainbow datasets. To address this, we created nTracer [Roossien, et. al, Bioinformatics 2019], a semi-manual tracing and annotation tool for the analysis of Brainbow datasets. nTracer runs as a plugin to the ubiquitous ImageJ/Fiji software, performing path-optimized tracing based on user-supplied starting and ending points along individual cell bodies or processes. Uniquely, our model includes color, in addition to position, as optimization dimensions, allowing the color of the cell to guide the tracing. We have updated the software (nTracer2) with algorithmic performance upgrades, support for terapixel-scale images via the HDF5 file format, multi-tracer collaboration, and an expanded toolset for the registration and normalization of tiled images. Additionally, user interface components have been optimized according to user feedback, leading to a more efficient workflow overall. Together, these changes allow nTracer to be applicable to much larger experiments than previously reported, such as the manual proofreading of whole-brain imaging experiments. In this interactive presentation, we will discuss these new developments to nTracer and provide a live demonstration of the utility it provides to scientists studying neuronal structure.

Title: Toward high-throughput, non-invasive seizure detection using piezoelectric motion sensors

Authors: *D. HUFFMAN[1], F. DUQUE QUICENO[1], S. CARRIZOSA[1], A. AJWAD[1], J. WANG[1], E. JOHNSON[2], K. HARGIS-STAGGS[2], K. DONOHUE[3,6], B. F. O'HARA[4,6], B. BAUER[5], E. BLALOCK[2], S. SUNDERAM[1];

Abstract: Outcomes in preclinical models of epilepsy-i.e., the likelihood and timing of epileptogenesis, seizure yield and frequency—can be quite variable. It is often desirable for experimental studies to commence only after spontaneous seizures have been verified and their frequency has stabilized. This determination is complicated by the diversity of seizure-related behaviors and the unpredictability of seizure recurrence. While invasive electroencephalography (EEG) is the standard for accurate seizure detection, it is resource-intensive and impractical in large cohorts. Visual observation or video analysis, while non-invasive, are labor-intensive and tedious. Thus, convenient non-invasive automated methods for seizure screening in animal models are desirable. Here, we investigate the utility of a piezoelectric ("piezo") motion sensor for noninvasive seizure screening in two rodent epilepsy models: mice and rats. Mice and rats of both sexes were treated with pilocarpine i.p. to induce acute status epilepticus (SE). In this model, seizures typically subside within 1-2 hours post-injection and spontaneously recurring seizures—the hallmark of chronic epilepsy—may emerge after a latent period of several weeks. Animals that survived SE (12 mice; 7 rats) were monitored continuously for 12 weeks in individual cages, where signals from the piezo sensors and continuous video were collected. Piezo signals were screened weekly for seizures using an algorithm that responded to significant deviations in piezo signal features from a moving baseline. Video review of the detections enabled timely identification of animals that developed chronic epilepsy. This demonstrates the feasibility of noninvasive epilepsy screening without exhaustive review of video. Animals with good seizure yield were then instrumented with EEG headmounts and, after recovery from surgery, monitored for four more weeks with simultaneous EEG, piezo, and video recording. Seizures detected from the EEG were used as the truth set to validate the performance of the piezo detection algorithm. In mice, the piezo detector gave a maximum sensitivity of 80% to EEG-verified seizures but at the cost of low precision (11%). Nevertheless, this greatly reduced the amount of data to be reviewed to about 20 minutes per 24-hour period. Using a supervised logistic classifier for the rats, sensitivity and precision reached peaks of 68 and 62% respectively. Efforts to improve these preliminary results, such as feature selection and algorithm development, are ongoing.

Abstract: Research and training in neural science and engineering necessitates the use of heterogeneous software and data analytic tools, multiple data archives and computing resources. Effective use of such resources and technologies is essential for bold advances in neuroscience, including bridging across the various ‘levels’ in neuroscience. However, to accomplish this, neuroscientists (often with limited software skills) are required to take valuable time away from their focus on knowledge discovery, to learn how to use such technology. Development of appropriate software automation and cyberinfrastructure (CI) technologies hold significant promise to aid the neuroscientist in this regard on both research and training fronts. We report the results from an on-going effort to develop automated modules of multiple types with application across the K-20 spectrum. The automation modules for research and training include the following: transcriptomics (RNAseq) analytic tool, and a job submission tool named SimAgent. The transcriptomics tool automates usage of genomic and molecular databases in neuroscience, HPC resource brokering options, and visualization tools, to simplify the diverse tasks for the neuroscientist. The SimAgent tool has two core functions of automated job submission and parameter sweep, with a point and click interface that accepts any project directory, submits the project files from a laptop and configures them to run remotely and watches it until completion with live updates to the user. The parameter sweep feature allows the same functionality with the added ability to specify sections of code to automatically change with each run. SimAgent presently supports NEURON and MATLAB scripts and python code. A series of Jupyter notebook modules for teaching and self-learning have been developed for cellular neuroscience topics such as Nernst and rest potential, spike generation, bursting, synaptic transmission, and the development of small networks. Another set of modules cover the

fundamentals of neural signals and digital signal processing concepts such as Fast Fourier Transforms (FFTs), band pass filters, power spectral densities, and local field potentials. A JupyterHub server was established on the JetStream cloud computing platform to host several of the teaching notebooks. Some of the K-12 neural engineering modules for teacher training will also be presented. One of these focuses on the basics of brain waves using python notebooks after a hands-on introduction to the topic using scalp-recording kits from BackyardBrains.com. This project was supported in part is supported by the grant NSF grants OAC-1730655 and ENG-1801666.

Title: Enabling data reproducibility with open science chain

Authors: *S. SIVAGNANAM, V. NANDIGAM, K. LIN, S. SAKAI;
San Diego Supercomputer Ctr., UCSD, San Diego, CA

Abstract: In neuroscience large amounts of experimental and imaging data are produced in a wide variety of formats and are utilized to develop data-driven computational models for elucidating neuronal and network functions. Significant advances in brain research have been made, however investigators working with these massive data require techniques to ensure its integrity, especially when trying to build upon prior research work done by other scientists. Reproducibility is fundamental to scientific inquiry and independent verification of results is an essential component. Several journals and funding agencies mandate that data and experimental details be made accessible and archived to allow for replication and consequent studies. However several independent studies show that the data withholding rates remain constant for various reasons including protecting scientific lead, and fear of misinterpretation of data. There are no cyberinfrastructure resources available for researchers to independently validate the authenticity of datasets, track the provenance and lineage of the data, and verify ownership information. Open Science Chain (OSC) provides a cyberinfrastructure platform, built using distributed ledger technologies, where verification information about scientific dataset is stored and managed in a consortium blockchain. OSC provides a unique verification identifier for the information stored

on blockchain. Other researchers have the ability to independently verify authenticity of scientific data using the information stored in the blockchain and provide feedback when the data cannot be validated.
In the initial implementation of OSC, the location of the dataset, information to verify the dataset (SHA256 hash) and the contributor information are required as the mandatory parts of the metadata but will gradually expand to other metadata elements based on feedback from the user community. In order to lower the complexity barrier for use of this technology and to promote adoption, a web-based portal is developed with seamless user interfaces and multi-platform client for interacting with the underlying blockchain. Neuroscience researchers, especially those involved in collaborative research will benefit from using the OSC to track the dataset that maybe generated and maintained at various locations. Members of research labs will benefit from tracking the provenance and lineage of data produced and referenced during different stages of research by various members. OSC aims to enhance data sharing and reproducibility in the neuroscience community by increasing the confidence of the scientific results.

Title: NIH funded nitrc's triad of services: Software, data, compute

Authors: *D. N. KENNEDY[1], C. HASELGROVE[2], N. PREUSS[3];
[1]U. Massachusetts Med., Worcester, MA; [2]Univ. of Massachusetts Med. Sch., Worcester, MA; [3]Preuss Enterprises, Miami, FL

Abstract: Aim: NeuroImaging Tools and Resources Collaboratory (NITRC) is a neuroinformatics knowledge environment for MR, PET/SPECT, CT, EEG/MEG, optical imaging, clinical neuroinformatics, computational neuroscience, and imaging genomics tools and resources.
Methods: Initiated in 2006 through the NIH Blueprint for Neuroscience Research, NITRC's mission is to foster a user-friendly knowledge environment for the neuroinformatics community. By continuing to identify existing software tools and resources valuable to this community, NITRC's goal is to support its researchers dedicated to enhancing, adopting, distributing, and contributing to the evolution of neuroinformatics analysis software, data, and compute resources.

Results: Located on the web at www.nitrc.org, the Resources Registry (NITRC-R) promotes software tools and resources, vocabularies, test data, and databases, thereby extending the impact of previously funded, neuroimaging informatics contributions to a broader community. NITRC-R gives researchers greater and more efficient access to the tools and resources they need, better categorizing and organizing existing tools and resources, facilitating interactions between researchers and developers, and promoting better use through enhanced documentation and tutorials—all while directing the most recent upgrades, forums, and updates. All services freely downloadable, NITRC-R offers over 1,090 public resources; NITRC-Image Repository (NITRC-IR) offers 16 data projects, 10,860 subjects, and 12,440 imaging sessions, and NITRC Computational Environment (NITRC-CE) provides cloud-based computation services downloadable to local machines or via commercial cloud providers such as Amazon Web Services.
Conclusions: In summary, NITRC is now an established knowledge environment for the neuroimaging community where tools and resources are presented in a coherent and synergistic environment. NITRC is a trusted source for the identification of resources in this global community. With over 6,230 citations on Google Scholar, NITRC has supported over 26,000 registered users, served up 10.8 million total, and of that, 9.7 million data downloads, to over 1.1 million users generating 2.5 million sessions. In addition to untold downloaded Virtual Machines, NITRC-CE currently supports over 180 subscriptions on AWS Marketplace running over 216,400 compute hours. We encourage the neuroinformatics community to continue providing valuable resources, design and content feedback and to utilize these resources in support of data sharing requirements, software dissemination and cost-effective computational performance.

Title: Schol-AR an augmented reality platform for scientific communication and data visualization

Authors: *T. ARD, A. W. TOGA;
USC Stevens Neuroimaging and Informatics Inst., Los Angeles, CA

Abstract: Scientific communication is dominated by the printable media of journals and papers, which have not kept pace with the rapid technological evolution of the ways we view information and communicate. While several attempts have been made to amend this, such as

providing links to data and expanded supplementary materials, we have largely failed to adopt digital media in standard scientific communication. This dramatically impedes the exchange of concepts and information, particularly as modern scientific fields are producing more complex data and results which remain constrained and simplified by what can be represented by the standard publishing of 2D static images.

Here, we present 'Schol-AR,' an augmented reality (AR) mobile application designed to provide printable scientific communications with the ability to seamlessly integrate digital media. Schol-AR enables you to point a smartphone at a scientific figure and have any accompanying digital media associated with that figure appear on the phone, 'augmented' over the printed figure. This approach combines the advantages and establishment of printable media with interactive 3D objects, video, original data, and more. The fluidity of this approach remedies critical issues of previous attempts such as needing specific software to view data, cumbersomely tracking down supplementary links and materials, and overall ease of access.

While the possible uses of this approach are numerous, one example is augmenting a single-slice printed image from a functional MRI into a full neuroimaging volume, showing the entire brain volume over time. Additionally, complex anatomy such as arterial networks which are simplified onto a projected 2D printed image can be augmented to a 3D interactive object, presenting the data in all of its structure and detail. Overall, our approach aims to support the modernization of scientific communication, offering seamless integration of complex data and digital media with standard printable communication.

Title: Neurodata without borders: Neurophysiology as a cross-species standard for electrocorticography

Authors: *B. K. DICHTER[1], M. DOUGHERTY[2], V. BARATHAM[3], K. NASIOTIS[4], A. TRITT[5], O. RUEBEL[5], E. F. CHANG[6], K. E. BOUCHARD[7];
[1]Computat. Res. Div., [2]Lawrence Berkeley Natl. Labs, Berkeley, CA; [3]UC Berkeley, Berkeley, CA; [4]Montreal Neurolog. Hosp., Montreal Neurolog. Inst., Montreal, QC, Canada; [5]Computat. Res. Div., Lawrence Berkeley Natl. Lab., Berkeley, CA; [6]Neurosurg., [7]UCSF, UCSF, San Francisco, CA

Abstract: Electrocorticography (ECoG) provides a rare opportunity to perform comparative analyses between humans and other species; however, sharing these datasets between the research communities is nascent, and there is a need for a neural data tools that facilitate cross-species data sharing, analyses and collaboration. Here, we demonstrate the use of Neurodata Without Borders: Neurophysiology (NWB:N) 2.0 format (Ruebel et al. 2019) for storage and analysis of ECoG data from humans and rats.
In human ECoG data, the precise position of each electrode with respect to the gyral patterns of the cortex is essential information, and since gyral patterns differ from subject to subject, the shape of the cortex must be stored for each. We present an extension to NWB:N 2.0 that allows for storage of cortical and subcortical surfaces as triangular meshes, as well as the position of the ECoG electrodes. We demonstrate high-quality rendering of 3D cortical surfaces in MATLAB using Brainstorm (Nasiotis et al. 2019), and in python using img_pipe (Hamilton et al. 2017).
Spectral decomposition is a standard analytical technique applied to ECoG data, allowing neuroscientists to study fluctuations of neural activity across both broad and fine spatial scales. We leverage recent advances in NWB:N 2.0 that facilitate storage of time-frequency decomposition with the necessary meta-data for analysis, visualization, and sharing with collaborators. We demonstrate the utility of NWB:N 2.0 in cross-species comparisons by performing a Hilbert transform spectral decomposition to data recorded from micro-ECoG arrays in rats and high-density ECoG arrays in humans. By analyzing these datasets side-by-side, we can precisely identify differences between species, motivating further modeling work to explain why such differences occur.

Title: Canonical pipelines for neurophysiology in DataJoint

Authors: S. SHEN[1], **T. T. NGUYEN**[1], *D. YATSENKO[2,1], E. Y. WALKER[2,1], J. REIMER[2], A. S. TOLIAS[2], Z. V. GUO[3], H. INAGAKI[3], M. N. ECONOMO[3], S. A. HIRES[3], J. YU[3], N. LI[3,2], K. SVOBODA[3];
[1]DataJoint Neuro, Vathes LLC, Houston, TX; [2]Neurosci., Baylor Col. of Med., Houston, TX; [3]HHMI / Janelia Farm Res. Campus, Ashburn, VA

Abstract: Many neuroscience research teams have designed specialized and efficient data pipelines for the collection and processing of experiment data with the use of DataJoint — a free, open-source framework for scientific databases and computational pipelines. Even in similar studies, their data pipelines vary in their design to accommodate lab-specific configurations and workflows. To provide starting points for new projects and to promote greater interoperability across groups, we introduce a collection of Canonical Pipelines for common neurophysiology data modalities. The Canonical Pipelines borrow best design elements from leading projects and include animal management, trial-based sensory stimulation, anatomical imaging, trial-based behavior, trial-based perturbation experiments (including optogenetics), extracellular and intracellular electrophysiology, and calcium imaging. Through modularity and parameterization, the Canonical Pipelines strike a careful balance between flexibility and standardization. Modules may be combined and extended to suit the specific evolving needs of active projects. Alternative preprocessing and analysis computations may be used. Principled data organization during experiments simplifies data sharing with collaborators for uniform analysis, publishing, and archiving. The Canonical Pipelines include examples of exporting data into the NeuroData Without Borders format NWB 2.0. We envision that the Canonical Data Pipelines will serve as starting points for accelerated development in collaborative research projects, evolving to reflect new experimental paradigms.

Title: How to collect genuine TEPs: A graphical user interface to control data quality in real-time

Authors: *S. CASAROTTO, M. FECCHIO, S. PARMIGIANI, S. SARASSO, C. C. DERCHI, A. MAZZA, A. VIGANÒ, T. NIEUS, M. MASSIMINI, M. ROSANOVA;
Univ. of Milan, Milan, Italy

Abstract: Electroencephalography (EEG) combined with transcranial magnetic stimulation (TMS) represents a unique tool to investigate brain potentials (TMS-evoked potentials - TEPs) evoked by a direct and non-invasive perturbation of cortical neurons. Obtaining genuine TEPs involves minimizing artifacts (magnetic pulse, muscle activation) and confounding factors (the effects of concurrent acoustic and somatosensory stimulation) while maximizing the direct impact of TMS on cortical circuits. The latter, depends on several factors that a priori are hard to control for, including coil design, E-field orientation with respect to axons, 3D morphology and cytoarchitectonics of the underlying cortical tissue in individual brains. We present a Matlab-based Graphical User Interface (GUI) that provides an optimal online data visualization tool allowing the experimenter to simultaneously minimize the contribution of artifacts and confounding factors while maximizing the signal-to-noise ratio of brain responses during data collection. Specifically, this GUI allows i) to remove the pulse artifact otherwise masking the early electrophysiological responses; ii) to visually inspect single-trial responses in order to rule out the presence of unwanted muscle activation or capacitive discharging artifacts; iii) to dynamically reject artifact-contaminated channels during the recordings; iv) to compute the average reference from artifact-free channels only; v) to display and measure the amplitude of the initial EEG response (first 50 ms) from the electrodes under the coil (the initial impact of TMS) as well as the time course of average TEPs according to their topographical distribution on the scalp, thus enabling the user for a real-time assessment of the presence/absence of confounding factors. We show that maximizing cortical impact using the GUI results in TEPs that are specific for the angle and site of stimulation and that are very different, at both early and late latency, from those obtained from the peripheral evoked potentials evoked by realistic sham (Conde et al., Neuroimage 2019). This GUI represents a fundamental software complement to any TMS-compatible EEG system providing appropriate visualization features for assessing data quality in real-time. In its present version, the GUI is compatible with different EEG amplifiers from BrainProducts, ANT and GTEC companies and will be released under the CC BY-NC-SA license. This GUI allows employing EEG as an immediate readout for an optimal real-time

titration of the stimulation parameters to collect genuine TEPs and to foster standardization within the TMS/EEG community.

Title: Delineate: A deep learning toolbox for neuroscientists

Authors: ***K. M. KUNTZELMAN**[1], J. M. WILLIAMS[2], A. SAMAL[2], P. K. RAO[2], M. R. JOHNSON[3];
[1]Ctr. for Brain, Biology, and Behavior, [2]Computer Sci. and Engin., Univ. of Nebraska - Lincoln, Lincoln, NE; [3]Dept. of Psychology, Univ. of Nebraska-Lincoln, Lincoln, NE

Abstract: Contemporary approaches to the analysis of neuroscience data often make use of machine learning (ML) classifiers in order to determine whether there is information present in a complex multivariate signal that can reliably distinguish between cognitive/behavioral states or experimental conditions in a manner unconstrained by an experimenter's preconceptions. In neuroimaging such techniques are most frequently referred to as multivariate pattern analysis (MVPA), although similar approaches are used in other fields, sometimes going by other names. The relatively simple linear algorithms that underlie most such analyses, however, are computationally inadequate for large datasets, and in at least some domains (e.g., image recognition) easily outperformed by deep neural networks (DNNs). Consequently there has been a recent surge of interest in approaches to data analysis that capitalize on these "deep learning" techniques. Still, adoption of DNNs within the neurosciences has been slowed by the greater complexity of DNN architectures, the programming expertise required to use current DNN tools, and the lack of built-in support for specific methodological requirements of the neuroimaging and systems neuroscience communities. To address these issues, we have created an open-source Python toolbox called Deep Learning In Neuroimaging: Exploration, Analysis, Tools, and Education (DeLINEATE). Notable features include support for several cross-validation and rescaling schemes; a text-based job description file format that requires no Python coding knowledge from users; and backend support for PyMVPA, enabling direct comparisons to

traditional techniques. Across multiple datasets analyzed with DNNs, we demonstrate advantages in computational speed and/or classification performance relative to traditional ML/MVPA techniques. DNNs can also implement novel forms of classifier and tackle research questions that were unavailable to older methods. The current release is available on the project website (http://delineate.it) and all project code is hosted on Bitbucket (https://bitbucket.org/delineate/delineate/src/master/). Development is ongoing and we invite feature requests from the community.

Abstract: Phasic changes in the activity of dopamine neurons and the ensuing alterations in the dopamine concentration in the target structures are thought to have critical roles in reinforcement learning, goal-directed behavior and locomotion. Fast scan cyclic voltammetry (FSCV) enables detection of dopamine release in the structures innervated by dopaminergic axons with high, subsecond temporal resolution. In this work, we present a low-cost FSCV system for the longitudinal measurement of dopamine in the rat striatum chronically implanted with carbon fiber microsensors. The hardware has been implemented using a microcontroller and a combination of analog integrated circuits (ICs) in order to generate triangular voltammetric waveforms. The timing of the voltammetric waveforms are controlled by a phase-locked loop so that the noise caused by the frequency drifts in the power line can be eliminated. The voltammetric current through the microsensor is converted to voltage, amplified and filtered using the present hardware and then fed to a data acquisition card on a PC. Applications developed using LabVIEW and MATLAB are used to control the data acquisition hardware and the behavioral experiments. The electrically controlled components in the behavioral

environment are optically isolated so that the voltammetric signal drifts caused by these components are eliminated. In order to validate the practicality of the system, we chronically implanted one rat with a carbon fiber microsensor in the ventromedial striatum (VMS) and recorded the voltammetric signals in response to presentation of unexpected primary rewards. Based on the recordings performed 176 days after the implantation surgery, the increase in the dopamine concentration in response to presentation of 0.16 ml 30% sucrose solution rewards was measured as 11.85±8.75 nM (n = 20 trials). Our results based on the longitudinal recordings from one rat indicate that phasic increases in dopamine concentration in the VMS during behavior can be detected using the present system.

Title: V-NeuroStack: 3-D time stacks for finding patterns in spontaneous activity of neurons in mouse brain slice

Authors: *A. G. NAIK[1], R. V. KENYON[2], T. BERGER-WOLF[2], B. IBRAHIM[3], D. A. LLANO[3];
[1]Univ. of Illinois At Chicago, Chicago, IL; [2]Computer Sci., Univ. of Illinois at Chicago, Chicago, IL; [3]Sch. of Mol. and Cell. Biol., Univ. of Illinois at Urbana Champaign, Urbana Champaign, IL

Abstract: V-NeuroStack is a web application which uses 3-D time stack approach to identify patterns in the neuronal activity and to understand functional relationships between neurons. Our research group aims to understand the auditory corticothalamic activity in the mouse. We used GCaMP6s calcium imaging to capture spontaneous activity of cortical neurons. V-NeuroStack uses a point cloud to visualize the behavior of neurons during spontaneous activity while also having the capability to drill down on a neuron at a single timestep. In V-NeuroStack we assemble the 2-D movie frame data captured during spontaneous activity to visualize it as a 3-D time stack that the user can manipulate using given controls. Additionally, for every cross-sectional frame of the 3-D time stack, we generate a 2-D projection of the data at any time step which may then be explored for detailed analysis of the activity. A line graph depicting the intensities over the entire set of timesteps can be generated by clicking on a neuron in the 2-D projection. Button and slider controls can be used to change the portion of data used for

visualization and a user interactive pointing device can be used to manipulate the 3-D time stack. Multiple data files are fed to our application: a timeseries file contains calcium intensities for each neuron at each timestep, an XYcoordinates file contains the location of each neuron on the image. Finally a file for each timestep identifies clusters of like-responding neurons; a Python script is used to extract the color associated with each cluster for the visualization. To generate the point cloud, V-NeuroStack uses the same x and y value for each neuron and populates a new z value to stack the neuronal activity in time. The result is a tube-like structure generated for each neuron for some or all available timesteps in the data. V-NeuroStack is written in JavaScript. In conclusion, we have implemented a tool to view patterns during spontaneous activity in mouse brain tissue that cannot be captured using a single 2-D view of the data. A visible pattern may either show like-colored neurons that belong to a particular cluster during a certain period of the activity or help in identifying strong correlation between the neurons for a given set of timesteps. An accompanying 2D image for any timestep can be viewed to gain greater detail of the neuronal activity. This flexibility in exploring patterns in firing of neurons has the potential to open up further research questions on understanding spontaneous as well as other forms of neuronal activity in any brain region.

Title: Birdsong syllable recognition with sparse spike sequence representations

Authors: *L. E. S. TAVARES, D. Z. JIN;
Dept Physics, Pennsylvania State Univ., University Pk, PA

Abstract: Birdsongs consist of sequences of stereotypical syllables. For species such as the Bengalese finch and the canary, song sequences are variable and can follow elaborate probabilistic rules. To study the structure and neural basis of birdsongs, it is critical to label large numbers of syllables from continuous recordings of individual birds. Since manual labeling is tedious and time consuming, a number of standard machine learning techniques have been applied with varying degrees of success to automate syllable recognition. Artificial deep neural networks (DNNs) in particular, the state of the art in automatic speech recognition, can be

trained to achieve very low error rates [1,2]. But the high performance comes at the expense of some limiting factors. DNNs require large numbers of pre-labeled training syllables, which directly translates into intensive manual labor. They also often need specialized hardware such as GPUs for training. In practice, most DNN implementations actually rely on sequence information to achieve low error rates. This is undesirable if the goal is to analyze the sequence itself.

Here we present an alternative approach for labeling birdsong syllables from continuous recordings. Most importantly, we have designed our method to minimize the number of training exemplars required. We make no use of sequence information and rely completely on pattern recognition. No special hardware is required.

In our method, we represent relevant sounds by sparse spike sequences of feature-detecting neurons. This approach has been previously shown to perform well in noise-robust speech recognition [3]. Two distinct ensembles of feature detectors are trained by support vector machines (SVMs) to respond to specific acoustic features. Given a continuous recording, one set of non-linear SVMs performs the discovery, segmentation, and initial classification of syllables. Meanwhile, a second set of linear SVMs produces sparse sequences of spikes from the discovered segments, which are then compared to pre-trained templates of spike patterns to check and correct the initial labels. Using only 10 training exemplars per syllable type, we achieve a 5% error rate on Bengalese finch songs. Our system can be efficiently trained and run on basic computers, and requires little technical expertise from the user. As more syllables are classified, our system can be re-trained online to further reduce the error rate.

We have encoded our method into an open-source software in Python for the community to use.

Title: WAAVES+: An environment- and animal-agnostic automated ultrasonic vocalization scoring tool

Authors: *C. L. DUVAUCHELLE[1], R. SNYDER[3], K. ABER[3], N. MITTAL[4], C. CERVANTES[1], J. BAILEY[2], E. J. PARK[1], W. T. MADDOX[5];
[1]Pharmacol. and Toxicology, [2]Engin., Univ. of Texas, Austin, TX; [3]Cornerstone Res. Group, Miamisburg, OH; [4]ZS Mgmt. Consulting, San Francisco, CA; [5]CD&SC, LLC, Austin, TX

Abstract: Ultrasonic vocalizations (USVs) are known to reflect emotional processing, brain neurochemistry, and brain function. USVs in the 22-28 kHz and 50-55 kHz frequency range are widely recognized forms of social and emotional expression in rodents. 22-28 kHz USVs reflect negative affect status and are initiated by regional activation along the ascending mesolimbic cholinergic (ACh) pathways. 50-55 kHz USVs reflect positive affect status and are initiated by regional activation along the mesolimbic dopaminergic (DA) pathway. Collecting and processing USV data is manual, time-intensive, and costly creating a significant bottleneck by limiting researchers' ability to employ fully effective, and nuanced experimental designs, and serving as a barrier to entry for other researchers. Duvauchelle et al (2013, 2014) addressed this bottleneck by developing WAAVES, an automated USV assessment program that utilizes a decision tree architecture. Unfortunately, WAAVES requires manual threshold calibration for each unique environmental context reducing its benefit to the wider research community. To expand WAAVES' capabilities and to generalize the tool for widespread use, UT collaborated with Cornerstone Research Group to develop "WAAVES+" (Snyder et al, 2018). WAAVES+ aims to 1) develop an environment-agnostic, automated USV scoring tool that works "out-of-the-box", 2) to automate call classification, and 3) to expand the parameterization of acoustic properties to provide researchers with additional data for investigating significant and behaviorally-relevant outcomes. WAAVES+ uses supervised and unsupervised machine learning techniques to detect, isolate, parameterize, group, and classify USVs. Rapid screening is used to limit complex calculations providing fast analysis while limiting required computing resources. Unlike template matching or neural networking approaches, the WAAVES+ parametric approach provides accurate detection and classification without the need for large training sets or lengthy trial and error environment-specific tuning. WAAVES+ has demonstrated fast (i.e., 20x faster than time-intensive hand scoring), accurate detection (88%) of USVs across three disparate rodent recording environments, as well as over 90% classification accuracy on a subset of calls.

Title: Open-source classification of rodent sleep states with a convolutional neural network

Authors: *Z. K. BARGER[1], C. G. FRYE[1,2], D. LIU[3], Y. DAN[3], K. E. BOUCHARD[1,2];
[1]Helen Wills Neurosci. Inst., [2]Redwood Ctr. for Theoretical Neurosci., [3]Mol. and Cell Biol., UC Berkeley, Berkeley, CA

Abstract: Sleep is a fundamental animal behavior and has long been the subject of intensive basic and clinical research. Studying sleep involves determining a subject's sleep state at each point in time. When performed manually, this step is time-intensive, scales poorly with both number of subjects and samples per subject, and could raise issues for reproducibility. Manual sleep state scoring remains prevalent in studies of rodent sleep despite advances in machine learning-based approaches. To make the benefits of machine learning more accessible, we present free, open-source MATLAB and Python implementations of a convolutional neural network architecture that achieves state-of-the-art accuracy for classification of rodent sleep states. Furthermore, we provide tools for interactive data visualization and model retraining. The inputs to the network are composite 'images' of electroencephalogram (EEG) spectrograms and electromyogram (EMG) data. We chose a convolutional neural network design because this class of models excels at image classification and has previously been used to classify human sleep stages from EEG spectrograms. To train the network and validate its performance, we recorded 440 hours of EEG and EMG data from 10 adult C57BL/6 mice during both light and dark cycles. Two expert scorers independently labeled the recordings at 2.5-second resolution. The network's classification accuracy approaches inter- and intra-rater reliability for all three brain states—wakefulness, non-REM sleep, and REM sleep—and comparable accuracy can be achieved with only a few hours of training data. In summary, we built a full-featured, flexible, and scalable sleep state classifier that accelerates data analysis and opens the door to increased data sharing and reproducibility of results.

Title: Automatic and qualitative scoring of interlocking pentagon drawing test based on U-Net and mobile sensor data for a cognitive screening of older adults with Parkinson's disease

Authors: *I. PARK, S. U. MARWAT, I. A. WAHLA, S. KAMAL, U. LEE;
Dept. of Electronic Engin., Hallym Univ., Chuncheon, Korea, Republic of

Abstract: Pentagon Drawing test (PDT) can be used for the prediction of a global cognitive dysfunction as well as the evaluation of praxis function. It has long been used in the assessment of the cognitive function of older adults since it may be possible to suggest the presence of neurodegenera¬tive disease, such as Alzheimer's disease, vascu¬lar dementia, or Parkinson's disease, among others, from apraxia. The interpretation of the PDT is usually binary. Bourke et al. described an easy scoring scale for the PDT with a total of 6 points. Micaela Mitolo et al. developed a qualitative scoring of the PDT (QSPT), which encompasses the assessment of different parameters of the drawing, such as number of angles, distance/intersection, closure/opening, rotation, and closing-in. The QSPT scores were used to compare between groups, in which it suggested that the QSPT might be a sensitive measure of visuo-constructive abilities. However, the scoring needs to be done manually and is prone to human errors. The necessities of automatic scoring have been increased. Therefore, we implemented the PDT as of a mobile phone application and develop a noble automatic scoring method of the mobile PDT based on U-Net, a convolutional networks for biomedical image segmentation, and the mobile sensor data obtained from the mobile PDT. The U-Net was trained with 480 512*512 PDT images to get a trained model for segmenting a right or left pentagon. The U-Net was also trained with 480 512*512 PDT images to get a trained model for segmenting an interlocking figure. Here, epochs were iterated until the accuracy is greater than 98% and it is saturated. The mobile senor data consisted of the coordinates of all the samples with 20ms sampling period extracted from the mobile touch sensor. The velocities and accelerates were then calculated using the coordinates and then smoothed. Number of angles, distance/intersection, closure/opening, rotation, and closing-in were estimated by using the trained model and sensor data, resulting in scaling with total 10 points. The Institutional Review Board of the Hallym University Sacred Heart Hospital approved this study. A total of 57 PD patients and 87 controls recruited. Two mobile PDTs were performed for each subject and the resulted scorings of number of angles, distance/intersection, closure/opening, rotation, and closing-in were compared the grounded truths to those obtained manually and cross-checked by 10 volunteers. The performance showed specificity of 94% and sensitivity of 89%, suggesting our method may be useful in clinical practice or field studies.

Title: A standardized framework for sorting, analysis, and evaluation of extracellular recordings

Authors: *C. L. HURWITZ[1], A. P. BUCCINO[2], J. MAGLAND[3], K. Z. GERLEI[1], M. F. NOLAN[4], M. H. HENNIG[5];
[1]Univ. of Edinburgh, Edinburgh, United Kingdom; [2]Informatics, Univ. of Oslo, Oslo, Norway; [3]Ctr. for Computat. Biol., Flatiron Inst., New York, NY; [4]Univ. Edinburgh, Edinburgh, United Kingdom; [5]Edinburgh Univ., Edinburgh, United Kingdom

Abstract: Recent breakthroughs in microelectronics have enabled high precision extracellular recording of thousands of neurons both *in vitro* and *in vivo*. While the increased data volume and complexity offers unprecedented opportunities for understanding brain function, it also heightens the need for standardized, reproducible analysis techniques. In particular, inferring the activity of single neurons from raw recorded signal, a blind source separation problem called spike sorting, is an essential preprocessing step in many electrophysiological studies, yet remains largely non-standardized across labs. Since sorting errors can affect subsequent analysis, it is important to establish community-accepted standards by validating and comparing preexisting spike sorting algorithms. Traditionally, running and comparing multiple spike sorting software packages is a laborious process, complicated by file format and algorithm differences. To enable straightforward validation and comparison, we developed SpikeInterface (https://github.com/SpikeInterface), a simple framework for extracting and analyzing relevant information from both raw and spike-sorted extracellular datasets of any established file format. SpikeInterface was designed to standardize how data is retrieved from files, rather than how it is stored, allowing users to access, sort, and analyze extracellular datasets with the same tools, regardless of the underlying file format. This design paradigm also allows for wrapping preexisting spike sorting algorithms within SpikeInterface, making the process of running and comparing multiple spike sorters accessible. We demonstrate SpikeInterface by analysing tetrode recordings from the entorhinal cortex of awake behaving mice with three popular spike sorters. A comparison of the sorted units and their functional characteristics shows how this tool can facilitate more reliable interpretation of extracellular recordings.

Title: Multivariate phase coupling across brain regions

Authors: ***J. ORELLANA**[1], N. KLEIN[1], S. L. BRINCAT[2], E. K. MILLER[3], R. E. KASS[1]; [1]Carnegie Mellon Univ., Pittsburgh, PA; [2]MIT, Arlington, MA; [3]Picower Inst. Learning Memory, Massachusetts Inst. Technol., Cambridge, MA

Abstract: The standard method for analyzing phase coupling in a pair of oscillating local field potentials (LFPs) is Phase Locking Value (PLV), which, under certain conditions, is a natural analogue to correlation for angles. When LFPs are recorded from multiple electrodes across several brain regions, it is possible to examine pairwise interactions by applying PLV to all pairs, but this does not take advantage of the multivariate nature of the recordings and can produce misleading results. We have developed a multivariate method that is much more powerful, producing a complete description of interacting phase relationships in a graphical model, i.e., a set of edges that connect nodes, where each node corresponds to the phase of a particular LFP (at a particular location) and the presence of an edge between two nodes indicates a direct functional

interaction of the corresponding LFP phases. In data from 24 electrodes in prefrontal cortex (PFC) and three subregions of hippocampus, CA3, Dentate Gyrus (DG), and subiculum (Sub), during an associative memory task, we find that PFC is functionally connected to CA3 and Sub but not DG. That is, phase locking between PFC and DG is driven by indirect rather than direct functional connectivity.
Because each phase is an angle on a circle and, mathematically, a product of circles is a torus, we call our graphical models Torus Graphs. We have shown that Torus Graphs are the natural analogue to standard multivariate Gaussian models known as Gaussian Graphical Models (GGM): as in GGM, the absence of an edge between two nodes indicates that the corresponding signals (here, phases) are conditionally independent given all the other nodes. We have also shown that all previous approaches to determining multivariate phase relationships arise as special cases of Torus Graphs under restrictive assumptions. In our numerical simulations, designed to be similar to the real data, Torus Graphs perform extremely well in the sense of correctly identifying presence or absence of direct functional connections.

Title: Software for extracting interpretable components in ensemble neural activity from multi-channel brain recordings

Authors: *S. MACKESEY[1], F. T. SOMMER[2];
[1]Univ. of California Berkeley, Berkeley, CA; [2]Univ. California, Helen Wills Neurosci Inst., Helen Wills Neurosci. Inst., Berkeley, CA

Abstract: With the size of experimental recording data sets exponentially growing, the exploration of data sets with respect to specific coding hypotheses becomes increasingly laborious. To address this problem, we present the prototype of a cross-platform desktop application for extracting and visualizing functional components of multi-channel electrophysiology data. The application is demonstrated on local field potentials from publicly available dataset “hc3” (Buzsaki lab) from CRCNS.org, consisting of 442 multielectrode hippocampal recording sessions on rats navigating a variety of environments. Our software enables visualization of the activity of LFP components extracted by a variety of methods (e.g.

ICA on a phase-demodulated signal), facilitating visual comparison of components extracted using different algorithms and/or hyperparameter settings from different sessions. Our software also allows the user to fit arbitrary tuning models to components and search, sort, and filter by variance explained, allowing users to test a range of modeling hypotheses over large datasets. We present a variety of spatially-tuned (e.g. place, border) components matching the activity patterns seen in hippocampal neurons. Our goal is to promote exploratory analysis of large electrophysiology datasets by providing users with rapid visual feedback on the results of different analysis techniques. Currently, the scope of our prototype is limited to datasets formatted in the style of CRCNS hc3. However, we plan to provide a common public interface to promote use of the tool for arbitrary data formats.

Title: JRCLUST: Toward comparing spike-sorting approaches for high-density extracellular electrophysiology

Authors: *A. C. LIDDELL, Jr, N. G. CLACK, B. KIMMEL;
Vidrio Technologies, Ashburn, VA

Abstract: JRCLUST is an open-source software application for visualization and semi-automated spike sorting with an emphasis on high-density extracellular electrode arrays, in particular, the Neuropixels probe. Our goal is to enable long-term support for JRCLUST as a community resource by maintaining a professional-quality code base and documentation while providing a platform for both official and peer support. As an open source project, we also want to encourage user contribution to the code. In order to achieve these goals, we have restructured the code base with an emphasis on interpretability and extensibility. This restructuring has had the additional benefit of enabling the incorporation and comparison of results from other sorting algorithms, such as Kilosort 2 and MountainSort. We have rearchitected the user interface so that visualizations pertaining to specific algorithms can be easily incorporated. Additionally, we have written and published comprehensive user documentation, including a tutorial, and have set up a real-time chat room. Both the chat room and the Github-based issue tracker are actively monitored. Algorithm development for spike sorting is an active field with several existing approaches optimized for various probe configurations. Our ultimate aim is to accelerate the

development of high-quality spike sorting approaches by identifying and incorporating algorithms and validation data sets into JRCLUST to facilitate comparison of these approaches, thus empowering users to select the best approach for their data.

Title: Machine-learning driven approach for the analysis of calcium spatio-temporal maps

Authors: W. LEIGH[1], *S. A. BAKER[2];
[1]Univ. of Nevada, Reno, Reno, NV; [2]Univ. of Nevada Reno, Reno, NV

Abstract: The widespread use of high-resolution Ca^{2+} imaging to study cellular Ca^{2+} dynamics, kinetics, and behavior has led to the creation of large datasets with a profound need for standardization and accurate analysis. In order to study these Ca^{2+} dynamics in a variety of cell types, researchers often make use of spatio-temporal maps (STMs). STMs allow for 2D visualization of Ca^{2+} signals as a function of time such that Ca^{2+} events can be detected. Previous methods of STM analysis rely on user defined segmentation of ROIs and involve a highly arduous process of event based data retrieval. This process is both time consuming and lacks accuracy. To ameliorate these limitations, we propose a machine-learning based pipeline for the analysis of Ca^{2+} STMs. This approach includes optimized tools for preprocessing, segmentation, and automated extraction of key STM Ca^{2+} event information such as: frequency, propagation velocity, intensity, area, and spatial spread. Our analysis relies on the use of multiple elements that work in concert to achieve high throughput analysis. To illustrate our analysis, we have generated STMs from a diverse group of cells, Interstitial Cells of Cajal (ICC), in situ. These cells are pacemakers with robust Ca^{2+} dynamics that mediate neurotransmission, slow wave potential, and muscle contractions in the gut.
Generation of ICC STMs, using Volumetry software (version G8d), enables detection of both stochastic and concerted Ca^{2+} events. Once an STM is generated, our method is fully implemented in ImageJ software and optimized to detect and analyze Ca^{2+} events from STMs. STMs are first preprocessed through our sequence of filtration steps that reduces background streaking and blur. Thereafter, STM Ca^{2+} events are accurately identified using a modified

machine-learning based Trainable Weka Segmentation algorithm. This algorithm implements a trainable automated process enhanced for STM event segmentation. Subsequent thresholding facilitates our analysis of STM event features and structured export of data. Our machine-learning based method dramatically reduces opportunities for user error and provides a consistent method to allow for high throughput analysis of STM datasets.

Title: A feature extraction method for noisy electrophysiology data

Authors: *E. M. JOHNSON[1], W. L. KATH[2];
[1]Engin. Sci. and Applied Mathematics, [2]Applied Mathematics, Northwestern Univ., Evanston, IL

Abstract: Extraction of features such as action potential peaks or widths, and determining how they change under different conditions, is an essential component of analyses of electrophysiology data. Current methods range from using simple voltage thresholds to more complicated wavelet decompositions, but all perform relatively poorly when applied to noisy or low-resolution data. Furthermore, many of these methods require user input or refinement of algorithm parameters, making them ill-suited for large data sets. A suite of tools for robustly extracting features automatically from electrophysiology data has been developed using the Python programming language. The tools in this package make use of the statistics of the data themselves to estimate algorithm parameters, minimizing user intervention while remaining robust to noise. To demonstrate the use of these methods, we have applied them to a set of electrophysiology recordings of DN1 "clock" neurons in *Drosophila* (from Flourakis [Cell, 162 (2015)]) to determine electrophysiological features that are coupled to the circadian rhythm.

Title: Neuronal population coding: A new algorithm to discriminate stimuli according to the labeled line hypothesis

Authors: E. A. SATUVUORI[1,2,4], ***T. KREUZ**[3];
[1]Univ. of Florence, Florence, Italy; [2]Cnr, [3]Inst. for Complex Systems, Florence, Italy; [4]Vrije Univ. Amsterdam, MOVE Res. Institute, Dept. of Human Movement Sci., Amsterdam, Netherlands

Abstract: The nervous system is believed to employ large populations of neurons to code and broadcast information. Population coding can be considered a more reliable and robust manner than coding via single neurons **[1]**. In neuronal recordings population coding can appear in two ways. Either responses to external stimuli are generated by the neuronal population as a whole (*Summed Population, SP*) or each individual neuron may have a unique and distinguishable role (*Labeled Line, LL*). Accordingly spike train distances such as the SPIKE-distance **[2]** can evaluate either the pooled activity over the whole population or each neuron separately. The aim is to identify the neuronal subpopulation that discriminates a given set of stimuli best.
Following our proposals of algorithms to deal with the SP case **[3,4]**, we here introduce a new LL optimisation algorithm **[5]**, which finds the most discriminative subpopulation by analysing the discrimination performance of every neuron separately. First, for every individual stimulus pair the algorithm identifies the discriminative neurons and selects the best one. These best neurons are then combined to form the optimal LL-population. The algorithm can handle quite involved coding scenarios, even though its computational complexity is much lower than in the SP case. Moreover, we are guaranteed to find the best subpopulation since this time no search in a high-dimensional subpopulation space is needed.
The three measures ISI-distance **[6]**, SPIKE-distance **[2]** and SPIKE-Synchronization **[7]** and their adaptive versions **[8]** as well as the new directional measure SPIKE-Order **[9]** are implemented in the Matlab-based graphical user interface SPIKY **[7]**, the Matlab command line library cSPIKE, and the Python library PySpike **[10] [11]**.

Title: Adaptive platform for online characterization of neural data

Authors: *A. DRAELOS[1], M. NIKITCHENKO[2], E. E. THOMSON[2], E. PNEVMATIKAKIS[3], A. GIOVANNUCCI[4], E. A. NAUMANN[2], J. M. PEARSON[1,2];

Abstract: Recently developed imaging and microscopy techniques have enabled the recording of whole-brain activity at cellular resolution, generating terabytes of data from the activity of thousands of individual neurons in a single experiment. While new algorithms have made true real-time preprocessing of such data feasible, these advances have not yet been matched by an equally powerful set of tools for analyzing and modifying neural activity during live experiments. Here, we report on the design and implementation of an online data pipelining and analysis system capable of both characterizing neural activity and adaptively selecting targets for intervention in real time.

This online analysis and adaptive experimental platform can ingest data from common experimental sources (calcium imaging, electrophysiology), apply standard preprocessing methods, and integrate custom visualization and streaming statistical analysis, offering experimenters real-time insights into their data. Our system is designed to meet the stability requirements of experimental use while ensuring zero data loss, offering speed (via parallelization) and data integrity (through intensive logging). Moreover, it facilitates the rapid prototyping of new analysis and visualization methods through a streamlined Python application programming interface with minimal configuration syntax. The result is a flexible preprocessing and analysis pipeline that can be customized for each experimenter's needs in a few lines of code, one that is agnostic to the experimental setup or model organism.
As proof of concept, we implement a streaming algorithm that computes tuning curves online and identifies candidate ensembles of functionally related neurons. Such curves represent a functional characterization of cells into distinct types, each of which contributes differently to behavior. Groups of functional neural subtypes can then be selected out for specific desired features (e.g., all neurons strongly tuned to one given stimulus). By facilitating the online assembly of such functional groups, this work offers both real-time insights and a highly configurable platform on which to build experiments that modify themselves adaptively in response to data.

Title: The IBL data architecture: Tools for storing and accessing diverse datasets collected at multiple sites

Authors: N. BONACCHI[1], G. A. CHAPUIS[2], A. K. CHURCHLAND[3], ***K. D. HARRIS**[2], C. ROSSANT[2], O. WINTER[4], M. J. WELLS[2], T. IBL COLLABORATION[2];
[1]Neurosci., Champalimaud Ctr. for the Unknown, Lisbon, Portugal; [2]Univ. Col. London, London, United Kingdom; [3]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [4]Champalimaud Inst. for the Unknown, Lisbon, Portugal

Abstract: The International Brain laboratory (IBL) is a collaboration aiming to understand the neural basis of decision-making. Ten experimental labs will use multiple neural recording modalities in diverse brain structures of mice making perceptual decisions. A primary requirement of IBL is to establish a data architecture that integrates data from all labs and modalities together. We have developed a system that allow users across 5 countries to automatically contribute data and metadata, search for relevant data, and share code for exploratory analysis.

To accurately record metadata about subjects and experiments in a searchable and accessible way, we have developed a user-friendly, web-based electronic lab notebook system for colony and experiment management (Alyx - https://github.com/cortex-lab/alyx). Alyx is a small relational metadatabase that records relevant information about each subject (age, strain, procedures), alongside information about experiments and their resulting data files. Once an experiment is completed, data registered in Alyx is automatically uploaded to a central server via Globus transfer.

Users can search and access the data using a lightweight interface called the Open Neurophysiology Environment (ONE - https://bit.ly/2V1v1ZW), implemented in Python and MATLAB. ONE defines a list of DatasetTypes, as arrays of predetermined shapes and units. For example, “spikes.times” defines a column vector of spike times in seconds, while “spikes.clusters” defines a column vector of integers of the same shapes, specifying each spike’s cluster assignment. Users search the database by running a command one.search that returns an ID identifying experiments matching their criteria. A command one.load returns the requested DatasetTypes as a numerical array, downloading it from the central server and caching on the user’s machine to avoid repeated downloads. Additional commands provide further ways to list experiments on the server, and the dataset types they each contain.

This system allows users to search, load and process data that was collected in laboratories spanning multiple geographical locations. To visualize these data, we have developed a pipeline for automated analysis, based on the DataJoint framework, described in a companion poster.

Abstract: Large-scale international collaborative projects require standardized and well-organized data architecture that supports timely data ingestion, robust data maintenance, and flexible data access and processing. Part of the International Brain Laboratory (IBL) data architecture, developed in collaboration with Vathes LLC, is a standardized data pipeline based on DataJoint (datajoint.io), a general purpose framework for building scientific data pipelines with a database backend. DataJoint allows users to quickly develop processing pipelines using Python or MATLAB, that automatically run as new data is collected. For example, a current application of this system automatically produces a daily graphical web snapshot of all animals' behavioral performance history, which serves as a convenient tool for users to visualize the training status of a subject. These snapshots are updated automatically as new data is collected, with no need for the user to run an update function. We are currently developing a website that provides interactive visualization of physiological data and includes multiple methods to search and navigate experiments performed across IBL labs.
Behind the scenes, the IBL DataJoint pipeline is composed of three parts. The first part is metadata, ingested from the Alyx colony management database (see companion poster). The second part contains behavioral and electrophysiological data with basic pre-processing, ingested using the Open Neurophysiology Environment protocol (ONE; see companion poster). The third part contains analyses results created within the DataJoint pipeline, for example, behavioral results such as psychometric functions and reaction times for specific stimulus conditions. These results are computed automatically as new data is recorded, using DataJoint's auto-populate features. The IBL DataJoint pipeline supports flexible data searching, fetching, and processing, allowing users to analyze the data in a sophisticated manner and keep track of their analyses. All code is available as open source, and we envision that this system can be used as a general framework for the neuroscience community.

Title: Behavioral and physiological measures of stress in the head-fixed method combined with the air-lifted platform using a mouse model

Authors: *K. JUCZEWSKI, J. KOUSSA, A. KESNER, D. M. LOVINGER;
NIH, Rockville, MD

Abstract: Head-fixing of an awake rodent is a great method to overcome common limitations related to physiological measurements and manipulations of cellular networks in the brain of anesthetized or awake and behaving rodents. We used the Mobile HomeCage system (Neurotar, Finland) for its “stress-free” conditions and multitude of potential behaviors that may be used with this system. It is a research device designed to enable recordings from awake mice that are head-fixed to an aluminum frame, but otherwise are freely moving in an ultralight carbon container floating above an air-dispensing base. To better understand this experimental environment before planned physiological and behavioral studies, we analyzed locomotion and head-fixation-induced stress during the extended habituation protocol. In our study, 1 week after the head-plate surgery and 2 days of handling and flannel-wrapping, we began 25-days habituation experiments. Each day the mouse was wrapped in the flannel, transferred to the head-fixation frame and left in the head-fixed position on the air-lifted container for 2 hours. Throughout 25 days, blood samples were taken periodically from the tail vein to measure corticosterone concentration that is known to correspond to the stress level. Additionally, locomotion data from the head-fixed mice were obtained from video recordings of the floating platform and/or the tracker sensor board compatible with the Mobile HomeCage system. Finally, at the end of the 25-days, animals were subjected to several behavioral tests commonly used as stress indicators, including the open-field, forced-swim, elevated plus maze, nesting behavior and sucrose preference tests. Our results show that habituation procedures reduce the stress level across the habituation days visible as a gradual decrease in the corticosterone levels. Further, they reveal that the head-fixation stress is not entirely relieved by giving the mouse ability to move its body in the air-lifted container, even with extended habituation time. In fact, in our initial analysis we observed changes in the stress-evaluating behavioral paradigms mentioned above after 25-days of habituation, but this data is still under evaluation. Therefore, even extended habituation does not make the head-fixation entirely “stress-free” which should be taken into consideration when interpreting physiological data obtained from the head-fixed animals.

Title: Smartphone controlled optofluidic device with replaceable Lego drug cartridges for chronic wireless *in vivo* pharmacology and optogenetics

Authors: R. QAZI[1,2], A. M. GOMEZ[3], D. C. CASTRO[3,4], Z. ZOU[2], J. SIM[5], Y. XIONG[2], J. ABDO[2], C. KIM[1], A. ANDERSON[2], F. LOHNER[2], S.-H. BYUN[1], B. LEE[6], K.-I. JANG[7], J. XIAO[2], M. R. BRUCHAS[3,4], *J.-W. JEONG[1,2];

Abstract: Optogenetics and pharmacology are powerful techniques for dissection of complex neural circuitry with high spatiotemporal specificity. Conventional methods used optical fibers and metal cannulas for deliveries of light and drugs, respectively. However, these approaches significantly limit *in vivo* studies due to their tethered operation and mechanical mismatch between rigid devices and soft neural tissue, which cause increased tissue damage and inflammation response. Recent advances in materials, microfabrication, and wireless technology have enabled minimally invasive polymeric optofluidic probes, which allow wireless drug delivery and micro-LED based photostimulation in freely behaving animals. Although this wireless device overcame the limitations associated with the traditional tools, they still lack capabilities to repeatedly deliver drugs over long periods of time and to offer reliable wireless control without line-of-sight (LoS) handicap, control orientation dependency, and need for a special, expensive remote controller. To address these issues, here we present a smartphone-controlled, programmable optofluidic neural device that can wirelessly deliver drugs and light indefinitely for “chronic” in vivo pharmacology and optogenetics. This novel neural implant can provide photostimulation at two distinct wavelengths (470 nm and 589 nm) and deliver multiple different drugs for desired periods of time through replaceable ‘plug-n-play’ Lego drug

cartridges. Furthermore, its integration with Bluetooth low energy (BLE) facilitates wireless control via an easy-to-use, yet powerful smartphone app. This BLE wireless approach offers a long range of operation (up to ~100 m), omnidirectional control access, no LoS handicap, highly accurate target selectivity, wirelessly reprogrammable configurations, and facile setup for scalable closed loop controls, therefore substantially leveraging behavior neuroscience research involving complex 3D environment and multiple animals. Through various *in vivo* studies, we highlighted its unique capabilities for chronic drug delivery, selective animal control within a group, high temporal control for multidrug deliveries and closed loop control with optogenetic and pharmacological effects. These experiments signify its powerful applications for chronic wireless *in vivo* pharmacology and optogenetics as well as its potential for drug development and optopharmacology.

Title: Effects of low intensity focused ultrasound on motor cortex excitability in human

Authors: ***K.-H. S. CHEN**[1,2], A. FOMENKO[3], J. SARAVANAMUTTU[2], M. EL-BABA[2], J.-F. NANKOO[2], A. M. LOZANO[4], R. CHEN[5];

Abstract: Background Focused ultrasound (FUS) is as an approved non-invasive intracranial ablation therapy for essential tremor. Low intensity FUS can also be used to reversibly modulate the human cortex non-invasively. We investigated how different fundamental sonication parameters influence the effects of low intensity FUS on the motor cortex.
Method We studied 11 healthy subjects (six women). A dual-element, annular phase arrayed FUS transducer was attached to a 70 mm transcranial magnetic stimulation (TMS) coil. The center of FUS transducer was placed on the motor hot spot of right first dorsal interosseous muscle. TMS was delivered at 10 ms before the end of FUS. Different fundamental FUS

parameters, including output power, pulse repetition frequency, duty cycle and sonication duration, were tested together with the sham (near-zero output) condition. Motor evoked potential (MEP) elicited by FUS plus TMS were measured. TMS conducted with flipping the FUS transducer with the active surface pointing away from the scalp was used as a second sham condition.
Results: No subjects reported any adverse effects. FUS showed significant motor cortical suppression with longer sonication durations of 0.4 and 0.5 second (p=0.0013; Kruskal-Wallis test). FUS with 10% duty cycle also showed significantly reduced MEP amplitude (p=0.037). Other FUS settings did not elicit significant changes. FUS sonication showed significant MEP suppression compared to sham FUS with the
transducer flipped over (p=0.011).
Conclusion Low intensity FUS is a safe method for non-invasive neuromodulation in human. It suppressed motor cortex excitability with certain parameter settings.

Title: Non-invasive, receptor-specific, millimetre-precision manipulation of brain circuits for neuropsychiatric disorders

Authors: *A. SHAH[1], M. S. OZDAS[1], P. M. JOHNSON[1], N. PATEL[1], M. MARKS[1], T. YASAR[1], W. VON DER BEHRENS[1], S. R. SIRSI[2], M. F. YANIK[1];
[1]ETH Zürich/Institute of Neuroinformatics, Zürich, Switzerland; [2]Bioengineering, UT Dallas, Richardson, TX

Abstract: Central nervous system (CNS) disorders arise from dysfunctions in brain networks, involving different brain areas as well as different cell-types and molecular targets. Non-invasive, receptor-specific, focal modulation of different brain circuits in a controlled, reliable manner can lead to breakthroughs in future treatments of brain disorders. To achieve this, we systemically deliver engineered ultrasound-controllable therapeutic drug carriers. We then apply a unique focused ultrasound pulse sequence at a region of interest inside the brain which concentrates the drug carriers by orders of magnitude and uncages the cargo locally with millimeter precision. Upon release from the carriers, the drug locally crosses the intact blood-brain barrier (BBB), achieving high target specificity and low off-target effects. We show a proof-of-concept circuit-specific manipulation of sensory signaling in motor cortex in rats by

locally concentrating and releasing a $GABA_A$ receptor agonist from ultrasound-sensitive carriers. This approach not only uses orders of magnitude lower amount of drug than is otherwise required by systemic injection, but also requires very low ultrasound powers. Additionally, we also show that BBB remains intact using sensitive measures. Furthermore, we apply our technique to alleviate a neuropsychiatric disorder in the SAPAP3 KO mouse model by focused drug delivery. The technology we developed enables the most precise type of non-invasive circuit manipulation by combining molecular/receptor specificity of existing small molecules with a spatially-targeted delivery technique.

Title: Magnetoelectric nanoparticles cobalt ferrite-barium titanate ($CoFe_2O_4$-$BaTiO_3$) for non invasive brain stimulation

Authors: *T. NGUYEN[1], Z. VRIESMAN[2], P. ANDREWS[2], S. MASOOD[3], T. STEWART[4], S. KHIZROEV[5], X. JIN[1];
[1]Stark Neurosci. Res. Inst., Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Dept. of Psychological & Brain Sci., Indiana Univ., Bloomington, IN; [3]IUPUI, Indianapolis, IN; [4]FIU, Miami, FL; [5]Electrical and Computer Engin., Univ. of Miami, Miami, FL

Abstract: Brain stimulation is widely used to diagnose and treat various neurological diseases. Current clinical stimulation techniques, however, are either invasive (e.g. deep brain stimulation) or have very low spatial and temporal resolutions as well as penetration depth (e.g. transcranial magnetic stimulation). Therefore, developing a non-invasive, efficient, precise, and translational brain stimulation approach will have significant value for brain study and disease treatments. In this study, we have developed a non-invasive brain stimulation technique using magneto-electric nanoparticles (MENs). The MENs have core-shell structures consisting of cobalt ferrite-barium titanate ($CoFe_2O_4$-$BaTiO_3$). They can be delivered to a focal brain region using a strong permanent magnetic field (~5000 Gauss), and produce an electric field only in the presence of a

weaker magnetic field (~450 Gauss) at specific frequency ranges. Their magnetic-electric property arises from its $CoFe_2O_4$ core vibration, in response to the weak magnetic field, which induces redistribution of the outer $BaTiO_3$ shell surface's charges to generate an electric field. After injecting fluorescently labeled MENs through a vein and attracting them to a specific cortical region using a strong magnetic field, we determined their distribution in the target cortical region. To assess the effect of MENs on activating neurons, we imaged calcium signals in organotypic cortical slices and *in vivo* in GCaMP6-expressing transgenic mice. On MENs-loaded slices or cortex *in vivo*, turning on the weak magnetic wave stimulation caused a dramatic increase in calcium transients of cortical neurons. Whole brain mesoscopic calcium imaging through a glass window of GCaMP6 mice showed a focal increase in calcium signal at the area where MENs localized and the signal attenuated at areas further away. To evaluate whether MENs resulted in brain toxicity and inflammation, we used immunostaining to IBA1 and GFAp for microglia and astrocyte activations and found no significance increases up to one week after MENs delivery. Taken together, the results indicate that MENs can be focally delivered to a specific cortical region and wirelessly activate cortical activity using magnetic wave with minimal toxicity. This technique shows promising potential to be a new approach for treating neurological diseases.

Title: Control of neuronal excitability with radiofrequency magnetic fields

Authors: *M. HERNANDEZ MORALES[1], E. J. BENNER[2], C. LIU[1];
[1]Helen Wills Neurosci. Inst. & EECS, Univ. of California Berkeley, Berkeley, CA; [2]Div. of Neonatology, Dept. of Pediatrics, Duke Univ. Med. Ctr., Duke Univ., North Carolina, NC

Abstract: The ability to control neuronal excitability with high spatial and temporal resolution is essential to understanding the complex circuitry of the brain. We have devised a technique termed “FeRIC” (Ferritin-iron Redistribution to Ion Channels) to remotely control neuronal excitability with non-invasive radio-frequency (RF) magnetic fields. FeRIC technology couples modified membrane ion channels with ferritin. Specifically, the intracellular domain of the

transient receptor potential vanilloid 1 and 4 (TRPV1 and TRPV4), and the Ca^{2+}-activated Cl^- channel Anoctamin 1 (Ano1 or TMEM16A) were fused with the ferritin-binding region (domain 5) of Kininogen. The resulting FeRIC channels redistribute endogenous ferritin to their proximity and could be activated with RF. Here we show that RF activates cultured hippocampal and cortical neurons expressing $TRPV1^{FeRIC}$ and $TRPV4^{FeRIC}$ channels. In those neurons, RF depolarizes the membrane potential, triggers Ca^{2+} transients, and increases the firing rate. Conversely, RF inhibits neurons expressing $TMEM16A^{FeRIC}$ via membrane hyperpolarization. To conclude, present work shows the feasibility of FeRIC technology to remotely control the neuronal excitability with spatiotemporal resolution.

Title: A fully implantable optofluidic cuff system for wireless optogenetic and pharmacological neuromodulation of peripheral nerves

Authors: *A. D. MICKLE[1], Y. ZHANG[3], P. GUTRUF[4], L. MCILVRIED[1], J. GOLDEN[1], J. G. GRAJALES-REYES[1], Y. HUANG[5], J. A. ROGERS[5], R. W. GEREAU, IV[2];

Abstract: Traditional neuromodulator technologies utilize fiber optic cables, catheters, injection needles and/or tethered systems that cannot be fully implanted. Furthermore, these are mostly constructed of hard, high modulus materials that can damage fragile tissues, create persistent inflammation at the biotic/abiotic interface and alter natural behaviors. Recent advances in implantable technologies that utilize thin, lower modulus materials have mitigated some of these limitations. Here we present a suite of technologies that advances on previous fully wireless implantable systems providing discrete optical and pharmacological stimulation, directly to peripheral nerves in a soft, bio-compliant cuff interface. This system provides the opportunity to selectively manipulate the activity of distinct neuron populations in awake, freely behaving

animals while removing experimental artifacts and confounds related to anesthesia and off-target pharmacological effects. This device utilizes near-field wireless communication to power independent time-locked delivery of up to four different pharmacologic agents as well as local light delivery at the nerve-cuff interface. Importantly, the cuff is designed with soft materials that mimic the physical properties of the peripheral nerve and as a result it imparts minimal effects on nerve health or function after chronic implantation. This opto-fluidic cuff will allow for future work discriminating the role of afferent populations in different aspects of nociception and sensory perception, with the potential to pair both optogenetics and local pharmacological approaches to increase neuromodulatory specificity and complexity of experiments. Title: Retrograde gene transfer efficiency and inflammatory response of two types of lentiviral vectors in the motor cortex input system of nonhuman primates and rodents

Authors: Y. OTSUKA[1], H. TSUGE[1], S. UEZONO[1], S. TANABE[1], M. FUJIWARA[1], M. MIWA[1], S. KATO[2], K. NAKAMURA[1], K. KOBAYASHI[2], K.-I. INOUE[1], *M. TAKADA[1]; [1]Primate Res. Institute, Kyoto Univ., Inuyama, Japan; [2]Fukushima Med. Univ., Fukushima-City, Japan

Abstract: Pseudotyped lentiviral vectors that allow retrograde gene transfer are powerful tools to achieve pathway-selective gene manipulation in the brain. We have so far developed two types of vectors, HiRet vector and NeuRet vector. The former vector is pseudotyped with the B2 type

of fusion envelope protein, which is composed of a combination of vesicular stomatitis virus glycoprotein (VSV-G) and rabies virus glycoprotein (RV-G), while the latter is pseudotyped with E or E2 type. We have observed that these HiRet (B2) and NeuRet (E and E2) vectors show a high efficiency of retrograde gene delivery in the striatal input system of nonhuman primates and rodents. However, since the efficacy of retrograde gene transfer varies depending on the species and input systems, the properties of these vectors in corticocortical projections need to be clarified to analyze the roles of complex circuits involving widespread cerebral cortical areas. Here, we investigated the pattern and efficiency of transgene expression of the HiRet and NeuRet vectors in the cortical input system of nonhuman primates (rhesus monkeys, common marmosets) and rodents (rats) by injecting the GFP-expressing vectors into the supplementary motor area, medal area 6, and the secondary motor cortex, respectively. In common marmosets, many GFP-positive neurons were located in regions projecting to the injection site, such as the ipsilateral motor thalamus and the cortical motor-related areas of both hemispheres. We found that retrograde gene transfer of the NeuRet vectors was equivalent to or greater than that of the HiRet vector. In macaque monkeys, injections of the NeuRet vector with higher titer resulted in sufficient efficiency. Moreover, the NeuRet vectors displayed a higher transduction efficiency in the rat. We also found that the HiRet vector yielded gene delivery into many glial cells around the injection site, whereas the NeuRet vectors preferentially transduced neuronal cells in both primates and rodents. In addition, neuroinflammation characterized by microglial and CD8+ lymphocytic infiltration appeared after the injection of the HiRet vector, but not of the NeuRet vectors in nonhuman primates. The present results indicate that the NeuRet vectors are more suitable than the HiRet vector for retrograde gene delivery into neural networks involving the cerebral cortex in both nonhuman primates and rodents.

Title: The modified adeno associated virus vectors enable neuron specific efficient gene transduction in the primate brain

Authors: *K. KIMURA[1], Y. NAGAI[2], *S. TANABE[1], A. ZHENG[1], M. FUJIWARA[1], M. NAKANO[1], T. MINAMIMOTO[2], K.-I. INOUE[1,3], M. TAKADA[1];

Abstract: Recombinant adeno-associated virus (AAV) vectors are promising tools to deliver functional molecules into the brains of nonhuman primates (NHP). Although the use of the AAV vectors for optogenetic and chemogenetic manipulation in the NHP demonstrates the validity of this strategy to elucidate neural network functions, the development of the AAV vectors that are more effective for foreign gene transfer is still needed. High-level expression of functional molecules is required for inducing reliable changes of neuronal activity and behavioral actions. However, viral infection to glial cells and/or transgene expression therein may cause inflammation. Therefore, it is critical that the development of a novel AAV vector with both high-level transgene expression and neuron-specific infection is desirable for controlling neural circuits in NHP. In the present study, we have developed modified AAV vectors (AAV2.1-A and AAV2.1-B), composed of AAV1 and AAV2 capsids. We injected these vectors into the cerebral cortex of macaque monkeys and examined the pattern and efficiency of their transgene expression by comparing with those via the AAV1 and AAV2 vector itself. We found that the AAV2 and AAV2.1-A vectors showed higher neuronal specificity, whereas the AAV1 and AAV2.1-B vectors had higher glial infectivity. On the other hand, it was revealed that both the AAV2.1-A and the AAV2.1-B vectors exhibited high-level transgene expression which was equivalent to that of the AAV1 vector and 3-4 times higher than that of the AAV2 vector. These results indicate that the newly developed AAV2.1-A vector possesses both high-level transgene expression capacity and neuron-specific infectivity. To examine the utility of the AAV2.1-A vector as a tool for neural manipulation, we injected the vector expressing the excitatory DREADD receptor into the striatum of macaque monkeys. We found that high level DREADD receptor expression and significant changes in regional brain glucose metabolism, an index of neuronal/synaptic activation by FDG PET imaging. Thus, the AAV2.1-A vector might be an ideal candidate for delivering functional molecules into neurons of the NHP brain.

Title: A high-speed, bright, red fluorescent voltage sensor to detect neural activity

Authors: *C. BECK, Y. GONG;
Biomed. Engin., Duke Univ., Durham, NC

Abstract: Genetically encoded voltage indicators (GEVIs) form a powerful class of tools that can effectively probe neural circuitry and function. Genetically encoded indicators enable recordings of neural activity with a combination of relative non-invasiveness, temporal precision, and cell-type specificity. GEVIs have demonstrated ultra-fast kinetics and high spike detection fidelity *in vivo*, but the spectral diversity of this class of sensors limits their potential applications. Expanding the spectral diversity of GEVIs would carry three benefits for the neuroscience community. First, a red-fluorescent GEVI would enable simultaneous investigations of the connections and interactions between distinct neural populations when used in parallel with existing green-fluorescent GEVIs. Second, a red-fluorescent GEVI would enable simultaneous, spectrally separable optogenetic control and voltage imaging with minimal crosstalk between imaging and excitation wavelengths, allowing researchers to probe the effects of manipulations of neural circuits without inadvertently influencing endogenous spiking activity. Third, a red-shifted fluorescent GEVI with a high quantum yield capable of resolving single action potentials would emit light that is less prone to scattering than green-fluorescent proteins, allowing for deeper imaging in tissue. We have developed a red-fluorescent GEVI that achieves these myriad benefits by fusing Ace, a voltage-sensitive inhibitory rhodopsin, with a bright red-fluorescent protein. Our sensor takes advantage of fluorescence resonance energy transfer to produce a fast, nearly linear change in fluorescence in response to changes in membrane potential. Our sensor detects action potentials *in vitro* with high signal-to-noise and with comparable kinetics to state-of-the-art redfluorescent GEVIs. When paired with appropriate optical design and existing protein sensors or actuators, this new sensor enables complete spectral separation in simultaneous two-channel experiments such as multispectral imaging applications and optogenetic “read-write” applications.

Title: AAV-mediated gene transfer targeting colon-innervating sensory neurons

Authors: *R. GORE[1], T. EMAIL[5], E. MARRON[2], K. KITTO[1], M. RIEDL[1], K. PFLEPSEN[3], A. KARLEN[4], S. MCIVOR[4], C. HONDA[1], C. FAIRBANKS[1], L. VULCHANOVA[1]; [1]Neurosci., [2]Phamacology, [3]Pharmaceutics, [4]Genetics, Cell Biology and Develop., Univ. of Minnesota, Minneapolis, MN; [5]Psychology, Macalester Col., Minneapolis, MN

Abstract: Adeno-associated viruses (AAV) have emerged as a preferred tool for gene transfer to neurons in basic research applications and as promising candidates for therapeutic gene delivery vectors. While AAV vectors have been widely used for gene transfer in the central nervous system, peripheral nervous system applications have been more limited. The colon has a dense intrinsic neural network and is also innervated by extrinsic afferent and efferent fibers. We previously demonstrated that intracolonic injection of AAV9 vectors leads to transgene expression in both dorsal root ganglion (DRG) neurons and enteric neurons. In this study, we test the hypothesis that a dual vector strategy that employs vectors injected intrathecally (i.t.) and intracolonically (i.c.) can achieve selective targeting of transgenes to colon innervating sensory neurons. First, we compared the capacity of AAV9.hSyn.GFPcre (i.t.) and AA2retro.hSyn.GFPcre (i.t.) to transduce DRG neurons and the percentage of neurons labelled with AAV9.CAG.tdTomato (i.c.), which was delivered a week after the intrathecal injections. AAV9 resulted in higher percentage of GFP+ neurons in the DRG (mean=30.6%, SD=19) as compared to AAV2retro (mean=2.4%, SD=2.1). In contrast, percent of tdTomato+ DRG neurons in AAV9 (i.t.) (mean=0.42%, SD=0.5) was lower compared to AAV2retro (i.t.) (mean=2.7%, SD=1.5) injected animals. We then injected AAV9.hSyn.GFPcre (i.t.) followed by AAV9.CAG.tdTomato (i.c.) on the same day or a week later to determine optimal injection paradigm to increase probability of expression of both vectors in colon-innervating sensory neurons. We found that injecting AAV9.CAG.tdT one week after AAV9.hSyn.GFPcre resulted in fewer tdT+ neurons (mean=0.1, SD=0.2) in lumbosacral DRG compared to the DRG of animals that received the two vectors on the same day (mean=70.8, SD=36.4). The same-day injections of two vectors resulted in overlap of the two fluorescent proteins in 6-20% of DRG

neurons (mean=11%, SD=5.1). Next, we used same-day treatment with AAV9 carrying Cre-dependent inhibitory DREADD (DREADDi) and AAV9.hSyn.GFPcre to express DREADDi in DRG neurons, and confirmed DREADDi expression using qPCR and immunohistochemistry. Work in progress is evaluating whether this expression is sufficient to modulate capsaicin induced nociceptive behaviors in mice. This study provides proof-of-concept for the application of combinatorial AAV vector strategies in the peripheral nervous system.

Title: Fast magnetogenetics in *Drosophila*

Authors: ***C. SEBESTA**[1], G. DURET[2], D. TORRES[1], C. TZOUANAS[1], S. TONG[1], G. BAO[1], H. DIERICK[3], J. T. ROBINSON[2];

Abstract: Magnetic activation of genetically targeted neurons enables circuit-level manipulations of deep-brain regions in freely moving animals without using implanted devices that could restrict animal movement or disrupt the natural neural architecture. Indeed, recent demonstrations of “magnetogenetic” technology have shown that coupling synthetic magnetic nanoparticles to temperature-gated TRPV1 channels enables remote, magnetic stimulation of select neurons in mice. While these landmark studies have demonstrated the tissue penetration capabilities of magnetogenetics, the latency of the magnetogenetic response limits some potential applications that require precise timing of neural activation. In fact, prior work has shown that for cells in a dish, activation occurs several seconds after the start of the magnetic stimulus. Response latencies are even longer *in vivo* with behavioral responses appearing tens of seconds after the magnet is activated. Here we demonstrate a magnetogenetic technology for *Drosophila* that has a ten-times-faster behavioral response than what has been reported in rodents. This fast magnetogenetic technology uses the temperature rate sensitive *Drosophila* channel TRPA1 in

place of the previous temperature threshold gated channels. Our results suggest that optimizing these channels that respond to the rate of temperature change provides a path toward fast magnetogenetic technologies that could rival the millisecond temporal resolution of optogenetics while maintaining the minimal invasiveness of magnetic activation. Additionally, magnetogenetics in *Drosophila* provides a neural activation technology that is orthogonal to the animal's natural senses allowing minimal off target effects compared to optogenetic stimulation.

Title: Nanotechnology-driven non-viral modulation of gene expression in the central nervous system enables fundamental and translational studies with minimum alterations to the native tissue and/or cell culture niche

Authors: *D. ALZATE-CORREA, W. LAWRENCE, L. ORTEGA, N. HIGUITA-CASTRO, *D. GALLEGO-PEREZ;
The Ohio State Univ., Columbus, OH

Abstract: A major challenge for the development of effective gene therapies for disorders related to the Central Nervous System (CNS) is the lack of safe and controlled gene transfer approaches to neurons, which hampers the study of basic neuronal physiology and the identification of novel therapeutic targets. Currently gene transfer to neurons is achieved via transfection with synthetic nanoparticles, or viral transduction, either locally or systemically with adeno-associated viral vectors. These approaches, however, are fraught with caveats, including low transfection efficiencies and high toxicity, especially when using synthetic nanoparticles, or calcium phosphate precipitation. Alternative methods such as standard electroporation require significant disruption of the native tissue or cell culture niche. Viral vectors, on the other hand, are prone to insertional mutagenesis and to induce adverse immune responses. To address these complications, we developed nanotechnology-driven platforms to efficiently and safely deliver genes to nerve tissue, both *in vitro* and *in vivo*, without the need for viral vectors, and without having to disrupt the cell culture or tissue niche, respectively. Such nanoscale systems rely on the use of nanochannels or engineered exosomes as delivery vehicles for the gene of interest. We tested both of these systems with *in vitro* cultures of mouse primary hippocampal neurons, and with hippocampal neurons *in vivo.* When nanochannels or exosomes were used to deliver a reporter protein gene, *GFP*, minimal perturbations to cell physiology and low to no toxicity were

observed, with cell viabilities close to 100%. In order to demonstrate the capacity of nanochannel- and exosome-mediated transduction to deliver therapeutic cargo to the CNS, we successfully transfected and controlled the expression level of the circadian clock gene Period 1 (*Per1*) in hippocampal neurons *in vitro* and *in vivo*. Changes in electrophysiological activity were monitored in response to nanochannel- or exosome-based delivery of *Per1*. A number of neurodegenerative disorders are accompanied by disruptions of circadian rhythms together with a decline of long-term memory. Circadian modulation of neuronal excitability likely underlies the pathophysiological changes observed in numerous neurodegenerative disorders. Here we demonstrate for the first time that nanochannels or exosomes could be used as powerful tools to control gene expression in neurons *in vitro* and *in vivo* without causing adverse responses. Such systems could potentially be implemented for fundamental studies, and in the development of highly promising and benign gene therapies for the CNS.

Title: A strategy for cell type-specific CRISPR/Cas9 activation and visualization in mice

Authors: *A. CRUZ, J. CAVARETTA, M. PAUKERT;
Cell. and Integrative Physiol., UT Hlth. San Antonio, San Antonio, TX

Abstract: CRISPR/Cas9 is used to generate knockout animals in a fraction of the time of conventional knockouts, however for acute gene editing in living animals there are still weaknesses in the approach. When delivering single guide RNAs (sgRNAs) *in vivo* using viruses, the extent of knockdown of the gene of interest is unknown, due to both the efficiency of the sgRNA and delivery of the virus, which influences the interpretation of data collected. Therefore, having a method to accurately determine which cells in a population have been exposed to CRISPR/Cas9 is essential to determine the effects of the targeted gene of interest. We have developed a construct linking expression of an sgRNA and tdTomato. After viral injection into a mouse ubiquitously expressing Cas9, the construct can undergo permanent Cre recombination, allowing for the expression of tdTomato and an sgRNA. Cells that have

tdTomato expression therefore have the sgRNA expressed and have CRISPR activity, while cells that do not have tdTomato expression are wildtype. With the dependence on Cre recombinase, this construct can be used with a cell type-specific Cre-driver mouse line for select recombination, and an sgRNA targeting a sequence of interest can be quickly added using standard cloning protocols. The expression of tdTomato after recombination was found to be successful in transfection tests in HEK cells, and preliminary *in vitro* tests of sgRNAs targeting eGFP knockdown have shown successful CRISPR/Cas9 activity. *In vivo* tests are ongoing.

Abstract: Chemical neurotransmission is a tightly regulated process that underlies animal behavior, perception and disease pathology. To reversibly manipulate these signalling events with increased spatial and temporal precision, photoswitchable drugs can add an optical switch to a target receptor or cell. Although azobenzene-based probes are widely used to understand cell physiology, their application to behavioral experiments has been hindered by the lack of available hardware for exploiting these probes to deep brain regions in freely moving rodents. Here, we will outline the development of a photoswitchable capsaicin derivative that can reversibly activate the TRPV1 cation channel with green/violet light. To expand our probes' use *in vivo*, we developed a flexible fiber-optic implant with microfluidic and optical capabilities that can deliver and stimulate photochemical tools within deep brain regions of freely moving mice. Combined, these technologies can be leveraged to manipulate reward behaviors via the mesolimbic reward system, and future efforts targeting endogenous receptors in the central

nervous system will allow us to explore the cellular mechanisms underlying animal behavior with increased precision.

Abstract: Human neural cells manufactured from patient-derived induced pluripotent stem cells (iPSCs) hold great promise for modeling neurodevelopmental disorders, discovering precision therapies, and screening for potential risks from environmental toxins. However, many neurological phenotypes arise in mature neurons, and human iPSC-derived neurons can require extensive time in culture (1-3 months) to reach full maturity. These lengthy cultures slow the discovery process and are costly due to labor and reagent requirements. We hypothesized that optimizing culture substrate properties through the use of tunable synthetic matrices would improve maturation. Currently, neurons are cultured on a variety of substrates including charged polymers (poly-lysines or poly-ornithines) or animal-derived matrices. Using JMP™ software, we employed Design of Experiment (DOE) methodology utilizing Box-Behnken response surface modeling to screen for synthetic polyethylene glycol-based (PEG) hydrogel formulations that promoted viability, cell adhesion, desired morphology, and accelerated maturation of cortical glutamatergic neurons. In the experimental design, we varied PEG concentrations, crosslinkers and cell adhesion peptide composition and concentrations. To facilitate the quantitative DOE analysis, we utilized neurons derived from a human iPSC reporter line with a fusion protein comprising nanoluciferase (Nluc, Promega) and synaptophysin (SYP), a synaptic vesicle glycoprotein that is expressed in virtually all mature neurons and acts as a marker for quantification of synapses. We identified hydrogel formulations that 1) support cortical glutamatergic neuron adhesion as scored morphologically and assessed quantitatively via cellular ATP (Cell Titer Glo 2.0, Promega) and 2) accelerate maturation, as demonstrated through a time-

course of synaptophysin expression. Finally, these hydrogel formulations supported over two-fold increases in neurite length over a poly-D-lysine substrate. When incorporated into neuronal high-throughput screening efforts, the identified hydrogel substrates will improve overall outcomes and decrease the culture time required to reach the necessary maturation state.

Title: Scaled expansion of pluripotent stem cells in suspension culture followed by direct neural differentiation from 3D cell aggregates

Authors: M. DERR, M. AKENHEAD, J. SAGAL, R. NEWMAN, D. KUNINGER; Thermo Fisher Scientific, Frederick, MD

Abstract: Culture systems for pluripotent stem cell (PSC) expansion enable generation of a nearly unlimited pool of cells for downstream differentiation, disease modeling, drug discovery, and therapeutic applications. While two-dimensional (2D) feeder-free expansion of PSCs is well established, the scale at which PSCs and subsequent PSC-derived cell types can be efficiently manufactured using traditional methods is limited without a significant increase in hands-on time, as well as a potential risk of contamination. Therefore, to fully realize the potential of PSCs in downstream applications where large numbers of cells are required, such as cell therapy and

high-throughput screening applications, alternative expansion methodologies may be beneficial. Here we describe a new system for highly scalable expansion of PSCs as three-dimensional (3D) spheroids in suspension as self-assembled aggregates followed by neural induction and differentiation starting from the expanded PSC aggregates or spheroids. While expansion potential is an important parameter for assessing a fit for purpose medium system (i.e., 2D vs. 3D), another important consideration is compatibility with downstream differentiation protocols. In recent years, 3D aggregate cell culture has been gaining traction as an enhanced culture technique which provides more physiologically relevant cell-cell interactions over the traditional 2D cell culture protocols. When determining whether to move from 2D culture environments to 3D culture environments, a number of considerations need to be made. These considerations include the quantity of desired cell type(s) required for downstream applications, compatibility of reagents and experimental endpoints designed for 2D, and importantly how neurons derived using 2D and 3D compare and contrast to each other. Here, we demonstrate the feasibility of directing expanded PSC 3D aggregates to neurons using neural induction and differentiation reagents designed originally for monolayer applications. Key parameters and consideration for both PSC expansion and neural differentiation are presented and discussed, which include scalability, expansion rates, and differentiation efficiency. Notably, 3D neural differentiation resulted in significantly higher expansion rates of neural stem and progenitor cells and similar marker expression compared to standard 2D methods. Finally, the impact of 2D vs 3D neural differentiation and expansion on neuronal maturation will be presented.

Abstract: Neuronal activity in the brain depends to a large extent on ATP generation and thus on the availability of oxygen. This makes the concentration of the latter molecule a highly relevant parameter for studying the interrelation between neuronal metabolism and computation. In order to evaluate the dependency of neuronal activity from oxygen availability, we employed semi-intact preparations of *Xenopus laevis* tadpoles with functional central and peripheral nervous systems. Trochlear motor nerve spike discharge served as physiological correlate for neuronal activity, while oxygen concentrations in the bath chamber and the brain, were concurrently monitored using a Clark-type oxygen microsensor during superfusion of Ringer solution with various levels of oxygen. The oxygen concentration was accurately set to a desired value by aeration with carbogen (95% O_2, 5% CO_2) or nitrogen. In air-saturated Ringer solutions (280 µM O_2), the IVth ventricle was devoid of oxygen likely due to consumption in the adjacent brain tissue. At oxygen bath concentrations > 300 µM, spontaneous burst discharge of the trochlear nerve caused a transient drop of the oxygen level within the IVth ventricle, indicating a neuronal activity-related increase in the local demand for oxygen. In contrast, decreasing the bath concentration of oxygen below ~40 µM completely ceased the trochlear motor nerve activity after ~30 min. Aiming at a spatially more accurate and faster means for the modulation of the oxygen level in the brain, we exploited the natural capability of algae to produce oxygen upon illumination. Injection of the green algae *Chlamydomonas reinhardtii* or the cyanobacteria *Synechocystis sp.* into the vascular system of *Xenopus* tadpoles immediately prior to the generation of the semi-intact preparation distributed these single celled eukaryotic and prokaryotic organisms throughout the blood vessels of the entire brain. While the hypoxic condition within the IVth ventricle persisted in such preparations in darkness, illumination with visible light increased the oxygen level up to ~80 µM. In addition, the abolished trochlear motor nerve activity in oxygen-depleted bath solutions restarted upon illumination, suggesting that algal oxygen production is sufficient to restore the energy equivalents required for maintained neuronal activity. Accordingly, introduction of algae and illumination represents a promising method to augment the oxygen level in any diffusion-limited *in vitro* neuronal preparation devoid of a functional circulation and potentially also under *in vivo* conditions.

Abstract: Perineuronal nets (PNNs) are dense extracellular matrix structures surrounding fast-spiking, parvalbumin-containing GABAergic interneurons throughout the brain. Within the medial prefrontal cortex (mPFC), PNNs are important for the stabilization of memories following learning. Much of our research focuses on fluctuations in the staining intensity of these PNNs, which may reflect their thickness, and in turn, their ability to help form and maintain memories for drugs of abuse. The most common method to degrade PNNs is by giving an intracerebral injection of chondroitinase-ABC (Ch-ABC), an enzyme that digests chondroitin sulfate proteoglycans, a key structure in PNNs. However, it is not known how long this enzyme remains active once it is dissolved in buffer and stored frozen. Therefore, we determined the period over which dissolved Ch-ABC that was maintained at -20 C would be enzymatically viable. To test the lifespan of enzymatic activity, we identified aliquots of Ch-ABC that were stored at -20 C for 0, 0.5, 1, 4, 5, 8, 13, 18, or 20 months. A 0.4 µL volume/hemisphere of Ch-ABC or vehicle was microinjected into the mPFC of adult male rats (n=9). Rats were perfused three days following injections, brains were then frozen, sliced into 40 µm coronal sections, and stained with *Wisteria floribunda* (WFA) to identify PNNs. The intensity and number of PNNs were analyzed for each time period using the PIPSQUEAK program and grouped into three time bins (0-4 mo., 5-8 mo., 13-20 mo.). While every age of Ch-ABC significantly reduced WFA intensity, Ch-ABC from the 0-4 mo. and 4-8 mo. time points were more effective at reducing the intensity of PNNs compared with Ch-ABC from the 13-18 mo. time point. Additionally, Ch-ABC from the 5-8 mo. time point significantly reduced the intensity of PNNs compared to all other time points. These data indicate that Ch-ABC was the most effective between five to eight months post reconstitution; however, significant enzymatic activity may still occur even after being maintained at -20 C for up to 20 months.
