Title: Cyclic AMP dependent protein kinase regulation of Nato3 induction of dopamine neuron gene expression

Authors: M. OKROS[1], M. FRANTZESKAKIS[2], P. CHOWDHARY[1], *M. K. DELANO-TAYLOR[3];
[1]Biomed. Sci., [2]Cell and Mol. Biol., [3]Grand Valley State Univ., Allendale, MI

Abstract: Nato3 has been shown to be necessary for normal dopamine neurogenesis *in vivo* but it is not known if Nato3 is sufficient to drive dopamine neurogenesis. Others have shown Nato3 can induce *Sonic hedgehog* and *Nurr1* mRNA expression in the immortalized mouse midbrain cell line SN4741. However it is not known if other factors such as phosphorylation may regulate the magnitude or number of dopaminergic genes induced by Nato3. In this study we test if the presence of the catalytic subunit of cAMP dependent protein kinase can promote the effect of Nato3 expression of dopaminergic genes.

Title: Gene regulatory interactions governing cranial neural crest cell differentiation along neurogenic and chondrogenic lineages

Authors: *M. R. REPLOGLE[1], A. RAU[3], P. L. AUER[2], A. J. UDVADIA[1];
[1]Biol. Sci., [2]Joseph J Zilber Sch. of Publ. Hlth., Univ. of Wisconsin - Milwaukee, Milwaukee, WI; [3]Animal Genet. and Integrative Biol., Inst. Natl. de la Recherche Agronomique, Jouy-en-Josas, France

Abstract: Disruption of cranial neural crest (CNC) development can result in a broad spectrum of congenital malformations, many of which are often associated with pediatric syndromes. As developmental precursors, CNC cells are known to give rise to a diverse array of ectodermal and mesoectodermal cell types, from neurons and glia of the peripheral nervous system to the cartilage and bone of the face. However, we currently have a limited understanding of the molecular programming underlying CNC differentiation along ectodermal versus mesoectodermal cell lineages. Recently, we established a murine culture system modeling CNC cell differentiation along the neurogenic and chondrogenic lineages. Systematic characterization of the cultured cells identified reproducible timelines for changes in cell shape, protein expression and aggregation behavior that mimic the progression of neurogenic and chondrogenic differentiation *in vivo*. Using this culture system, we are assessing global changes in transcription and chromatin accessibility that accompany CNC cells as they transition to (1) intermediate progenitors, and then (2) differentiated peripheral neurons or cartilage matrix-producing chondrocytes. Integration of the information gathered will provide a detailed roadmap of changes in gene expression during CNC cell differentiation and the unique lineage-specific regulatory interactions that drive cell fate acquisition in a stepwise and time-sensitive manner. Together, these analyses will allow further investigation into the hierarchical, cell-intrinsic circuitry contributing to the plasticity and developmental potential of the CNC. Moreover, elucidation of the gene regulatory networks governing CNC cell differentiation provides a platform for discovering the molecular targets of genetic and environmental factors that lead to CNC-related birth defects and disorders.

Abstract: The cerebral cortex is the seat of higher-order brain functions. It consists of a multitude of specialized, precisely positioned and interconnected cell types that assemble into specialized neuronal circuits to execute complex behaviors. One major goal of neuroscience is to understand how small pool of neural progenitor cells generate the vast diversity of neuronal cell types during cortical development. The cerebral cortex contains a heterogeneous collection of GABAergic interneurons with unique morphological, electrophysiological and molecular characteristics, but the mechanisms generating interneuron diversity remain controversial. One model proposes that interneuron identity is specified at the level of progenitors or shortly after becoming postmitotic; the competing model postulates that interneuron identity is established relatively late, through interactions with the cortical environment. Here we use single-cell transcriptomics to study the origins of cortical interneuron diversity in mouse. We identify distinct types of progenitor cells and newborn neurons in the ganglionic eminences, the embryonic proliferative regions that give rise to cortical interneurons. These embryonic precursors show temporally and spatially restricted transcriptional patterns that lead to different classes of interneurons in the adult cerebral cortex. Our findings suggest that shortly after the interneurons become postmitotic, their diversity is already patent in their diverse transcriptional programs which subsequently guide further differentiation in the developing cortex.

Title: Transcriptomically defined neuronal subtype specification in the type-II neuroblast lineages of *Drosophila melanogaster*

Authors: *N. S. MICHKI[1], Y. LI[2], K. SANJASAZ[3], C.-Y. LEE[2,4], D. CAI[2,5,1];
[1]Biophysics, [2]Cell and Developmental Biol., [3]Moleclular, Cellular, and Developmental Biol., [4]Life Sci. Inst., [5]Neurosci., Univ. of Michigan, Ann Arbor, MI

Abstract: The expansive neural diversity observed in vertebrates requires efficient and robust subtype specification mechanisms. However, the scale of neurogenesis in even simple vertebrates has made studying these mechanisms particularly challenging. The 16 type-II neural stem cells (neuroblasts) in *Drosophila melanogaster* (the fruit fly) provide an excellent *in vivo* model system for probing the mechanisms behind neural subtype specification, as the intermediate neural progenitors (INPs) they generate are remarkably similar to the neural progenitors found in lower vertebrates and humans [Hansen et al., Nature, 2010]. We aim to better understand both *which* neural fates are specified during type-II neurodevelopment and *how* they are specified by their progenitors. Using genetic targeting to fluorescently label and sort the type-II neuroblasts' progenies, we acquired scRNA-seq data from ~3800 fluorescently sorted cells and used standard bioinformatics pipelines to identify a variety of different cell type clusters representing putative progenitor (INP), precursor (GMC), neuronal, and glial subtypes. The presence of clusters clearly expressing previously identified type-II system markers, such as *Dichaete*, *grainy-head*, *eyeless*, *bsh*, and *toy* [Bayraktar and Doe, Nature, 2013], give us confidence that our cell population is pure. Guided by this and the many other prior studies of the type-II system, we manually identified known and new subtype clusters and performed differential gene expression analysis to identify a variety of new marker genes that may also play a role in specifying final cell fates. Using gene-reporter fusion constructs and immunostaining, we show that these genes are in fact upregulated in a subset of the type-II progenies. By performing RNAi knock-down experiments, we hope to determine which, if any, are necessary for correctly carrying out the stereotypical INP temporal transcription factor progression. These critical insights will enable us to better understand both the scale of and mechanisms underlying neuronal subtype specification in the type-II neuroblasts and, due to their similarity to vertebrate neural stem cells, may further our understanding of why neurogenesis via intermediate progenitors is the predominant form of neurogenesis in vertebrates.

Title: Notch signaling in the cerebellar granule cell development

Authors: T. ADACHI[1,2], S. MIYASHITA[1], M. YAMASHITA[1,3], R. D. SHIRAISHI[1,3], M. M. SHIMODA[1,2], T. OWA[1], M. HOSHINO[1];

Abstract: The development of the mammalian nervous system is controlled by a variety of extracellular signals at the timing of cell division, differentiation and migration to proper locations. Cerebellar granule cell progenitors (GCPs) are produced in the Rhombic lip, migrate along the surface of the cerebellar primordium to form the external granule layer (EGL), and exit cell cycle to differentiate into granule cells (GCs). It is known that GCP proliferation and GC differentiation are controlled by extracellular stimuli such as WNT, SHH, and BMP during their development. However, the function of Notch signaling in the granule cell development is poorly understood, despite the numerous previous studies for this pathway in the development of varous tissues in vertebrates and invertebrates. In this study, we investigated the expression profiles of Notch singaling molecules in GCPs and GCs during cerebellar development. Then we introduced overexpression/knockdown vectors for various Nocth-signaling molecules into the EGL by *in vivo* electroporation to investigate their roles in granule cell development. Overexpression and knockdown for some molecules obviously affected proliferation and differentiation of GCPs/GCs, suggesting that Notch signaling regulates the development of cerebellar granule cells.

Title: Differential regulation of neocortical and hippocampal astrogliogenesis by neogenin

Authors: *D. SUN, W. XIONG;
Case Western Reserve Univ., Cleveland, OH

Abstract: Astrocytes, a major type of glial cells in the brain, play important roles in modulating synaptic transmission and information processing, and maintaining CNS homeostasis. The abnormal astrocytic differentiation contributes to dysfunctions of synaptic plasticity and neuropsychological disorders. Thus, it is of considerable interest to investigate how astrogliogenesis is regulated. Neogenin, a member of deleted in colorectal cancer (DCC) family receptors, appears to play important roles in regulating cortical astrogliogenesis. Neogenin is highly expressed in neural stem cells (NSCs) and astrocytes. Knocking out (KO) Neogenin in NSCs as well as in adult astrocytes selectively reduced neocortical astrocytes, which are likely due to impaired BMP-induced cortical astrogliogenesis and decreased astrocyte self-renewal. Further mechanical studies suggest that neogenin in NSCs is required for BMP2 activation of YAP, a crucial transcriptional factor for cortical astrocytic differentiation. Interestingly, neogenin in NSCs is only required for cortical, but not hippocampal, astrogliogeneis, and in hippocampus, neogenin in NSCs is necessary for adult dentate gyrus neurogenesis. The latter function appears to be due to neogenin regulation of Gli1, a transcriptional factor downstream of sonic hedgehog (Shh) pathway. Taken together, these results demonstrate a differential regulation of cortical and hippocampal astrogliogenesis by neogenin, and implicate neogenin as a co-receptor for BMP or Shh in a brain region dependent manner.

Title: Neurogenesis of retinal ganglion cells in the pigmented and albino retina

Authors: *N. SLAVI, R. L. OAKS-LEAF, S. KHALID, C. MASON;
Mortimer B. Zuckerman Mind Brain Behavior Inst., Columbia Univ., New York, NY

Abstract: Proper binocular vision in higher vertebrates depends on specific proportions of retinal ganglion cells (RGCs) projecting to the same (ipsilateral) or opposite (contralateral) side of the brain. In albinism, the ipsilateral retinogeniculate projection is diminished, and the

contralateral projection is increased, leading to impaired stereo vision. To understand the long-standing enigma of how the lack of melanin in the retinal pigment epithelium (RPE) relates to aberrations in the circuitry from the eye to brain in albinism, we are investigating the events that govern early neural retinal development in pigmented and albino (tyrosinase mutants; $Tyr^{c\text{-}2J}$) C57BL/6J mice. Besides the neural retina itself, the ciliary margin zone (CMZ) at the distal-most tip of the embryonic retina was recently described as a niche for RGC neurogenesis. The cell cycle regulator Cyclin D2 and the transcription factor Msx1 are enriched in the ventral CMZ and are associated with neurogenesis and control of cell fate. We quantified the apical vs basal, and peripheral vs central distribution of Msx1- and Cyclin D2-expressing cells, to create a detailed spatiotemporal atlas of progenitors in the CMZ over time. We found that during embryonic retinal development, Cyclin D2 expression is altered in the albino compared to pigmented CMZ. In addition, using birthdating techniques, we probed for differences in the rates of cell proliferation and cell cycle exit within the CMZ. We are also performing fate mapping studies to characterize the generation and identity of cells originating from the CMZ. This study will elucidate how RGC neurogenesis is controlled in the normal visual system, and provide information on the underpinnings of perturbed retinogeniculate connectivity leading to visual syndromes such as albinism.

Title: Single cell transcriptomics resolves intermediate glial progenitors and uncovers pivotal determinants of cell fate and gliomagenesis

Authors: *J. WANG[1,2], J. WANG[1,2], Q. WENG[2], D. HE[1], Z. CHENG[3], F. ZHANG[1], S. S. POTTER[1], G. YU[3], Q. R. LU[1];

Abstract: Abnormal development of glial progenitors, including astrocyte lineage precursors and oligodendrocyte precursor cells (OPCs), contributes to tumorigenesis and various neurological diseases. Although single-cell analysis of human glioma tissues has been reported, the tumorigenic cell of origin and the molecular links between native glial progenitors and pre-

cancerous or neoplastic cells during glioma transformation have not been fully defined. By using single-cell RNA sequencing (scRNA-seq) on prospective astrocyte lineage cells and OPC populations from neonatal mouse cortices, we uncovered an unanticipated diversity of glial progenitor pools with unique molecular identities in developing brain. We found that astrocyte lineage cells are much more dynamic than previously appreciated in the developing cortex and uncovered an intermediate glial progenitor cell population (iGCs), which express the markers of both astrocytic signature genes and oligodendrocyte lineage genes during astrocyte lineage development. In contrast to the astrocyte lineage, the progenitors of oligodendrocytes exhibited a fate-restricted continuum in the lineage, encompassing a primitive OPC intermediate (pri-OPCs) prior to OPC commitment. Application of scRNA-seq to a murine model of GBM revealed that primitive OPC intermediates disproportionately contributed to glioma formation. Analyses of different tumorigenic phases showed that reprogramming of the OPC intermediates into a stem-like state, rather than direct stem-cell proliferation, resulted in their malignant transformation. Similar actively cycling pri-OPC intermediates were prominent components in different human gliomas caused by distinct driver mutations. Moreover, we established a machine-learning algorithm to identify glial lineage-driving networks and discovered an RNA-binding protein, Zfp36l1 as a critical regulator for both glial fate specification and glioma growth. Together, our results resolve the dynamic repertoire of common and divergent glial progenitors during development and tumorigenesis and indicate a conserved regulatory network underlying brain development and tumorigenesis.

Title: Temporal, regional, and functional intersection of microglia, precursor cells, and vasculature in developing cerebral cortex

Authors: E. PENNA, *S. C. NOCTOR;
MIND Inst., UC Davis, Sacramento, CA

Abstract: Formation of the cerebral cortex begins during gestation with the establishment of fundamental building blocks that include neural precursor cells. Precursor cells that line the

lateral ventricles produce the vast majority of cortical neurons and glia that populate mature neocortex. Evidence gathered to date reinforces the concept that precursor cells function within a complex milieu comprising multiple cell types. Our published work showed that microglial cells are present in the proliferative zone cells during cortical neurogenesis; that microglia make extensive contact with the soma and processes of precursor cells that undergo division at the margin of the lateral ventricle; and that microglia also phagocytose neural and glial precursor cells during peak stages of cell genesis. Published evidence also shows that endothelial cells influence the function of neural precursor cells, and that precursor cells are often located near blood vessels. We have shown that microglia also associate with vasculature in the developing neocortex for reasons not yet clear. Microglia derive from precursor cells in the yolk sac and enter the cerebral cortex during prenatal stages of cell genesis. Previous work proposed that microglia seeding the cerebral cortex travel along vasculature as a means of entry to the cortical parenchyma. To investigate the temporal, regional and functional relationships between precursor cells, microglia, and vasculature in the developing cerebral cortex, we completed a developmental study of microglial colonization examined in the context of vascular development and precursor cell distribution. Our findings demonstrate that microglia contribute to the complex environment in which mitotic precursor cells, neuronal and glial progeny, and blood vessels are embedded in the cortical proliferative zones. The most relevant implication of these results is that cortical histogenesis proceeds from an appropriate interplay between multiple systems. Furthermore, factors that impinge on any single component may put development of the cerebral cortex at risk, and altering the development of a single component could change the timing and trajectory of cortical development and increase susceptibility for altered neurodevelopmental outcomes.

Title: RNAi inhibition of KAT II during postnatal development alters cell generation in the subventricular zone and oliodendrogenesis in the corpus callosum

Authors: *S. M. CLARK[1], T.-C. MOU[1], A. LANIYAN[1], R. CHANDRA[2], L. H. TONELLI[1]; [1]Psychiatry, [2]Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Kynurenine/alpha-aminoadipate aminotransferase (AADAT/KAT II), has been extensively studied for its role in the catabolism of tryptophan and the conversion of kynurenine into kynurenic acid, a metabolite with glutamatergic and cholinergic modulatory activity. We have previously reported that KAT II is expressed in astrocytes found in the proliferative zones of the adult rat brain: the subventricular zone (SVZ) of the lateral ventricles, which shows the highest expression, and the subgranular zone of the dentate gyrus in the hippocampus. In the present study we examined KAT II mRNA expression during rat brain development from embryonic day 15 through adolescence. Consistent with prior reports on KAT II catabolic activity, mRNA for this enzyme was not detectable in the embryonic brain; however, by postnatal day (PND) 7 KAT II expression was evident in the SVZ, whence expression spread to the corpus callosum (by PND 14) and hippocampus (PND 21), reaching stable levels by PND 28. Interestingly, KAT II expression regionally and temporally parallels myelination during postnatal development. Hence, we hypothesized that KAT II may play a role in cell proliferation and white matter development in the postnatal brain. To test this, we administered AAV-shRNAi targeted against KAT II to Wistar rat pups on PND 7 via intranasal inoculation followed by daily injections of 5' Bromo-2' deoxyuridine (BrdU; 100 mg/kg, i.p.) for one week starting on PND 14. BrdU incorporation and the generation of oligodendrocytes were assessed 3 weeks later (PND 42). Examination of the SVZ revealed a significant increase in BrdU+ cells in animals treated with shRNAi. Nevertheless, there were fewer BrdU+ cells in the corpus callosum and a reduction in the number of Olig2+ cells. Analysis of Ki67 in the corpus callosum also showed a significant reduction in the number of cells in the cell cycle. These findings support a role for KAT II in oligodendrogenesis during postnatal development, specifically in the proliferation and migration of precursor cells to the corpus callosum. While additional studies are required, these results suggest that perturbation of this system during postnatal development could result in long term effects on white matter integrity and function.

Title: Integration of single cell transcriptomes and chromatin profiles to detect regulatory elements critical to interneuron development

Authors: *C. RHODES, D. LEE, Y. ZHANG, T. PETROS;
NIH, Bethesda, MD

Abstract: Mitotic progenitors in the ventricular/subventricular zones (VZ/SVZ) of the dorsal and ventral forebrain display similar cell cycle and neurogenic dynamics. Yet the dorsal telencephalon gives rise to glutamatergic excitatory cells whereas GABAergic inhibitory interneurons arise from three ganglionic eminences in the ventral telencephalon (MGE, LGE and CGE). GABAergic interneurons are an incredibly diverse cell population that perform critical roles in neural network function. Despite substantial evidence that initial interneuron subgroup fate is specified within the GEs, very few fate determining genes have been identified. One possibility is that interneuron progenitors contain epigenetic signatures biasing cells towards a particular interneuron fate that are not yet apparent in the transcriptome. Transcription of a gene is highly dependent upon chromatin modifications at enhancers and promoters, but we lack a comprehensive understanding of how such non-coding genomic regions influence cell fate during embryogenesis.
In this study, we perform single cell assay transposase-accessible chromatin (scATAC-Seq), in combination with single cell RNA (scRNA-Seq) sequencing to characterize the relationship between chromatin modifications and gene expression in progenitors from the dorsal and ventral telencephalon. Our initial analysis detects significant differences in chromatin accessibility within cis-regulatory elements of developmentally critical genes between brain regions. By examining chromatin profiles of lineage-specific genes across cell types, we can detect putative enhancers associated with interneuron fate determination. Experiments are ongoing to assess the functional role of candidate enhancer-gene interactions in regulating interneuron fate determination. These insights increase our knowledge of fate determining mechanisms and could open new avenues for understanding how disease-associated genes could perturb interneuron fate and maturation.

Title: Mapping gene regulatory networks generating cell diversity in the embryonic basal ganglia

Authors: *A. N. RUBIN[1], L. SU-FEHER[2], S. N. SILBERBERG[1], K. J. LIM[1], H. TIAN[1], A. S. NORD[2], J. L. R. RUBENSTEIN[1];
[1]Nina Ireland Lab. of Developmental Neurobio., Univ. of California San Francisco, San Francisco, CA; [2]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

Abstract: The progenitor domains of the basal ganglia - the medial, caudal and lateral ganglionic eminences (MGE, CGE, LGE) - produce the GABAergic projection neurons that populate the adult striatum, globus pallidus, amygdala and other subpallial structures, as well as interneurons that migrate to pallial (e.g. cortex) and subpallial regions (e.g. striatum). During development, several transcription factors with regionally defined expression patterns within the ganglionic eminences participate in specifying the cell types produced there, including Nkx2-1, Nr2f2 and Otx2. However, efforts to elucidate the complete transcriptional circuitry that generates cell diversity in the basal ganglia have been hampered by the heterogeneity of the ganglionic eminences and their derivatives. We also do not know how early the known cell type specification factors begin to have a role. We aim to use single cell RNA-seq on embryonic day (E)11.5 to probe early transcriptional differences, and to integrate this with epigenomic characterization by histone ChIP-seq and ATAC-seq to elucidate the regulatory elements that are part of the transcriptional networks driving specification at this stage. We hypothesize that transcriptional networks with specific spatial activity drive MGE cell fate decisions to generate neuronal diversity. We have used previously identified, defined activity patterns of regulatory elements to label and purify regionally distinct progenitor domains of the ganglionic eminences, as well as spatially intermixed lineages that have been fate-mapped to distinct populations in the adult. We have identified differentially expressed candidate regulators of early cell fate decisions in the MGE and are assessing their roles in cell type specification. This work contributes to mapping of the transcriptional circuitry driving fine-grained cell fate decisions within the developing basal ganglia.

Title: Identification of transcribed enhancers critical for cerebellar development

Authors: *M. RAMIREZ[1], R. ROBERT[3], J. T. YEUNG[2], F. CONSORTIUM[4], D. GOLDOWITZ[5];
[2]Med. Genet., [1]Univ. of British Columbia, Vancouver, BC, Canada; [3]Univ. of Rennes 1, Rennes, France; [4]RIKEN, Yokohama, Japan; [5]Med. Genetics; U of BC, Ctr. for Mol. Med. & Ther., Vancouver, BC, Canada

Abstract: The developing cerebellum requires intricate spatial and temporal expression of genes. The spatiotemporal control of gene expression is partially driven by non-coding regulatory sequences known as enhancers. Bi-directional transcription of non-coding enhancer RNAs (eRNAs) at enhancer sequences has been described as a signal of active enhancers and can be used to identify active enhancer elements during development. The FANTOM5 consortium has defined a catalogue of transcribed mouse enhancers from several mouse tissues, including cerebellum samples from 12 time-points spanning embryonic and postnatal development submitted by our lab. *This study aims to establish a comprehensive atlas of transcribed enhancer elements critical for cerebellar development and characterize the role of transcribed enhancers and their respective eRNAs in brain development.*
We have identified 2359 transcribed enhancers through eRNA expression analysis and validated activity using ChIP-seq of enhancer associated histone marks H3K27ac and H3K4me1. Co-expression analysis between eRNA and expression of genes located in *cis* was conducted to identify correlated predicted gene targets highly enriched for developmental function. Using a specific set of biological criteria, we have identified clusters of transcribed enhancers predicted to regulate genes involved in postnatal granule cell differentiation and maturation. *In situ* hybridization has revealed that expression of eRNAs from these enhancer clusters is spatially identical to the predicted gene target (ex. Nfib), validating our predictive pipeline. We plan to investigate the role of transcribed enhancers and eRNAs in neuron development by perturbing activity using a CRISPR interference system and knocking down their eRNAs in a granule cell culture systems. Validated enhancers will then be knocked out of in the whole mouse the mouse genome for further characterization *in vivo.*

Title: Critical roles of ARHGAP36 as a signal transduction mediator of Shh pathway in lateral motor columnar specification

Authors: H. NAM[1], S. JEON[2], S.-K. LEE[2], ***S. LEE**[1];
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: During spinal cord development, Sonic hedgehog (Shh), secreted from the floor plate, plays an important role in the production of motor neurons by patterning the ventral neural tube, which establishes MN progenitor identity. It remains unknown, however, if Shh signaling plays a role in generating columnar diversity of MNs that connect distinct target muscles. Here, we report that Shh, expressed in postmitotic MNs, is essential for the formation of lateral motor column (LMC) neurons at the brachial level. This novel activity of Shh is mediated by its downstream effector ARHGAP36, whose expression is directly induced by the MN-specific transcription factor complex Isl1-Lhx3. Furthermore, we found that AKT stimulates the Shh activity to induce LMC MNs through the stabilization of ARHGAP36 proteins. Taken together, our data reveal that Shh, secreted from MNs, plays a crucial role in generating MN diversity via a regulatory axis of Shh-AKT-ARHGAP36 in the developing spinal cord.

Title: Behavioral and thalamic repercussions following the reduction of primary visual area size by cortical Emx2 deletion

Authors: ***C. SCHAFFER**[1], O. AJAYI[1], D. DELBRUNE[1], A. SHASTRI[1], S. AKHIDENOR[1], A. B. ZEMBRZYCKI[2], A. M. STOCKER[1];

Abstract: The neocortex is unique to mammals and possesses distinct functional areas responsible for processing specialized information. Among these functional areas are the primary sensory areas that process different types of sensory information. Gene expression gradients in the early telencephalon provide positional cues and ultimately play a prominent role in determining the size and location of these functional areas during corticogenesis, a process called area patterning. The transcription factor Emx2 has been found to play a crucial role in this process, and the removal of this gene from the cortex has been shown to result in a significant

shift of primary sensory area location and a decrease in primary visual area (V1) size. Previous research has demonstrated that cortex-specific genetic changes result not only in alterations in primary area size, but also in rearrangements in the corresponding thalamic nucleus. We explored whether the reduction in V1 mediated by a cortex-specific deletion of Emx2 (cKO) resulted in thalamic changes. Our results indicated that the size of the visual thalamic nucleus, dorsal lateral geniculate, did not change in Emx2 cKO mutants that possess a smaller V1. However our results also demonstrated that the thalamic reticular nucleus (TRN) is reduced in size in Emx2 cKOs, despite the lack of genetic manipulation outside of the cortex. Furthermore this reduction in TRN occurred during the critical period, as no changes were observed prior to its onset (postnatal day 18 in mice). We also explored whether these anatomic alterations also had behavioral repercussions. To test for a change in visually-mediated behaviors we employed the looming visual stimulus behavioral paradigm. Behavioral alterations that accompany top-down plasticity driven changes will be further explored and discussed.

Title: Diversity and embryonic origin of septal neurons: Analysis of developmental trajectories

Authors: *M. TURRERO GARCIA[1], S. HRVATIN[1], C. WEINREB[2], A. KLEIN[2], C. C. HARWELL[1];

Abstract: The septum is ventral forebrain structure responsible for the regulation of emotional states including anxiety, fear and depression. The septum contains an extremely diverse array of short- and long-range projecting GABAergic neurons distributed across its two histological subdivisions, the medial and lateral septal nuclei. Both of these regions are heavily interconnected with other brain areas through efferent and afferent projections. It is currently unclear how septal neuronal diversity and the wiring of its circuits are specified during development. We used a combination of single-cell RNA-seq, histology and genetics to study the

developmental trajectories by which embryonic septal progenitors give rise to different types of neurons, and how these transition through subsequent maturation steps towards their mature function. We studied the septa of mice at six different developmental stages, finding key molecular differences between diverse types of neurons in the mature lateral and medial septum and the progenitor types that give rise to them. We present evidence in support of a general model for the specification of diverse septal neuron subtypes. Our results provide novel insights into the assembly of the complex circuitry underlying the regulation of internal states carried out by the septum.

Abstract: Transcription factors (TFs) are proteins that positively or negatively regulate gene expression. This regulatory control enables genes to be expressed in the correct cells at the appropriate amount in each cell of an organism. Homeodomain TFs have been shown to play important roles in imparting cellular and regional identity during embryonic development. Emx2 is a homeodomain TF that participates in the regulation of a number of important developmental processes including area fate decisions (i.e. area patterning); migration and lamination; cortical specification; and the switch from neuronal to glial production in neural progenitors. Previous studies have investigated changes in transcription following Emx2 deletion, however many were done at late embryonic time points after Emx2 has been downregulated and thus after many of the developmental events detailed. Furthermore, transcriptomic based studies are unable to provide information on the abundance or diversity of protein products. To circumvent these issues we utilized label-free proteomic analysis by ultra high performance liquid chromatography coupled with tandem mass spectrometry (UPLC-MS/MS) to identify changes in protein expression between different embryonic brains of Emx2 mutant mice. Brains were harvested at embryonic day 13.5, when neurogenesis in the telencephalon and Emx2 expression are both abundant. A nestin promoter driven overexpression and a cortex specific deletion mediated by

Emx1 driven Cre-recombinase of Emx2 were compared to control tissues with intact endogenous Emx2 expression. Differences in protein expression and abundance will be explored.

Title: Temporal transcription factors interact with chromatin remodelling complexes to regulate competence transitions during neural development

Authors: S. SHAH[1], C. JOLICOEUR[2], T. DANG[1], ***P. MATTAR**[1], *M. CAYOUETTE[2]; [1]Regenerative Med., OHRI, Ottawa, ON, Canada; [2]Cell. Neurobio., IRCM, Montreal, QC, Canada

Abstract: During development, neural progenitor cells dynamically alter their potential in order to generate different types of neurons and glia in the correct sequences. A number of 'temporal transcription factors' have been identified that are dedicated to controlling transitions in progenitor multipotency, but the molecular mechanism employed by this class of transcription factors remains unclear. To identify the molecular pathway used by temporal factors to regulate competence states in neurogenesis, we focused on the zinc finger transcription factor *Casz1* - the mammalian orthologue of *Drosophila castor*. We have previously shown that Casz1 encodes late multipotency in murine retinal progenitor cells. Here, focusing on postnatal retinal development, we show that *Casz1* controls the rod versus Müller glia cell fate choice. Next, we performed Bio-ID proteomics, which revealed that Casz1 interacts with the Mi2/Nurd complex in postnatal retinal progenitors. Finally, we show that both the Mi2/Nurd complex and the downstream polycomb repressor complex are required for Casz1 to promote the rod fate and suppress gliogenesis. Since other temporal transcription factors have been shown to interact with these complexes in other contexts, we propose that temporal transcription factors modulate the functions of the same co-factor complexes in a step-wise fashion in order to regulate competence transitions.

Title: The role of E-proteins Tcf3 and Tcf12 in ventral telencephalon development

Authors: *M. J. TALLEY[1,2], D. NARDINI[1], L. EHRMAN[1], R. R. WACLAW[1];
[1]Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [2]Univ. of Cincinnati, Cincinnati, OH

Abstract: The mouse telencephalon contains progenitor cells that eventually differentiate into numerous subtypes of neurons, myelinating oligodendrocytes, and astrocytes. In most cases, these diverse cells are generated from progenitor cells that are spatially and temporally distinct at specific stages of development. Proper progenitor proliferation and differentiation are required to establish regional identify and to specify the correct balance of cell types in the brain. The class I basic helix-loop-helix (bHLH) transcription factors, also called E-proteins, were thought to be ubiquitously expressed and play key roles in brain progenitor dynamics largely through their interactions with pro-neural and pro-glial class II bHLH transcription factors. However, specific roles of E-proteins have been elusive as their expression has not been fully characterized in the developing forebrain and germline single E-protein KOs have not identified specific roles during forebrain progenitor cell development or differentiation. Using *in situ* hybridization and immunofluorescence, we have characterized Tcf3, Tcf4, and Tcf12 expression in the developing telencephalon. To address a role for Tcf3 and Tcf12 during development, we generated conditional knockouts using *Olig2*$^{cre/+}$ to target the ventricular zone progenitor cells in the ventral telencephalon and the entire oligodendrocyte lineage. We did not detect a phenotype in *Tcf3* or *Tcf12* single conditional mutants. However, our preliminary data has revealed that combined loss of *Tcf3* and *Tcf12* results in developmental defects in early forebrain progenitor cells, oligodendrocyte progenitor cell generation, and oligodendrocyte differentiation. Our future directions will focus on the mechanism by which Tcf3 and Tcf12 impact ventral telencephalon progenitors and oligodendrogenesis.

Abstract: Precise temporal control of gene expression in neuronal progenitors is necessary for correct regulation of neurogenesis and cell fate specification. However, the cellular heterogeneity of the developing CNS has posed a major obstacle to identifying the gene regulatory networks that control these processes. To address this, we used single-cell RNA sequencing to profile ten developmental stages encompassing the full course of retinal neurogenesis. This allowed us to comprehensively characterize changes in gene expression that occur during initiation of neurogenesis, changes in developmental competence, and specification and differentiation of each major retinal cell type. We identify NFI transcription factors (Nfia, Nfib, and Nfix) as selectively expressed in late RPCs and show that they control bipolar interneuron and Müller glia cell fate specification and promote proliferative quiescence. To futher explore this developmental system, we developed a novel computational workflow which defines latent spaces from a source scRNA-seq dataset and evaluates these latent spaces in independent target datasets via transfer learning. Application to the developing mouse retina reveals intrinsic relationships across biological contexts and assays, while avoiding batch effects and other technical features associated with current single cell measurement techniques. We compare the dimensions learned

in this source dataset to adult mouse retina, a time-course of human retinal development, select scRNA-Seq datasets from developing brain, ATAC-Seq data, and a murine cell type atlas to identify shared biological features. These data and tools provide a comprehensive picture of the transcriptional landscape of the developing retina, and are used to identify shared and unique transcriptional signatures of cellular features across diverse developmental systems in the CNS and beyond.

Title: DNA methylome identify differentiation potential of NS/PCs during brain development

Authors: *T. SANOSAKA[1], T. IMAMURA[2], K. NAKASHIMA[2];
[1]Kieo Univ. Sch. of Med., Tokyo, Japan; [2]Kyushu Univ., Fukuoka, Japan

Abstract: Epigenetic regulation during *in vivo* specification of CNS stem cells are still poorly understood. Here we report comparative methylome analyses of directly sampled cortical neural stem and progenitor cells (NS/PCs) at different development stages, as well as those of terminally differentiated cortical neurons, astrocytes and oligodendrocytes. We found that sequential specification of cortical NS/PCs is regulated by two successive waves of demethylation at early and late development stages, respectively, which are responsible for the establishment of neuron- and glia-specific low methylated regions (LMRs). We further found that Nuclear factor I (NFI) induces demethylation of glial lineage-specific genes, orchestrating the onset of glial differentiation. We provide evidence showing that eventually DNA methylation of neuronal-specific LMRs is required to maintain glial specific-epigenotypes, essentially by silencing neuronal genes. Our data highlight the *in vivo* implications of DNA methylation dynamics in shaping epigenomic features that confers lineage competence in the developing CNS.

Title: Molecularly dissociable roles of chromatin remodeling in cortical development

Authors: J. M. KEIL, A. QALIEH, M. M. LAM, L. SHI, *K. Y. KWAN;
Univ. of Michigan, Ann Arbor, MI

Abstract: Emerging human genetic findings have convergently implicated dysregulation of chromatin as a key contributor to disorders of brain development. Recent studies have shown that altered chromatin function can perturb neural cell fates, cell-type dependent gene expression, or neuronal plasticity via defective transcriptional regulation. However, in addition to gene transcription, chromatin also plays key roles in other processes on DNA, including DNA damage detection and repair. Here, we found that disruption of chromatin remodeling in cortical neural progenitor cells impairs DNA double-strand break repair, thus triggering p53 activation, robust apoptosis, and microcephaly. Transcriptome analysis revealed that this function of chromatin

remodeling is molecularly distinct from direct regulation of transcription. Furthermore, chromatin-mediated DNA repair showed developmental stage and cell-type dependence. Thus, chromatin remodeling is required for the maintenance of genome stability during cortical development, and its disruption can contribute to neurodevelopmental disorders in a transcription-independent manner.

Title: Chromatin remodeling and non-cell-autonomous regulation of cortical connectivity

Authors: *D. J. DOYLE, A. QALIEH, M. M. S. LAM, K. Y. KWAN;
Mol. and Behavioral Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI

Abstract: Chromatin remodeling dynamically regulates spatiotemporal gene expression and cell-type specific identity. In cortical development, chromatin regulation can function cell-autonomously to specify or refine the molecular identity of diverse neuronal subtypes during neurogenesis. During the subsequent assembly of neural circuitry, chromatin regulation can also mediate non-cell-autonomous mechanisms, potentially by directing spatiotemporal expression of axon guidance molecules and their cell surface receptors. With the potential to mediate lasting molecular changes, chromatin remodelers are well-positioned to regulate multiple aspects of cortical development. However, potential cell-type dependent roles of chromatin remodelers in cortical neuron identity and connectivity have remained largely unexplored. Here, we found that the mammalian SWI/SNF remodeling complex plays a key role in the maintenance of cell type-specific neuronal transcriptomes. In the absence of this transcriptional regulation, cortical connectivity was widely disrupted as a combined result of both cell-autonomous and non-cell-autonomous dysregulation. Therefore, the mammalian SWI/SNF chromatin remodeling complex plays cell- and non-cell-autonomous roles in the specification of neuronal identity and wiring of cortical connectivity.

Title: Successful prediction of scan task and individual identity, but not ASD status, from functional connectomes in an extensively and densely sampled multiband fMRI dataset

Authors: *L. BYRGE, D. P. KENNEDY;
Indiana Univ., Bloomington, IN

Abstract: There is currently much interest in using functional connectivity (FC) MRI to identify neural biomarkers of ASD, despite many inconsistent and null results in the literature. Such failures to replicate could potentially stem in part from limitations in scan resolution and scan duration as well as the use of resting state protocols that lack a shared stimulus. Here, we evaluate FC similarity and diagnosis prediction in a sample of adults with ASD and controls using extensively and densely sampled fMRI data from each subject. We acquired multiband resting-state and video-watching scans (813ms TR) from 29 adult controls and 22 matched individuals with ASD across two scan sessions, comprising about 2 hours of functional data per individual. Preprocessing and FC matrix construction are described in Byrge & Kennedy (2018); we examined two parcellations and several approaches to addressing data quality (multiple censoring thresholds with and without downsampling to equate data quantity). We found that within-individual similarity of functional connectomes did not differ across groups after controlling for data quality covariates, indicating equivalent reliability across scans. Individual connectomes were highly distinct from other individuals, such that we could predict subject identity with ~98% accuracy. Using the same fingerprinting method, however, we could not predict subject diagnosis (under 62% accuracy). In contrast, this same method could be used to predict scan type (rest/video) with ~97% accuracy, indicating that scan type elicited a stronger common FC pattern than diagnosis. Similar results were obtained using classifiers trained on only the most informative FC edges and controlling for data quality (~60% accuracy for diagnosis; ~97% accuracy for scan type). Consistent with the diagnosis prediction results, group differences in FC similarity to controls were small and sensitive to choices of parcellation and data quality approach. We found no evidence for a shared ASD-specific pattern of FC; in no case was FC similarity to ASD individuals higher in the ASD group. Enhancing scan resolution, increasing scan duration, and adding video scans were thus not sufficient to reveal an FC-based

biomarker of ASD, despite high-quality data that permitted near-perfect prediction of individuals and scan task. Our results suggest that the development of useful biomarkers and mechanistic insight into neural differences in ASD may require employing and developing analytic techniques that operate fundamentally at the individual or subgroup level, rather than at the group level where no robust systematic differences were observed.

Title: Amygdala volume and social impairment in youth with autism spectrum disorders

Authors: *Y. KIM, M. C. DUGGINS, J. DAVIS, K. PAULSON, C. DEMOPOULOS, B. KOPALD, K. DEPLONTY, J. D. LEWINE;
The Mind Res. Network, Albuquerque, NM

Abstract: Social impairment is a defining characteristic of Autism Spectrum Disorder (ASD). Identification of correlated biomarkers has the potential to improve early diagnosis, elucidate neurobiological mechanisms, and provide novel metrics for tracking the effectiveness of treatment. Although there does not appear to be a single convergent neurobiological etiology for all ASDs, there is mounting evidence for distinct patterns of structural and functional compromise in ASD sub-types. Previous research has highlighted the role of the amygdala in social impairment. The present study aims to expand and confirm previous research investigating (1) amygdala structural differences between subjects with an ASD and controls and (2) the relevance of the amygdala to social impairment phenotype in ASD. An automated, MRI region-of-interest pipeline based on FreeSurfer, was used to measure total intracranial volume and right and left amygdala volumes in 22 children and adolescents with an ASD (16 males, 6 females) and 12 typically developing controls (8 males, 4 females). Both absolute and relative amygdala volume (corrected for total intracranial volume) were examined as correlates of social impairment. Participants were assessed using the Social Responsiveness Scale (SRS) as a measure of the clinical phenotype of social impairment. There was no group difference in absolute or relative amygdala volumes and intracranial volume. However, strong correlations between amygdala volumes and SRS scores were found in ASD group. Regression analysis revealed increased amygdala volumes (both right and left hemispheres) were significantly

correlated with higher SRS scores in participants with ASD. That is, greater amygdala volume was associated with greater social impairment in the ASD group. Such a correlation was not seen in the control group. Most previous research on amygdala structure in the ASDs has focused on young children with ASD. There, it has been shown that young children with autism have greater amygdala volumes than age matched control subjects. As has been reported by some other, and is seen in our data, this difference does not appear to be maintained as children get older. The data thereby suggest altered developmental pathways in autism. The data also indicate that the relationship between amygdala volume and social impairment is complex and only seen in the autism group. Nevertheless, amygdala volume may prove to be a useful biomarker of social impairment in the ASDs. Future longitudinal studies will help to clarify relevant developmental trajectories. These findings have implications for future identification and intervention to support individuals with ASD.

Title: Microbiota transplant intervention shows promising results in some children with autism spectrum disorder (ASD)

Authors: *H. B. WALKER[1], T. MIDTVEDT[2];
[1]Biomed Clin., Oslo, Norway; [2]Dept. of Microbiology, Tumor and Cell Biol., Karolinska Institutet, Stockholm, Sweden

Abstract: For most biochemical pathways there are different “security pathways”, which in an exposed first generation may impose a shut-down or activation of genes with other consequences than in second generation. Current scientific data suggests that many illnesses may stem from the similar, underlying patho-physiological process as autism. The second generations’ exposure will likely lead to compounded epigenetic factors. We are born germfree. Microbiota will develop in specific order-in a window of establishment - during the first two years of life. If a window is missed, it may give lifelong consequences. Since the 1950’s infants have been exposed to more xenobiotics before the age of 2 than ever before (new xenobiotics -vaccines, additives, pharmaceuticals, antibiotics, etc.). All of these influences upon the establishment of a healthy microbiota. Most often children with autism have a different - dysbiotic - microbiota then controls. The number of children diagnosed with ASD have been rising in the past decades. It may indicate that people with a certain genetic DNA profile are more vulnerable to changes in

microbiota, which may affect their biochemical functions manifesting itself as autism. We have followed some families that have successfully regulated relevant functions in their ASD children with microbiota transplantation. Their successful regulation has been sustained as long as the children are receiving microbiota transplants. The children have regressed to an autistic behaviour after stopping receiving transplant. It seems that a systematic transplantation is necessary for regulation of dysbiosis- at least for a longer period. Cases will be presented.

Title: Term or preterm cesarean section delivery transiently alters but does not lead to long-term detrimental consequences in mice

Authors: M. CHIESA[1,2], B. RIFFAULT[1,2], H. RABIEI[1,2], ***D. C. FERRARI**[1,2], Y. BEN-ARI[1,2]; [1]Neurochlore, Marseille, France; [2]Ben-Ari Inst. of Neuroarcheology (IBEN), Marseille, France

Abstract: Delivery is one of the most complex biological processes in mammals which involves hormonal and mechanical stimuli that together allow the survival and development of the newborn. Alterations to the time and mode of delivery could lead to modification of survival functions and have been hypothesized to promote the emergence of neurodevelopmental disorders. Epidemiological studies have controversially suggested that cesarean section (C-Section) delivery might increase the risk of neurodevelopmental disorders including Autism Spectrum Disorders (ASD). Yet, the complexity and heterogeneity of factors associated with delivery render existing epidemiological studies debatable. We have recently shown in an experimentally controlled mouse model of C-section delivery that mice born by term or preterm C-section did not present long-term autistic-like behavioral or physiological deficits. Nevertheless, mice born by preterm C-section presented early transient neuronal and communicative defects. Our recent results with the iDISCO clearing method reveal global modifications in the brains of preterm C-section delivered mice, and the alterations in communicative behaviors are due to the association between C-section delivery and preterm birth, and not to either deviation to birth on its own. Our results suggest that preterm C-section delivery might impact early brain development, rendering it more vulnerable to perinatal and postnatal insults. Our work sheds light on the intricacy of birth alterations and might explain the disparities reported in epidemiological studies.

Title: Sensorimotor issues and core clinical symptoms in autism spectrum disorder (ASD)

Authors: S. BRIDWELL[1], G. GABRIELLI[2], *J. BARTOLOTTI[1], M. W. MOSCONI[1]; [1]Life Span Inst., Univ. of Kansas, Lawrence, KS; [2]Weinberg Col. of Arts and Sci., Northwestern Univ., Evanston, IL

Abstract: Background: Sensorimotor issues are common in autism spectrum disorder (ASD), and they are associated with worse functional outcomes in patients. It is possible that atypical sensorimotor development interferes with the maturation of core social-communication and cognitive systems in ASD. Characterizing sensorimotor impairments and their relationship to social-communication and cognitive symptoms of ASD thus holds promise for identifying key mechanisms of core symptom traits.
Methods: Sixty-six individuals with ASD (57 male, 9 female) and 83 age-, sex- and IQ-matched typically developing (TD) controls (50 male, 33 female) performed a test of manual motor control. During this test, participants viewed a horizontal white force bar that moved upward with increased force and a horizontal red stationary target bar that turned green at the beginning of each trial. Participants were instructed to press on two precision load cells with their thumb and index finger and maintain the force bar at the level of the target bar for 8- or 15- seconds. The target force level was varied at 15%, 45%, and 85% of the participants maximum voluntary contraction (MVC). The variability (SD) and regularity (or approximate entropy, ApEn) of participants' sustained force were examined. Manual motor behavior was examined in relation to clinical ratings of ASD severity, including the social communication questionnaire (SCQ), the social reciprocity scale (SRS-2), and the repetitive behavior scale – revised (RBS-R)
Results: For force SD, a group x sex interaction was observed (F_1=4.9, p=.03); males with ASD

showed elevated force SD compared to male TD controls (p=.07), but females with ASD and TD females did not show any differences in force SD (p=.15). Greater force SD was associated with more severe RBS-R rated repetitive behaviors (r=.32, p<.001) and SRS-2 ratings of ASD symptoms (r=.31. p=.05). Lower ApEn was associated with more severe RBS-R rated repetitive behaviors in ASD (r=-.31, p<.001) and more severe ASD symptoms on the SCQ (r=-.52, p<.001) and SRS (r=-.33, p=.03).
Conclusions: We examined a large cohort of individuals with ASD and document new evidence that patients show a reduced ability to precisely and dynamically adjust motor output in response to sensory feedback. Importantly, increased force variability and regularity each were associated with more severe ASD symptoms suggesting atypical sensorimotor processing may interfere with the development of social-communication and behavioral flexibility abilities in ASD, or that these separate sets of issues reflect common pathophysiological or developmental processes.

Title: Gastrointestinal symptomatology is associated with amygdalar reactivity to negative facial affect in autism spectrum disorder

Authors: *C. RIECKEN[1], D. SCALES[1], J. P. HEGARTY II[2], R. M. ZAMZOW[3], D. Q. BEVERSDORF[4], B. FERGUSON[1];
[1]Univ. of Missouri Thompson Ctr. For Autism, Columbia, MO; [2]Ctr. for Translational Neurosci., [3]Univ. of Missouri, Columbia, MO; [4]Dept Radiol, Neurol, Psychol Sci, DGS of INP, Univ. of Missouri Columbia, Columbia, MO

Abstract: Autism spectrum disorder (ASD) is characterized by repetitive behaviors and impaired social communication, but gastrointestinal (GI) symptoms are often reported as well. Alterations in endocrine and psychophysiological measures of stress reactivity have been shown to be associated with increased GI symptomatology in ASD. Furthermore, presence of a co-occurring anxiety disorder significantly enhances the relationship between GI symptoms and the psychophysiological response to stress. Existing studies have also shown that atypical emotional-face processing in ASD is associated with altered brain activity, measured by functional magnetic resonance imaging (fMRI), compared to controls. It is not known if reactivity in brain

areas that respond to fear and anxiety is associated with GI symptoms in ASD. Therefore, to begin understanding neural correlates of altered stress reactivity associated with GI symptoms in ASD, this study assessed the potential relationship between GI symptomatology and amygdalar reactivity during presentation of emotional faces in individuals with ASD. In an initial pilot investigation, fMRI data from 12 high-functioning adults with ASD was processed using FMRIB Software Library (FSL) version 6.0.0. to determine differences in amygdalar blood oxygen level dependent activation during presentation of fearful and angry faces during face-matching tasks presented in the scanning session. GI symptomatology was assessed using scores created from the Autism Treatment Network GI Symptoms Inventory, such that higher scores indicate increased frequency, duration, and severity of GI symptoms over the past month. Relationships between amygdalar reactivity and GI symptomatology scores were assessed using R to perform one-sample *t*-tests. Initial results from this pilot investigation revealed a significant positive correlation between changes in activation of bilateral amygdala when looking at faces with fearful and angry expressions compared to neutral expressions and changes in GI symptomatology. In addition, a significant positive correlation was found between changes in activation of the right amygdala when viewing faces with an angry expression compared to no stimulus and GI symptomatology. As such, these results suggest that some individuals with ASD may experience an augmented anxiety response to negative facial affect which is associated with increased GI symptomatology. More work is needed to determine whether a causal relationship between these common aspects of ASD exists. Obtaining this information may help with the development of new treatments for those with ASD and GI problems to increase their quality of life.

Title: Associations between resting-state EEG alpha-band power and atypical sensory processing and social communication impairments in children with autism spectrum disorder

Authors: *S. PIERCE, G. KADLASKAR, B. KEEHN;
Purdue Univ., West Lafayette, IN

Abstract: Autism spectrum disorder (ASD) is a complex neurodevelopmental disorder diagnosed on the basis of impairments in social communication and the presence of restricted and repetitive behaviors, including atypical responsivity to sensory input. Neural oscillations, as measured by electroencephalogram (EEG), play a key role in brain function and are associated with a variety of perceptual and cognitive processes. In particular, resting alpha (8-12 Hz) levels are associated with peripheral measures of autonomic activity. Previous studies have attempted to identify the mechanism(s) associated with sensory processing abnormalities in ASD with contradictory results. Thus, the objective of this study is to examine the differences in alpha-band power in children with ASD and their typically developing (TD) peers, and to investigate the association between alpha power and measures of ASD symptomatology. Participants included 21 children with ASD and 17 age- and sex-matched TD children. EEG data were recorded for 3, 2-minute blocks of eye-open resting state. Participants saw a black central crosshair was presented on a grey background, and were instructed to relax, remain still, and to look at the crosshair. EEG was recorded using 128-channel Geodesic electrode array. Alpha power was extracted from frontal, central, and posterior regions of interest (ROIs). The Sensory Profile - 2 (SP-2) and the Autism Diagnostic Observation Schedule (ADOS) were used as measures of sensory processing differences and sociocommunicative impairment. Findings from EEG analyses revealed that absolute alpha levels were significantly reduced in the ASD group compared to the TD group, particularly in the posterior ROI (Figure 1). For the ASD group, no relationship was found between the SP-2 subscales and the alpha levels. However, there was significant association between alpha power and ASD severity scores as measured using the ADOS. These findings suggest that children with ASD may be more physiologically aroused compared to their TD peers, and that this may be associated with greater ASD symptomatology.

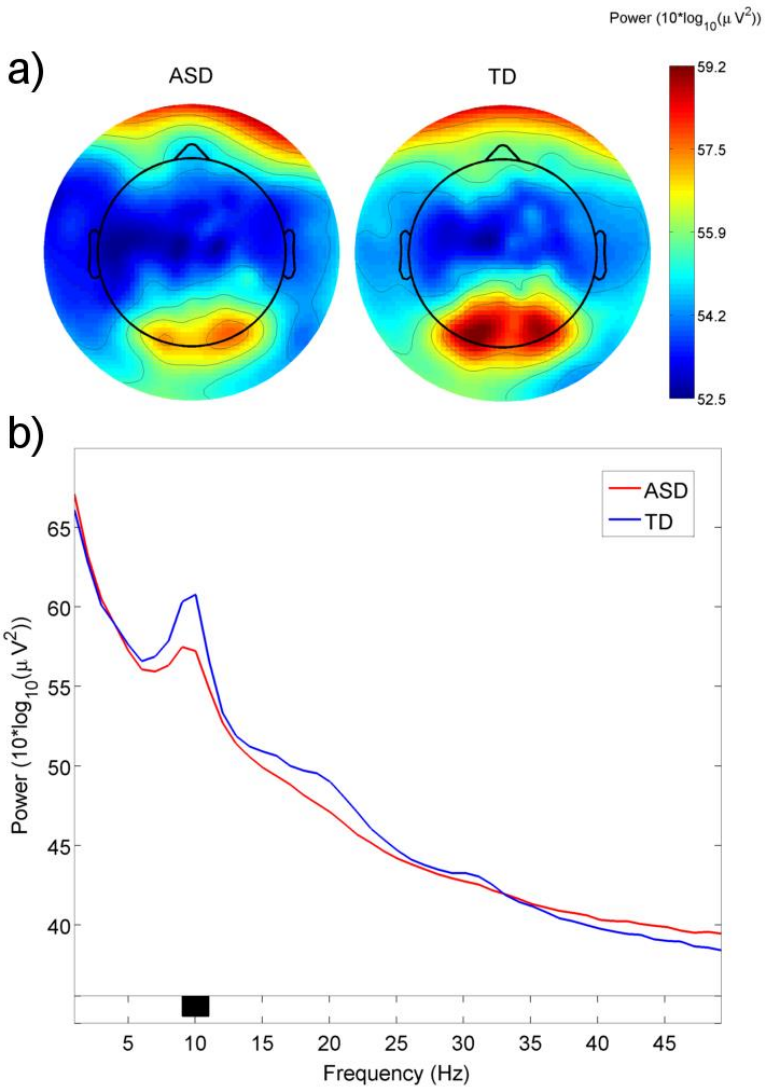

Figure 1: (a) Scalp maps of resting-state alpha (8–12 Hz) power for the autism spectrum disorder (ASD; left) and typically developing (TD; right) groups. (b) Spectra for each group from the posterior region of interest (ROI). Only significant differences in power show by blank bar on x-axis within alpha-band.

Title: Differential utilization of visual and proprioceptive information for postural control stability in individuals with autism spectrum disorder (ASD)

Authors: *Z. WANG[1], J. CHEN[1], E. IN[1], W. MCKINNEY[2], Z. LI[1], M. MOSCONI[2];
[1]Univ. of Florida, Gainesville, FL; [2]Univ. of Kansas, Lawrence, KS

Abstract: Sensorimotor impairments are common in autism spectrum disorder (ASD), although the extent to which sensory processing issues affect motor control and movement coordination in individuals with ASD is not well understood. Previous studies have suggested that individuals with ASD show increased postural sway variability in stances during which either visual or proprioceptive information is occluded. No known study to date has examined the interactive effect of visual and proprioceptive inputs on postural stability in individuals with ASD. The aim of this ongoing research is to fill this critical knowledge gap by quantifying individuals' postural sway variability during tasks with and without the availability of visual and proprioceptive information. Twenty-eight school-aged children with ASD and 11 age-, sex- and IQ- matched healthy controls participated in tests of static stance on an AMTI force platform. During the assessment, a pair of lightweight tendon vibrators (TVs) was attached on participants' Achilles tendon of the ankle joints. When turned on, both TVs vibrate at a high frequency of 80Hz to create a transient proprioceptive illusion of lengthened Achilles tendon of both legs. Participants completed tests with and without the TVs (i.e., TV_{on} vs. TV_{off}) and lights on and off (LT_{on} vs. LT_{off}). Postural sway variability was assessed using the center of pressure (COP) trajectory length and COP standard deviation in the anterior-posterior (COP_{AP}) and mediolateral (COP_{ML}) directions. Both individuals with ASD and healthy controls showed increased COP trajectory length and COP_{AP} standard deviation during TV_{on} conditions regardless of the light condition. The COP trajectory length of patients, relative to controls, showed a larger increase during TV_{on} compared to TV_{off} conditions. Individuals with ASD showed increased COP_{AP} and COP_{ML} standard deviation compared to controls across all task conditions. Proprioceptive information serves as the primary sensory source for gross motor activities including postural control. Our results suggest that postural instability in individuals with ASD and healthy controls is more severely impacted by proprioceptive illusions compared to perturbations in visual feedback.

Although both individuals with ASD and TD controls were affected by the proprioceptive illusion, postural stability was more strongly impacted in ASD suggesting a heightened dependency on proprioceptive information during standing. These findings inform a more mechanistic view of postural issues in ASD indicating that over-reliance on proprioceptive feedback may interfere with stability in patients.

Title: A possible involvement of ca^{2+}-dependent activator protein for secretion 2 (CAPS2) in regulating release of the hypothalamic neuropeptide oxytocin that hs pivotal role in social behavior

Authors: *S. FUJIMA[1], R. YAMAGA[1], H. MINAMI[1], R. MANIWA[1], N. AMEMIYA[1], M. ABE[2], K. SAKIMURA[3], Y. SHINODA[4], Y. SANO[1], T. FURUICHI[1];

Abstract: CAPS family proteins (CAPS1 and CAPS2) promote exocytosis of dense-core vesicles containing neuropeptides, peptide hormones and monoamine neurotransmitters. We previously reported that CAPS2 knockout mice not only showed decreased release of neurotrophic factors and consequently impaired synaptic development and function but also displayed abnormalities in social and anxiety behavior. There are multiple reports that suggest a possible link between autism spectrum disorder (ASD) and CAPS2, due to the fact that alterations in CAPS2 gene and its expression (*de novo* copy number variation, single nucleotide variation, aberrantly-increased expression of a rare splicing variant) have been found in some ASD patients. However, it is yet unknown how failed CAPS2-mediated release mechanism contributes to ASD risk. We also showed that CAPS2 is expressed in the hypothalamic paraventricular nucleus (PVN), producing neurohypophysial hormones oxytocin (OXT) and vasopressin (AVP) both of which are known to modulate social behavior in several animal species. From this point of view, we got an idea that abnormality of CAPS2 affects release of OXT and/or AVP, thereby resulting in impaired social behavior.To address this question, we

analyzed cellular expression of CAPS1 and CAPS2 in OXT- or AVP-positive neurons in the PVN. As a result, CAPS2 protein was largely localized in OXT and AVP neurons in the anterior than posterior PVN. CAPS1 protein was also expressed in approximately half of OXT neurons. CAPS2 and CAPS1 protein was also concentrated in the posterior pituitary (PP), in which OXT and AVP are secreted from the axon terminals to blood vessels. Next, we compared serum OXT levels between control and CAPS2 KO mice by OXT ELISA. As a result, CAPS2 KO mice showed decreased serum OXT levels compared to those of control mice. We also analyzed OXT immunoreactivity in the PP of mice with conventional KO and OXT neuron-specific conditional knockout (cKO) of CAPS2. We found accumulated levels of OXT in the PP of both CAPS2 KO and cKO mice compared to their control mice. These results suggest that CAPS2 plays a role in OXT secretion. Our preliminary data also suggest that both CAPS2 and CAPS1 probably regulate the release of social hormones OXT and AVP. Taken together, we suggest that a deficit in CAPS2-mediated release mechanism may be associated with OXT-related social behavior.

Title: Measures of tonic and phasic activity of the locus coeruleus - norepinephrine system in children with autism spectrum disorder

Authors: *B. KEEHN[1], G. KADLASKAR[1], R. MCNALLY KEEHN[2];
[1]Purdue Univ., West Lafayette, IN; [2]Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: The locus coeruleus-norepinephrine (LC-NE) system, which is known to play an important role in arousal regulation and selective attention, has been shown to function atypically in individuals with autism spectrum disorder (ASD). For example, indirect measures of LC-NE activity, such as pupil diameter and event-related potential (ERP) P3 component, differ in individuals with ASD. However, no study to date has examined both tonic (pupil) and phasic (P3) indices of LC-NE activity in a single cohort of individuals with ASD. The objective of the present study is to investigate tonic and phasic LC-NE activity in children with ASD. Participants included 18 children with ASD and 20 age- and non-verbal IQ-matched typically developing (TD) children. The study consisted of separate baseline eye-tracking and odd-ball

ERP tasks. For the baseline paradigm, a black central crosshair was presented on a grey background, and participants were instructed to relax, remain still, and to look at the crosshair. For the odd-ball paradigm, stimuli were isoluminant shapes (small circle = standard [76% of trials]; large circle = target [12%]; square = novel [12%]) displayed on a gray background. Participants were instructed to respond via a button press when a large circle was presented. Pupil diameter was monitored using an EyeLink 1000 Plus remote eye-tracking system and EEG was recorded using 128-channel high-density Geodesic electrode array. Findings from baseline task revealed that individuals with ASD showed significantly increased pupil size compared to their TD peers ($p < .05$). For the odd-ball paradigm, mean amplitude of P3 component (400-600ms) was maximal at posterior leads, but did not differ between TD and ASD groups ($p = .53$). However, groups did differ in frontal channels, with the ASD group exhibiting significantly reduced amplitude compared to their TD peers ($p < .05$). For the ASD group, larger pupil size was associated with reduced P3 amplitude. Consistent with prior reports, our preliminary results show that children with ASD exhibit increased tonic (pupil) and reduced phasic (P3) activation of the LC-NE system. The preliminary findings add to the growing body of evidence that suggest that LC-NE system may function atypically in individuals with ASD.

Abstract: Oxytocin is an endogenous neuropeptide that plays a critical role in the development and expression of social behavior. The primary postsynaptic mediator of oxytocin signaling is the oxytocin receptor (OTR). OTR expression undergoes dramatic developmental shifts with

peak expression during early postnatal critical periods. Previous evidence suggests strong links between oxytocin receptor dysfunction and the pathogenesis of neurodevelopmental disorders such as autism spectrum disorder. Despite its significance to human health, knowledge of quantitative brain-wide spatial and temporal OTR expression patterns remain limited particularly in the early postnatal brain. Therefore, we imaged whole brain OTR expression patterns at the cellular resolution via serial two-photon tomography on two different transgenic mouse lines (OTR-eGFP and $OTR^{venus/+}$). Using newly generated 3D postnatal brain templates for early postnatal timepoints, we quantified OTR expressing cell density at postnatal days (P) P7, P14, P21, P28, and P56. These quantifications revealed that the heterozygote $OTR^{venus/+}$, but not the OTR-eGFP line, faithfully reports OTR expression at the cellular level. We found that there is significant temporal and regional heterogeneity in OTR expression patterns across cortical and subcortical regions. We then used OTR-Cre:Ai14 cumulative labelling to identify expression downregulation and not cell death as the main mechanism driving developmental OTR patterns. Moreover, immunohistochemistry showed that majority of OTR-expressing neurons in the cortical layers except layer 6b are glutamatergic at P21. These results provide quantitative data that is essential to understanding the OTR development in the mouse brain.

Title: Reduced VTA Drd2 expression increases sociability in adult mice

Authors: A. KHASNAVIS, B. SULAMAN, *B. ZUPAN;
Vassar Col., Poughkeepsie, NY

Abstract: The mouse model of Fragile X Syndrome (FXS), the most common form of inherited intellectual disability and a leading known monogenic cause of autism caused by silencing of *FMR1*, exhibits hyperactivity, abnormal sociability, and sensory hyperreactivity. Our research suggests that a subset of the phenotype is programmed in part by maternal *Fmr1* genotype: haploinsufficiency of maternal *Fmr1* ($Fmr1^{+/-}$ or H) is sufficient to induce hyperactivity and hypersociability in genetically normal (WT; $Fmr1^{+/y}$) male offspring, indicating developmental sensitivity to maternal FMRP levels. Dopamine (DA) signaling modulates both activity and social behavior, the dysfunction of which is a core symptom of FXS and autism. Increased

activity of VTA DA neurons projecting to NAc increases while decreased activity decreases time spent with a novel same-sex conspecific. We've previously reported that both WT and KO offspring of FMRP deficient dams exhibit attenuated locomotor-reducing effects of dopamine autoreceptor 2 (D2aR) activation, suggesting that maternal FMRP deficiency may program altered sociability and hyperactivity by downregulating a negative feedback mechanism of DA signaling. Indeed, *Fmr1* H dam-derived male offspring show reduced VTA *Drd2* expression in VTA irrespective of their own *Fmr1* genotype. Here we asked if reduced VTA *Drd2* expression is sufficient to cause the hypersociability previously reported by our lab. We crossed C57Bl/6 *Drd2*$^{fl/fl}$ (B6.SJL-Slc6a3$^{tm1.1(cre)Bkmn}$/J) male with FVB *Fmr1* WT female mice to generate C57 x FVB F1 mice expressing *Drd2*$^{fl/+}$. *Fmr1* WT F1 offspring of H dams show hypersociability relative those reared by *Fmr1* WT dams, indicating that F1 hybrid mice are sensitive to maternal FMRP levels. Next, we co-injected TH-Cre (AAV9.rTH.PI.Cre.SV40, UPenn Vector Core) and DIO-EGFP (pAAV.synP.DIO.EGFP.WPRE.hGH, Addgene) viral vectors into the VTA of adult F1 *Drd2*$^{fl/+}$ mice, aiming to reduce *Drd2* expression by ~50% in TH+ cells. Preliminary qPCR data showed a 40% reduction in VTA *Drd2* expression by three weeks post-injection, so sociability and quinpirole sensitivity were assessed in a second cohort four weeks post-injection. Th-Cre+ mice exhibited increased sociability relative to GFP-injected controls, and failed to show quinpirole-induced reduction of locomotor activity. Following behavioral testing, *Drd2* expression in TH+ VTA neurons in these mice was confirmed by qPCR and those that failed to show reduced *Drd2* expression were excluded from analysis. Our data show that reduced VTA *Drd2* expression is sufficient to increase sociability in adult mice, phenocopying hypersociability of mice reared by *Fmr1* deficient dams.

Title: Mapping neural correlates to biological motion in school-aged children with autism using high density diffuse optical tomography

Authors: *A. M. SVOBODA[1], M. L. SCHROEDER[2], A. T. EGGEBRECHT[3];
[1]Washington Univ. In St. Louis, St. Louis, MO; [2]Washington Univ. In St. Louis, Saint Louis, MO; [3]Mallinckrodt Inst. of Radiology, Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder characterized by marked impairments in social communication and heightened restrictive and repetitive patterns of behavior. Understanding the disruption to neural systems underlying ASD will be crucial in early diagnosis and developing targeted treatments and interventions. However, traditional neuroimaging modalities like functional magnetic resonance imaging (fMRI) require participants to remain still in a loud, enclosed environment that can be challenging for children with ASD and limits imaging studies to primarily high-functioning children. To overcome these challenges while acquiring fMRI comparable images, we have developed high-density diffuse optical tomography (HD-DOT), a silent, wearable, and minimally constraining neuroimaging modality that can map brain function in a naturalistic environment more feasible for children with ASD. In the current study, we aim to validate the use of HD-DOT in children with ASD. We utilized a socially relevant stimulus paradigm consisting of scrambled and coherent point-like animations of biological motion. Biological motion is a well-validated paradigm that has been used in fMRI and eye-tracking studies to evaluate altered patterns of social perception and processing in those with ASD. It has indicated that compared to typically developing children, those with ASD show reduced contrasts to coherent vs scrambled motion in multiple cortical regions including the posterior temporal sulcus (pTS), parietal cortex, and dorsolateral prefrontal cortex (dlPFC). We collected HD-DOT data in 10 children with ASD age 8-13 years (5 females and 5 males) and 12 unaffected adults age 23-32 (8 females and 4 males) during the presentation of scrambled and coherent biological motion in a 24-second block design. Each block includes 12 seconds of scrambled followed by 12 seconds of coherent biological motion. Results indicate that, consistent with prior literature, participants demonstrate localized activity in dlPFC, pTS, and visual cortex, specifically in motion sensitive area MT. From these results, we conclude that HD-DOT is a suitable neuroimaging modality to detect responses from biological motion in children with ASD. Future directions include assessing differences in neural responses of TD children vs those with a diagnosis of ASD in their response to biological motion and using HD-DOT to measure brain activity in lower-functioning children including infants and toddlers at risk of ASD and school-aged children with more severe ASD.

Title: Sub-groups of sensory connectivity profiles in autism and typical development

Authors: *A. R. ZOLTOWSKI[1], M. D. FAILLA[2], C. OKITONDO[3], L. E. MASH[4], S. DAVIS[3], B. HEFLIN[5], B. ROGERS[1], C. J. CASCIO[2];

Abstract: Sensory processing differences have been recently recognized as part of the diagnostic criteria for autism spectrum disorders (ASD), but these symptoms are highly heterogeneous across individuals. Individuals may differ both in the sensory system affected, and whether they show hyper- or hypo- responsiveness to these sensory stimuli. Efforts to identify subgroups of ASD with more similar within-group sensory responsiveness have typically focused on a phenotype-first approach, identifying groups by behavioral responses to sensory stimuli. We aimed to take a neurobiology-first approach and investigate subgroups of individuals based on brain networks, assessing connectivity between intrinsic networks and primary sensory regions. N=28 individuals with ASD (ages 8-54) and N=45 typically developing individuals (TD, ages 8-41) completed a resting-state fMRI scan. Subject-level networks were identified using independent component analysis and the components with the highest default mode and salience network overlap with templates from Yeo et al. (2011) were selected. Associations between these networks and visual, somatosensory, and interoceptive regions were calculated and used for k-means clustering to identify sub-groups of connectivity profiles. Relationships between the clusters and sensory signals (heart rate variability, HRV) and sensory awareness (body perception questionnaire, BPQ) were assessed. Two main clusters emerged across both our ASD and TD groups, primarily stratified by high versus low salience network connectivity with primary interoceptive cortex and secondary somatosensory cortex. The high connectivity cluster showed lower HRV than the low connectivity cluster (Cohen's d=0.38), indicating similar interoceptive signaling. However, ASD and TD individuals showed trends towards opposite patterns of self-reported body awareness by cluster (diagnosis by cluster interaction p-value=0.117). These results indicate trans-diagnostic subgroups based on salience network connectivity with somatic and interoceptive sensory regions. Further, these subgroups show consistently lower heart rate variability, suggesting that individuals with less variable interoceptive signals may attribute higher salience to these signals. However, the ASD and TD subgroups showed opposite patterns of reported body awareness. Future directions may include more intermediate variables (e.g., sensory integration measures) to fully understand the link between interoceptive connectivity patterns and behavioral sensory reports.

Title: Lateral and central nuclei volumes predict anxiety and depression scores in children with neurodevelopmental disorders

Authors: D. SEGUIN, **J. CHEN**, J. MARTINEZ-TRUJILLO, R. NICOLSON, *E. G. DUERDEN;
Western Univ., London, ON, Canada

Abstract: Previous research has indicated that alterations in the structural maturation of the basolateral and central nuclei of the amygdala are associated with anxiety behaviours in typically developing adults and children with autism spectrum disorder. This study investigated neurodevelopmental disorder diagnoses and basolateral and central amygdala nuclei volumes in relation to anxiety and depression scores in a large pediatric sample consisting of 233 individuals, aged 6-18 years. Parents completed the Child Behavior Checklist (CBCL) and the children underwent structural MRI at 3T (Tesla). The children received a research confirmed diagnosis of neurodevelopmental disorder. Children included in this study received a diagnosis of autism spectrum disorder (ASD, n=111), attention deficit hyperactivity disorder (ADHD, n=38), obsessive-compulsive disorder (OCD, n=27), or were typically-developing (n=57). Freesurfer software was used to automatically segment the amygdala into 9 subnuclei. A generalized linear model revealed that the left lateral and right central nuclei demonstrated significantly different volume sizes relative to typically developing controls ($p<0.05$), after controlling for total brain volume, age and gender. A subsequent analysis examined the interaction of disorder diagnosis and individual nuclei volume on anxiety and depression scores of the CBCL. Disorder diagnosis and decreasing left lateral amygdala nuclei volume significantly predicted total anxiety and depression scores in children with ASD ($p=0.04$) and ADHD ($p=0.025$). Anxiety and depression scores were significantly predicted by increasing right central amygdala nuclei volumes for all clinical groups ($p<0.05$), but not for typically-developing children. Increasing right central nuclei volumes also significantly predicted CBCL anxiety scores for all disorder categories. These results demonstrate that amygdala subnuclei volumes show varying developmental trajectories in children with neurodevelopmental disorders. Amygdala nuclei volumes may be potential biomarkers to differentiate neurodevelopmental disorders in high risk children. These methods may be used to identify children who would

benefit from targeted behavioral interventions to address anxiety and depression behaviors, and to assess the effects of such interventions in these groups of children.

Title: Behavioral deficits and rescue in the Protocadherin 10 (Pcdh10) mouse model relevant to autism

Authors: *S. L. FERRI[1], E. S. BRODKIN[2], T. ABEL[1];
[1]Iowa Neurosci. Inst., Univ. of Iowa, Iowa City, IA; [2]Psychiatry, Univ. of PA Sch. of Med., Philadelphia, PA

Abstract: Protocadherin10 (Pcdh10) is a member of the cadherin superfamily and a nonclustered protocadherin. The activity-dependent cell adhesion molecule is highly expressed in the amygdala, striatum, and cerebellum, and is involved in the formation and elimination of dendritic spines and the guidance of thalamocortical projections. It has been linked to Autism Spectrum Disorder (ASD), a neurodevelopmental disorder that causes a number of symptoms, including impairments in social behavior and cognition. ASD affects four times as many males as females. Our group has previously reported male-specific deficits in social behavior and fear memory in mice heterozygous for a deletion of *Pcdh10* ($Pcdh10^{+/-}$), as well as increased spine density and decreased expression of NMDAR in the basolateral amygdala (BLA). Additionally, social behavior was rescued by systemic administration of the NMDAR partial agonist d-cycloserine. Currently, we are using a new transgenic mouse line with the Pcdh10 gene flanked by *loxP* sites in combination with a fast-expressing helper-dependent Cre-expressing virus to determine the effects of ablation of Pcdh10 in specific cell types and brain areas. In addition, preliminary data suggests that male $Pcdh10^{+/-}$ mice have decreased expression of the estrogen receptors alpha and beta, which may contribute to the sex differences observed. Future studies will focus on functional activity in the BLA and mechanisms underlying sex-specificity and behavioral rescue.

Title: Sex specific involvement of indirect pathway medium spiny neurons in behavioral alteration of 16p11.2 hemi-deletion mouse model

Authors: *J. KIM[1], C. C. ANGELAKOS[2], J. F. LYNCH[2], S. L. FERRI[1], T. ABEL[1];
[1]Dept. of Mol. Physiol. and Biophysics, Univ. of Iowa, Iowa City, IA; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: One of most common genetic variations found in autism spectrum disorder (ASD) is 16p11.2 deletion syndrome. Patients with this deletion usually display developmental delay and intellectual disability, including at least some features of ASD. Moreover, Attention-Deficit/Hyperactivity Disorder (ADHD) is commonly reported in the patients. Because the 16p11.2 chromosomal region in humans is highly conserved in mice, 16p11.2 deletion mouse model is considered a faithful model. Using the mouse model, we previously showed both male and female 16p11.2 hemi-deletion mice display hyperactive behavior compared to wild type sex-matched control mice. Because the striatum is the input structure of the basal ganglia, the key neural substrates for motor control, the present study examined the role of medium spiny neurons (MSNs), the major type of neuron in the striatum, in hyperactivity in 16p11.2 mouse model. MSNs can be characterized by their projections as either direct-pathway or indirect-pathway. The direct-pathway MSNs express dopamine receptor 1 and project to the SNr/GPi directly. The indirect-pathway MSNs express dopamine receptor 2 as well as adenosine receptor 2a (A2A) and extend their projections primarily to the GPe. We hypothesized that the medium spiny neurons play an important role in behavioral alteration of 16p11.2 hemi-deletion mouse model. To identify the importance of indirect-pathway MSNs, we crossed 16p11.2 flox mice to the A2A-CRE mice to produce A2A-CREx16p11.2 flox mice that lack genes of the 16p11.2 region in MSNs expressing dopamine receptor 2. Interestingly, male A2A-CREx16p11.2 flox mice showed hyperactivity compared to sex matched control group, suggesting the importance of indirect-pathway MSN. However, female A2A-CREx16p11.2 flox mice did not show the hyperactivity. These results imply the possibility that two different types of MSNs are involved in a sex-dependent manner in behavioral alteration in the 16p11.2 mouse model. We are currently assessing the role of direct-pathway MSNs using a similar approach.

Title: Subconvulsive stimulation in early postnatal life produces sex-related differences in stereotypic behavior, mood, and the seizure threshold during the juvenile period

Authors: *B. A. KAHEN[1], J. VELISKOVA[1], L. VELISEK[1], L. K. FRIEDMAN[2];
[1]Cell Biol., [2]New York Med. Col., Valhalla, NY

Abstract: Previously we observed that subconvulsive treatment in early postnatal life leads to sex-related autistic traits during the juvenile period including aberrant changes in handling, memory and social behavior. We hypothesized that immature males are more susceptible to behavioral deficits and alterations in the seizure threshold following sustained subconvulsive activity. To elevate glutamate levels and neuronal activity in early life without elicitation of seizures, low step-up doses of kainic acid (KA) were administered daily to male and female rat pups for 15 days beginning on postnatal day 6. Behavioral tests included the spontaneous alternating T-maze and forced swim test (FST). Latency to seizures was tested 24h after the last subconvulsive treatment with flurothyl or by a single convulsive dose of systemic KA administration. Brains were evaluated with Nissl staining. In the spontaneous alternating T-Maze, control groups, ASD males and females had more entries into the left arm but with similar spontaneous alteration rates and decision time. At 24 h after KA-induced status epilepticus, spontaneous alteration rates decreased; directional preference switched to the right arm. A marked reduction in decision time was noted for convulsive groups. In the forced swim test, control females traveled a greater distance with higher mobility and faster mean speed than males but less so after subconvulsive treatment. In Trial 2, decreased immobility was observed in ASD males compared to controls and ASD females. After administering the convulsive dose of KA, there was delayed onset to wet dog shakes and fore limb clonus in ASD males with fewer episodes. When flurothyl was administered, control males had faster onset to twitches and clonic seizures than females. After subseizure treatment, no sex-related differences were observed. Subconvulsive treatment, revealed no histological injury within the hippocampus or other brain regions unlike juvenile pups undergoing KA-induced status epilepticus. The marked reduction in the rate of spontaneous alteration and switching directional preference after convulsive seizures is likely due to hippocampal injury whereas, delayed onset to KA induced status epilepticus in the ASD group may be due to desensitization of KA receptors by our ASD protocol.

Subconvulsive treatment removed the sex difference associated with flurothyl suggesting the forebrain and not the brain stem are responsible for the alterations in the seizure threshold. The FST showed that juvenile control animals of both sexes were less mobile than the ASD groups suggesting subseizure activity increases anxiety but reduces behavioral despair.

Title: Postnatal subconvulsive activity selectively reduces NeuN antigenicity and polyphosphoinositide hydrolysis within limbic structures of juvenile rats

Authors: *L. K. FRIEDMAN[1], B. A. KAHEN[1], J. VELISKOVA[1], L. DI MENNA[2], F. NICOLETTI[3], L. VELISEK[1];
[1]Cell Biol. & Anat., New York Med. Col., Valhalla, NY; [2]IRCCS Neuromed, Molecular Neuropharmacology, Italy; [3]Physiol. and Pharmacol., Univ. Sapienza, Roma, Italy

Abstract: Previously we observed that subconvulsive treatment in early postnatal life leads to autistic traits including impairments in handling, memory and social behavior during the juvenile period. Group-I metabotropic glutamate (mGlu) receptors, such as the mGlu5 receptor subtype, play an important role in learning and memory suggesting that positive allosteric modulators (PAMs) may improve cognitive impairment associated with autism spectrum disorder (ASD). To elevate early life neuronal activity without elicitation of seizures, micromolar doses of kainic acid (KA) were administered to rat pups for 15 days beginning on postnatal day 6. The seizure threshold was subsequently tested with flurothyl. Pups were treated with LiCl (80 mg/kg) ± the mGlu5 receptor PAM, VU0360172 (10 mg/kg), 1 h prior to sacrifice. Dissected brain regions were used to measure inositolmonophosphate (InsP) formation, an indicator of polyphosphoinositde (PI) hydrolysis. Endogenous IsnP levels were measured by ELISA. Brains were histologically evaluated with NeuN, parvalbumin (PV), and Nissl stain. When flurothyl was administered, control males had faster onset to twitches and clonic seizures than females. After subseizure treatment, no sex-related differences were observed. Basal, unstimulated PI hydrolysis was reduced in the medial prefrontal cortex, thalamus, and amygdala following the subconvulsive treatment which was reversed by flurothyl administration. The mGlu5 receptor PAM did not enhance PI hydrolysis because of the subthreshold dose of the VU compound, except for in the thalamus suggesting that induction of seizures in pups sensitized with low doses of KA enhances mGlu5 receptor signaling in this region. Decreased basal PI hydrolysis, which

reduces mobilization of intracellular Ca^{2+}, was associated with selective loss of NeuN antigenicity (in the absence of cell loss) in the medial prefrontal cortex and amygdala. PV immunolabeling was preserved in the hippocampus, but significantly reduced in the amygdala. It appears that metabolism of the extra-hippocampal loop is predominantly affected by subtle but steady release of glutamate triggered by the ASD protocol. Loss of metabolic activity in critical brain regions could be responsible for deficits previously observed in the two-object recognition memory test and social interaction environments. We propose that PI hydrolysis is defective in the medial prefrontal cortex, thalamus, and amygdala regions in our model of ASD and is not rescued by pharmacological activation of mGlu5 receptors. Instead, mGlu5 potentiation with PAMs to improve cognition may be a more effective treatment strategy for children with epilepsy.

Title: A neuroanatomical basis linking perceptual inflexibility to cognitive rigidity in autism

Authors: *T. WATANABE[1,2], R. P. LAWSON[3,4], Y. S. E. WALLDÉN[4], G. E. REES[2,4];
[1]RIKEN Ctr. for Brain Sci., Saitama, Japan; [2]UCL Inst. of Cognitive Neurosci., London, United Kingdom; [3]Dept. of Psychology, Univ. of Cambridge, Cambridge, United Kingdom; [4]UCL Wellcome Ctr. for Human Neuroimaging, London, United Kingdom

Abstract: Behavioural studies have reported high perceptual stability in individuals with autism spectrum disorder (ASD). However, neural mechanisms by which such sensory-related symptoms can coexist and often correlate with seemingly independent core symptoms of the condition remain unknown. Here, we have identified such a key neuroanatomical substrate in high-functioning adults with autism. First, we assessed perceptual stability using a test of

bistable visual perception with a structure-from-motion stimulus, and quantified cognitive rigidity by a spontaneous task-switching test. By comparing behavioural responses to these tests, we found that over-stable visual perception of individuals with autism is linked with their cognitive rigidity, which in turn is associated with core restricted, repetitive behaviours symptoms. Measuring grey matter volume with MRI, we next found that both perceptual and cognitive inflexibility were correlated with a smaller grey matter volume in the posterior superior parietal lobule (pSPL) in participants with ASD. Moreover, a non-parametric mediation analysis suggested that the pSPL is a mediator linking perceptual stability to cognitive rigidity. Furthermore, a structural equation modelling analysis indicated the possibility that, in both individuals with ASD and neurotypical controls, this region could be related to domain-general behavioural/mental flexibility. These findings uncover a key neuroanatomical mediator of the perceptual and cognitive inflexibility in autism and open up the possibility of future studies on how the core symptoms of this spectrum interact with characteristic features of sensory perception.

Title: Evidence of wide spread white matter compromise in children and adults with autism: A large scale diffusion imaging study using the ABIDE II repository

Authors: *S. R. OTTO, L. M. RAY, J. A. TRAVERS, I. BRUKETTA, M. L. MONTERO, J. J. HUTSLER, S. M. HAIGH;
Psychology, Univ. of Nevada, Reno, Reno, NV

Abstract: Autism Spectrum Disorder (ASD) is characterized by a variety of abnormal behaviors ranging from difficulties in social communication to heightened sensory processing. One potential mechanism that can explain how these disparate behaviors are related is alterations to white matter connectivity. Disturbances to the underlying white matter in ASD may lead to impaired functional processing between distributed neural networks. Previous studies using diffusion magnetic resonance imaging (dMRI) have consistently reported findings of white matter disruption in ASD, however the results from many of these studies are often limited by small sample sizes and are frequently conducted on children, despite little being known about the

developmental trajectory of white matter tracts. The findings from the few studies in adults with ASD do not provide conclusive evidence as to whether white matter tracts are abnormal are not. The present study aimed to investigate whether there is evidence of abnormal white matter connectivity in ASD across a large sample of subjects in adults with ASD compared to a pediatric population. Diffusion MRI data was acquired from the Autism Brain Imaging Data Exchange II, which is an international neuroimaging data-sharing initiative to promote discovery science on the brain connectome in ASD. In addition, we acquired dMRI data from research groups both at Carnegie Mellon University and the University of Pittsburgh. In total, we analyzed 335 subjects (186 ASD, 149 NT), with 156 subjects in the pediatric group (96 ASD, 60 NT; ages 7-17 years old) and 179 in the adult group (90 ASD, 89 NT; ages 18-64 years old). Control subjects were matched on age, gender and IQ. All data were collected on a 3-Tesla scanner. Tract Based Spatial Statistics (TBSS) was performed using FMRIB's FSL software. TBSS analyses revealed decreased FA in the ASD pediatric group and in the adult ASD group compared to NT controls. The findings in the pediatric group were evident in nearly all white matter tracts in the brain. Interestingly, FA reductions in the ASD adult group were less wide spread compared to the ASD pediatric group. Together, these results show that white matter integrity is more compromised in ASD and the reduced integrity persists throughout adulthood. These findings highlight the need for longitudinal studies on the impact of white matter integrity throughout adolescence and into adulthood, and the impact it has on behavioral functioning in ASD.

Title: Lack of replication of case-control differences in functional connectivity in ASD across multiple sites

Authors: *Y. HE, L. BYRGE, D. P. KENNEDY;
Indiana Univ., Bloomington, IN

Abstract: Studies on Autism Spectrum Disorder (ASD) have been increasingly using resting-state functional Magnetic Resonance Imaging (rs-fMRI) to investigate alterations of functional connectivity. While findings have the potential to advance our knowledge about the

neuropathology of ASD, largely inconsistent results across studies have hampered the identification of clinical biomarkers or neural mechanisms underlying ASD. In this study, we investigated two factors -- denoising methods and site effects -- that could influence the replicability of functional connectivity. We analyzed rs-fMRI data of four independently acquired datasets (each including ASD and control participants) from the Autism Brain Imaging Data Exchange (ABIDE-I and II), using 31 different denoising strategies. We evaluated the replicability of group-average functional connectome and group-comparison differences in functional connectivity. Within datasets, both group-average functional connectomes and group-differences were consistent across different denoising pipelines (r = .80-1.0 / r = .55-0.99), with the largest disparity dependent on whether global signal regression (GSR) was used or not. However, across sites, while group-average connectomes were highly consistent (r = .82-.89), the consistency of group-differences was dramatically low (r = -.02-.16) regardless of denoising pipelines, even when comparing groups at a large-scale network level (relative to a fine edge level). These results indicate that case-control differences in functional connectivity could not be replicated across multiple sites, even when using the same denoising pipeline. As there are other methodological factors that potentially influence across-site replication (e.g., scanner-related differences, subject or cohort differences, post-processing analyses, the true effect size of ASD alterations), current results cannot rule out the possibility of replicable differences of functional connectivity existing in ASD. However, they do highlight the importance of examining replicability in future studies of ASD, and, more generally, call for extra caution when describing and interpreting alterations in functional connectivity across groups of individuals.

Title: Maternal sleep disordered breathing during pregnancy induces behavioral and synaptic aberrations in the offspring: Potential implications for autism spectrum disorders

Authors: *A. M. VANDERPLOW, B. A. KERMATH, A. C. EWALD, S. M. JOHNSON, T. L. BAKER, J. J. WATTERS, M. CAHILL;
Comparative Biosci., Univ. of Wisconsin - Madison, Madison, WI

Abstract: Sleep disordered breathing (SDB) is characterized by recurring breathing cessations during sleep, causing intermittent hypoxia (oxygen deprivation) often several hundred times per night. SDB is present in ~15% of pregnant women as compared to ~2-4% of non-pregnant women of childbearing age. Risk factors for gestational SDB development bear striking similarities to the collection of maternal risk factors for autism spectrum disorders (ASD), including advanced maternal age and maternal obesity. Maternal immune activation/inflammation is both a consequence of SDB, and an independent risk factor for, ASD. We posit that an overlooked, yet increasingly common inflammatory stimulus, maternal SDB, contributes to ASD etiology. We recently developed a rat model in which to study the consequences of maternal SDB on the offspring by exposing pregnant rats to nightly intermittent hypoxia from gestational days 10-21. Our findings indicate that offspring of mothers subjected to intermittent hypoxia during pregnancy exhibit deficits in several autism-relevant behaviors, including a constellation of cognitive impairments, reduced interest in social interaction, and heightened anxiety. In most instances, the magnitude of behavioral disruption was more severe in male than female offspring. To begin to understand the mechanisms contributing to these behavioral aberrations, we examined the density of dendritic spines in the prefrontal cortex and found that offspring of mothers subjected to nightly intermittent hypoxia exhibited a striking increase in dendritic spine density as compared to control offspring. Similar to our behavioral observations, dendritic spine aberrations were more prominent in male vs. female offspring. Taken together, these findings indicate that maternal sleep disordered breathing not only induces autism-relevant behavioral impairments, but also mimics the heightened cortical synaptic connectivity phenotypes recently uncovered in autism. Future studies are aimed at identifying a role for microglial inflammation and concomitant reduction in microglial-mediated synaptic pruning in the behavioral and synaptic structural alterations that we have revealed in this model.

Title: Using human HPSC-derived cerebral organoid to model deficits of cortical neurogenesis in Down syndrome

Authors: *X. TANG[1], L. XU[1], Y. HONG[1], M. XU[1], Y. HU[1], Y. LIU[2];
[1]Stem Cell and Neural Regeneration Inst., Nanjing, China; [2]Inst. for Stem Cell and Neural Regeneration, Sch. of Pharmacy, Nanjing Med. Univ., Nanjing, China

Abstract: Down syndrome (DS), caused by trisomy of chromosome21, approximately occurs in 1 of every 800 live births. Alterations in brain growth during early cortical development process are thought to underlie the cognitive impairments in DS, but its mechanism remains unknown. Here, we employed patient iPS-derived cerebral organoids to investigate pathological abnormalities associated with DS. Our results revealed that DS-derived cerebral organoids showed a reduction in number of cortical neurons in IV and II layers, which is associated with diminished proliferation of progenitors in VZ-like region. By whole-transcriptome analysis, we found neurogenesis-related pathway were altered in DS. Furthermore, correction of DSCAM gene and its downstream PAK1 pathway reverse the abnormal neurogenesis in DS. Our data suggest that impaired proliferation in DS apical progenitors as well as defective neurogenesis may contribute to the reduced cortical thickness of DS patients, and emphasize the role of DSCAM and PAK1 in regulating the cortical development, which provide the basis for prenatal therapeutic interventions in DS.

Abstract: Proper GABAergic transmission through Cl-permeable $GABA_A$ receptors is fundamental for physiological brain development and function. Indeed, defective GABAergic signaling -due to a high ratio of expression of the Cl importer NKCC1 and Cl exporter KCC2- has been implicated in several neurodevelopmental disorders, including Down syndrome (DS). Interestingly, NKCC1 inhibition by the FDA-approved diuretic bumetanide reverts cognitive deficits in the TS65Dn mouse models of DS and core symptoms of other brain disorders (e.g., autism) in a number of rodent models and/or clinical trials. However, the required chronic treatment with bumetanide is burdened by its diuretic side effects caused by the antagonism of the kidney Cl^- importer NKCC2, which leads to hypokalemia and jeopardizes drug compliance. Crucially, these issues would be solved by selective NKCC1 inhibitors, thus devoid of the diuretic effect. Starting from bumetanide's structure, we applied a computational ligand-based approach to design new molecular entities that we tested *in vitro* for their capacity to selectively block NKCC1. Among the 3 newly-identified and highly promising NKCC1 inhibitors, one showed excellent solubility and metabolic stability *in vitro.* Moreover, analysis of WT and Ts65Dn mice systemically treated with this NKCC1 inhibitor revealed no diuretic effect. Finally, chronic treatment with our novel, selective NKCC1 inhibitor was able to rescue cognitive deficits in Ts65Dn mice in four different memory tasks, and social impairments in a mouse model of autism, with no major signs of toxicity. Thus, our selective NKCC1 inhibitor devoid of the diuretic effect could represent a suitable and solid therapeutic strategy for the treatment of Down syndrome, autism and all the brain disorders with depolarizing GABAergic transmission.

Title: Early pharmacological treatment with bumetanide rescues cognitive impairment and increased susceptibility to seizures in the Ts65Dn mouse model of Down syndrome

Authors: *I. ZIOGAS[1,2], M. PARRINI[1], A. CONTESTABILE[1], L. CANCEDDA[1,3];
[1]Inst. Italiano Di Tecnologia, Genova, Italy; [2]Univ. Degli Studi di Genova, Genova, Italy; [3]Dulbecco Telethon Inst., Rome, Italy

Abstract: Down syndrome (DS) is the leading cause of genetically-defined intellectual disability. Additionally, DS individuals often present with increased susceptibility to epileptic seizures and hyperactivity. Recently, several studies identified altered GABAergic activity

trough chloride-permeable $GABA_A$ receptors as one of the main contributors to impaired cognitive performance in the Ts65Dn mouse model of DS. Data from adult Ts65Dn mice and DS individuals showed an increased expression of the chloride importer NKCC1. As a result, intracellular chloride concentration is higher in Ts65Dn mice and GABAergic responses are depolarizing (rather than hyperpolarizing and inhibitory). Accordingly, treatment with the FDA-approved diuretic and NKCC1 inhibitor bumetanide during adulthood, rescues inhibitory GABAergic transmission and cognitive deficits in DS mice, although the beneficial effect of the treatment is rapidly lost upon drug withdrawal. However, hyperactivity and susceptibility to seizures are not rescued by bumetanide treatment in adulthood. Here, we investigated the long-lasting effects of an early bumetanide administration during the first 2 weeks of development on cognitive performance, seizure susceptibility and hyperactivity in Ts65Dn mice. We found a rescue in long-term memory as assessed by the novel object recognition and contextual fear conditioning tests in adult animals. Moreover, early bumetanide treatment also rescued susceptibility to seizures in adult Ts65Dn mice. Finally, since bumetanide treatment of human infants can lead to deafness, we assessed ototoxicity in adult WT and Ts65Dn mice treated in early development and found no significant deficits in acoustic startle-response. Currently, we are assessing the impact on hyperactivity in adulthood and the mechanisms underlying the long-lasting behavioral effects of early bumetanide administration at the molecular and circuit levels. Our results suggest that time-specific intervention possibly impacting on the trajectories of the developing brain could rescue cognitive performance and deficits that are not rescued by treatment in adulthood, avoiding the adverse diuretic effects of a lifetime treatment.

Abstract: Down syndrome (DS) is one of the most common forms of intellectual disability that is caused by trisomic repeat of chromosome 21. Later in their life, individuals with DS usually develop brain pathology and dementia syndrome typical of Alzheimer's disease (AD). Previous studies have shown that synaptic failure is a key pathophysiology for both AD and DS. *De novo* protein synthesis is essential for memory formation and synaptic plasticity, and recent studies indicate a critical role of impaired *de novo* protein synthesis in AD pathogenesis. Here we explored the role of eukaryotic elongation factor 2 (eEF2) in Down syndrome. eEF2 is a part of the ribosome machinery and facilitates transfer of tRNA from A site to P site, thus plays important role in protein synthesis. eEF2 can be phosphorylated and deactivated by the only known kinase eEF2K, resulting in inhibition of general protein synthesis. We crossed eEF2K+/- mice to Ts65Dn DS model mice, generating four genotypes: WT, eEF2K+/-, Ts65Dn, and Ts65Dn/eEF2K+/-. Multiple behavioral tasks were performed to evaluate learning and memory including: novel object recognition, hidden platform Morris water maze, and passive avoidance. In brief, our data suggest that DS-associated memory deficits were ameliorated by repressing eEF2K, as indicated by improved performance in Ts65Dn/eEF2K+/- mice compared to that of Ts65Dn mice. Electrophysiological study showed that long-term potentiation (LTP) failure in Ts65Dn mice was alleviated by knocking down eEF2K. Taken together, these data suggest that genetic reduction of eEF2K can ameliorate memory deficits and synaptic failure in a mouse model of Down syndrome. Our findings thus provide insights into a potential therapeutic target for the treatment of cognition impairments in Down syndrome.

Title: Pharmacological modulation of intracellular chloride concentration restores GABA mediated inhibition in down syndrome neuronal networks

Authors: *I. COLOMBI, M. ALBERTI, M. CHIAPPALONE, A. CONTESTABILE, L. CANCEDDA;
Fondazione Inst. Italiano Di Tecnologia, Genova, Italy

Abstract: Down syndrome (DS) is a genetic disorder that causes intellectual disability in children and adults. Altered GABAergic signaling through chloride-permeable GABAA

receptors (GABAARs) has been shown to play a major role in brain dysfunction and cognitive impairment in the Ts65Dn mouse model of DS. In particular, higher intracellular chloride concentration ([Cl-]i) due to increased expression of the chloride importer NKCC1 alters synaptic inhibitory/excitatory balance in neurons. In fact, treatment of Ts65Dn mice with the FDA-approved NKCC1 inhibitor Bumetanide restored the [Cl-]i to value comparable with wild-type (WT) mice and rescued both inhibitory GABAergic signaling and hippocampus-dependent memory in adult mice. However, the effect of the pharmacological treatment on neuronal network dynamics has never been directly studied in DS. To this aim, we used primary hippocampal cultures and acute brain slices from Ts65Dn and WT mice coupled to Microelectrodes Array technology (MEA) to evaluate the efficacy of the pharmacological treatments with Bumetanide in restoring inhibitory GABAergic transmission in Ts65Dn neuronal networks. We found that Ts65Dn cultures and slices exhibited alterations in network dynamics and GABAergic inhibition. Moreover, the application of Bumetanide restored the normal inhibitory action of GABA in Ts65Dn cultures and slices. Our findings indicate that MEA recordings coupled to neuronal networks could be used to predict the effectiveness of new therapies in pathologies that exhibit alterations of GABAergic inhibition, such as neurodevelopmental disorders and autism.

Title: Gene expression analysis of dorsal and ventral cortical progenitors from Down syndrome iPSC models

Authors: *J. L. MARTINEZ[1,2], C. L. SIROIS[2], Y. GIFFIN-RAO[2], A. BHATTACHARYYA[3,2]; [1]Cell. and Mol. Biol. Program, Univ. of Wisconsin-Madison, Madison, WI; [2]Waisman Ctr., [3]Cell. and Regenerative Biol., Univ. of Wisconsin, Madison, WI

Abstract: Down Syndrome (DS), or trisomy 21, is a complex brain disorder that leads to altered cortical development resulting in intellectual impairment. Affecting one in every 700 babies born

in the U.S., DS is the most common genetic form of intellectual disability. It is estimated that there are more than 400,000 people living with DS in the U.S. However, our understanding of how this extra human chromosome 21 (HSA21) contributes to the altered neural development remains unknown. Our study uses human pluripotent stem cells (hPSC) that carry the trisomy 21 mutation to study the underlying mechanisms of DS neuropathophysiology. The process of neuroepithelial differentiation from hPSCs resembles *in vivo* cortical development in temporal course, morphogenesis and biochemical changes. Using this model, we aim to define the intrinsic differences in DS cortical development that may lead to the characteristic intellectual impairment.
Isogenic trisomy 21 and control iPSCs were differentiated to dorsal or ventral cortical progenitors following established protocols. The cells were harvested at Day 17 and gene expression was analyzed using RNASeq, resulting in four comparative groups; DS Ventral, DS Dorsal, Control Ventral and Control Dorsal. Principal component analysis (PCA) showed that ventral and dorsal patterning was the greatest source of variance (69% for patterning vs 20% for genotype). This high variance validated the dorsal versus ventral patterning of the cells. Because of this high variance, we focused our analysis on ventral and dorsal differentiation independent of one another. PCA results between DS Ventral/Control Ventral and DS Dorsal/Control Dorsal showed clear clustering based on the genetic mutation (80% and 66% respectively). Further gene expression analysis showed over 2,000 differentially expressed genes in ventral DS versus Control and over 1,000 differentially expressed genes in dorsal DS versus Control, all with padj values <0.01. Of these differentially expressed genes, 36 of the ventral genes and 45 of the dorsal genes are encoded on HSA21. We focused our analysis on differential expression amongst genes with a padj <0.01 and a log2Fold change greater than 5, which resulted in 25 and 28 genes of interest for ventral and dorsal respectively. This comprehensive analysis defines gene expression changes due to trisomy 21 in two different cortical lineages. Thus, this study highlights potential target genes for further pathway and expression analysis in an ongoing effort to understand the mechanisms underlying DS intellectual disability.

Title: Non-linear developmental overexpression of DYRK1A in the Down syndrome brain—A paradigm shift in gene dosage imbalance

Authors: *L. E. HAWLEY[1], R. ROPER[1], C. R. GOODLETT[2];
[1]Dept. of Biol., [2]Dept. of Psychology, Indiana Univ. Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: Down syndrome (DS) is caused by trisomy of human chromosome 21 (Hsa21) and is the leading genetic cause of intellectual disability. Trisomy of Dual-specificity tyrosine-phosphorylated regulated kinase 1A (DYRK1A), found on Hsa21, has been linked to DS neurological deficits. The traditional model relating trisomy to DS-related brain phenotypes is that trisomic gene expression is upregulated by ~1.5-fold, corresponding to gene dosage in all brain tissues throughout development. There are no systematic studies in DS mouse models that assess the developmental regulation of DYRK1A protein expression across different brain regions. Using Western blot, we quantified DYRK1A at different ages over early postnatal development in the cerebellum, hippocampus, and cerebral cortex of Ts65Dn DS mice and found that trisomic expression (relative to euploid control) is increased an average of 4.5 fold on postnatal day ([P]6), declining to an average of 1.1 fold by the third postnatal week (P24). The trisomic cerebellum exhibited the highest elevation at P6 (>5-fold increase), corresponding to reduced cerebellar size and cellular density in DS mice at this age, suggesting that the structural deficit during this period of rapid development in the cerebellum may result from the non-linear amplification of DYRK1A. These data imply that trisomic *Dyrk1a* expression is developmentally regulated and interacts with one or more trisomic or disomic genes and is not simply a linear function of gene dosage at all ages and in all tissues. To test this hypothesis, we reduced *Dyrk1a* copy number at conception in both trisomic and euploid mice and quantified postnatal DYRK1A expression, with the prediction that reduced *Dyrk1a* copy number in otherwise trisomic animals would significantly reduce DYRK1A protein levels, but that the extent of reduction would be non-linear in trisomic animals depending on age and tissue. Our data indicate normalizing only *Dyrk1a* copy number in trisomic animals yielded highly variable levels of DYRK1A protein expression that depended on tissue type, even resulting in expression lower than euploid levels in some instances. In euploid mice, reducing *Dyrk1a* by one copy generally reduced DYRK1A expression by 50%, regardless of tissue type. The non-intuitive relationship between gene dosage and protein expression suggests more complex developmental regulation of DYRK1A beyond gene copy number. These data emphasize the need to understand the age-dependent regulation of antecedent conditions that are causing changes in *Dyrk1a* expression in the brain.

Title: Investigating the abnormal expression of critical neurogenesis and gliogenesis control genes in trisomy 21 using iPSCs

Authors: *D. J. QUIRICONI[1], Y. TAO[2], S.-C. ZHANG[3], A. BHATTACHARYYA[4];
[1]Univ. of Wisconsin, Madison, Madison, WI; [2]Dept. of Neurosci., Univ. of Wisconsin Madison, Madison, WI; [3]Waisman Ctr., Univ. Of Wisconsin - Madison, Madison, WI; [4]Waisman Ctr., Univ. of Wisconsin Madison Waisman Ctr., Madison, WI

Abstract: Trisomy 21, or Down Syndrome, is the most common genetic cause of intellectual disability, affecting about 1 in every 700 babies born. Individuals with trisomy 21 display several central nervous system (CNS) abnormalities, including decreased volume in several brain regions. In addition, a well-documented and prominent cellular abnormality in the CNS of individuals with trisomy 21 is a lower ratio of neurons to astrocytes relative to control individuals. A possible explanation for this disparity is a premature end of neuron generation and subsequently a premature shift to predominantly gliogenesis. To investigate this hypothesis, we used isogenic control and trisomy 21 iPSCs differentiated to neural progenitors to recapitulate early CNS development in vitro. We compared expression levels of critical neurogenesis and gliogenesis genes at 30, 50, and 60 days in vitro. Preliminary data demonstrates altered temporal expression patterns in trisomy 21 neural progenitors relative to controls. S100B, a glial gene, demonstrates constitutive overexpression, consistent with its location on chromosome 21. The expression of the neural progenitor transcription factor Pax6 is higher at earlier time points relative to controls, but expression decreases earlier. NFI-A, a transcription factor that controls the onset of gliogenesis, shows early overexpression. Data from fetal brain tissue showed similar overexpression of S100B and NFIA in trisomy 21 at the end of the early fetal period and beginning of early mid-fetal period. These results support the idea that abnormal expression of these established neurodevelopmental transcription factors, transcription regulators, and signaling proteins contribute to the atypical neuron:astrocyte ratio due to the premature onset of gliogenesis.

Title: Systematic functional analysis of 21st chromosome genes using *C. elegans*

Authors: *J. PIERCE, S. M. SANCHEZ, S. NORDQUIST, S. R. SMITH;
Univ. of Texas at Austin, Austin, TX

Abstract: Down syndrome (DS), caused by trisomy of the 21st chromosome, leads to lifelong cognitive impairment. Efforts to understand this disorder first require an understanding of the genes encoded on the 21st chromosome (HSA21). While progress has been made using traditional mouse models, C. elegans represents a model complementary to uncovering the in vivo function of genes. Using RNAi and loss-of-function mutants, we systematically investigated the role of all HSA21 orthologs, excluding keratin-encoding genes, in viability and neuronal function. We identified ten HSA21 orthologs that are required for behavioral phenotypes. We also found that three of these genes are required for normal release of the neurotransmitter acetylcholine. This includes a known synaptic gene unc-26 (SYNJ1), as well as uncharacterized genes pdxk-1 (PDXK) and mtq-2 (N6ATM1). Furthermore, we found that the glutamine methyltransferase MTQ-2 localizes to cholinergic synapses where it appears to regulate neurotransmission via methylation of a Gα/o signaling protein. Going forward, we are overexpressing each of the HSA21 orthologs in worm and investigating which contribute to overexpression phenotypes, and which are subject to either direct or indirect forms of compensation. Differences in compensation could underlie the variable penetrance and expressivity in individuals with DS. As the first systematic functional analysis of HSA21 orthologs, our study may serve as a platform to understand genes that underlie phenotypes associated with DS.

Title: Activation of the integrated stress response underlies the behavioral and neurophysiological abnormalities in Down syndrome

Authors: *P. ZHU[1], S. KHATIWADA[1], Y. CUI[2], S. DOOLING[1], J. J. KIM[3], W. LI[2], P. WALTER[4], M. COSTA-MATTIOLI[1];

Abstract: Little is known about the role of protein homeostasis networks in brain function. Using a mouse model of Down syndrome (DS), the most common genetic cause of intellectual disability in humans, we investigated the translational landscape in DS. We found that activation of the integrated stress response (ISR)—an evolutionarily conserved signaling network that maintains proteostasis by controlling protein synthesis—in the brain of DS mice and humans leads to a reduction in translation. Genetic and pharmacological inhibition of either the double-stranded RNA-activated protein kinase (PKR) branch of the ISR or the function of eIF2•eIF2B, where the ISR exerts its central control, reversed the enhanced inhibitory synaptic transmission as well as the deficits in long-term synaptic plasticity and memory in DS mice. Our findings unveil a crucial role for the ISR in DS pathophysiology and suggest tuning of the ISR as a promising therapeutic intervention for DS.

Title: RCAN1 overexpression and mitochondrial dysfunction

Authors: *H. WONG, J. LEVENGA, C. ARDIZZONE, C. HOEFFER;
Inst. for Behavioral Genet., Univ. of Colorado Boulder, Boulder, CO

Abstract: *Regulator of Calcineurin 1 (RCAN1)* is a gene overexpressed in Down syndrome (DS) and regulates activity of the calcium/calmodulin-dependent phosphatase calcineurin (CaN), which is involved in many neuromolecular signaling pathways. DS is associated with neurodevelopmental defects and intellectual disability which may be linked to abnormal neural CaN activity. Additionally, because DS patients and DS model mice develop symptoms consistent with early onset Alzheimer's disease (AD), DS-linked genes such as *RCAN1* may also play a role in AD-related neurodegeneration. We found previously that brain-specific overexpression of a human RCAN1 isoform in mice promotes early age-dependent memory and synaptic plasticity deficits, tau pathology, and dysregulation of the CaN substrate dynamin-related protein 1 (DRP1) associated with mitochondrial dysfunction and oxidative stress, reproducing key DS and AD features. In the current study, we examine CaN signaling and mitochondrial function in the *Dp(16)1Yey/+* (Dp16) mouse model of DS with and without *Rcan1* gene dosage correction. This work should improve understanding about the molecular basis of neurological phenotypes and AD progression in DS and whether RCAN1 may be a therapeutic target for treatment.

Title: Cerebellar Purkinje cells alterations in demented and non-demented subjects with Down syndrome

Authors: *E. J. MUFSON, J. C. MIGUEL, S. E. PEREZ;
Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Despite extensive brain beta amyloid (Aβ) plaque and tau containing neurofibrillary tangles (NFTs) in individuals with Down syndrome (DS), only two thirds develop dementia. In addition, cerebellar hypoplasia is another neuropathologic characteristic, which may underlie defects in fine motor learning in subjects with DS. Cerebellar Purkinje cells (PC) inhibit neurons that regulate motor movement by releasing gama-aminobutyric acid. PC are characterized by the presence of the low affinity $p75^{NTR}$ and high affinity TrkA cognate receptors for nerve growth factor as well as the calcium binding protein calbindin D-28K (Calb). The pathobiology of cerebellar PC in DS is an under investigated area. To gain greater insight in cerebellar cellular pathology we quantitated the number of PC immunoreactive for TrkA, $p75^{NTR}$ and Calb in sections obtained from cases with a clinical diagnosis of DS without dementia (DSD-), DS with dementia (DSD+), Alzheimer's disease (AD) and non-demented controls (ND) by combining imunohistochemistry and densitometry. Plaque load was measured using antibodies against amyloid precursor protein APP/Aβ (6E10), Aβ42 and Aβ40. Counts revealed that the number of TrkA positive PC neurons were significantly lower in AD compared to ND controls, but not in DSD- or DSD+. However, $p75^{NTR}$ positive PC counts were reduced in DSD+ and AD compared to ND cases. Of the two amyloid peptides, Aβ42 but not Aβ40 was present in the cerebellum of both DS groups and AD. Both DSD+ and DSD- had higher Aβ42 plaque loads in the cerebellar molecular layer compared to ND controls. We found a correlation between Aβ42 and APP/Aβ plaque loads (P<0.001). Counts of Calb positive PC were highly correlated with optical density (OD) measurements for Calb and the number of $p75^{NTR}$ PC (P<0.001), but not with the number of TrkA positive PC across groups. Counts of $p75^{NTR}$ positive PC neurons correlated with both $p75^{NTR}$ OD and numbers of Trk A positive PC. There were also correlations between the OD of Calb and $p75^{NTR}$ positive PC and their dendritic fields, respectively (P<0.01). The data indicate a differential dysregulation between $p75^{NTR}$ and TrkA in cerebellar PC, which may contribute to the cognitive and motor deficits seen in DS.

Title: Behavioral and electrophysiological assessments of the Ts65Dn mouse model of Down syndrome

Authors: *D. B. VICTORINO[1,2], J. J. SCOTT-MCKEAN[2], S. BAKER[2], C. A. SCORZA[1], A. C. S. COSTA[2,3];
[1]Dept. of Neurol. and Neurosurg., Univ. Federal de Sao Paulo, Sao Paulo, Brazil; [2]Dept. of Pediatrics, [3]Dept. of Psychiatry, Case Western Reserve Univ., Cleveland, OH

Abstract: Down syndrome (DS) is the most frequent cause of genetically defined intellectual disability, and results from the presence of an extra copy of chromosome 21. A wide range of neurological phenotypes is typically observed in persons with DS, including increased incidence of seizure and anxiety disorders. Mouse models of DS, particularly Ts65Dn mice, represent important tools for studying and understanding the pathophysiology of DS co-morbidities. As a model of trisomy 21, Ts65Dn mice exhibit several DS-like phenotypes, including impaired synaptic plasticity. It has been proposed recently that the hippocampus of Ts65Dn mice shows an intracellular accumulation of chloride, which leads to the reversal of GABA type-A receptor ($GABA_AR$) responses from inhibitory to excitatory. In this context, positive allosteric modulators of $GABA_AR$ might produce paradoxical effects that might aggravate rather than ameliorate pre-existing cognitive and behavioral dysfunctions in such mice. Here we assessed unconditioned anxiety and conditioned fear responses by challenging Ts65Dn mice in the elevated plus maze (EPM) and Pavlovian fear conditioning tests. Baseline analysis showed that Ts65Dn mice had increased percentage of time spent in the open arms compared to euploid control mice during the test session in the EPM, while there was no difference in the percentage of time spent in the closed arms between those mice. During the context test, control mice displayed a larger percentage of freezing compared to Ts65Dn mice. Our behavioral results confirm previous findings by others of decreased general anxiety and deficits in fear acquisition for Ts65Dn mice. Due to the modulatory role of GABA in synaptic plasticity, we also assessed the effects of GABA on theta burst stimulation (TBS; 5 trains of 4 pulses at 100 Hz, 200 ms intertrain interval) LTP in Ts65Dn and euploid control derived slices. We found that the application of 200 μM GABA decreased TBS LTP at Schaffer collateral-CA1 synapses in hippocampal slices from Ts65Dn when compared to slices from euploid control mice. These experiments, which are still ongoing, should provide us with a better understanding of the role of GABAergic modulation of behavioral and electrophysiological phenotypes in this important mouse model of DS.

Title: On the implementation of computational psychiatry to study ADHD subtype differences

Authors: *N. GING-JEHLI[1], E. ARNOLD[1], R. RATCLIFF[1], R. DE BEUS[2], S. CONNOR[2], C. PANCHYSHYN[1], A. LINGEL[1];
[1]The Ohio State Univ., Columbus, OH; [2]Univ. of North Carolina Asheville, Asheville, NC

Abstract: Attention-Deficit and Hyperactivity Disorder (ADHD) is a frequent neurodevelopmental disorder, but the neurophysiological and cognitive underpinnings of ADHD remain incompletely explained. For example, neurocognitive test procedures that could be used to differentiate ADHD from controls remain unclear. Similarities and differences between various phenotypes of ADHD are not established thus far. Discriminating between ADHD phenotypes is important, because evidence suggests that different phenotypes respond differently to certain treatments.
The field “Computational Psychiatry” can link specific cognitive components with ADHD phenotypes. Applying the Ratcliff Diffusion Model (RDM) to the performances of children aged 7 to 10 with (N=74) and without (N=60) ADHD on the “Integrated Visual and Auditory Continuous Performance Test” (IVA), we examine cognitive differences among the different ADHD presentations (subtypes) distinguished by the Diagnostic and Statistical Manual of Mental Disorders (DSM), and between the ADHD subtypes and controls.
Applying such a computational approach, we have found strong sequential effects and significant differences between ADHD subtypes. Specifically, when stimuli are auditorily presented, the ADHD predominantly inattentive presentation (ADHD-I) exhibits a greater bias towards repeating previously made choices, as indexed by starting point biases, than the ADHD, combined presentation (ADHD-C) [$F(1,72)=7.106$, $p=0.009$, $\eta p^2=0.090$].
Moreover, a repeated mixed-model ANCOVA, adjusting for gender, suggests: in comparison to ADHD-I, when target stimuli are frequently presented, ADHD-C is better (e.g., faster and more accurately) able to detect visually presented non-target stimuli, as indexed by higher drift rates ($p=0.014$). In contrast, when non-target stimuli are frequently presented, ADHD-C is better able

to detect visually presented target stimuli, as indexed by higher drift rates (p=0.019). Hence, while ADHD-C have higher drift rates for infrequently presented stimuli, ADHD-I have higher drift rates for frequently presented stimuli, but only when they are auditorily presented (p=0.004).
Currently, we are collecting data of children without ADHD (N=60) to examine whether: i) the sequential effects found are a hallmark of ADHD, and ii) the RDM could be used to not only distinguish between ADHD subtypes, but also between children with and without ADHD. Eventually, linking EEG measures to RDM parameters suggests that the RDM may be used to measure a broader spectrum of ADHD phenotypes (e.g., late starters, mind wanderers) that may show deficits in distinct cognitive components.

Title: Increased left inferior fronto-striatal activation during error monitoring after fMRI neurofeedback of right inferior frontal cortex in ADHD

Authors: ***M. CRIAUD**, M. WULFF, A. A. ALEGRIA, G. BARKER, V. GIAMPIETRO, K. RUBIA;
Inst. of Psychiatry, Psychology & Neuroscience; King's Col. London, London, United Kingdom

Abstract: ADHD is associated with poor self-control, underpinned by inferior fronto-striatal deficits including poor self-monitoring skills typically associated with reduced activation in error monitoring networks of left inferior frontal cortex (IFC), insula, cingulate and striato-thalamic regions. We showed previously that 11 runs of 8.5 minutes of real-time functional magnetic resonance imaging neurofeedback (fMRI-NF) of right IFC in 18 ADHD adolescents resulted in

increased activation in rIFC as well as of entire fronto-cingulo-striatal networks,which were associated with clinical symptom improvement. Furthermore, rIFC-NF also increased activation in rIFC and parietal areas during successful Stop task performance. In this study, we investigated whether fMRI-NF would also improve the neural correlates of error monitoring during failed stop trials. Twenty-seven boys with ADHD underwent fMRI-NF; 16 in the active group received fMRI-NF of the rIFC and 11 in the control group received fMRI-NF of the left parahippocampal gyrus. They performed a tracking fMRI Stop task before and after fMRI-NF. An ANOVA time (pre- vs post-fMRI NF) x group (active vs control) was applied to brain activation and performance to failed stop trials. We furthermore tested for correlations between brain changes and performance and clinical changes. The active relative to the control group showed increased activation in left IFC, insula and putamen during the failed stop trials, after relative to before fMRI-NF. This activation change was furthermore correlated with decreased post-error reaction times, indicating more efficient error monitoring, and trend-wise with decreased clinical symptoms. fMRI-NF of rIFC improved performance and activation of left-hemispheric IFC-insular-striatal regions during error monitoring in association with clinical symptom improvement. The findings show that rIFC-NF of rIFC has more widespread upregulation effects - not limited to right IFC- that extend to contralateral fronto-insular-striatal areas of error monitoring, which have previously been shown to be upregulated with stimulant medication.

Title: Foveal hypoplasia in a genetically engineered anole lizard

Authors: *C. SABIN[1], A. M. RASYS[2], B. M. MCKINNON[3], J. COLCLOUGH[1], H. KIM[4], D. MENKE[1], J. D. LAUDERDALE[2];

Abstract: In humans, mutations in genes that impact melanin synthesis or melanosome biogenesis and trafficking in cells of the retinal pigmented epithelium (RPE) result in visual

defects. These defects include the loss or abnormal development of the fovea and misrouting of the normal ipsilateral axon projections from the retina to the brain. The link between the pigmentation pathway and retinal development is poorly understood but almost certainly involves signaling between the RPE and non-pigmented neural retina. We hypothesize L-DOPA production by the RPE cells acts to control development of the fovea. Recent studies have established that L-DOPA can act on RPE cells in an autocrine manner through GPR143, a G protein-coupled receptor, to increase secretion of SERPINF1 (also known as PEDF). SERPINF1, a multifunctional secreted glycoprotein and a non-inhibitory member of the serine protease inhibitor (serpin) family, is known to exhibit diverse and significant biological activities including the regulation of neural differentiation. Other studies have suggested that L-DOPA may play a direct role in cell proliferation and/or neurogenesis. Rodents and many other mammals, such as dogs and cats, lack fovea and cannot be used to test if disruptions in L-DOPA production, GPR143 signaling activity, or SERPINF1 release have any effects on fovea development. Therefore, we are developing the brown anole, *Anolis sagrei*, as a model system to study the cellular and molecular mechanisms underlying foveal development. These small lizards of the Caribbean are normally bifoveated, with morphologically distinct fovea in the central and temporal retina. As proof-of-principle, we have used CRISPR-cas9 to generate a series of mutations in the *tyrosinase* gene of *A. sagrei*. Lizards harboring loss-of-function *tyr* mutations exhibit an absence of pigmentation and loss of the temporal retina. These findings suggest the lizard is a useful model to investigate the underlying effects of albinism on fovea formation.

Title: Elucidating the role of tyrosinase in fovea development using the Anolis sagrei lizard

Authors: ***B. M. MCKINNON**[1], A. M. RASYS[2], D. B. MENKE[1], J. D. LAUDERDALE[2]; [1]Genet., [2]Cell. Biol., Univ. of Georgia, Athens, GA

Abstract: Although most often associated with color diversity in animals, pigments play a critical role in vision by protecting cells from harmful wavelengths of light. Pigment production

is also thought to be important for eye development—particularly with the formation of the fovea. The fovea is a pit/depression found in the retina in a region where there is a high density of photoreceptor cells that are crucial for a person's high visual acuity. When pigmentation is absent, a condition known as albinism, the fovea fails to develop and, in such individuals, vision is often extremely poor. The most commonly mutated gene in albinism is *tyrosinase*, which encodes an enzyme that mediates the conversion of precursors (i.e. L-tyrosine into L-DOPA and L-DOPA into Dopaquinone) necessary for melanin synthesis. Because current model systems to study eye development, like the mouse, chick, and zebrafish, lack a fovea, it is unclear how affecting this pathway leads to a dysregulation of fovea formation. To address this, our lab recently established CRISPR genome editing tools in the *Anolis sagrei* lizard—a novel foveated model system and created the first *tyrosinase* mutant lizard. By using *tyrosinase* mutant lizards and pharmacological agents that affect the melanin synthesis pathway, we aim to determine when tyrosinase activity is crucial for fovea formation in embryonic development. Towards this goal, we have developed an egg drug-delivery system and describe here the histological effects of 1-phenyl-2-thiourea, a drug known to inhibit tyrosinase, in the developing wild-type lizard embryonic eye. This work lays the foundation for understanding how pathways governing pigment production may regulate fovea development in *Anolis* lizards.

Title: Lactational ethanol exposure: Brain and behavioral development in a breastfeeding model

Authors: *R. F. PEREZ, Jr[1], K. E. CONNER[2], M. NABATANZI[1], K. J. HUFFMAN[1]; [1]Psychology, [2]Neurosci., Univ. of California, Riverside, Riverside, CA

Abstract: Prenatal ethanol exposure (PrEE) alters neocortical connectivity, gene expression, and behavior in offspring. Early postnatal exposure in humans, from ethanol in breastmilk, can result in low body mass, and verbal IQ scores, as well as altered infant sleeping patterns. In the US, approximately 36% of breastfeeding mothers consume alcohol; incidence rates are higher in Australia (60%) and, surprisingly, lower in Canada (20%) (Popova et al., 2013; Tay et al., 2015; May et al., 2016). Here, we investigate how lactational ethanol exposure (LEE) impacts brain and behavioral development using a novel CD-1 breastfeeding mouse model. Control dams were provided water throughout gestation and all dams were given unlimited chow. Dams in the experimental group were given a 25% EtOH in water solution *ad libitum* when pups were 6 days

old (postnatal day (P) 6) until weaning at P20. P6 was chosen for the start of LEE as P7 in mice is approximately equivalent to the day of birth in humans. At weaning, a subset of LEE and control mice were euthanized for P20 experiments while the remaining offspring were separated from the dam and raised without ethanol until P30, when behavioral assays were performed. Dam blood ethanol content (BEC) and plasma osmolality (POSM, a measure of hydration) were measured at weaning. Experimental dams had significantly higher BECs when compared to controls, as did LEE pups at P20, as expected. POSM did not differ between experimental and control dams or LEE and control offspring at P20. LEE mice had decreased body and brain weights at P20 when compared to controls. However, these phenotypes were rescued by P30. *In situ* RNA hybridization was used to examine neocortical expression of two genes important for patterning in brain development, *Id2* and *RZRβ*. Laminar and region-specific expression patterns within neocortex were observed in LEE and control offspring at P20 and P30. A series of behavioral assays were conducted in all offspring at P30. LEE mice spent significantly more time in the open arms of the Elevated Plus Maze, suggesting increased risk-taking behavior, as has been observed previously in PrEE mice from our laboratory. There were no significant differences observed between LEE and control mice at age P30 on the Forced Swim Test (depressive behavior), the Suok Assay (sensorimotor integration) or the 3-chamber Sociability Test (social behavior). There is a paucity of research regarding the dangers of maternal consumption of alcohol during breastfeeding and studies such as this, using animal models of lactational exposure, are important to advance our understanding and recommendations of safe maternal practices in early infancy.

Title: Embryonic gross anatomy in mouse model of FASD

Authors: *K. E. CONNER[1], K. J. HUFFMAN[2];
[1]Interdepartmental Neurosci. Program, [2]Psychology/Neuroscience, Univ. of California, Riverside, Riverside, CA

Abstract: Fetal alcohol spectrum disorders (FASD) describe a wide array of phenotypes that arise in offspring whose mothers consumed alcohol, or ethanol, during pregnancy (Hoyme et al., 2016). It is currently estimated that 5% of children born in the United States have been affected by maternal consumption of alcohol during pregnancy; this number may be underestimated due

to lack of reporting (May, et al., 2018). Previous work in our laboratory has documented many deleterious effects of prenatal ethanol exposure (PrEE) via multilevel experiments in a novel CD-1 mouse model of FASD. For example, abnormal neocortical gene expression, altered neuroanatomy, and development of ectopic intraneocortical connections in postnatal mice were induced by PrEE (El Shawa et al., 2013; Abbott et al., 2016). Many of these phenotypes were passed to subsequent generations, as demonstrated in our transgenerational model of FASD (Abbott et al., 2018). In our prior work, we focused on the postnatal effects of PrEE. In the current study, we extended our research by investigating the effects of PrEE in embryonic mice. We have identified gross neuroanatomical phenotypes in PrEE and control offspring at different embryonic stages prior to birth (embryonic day (E) 12.5, E14.5, E16.5, E18.5) in our mouse model of FASD. *Methods:* Adult dams self-administered 25% EtOH *ad libitum* beginning immediately after confirmation of conception via detection of the vaginal plug. At the preselected embryonic dates, dams were cervically dislocated and a postmortem caesarian section was performed to extract embryos. Embryos were euthanized via hypothermia. The E12.5 and E14.5 embryos were exsanguinated post mortem; the E16.5 and E18.5 embryos were transcardially perfused with 4% PFA (pH=7.4). All embryos were then post-fixed in PFA and examined for gross physical and neuroanatomical differences. *Results*: PrEE embryos were smaller than controls at all ages; they also consistently exhibited decreased body weights. Additionally, brain weights were significantly lower in PrEE embryos compared to controls at all ages. Cortical lengths were significantly reduced in PrEE embryos at E14.5, E16.5, and E18.5 when compared to controls. Variations in facial morphology were observed between control and experimental groups. By examining anatomical defects present before birth in our mouse model of FASD, we can gain additional insight into the mechanisms that may regulate the atypical developmental features we have described postnatally in these mice. Elucidating the developmental trajectories of prenatal ethanol exposure-related deficits will aid in our understanding and prevention of FASD in humans.

Title: Multi-unit electrophysiological mapping of neocortex and behavior in a mouse model of FASD

Authors: *R. T. BOTTOM[1], K. E. CONNER[1], M. ENGLUND[3], C. R. PINEDA[3], C. S. BRESEE[3], M. NABATANZI[2], L. A. KRUBITZER[3], K. HUFFMAN[2];

[1]Interdepartmental Neurosci. Program, [2]Psychology, Univ. of California, Riverside, Riverside, CA; [3]Ctr. for Neurosci. and Dept. of Psychology, Univ. of California, Davis, Davis, CA

Abstract: Fetal alcohol spectrum disorders (FASD) describe the range of adverse neurological and behavioral effects that result from prenatal ethanol exposure (PrEE). Human behavioral and imaging data suggest that the neocortex constitutes a focal point of ethanol's teratogenic effects. Accordingly, rodent models of FASD have described widespread neocortical dysfunction including altered cortical cell migration and postsynaptic current frequencies *in vitro* (Delatour et al., 2018), as well as aberrant patterns of neuronal connectivity and gene expression (Abbott et al., 2018). This suggests an overall disorganized neocortex due to PrEE. However, no study has directly examined the impact of PrEE on the functional organization of sensory areas within neocortex and related it to behavioral phenotypes. To address this, we conducted behavioral assays and multiunit electrophysiological recordings in 6-month-old PrEE mice using our previously established prenatal exposure model, created with 25% ethanol dam self-administration (El Shawa et al., 2013). Prior to electrophysiological experiments, we assessed behavior using a battery of assays. Adult PrEE mice spent significantly more time in open arms of the elevated plus maze as compared to controls, suggesting increased risk-taking behavior. Also, PrEE mice showed impairment on the Accelerated Rotarod and social behavior as measured on the 3- chambered social approach test. No differences were observed between groups on the forced swim assay. After completion of behavior tests, PrEE and control mice underwent electrophysiological experiments. Multiunit neuronal activity was recorded at a number of closely spaced sites across the neocortex and the type of sensory stimuli that elicited a response, as well as the receptive field for neurons at all somatosensory sites, was recorded. Stimuli used to elicit responses included visual (light flash), auditory (clicks), and somatosensory (tactile). Analyzing electrophysiological recording data matched to cytochrome oxidase stained tissue, we were able to create maps of sensory neocortex in both PrEE and control mice and observed boundaries between specific sensory regions. It is clear that PrEE induces long-term behavioral effects in the offspring, spanning to later adulthood, in a mouse model of FASD. Additionally, this is the first study where functional, electrophysiological maps of the adult PrEE neocortex have been established and results of this study will provide key information regarding how functional features of the adult neocortex relate to behavioral phenotypes in FASD.

Cochin, Paris, France; [5]Div. of Neonatology and Pediatric Intensive Care, Children's Univ. Hosp. of Geneva, Geneva, Switzerland; [6]Div. of Child Develop. and Growth, Dept. of Pediatrics, Gynecology and Obstetrics, Sch. of Med. Univ. of Geneva, Geneva, Switzerland

Abstract: Fetal growth restriction (FGR) is a neurodevelopmental condition associated with high risk to develop cognitive and neurobehavioral handicaps. Abnormal neuro-inflammatory responses orchestrated by microglia cells lies at the core of this abnormal neurodevelopmental trajectory. Thus, normalization of microglia reactivity could represent a promising therapeutic strategy. During the perinatal period the neurotransmitter glutamate plays both positives and negatives roles depending on the receptors and cells types on which its action is considered. Metabotropic glutamate receptor (mGluR3) activation reduce neuro-inflammation in several adult pathological conditions (e.g Alzheimer, schizophrenia). However, mGlu3 receptors function is totally unexplored on microglia in the context of neurodevelopmental disorders and in the early postnatal period when his expression is high.
We developed a rat model of FGR (gestational low-protein diet + IL-1b, i.p. at postnatal days (PND) 1 & 2, LPD IL-1b) that shows increased early pro-inflammatory microglia reactivity conducing to cognitive and behavioral disorders. Magnetic sorted microglia from PND4 CTRL and LPD IL-1b pups are analyzed by Affymetrix assay. The expression of GRM3 is analyzed in CTRL and LPD IL-1b cortex and microglia cells at PND1, 2, 4 & 7, and protein level is analyzed at PND4 & 7. PND4 & 7-cultured microglia are treated with the mGluR3 agonist (LY 379268) prior to a pro-inflammatory challenge with IL-1b and INFg for the measurement of pro- and anti-inflammatory markers and of GRM3. Same experiments are performed in presence of the mGluR3 negative allosteric modulator, LY 2389575, only in CTRL cells.
Microglia microarray analysis evidenced that GRM3 is the highly expressed GRM at PND4 and the most down-regulated by LPD IL-1b. This result is confirmed by RT-qPCR from PND2 to 7 and by western blot at PND4 & 7. Low levels of GRM3 are observed in LPD IL-1b cortex at PND2 & 4. Reduced GRM3 expression is confirmed on PND4 & 7 microglia cultures from LPD IL-1b and is associated to pro-inflammatory phenotype both in basal and IL-1b+INFg conditions. Expression of pro-inflammatory markers is reduced in presence of mGluR3 agonist in both groups. The ability of mGluR3 to modulate inflammatory response is confirmed by the increase of pro-inflammatory cytokines observed in response to LY 2389575.
In conclusion, reduced postnatal mGluR3 microglia expression/stimulation is associated to increased pro-inflammatory cell activity and reactivity. The modulation of central inflammatory response by mGluR3 activation could then represent a valid therapeutic strategy to improve the neuro-protection in the immature brain.

Univ., Inst. Langevin, Paris, France; [5]Div. of Neonatology and Pediatric Intensive Care, Children's Univ. Hosp. of Geneva, Geneva, Switzerland

Abstract: Fetal Growth Restriction (FGR) is one of the most common deleterious antenatal conditions in newborns, leading to a significant increase in perinatal mortality, neurological handicaps and chronic diseases in adulthood. Interestingly, the brain injuries and the subsequent neurodevelopmental impairments observed in children born growth restricted seem to be closely associated with an exacerbated neonatal neuro-inflammation. In this context, advance in early life neuroimaging in animal model of FGR associated with neuro-inflammation represents major opportunity for diagnosis, prognosis and targeted therapeutic strategies. We developed a rat model of FGR (gestational low-protein diet + IL-1b, i.p. at postnatal days (P) 1 & 2, LPD/IL-1b) that shows increased pro-inflammatory microglia reactivity at P2 & P4 leading to a reduced myelination at P10 and cognitive and behavioral disorders in young adults animals. Here, we investigated structural and functional abnormalities associated with FGR and postnatal neuro-inflammation in this model. At P10 and P21, advanced ex-vivo diffusion MRI techniques, DTI (diffusion tensor imaging) and NODDI (neurite orientation dispersion and density imaging), performed at 9.4T were used to investigate brain cortical and white matter microstructure. Axial and radial diffusivities and fractional anisotropy were found significantly reduced in LPD/IL-1b animals in most of the observed structures (cingular cortex and white matter, somatosensory cortex dorsal, corpus callosum and external capsule). Conversely, intra-neurite volume fraction and orientation dispersion index were found significantly increased. At P26/28, we used high-resolution functional UltraSound (fUS) to generate highly sensitive cerebral blood volume (CBV) maps underlying neuronal activity in order to assess inter- and intra- hemispheric cortical

functional connectivity. fUS imaging revealed that FGR was associated with a significant reduction in intra- and inter-hemispheric connectivity in most of the explored cortical area. In conclusion, our rat model of FGR associated to early postnatal neuro-inflammation recapitulated microstructural and functional cortical alteration readily observable by advanced neuroimaging technics. Innovative neuroimaging tools used in this study pave the way for their translational use in human neonates and to assess new neuroprotective therapies.

Title: Distribution of neurofilament immunoreactive neurons (SMI-32) in the prefrontal cortex in Williams syndrome

Authors: *B. HRVOJ MIHIC[1], K. L. HANSON[2], C. H. LEW[3], D. N. CUEVAS[3], D. GREINER[3], K. SEMENDEFERI[4];
[1]Anthrop., Univ. of California San Diego, La Jolla, CA; [2]UC San Diego, La Jolla, CA; [3]UC San Diego, La Jolla, CA; [4]Univ. California San Diego, La Jolla, CA

Abstract: Williams syndrome (WS) is a neurodevelopmental disorder characterized by a set of compromised features in social behavior, including an increased desire to interact socially with strangers and inadequate responses to social situations. Several regions of the prefrontal cortex involved with processing of socially salient information - including the frontal pole and the orbitofrontal cortex -- display abnormalities in WS: decreased density of neurons compared to controls, and deficiencies in length and branching of dendrites, and the number of dendritic spines in the prefrontal cortex compared to unimodal cortical areas. Supragranular (layers II/III) are more affected than infragranular layers (layers V/VI). In order to examine if a particular subclass of neurons within the prefrontal cortex is affected in WS, we used an antibody against non-phosphorylated epitope of neurofilament protein (SMI-32) to examine distribution of SMI-32ir neurons in the frontal pole of WS and neurotypical controls. SMI-32ir neurons represent important parts of cortical circuitry, underlying long cortico-cortical connections. They are especially prominent in supragranular layers in the prefrontal cortex and have previously been implicated in deficiencies in schizophrenia, bipolar disorder, and other psychiatric disorders. Our analysis revealed that SMI-32ir neurons in WS occupied the same relative position within layer III as in neurotypical controls, being restricted to the lower layer III of the frontal pole, but with important differences between WS and controls. More specifically, we found that density of

SMI-32ir neurons was lower in WS and the neurons were characterized by smaller cell bodies. These findings imply that lower layer III magnopyramidal neurons in the prefrontal cortex appear particularly affected in WS, suggesting deficiencies in cortico-cortical connectivity between the frontal pole and other cortical regions in the disorder.

Title: Mutations of E3 ubiquitin ligase adaptor protein KLHL15 in X-linked intellectual disability

Authors: *J. SONG[1], R. MERRILL[1], R. KEPHART[1], Y. LIU[1], M. SHAW[2], R. CARROLL[2], A. GARDNER[2], L. JOLLY[2], F. MCKENZIE[3], J. GECZ[2,4], V. KALSCHEUER[5], S. STRACK[1]; [1]Dept. of Pharmacol., Univ. of Iowa, Iowa City, IA; [2]Adelaide Med. Sch. and Robinson Res. Institute, The Univ. of Adelaide, Adelaide, Australia; [3]Genet. Services of Western Australia, Women and Newborn Hlth. Service, King Edward Mem. Hosp., Subiaco, Australia; [4]South Australian Hlth. and Med. Res. Inst., Adelaide, Australia; [5]Max Planck Inst. for Mol. Genet., Department of Human Molecular Genetics, Germany

Abstract: Intellectual disability (ID), which affects 1-2% of the general population, is a devastating neurodevelopmental disorder with the most lifetime costs of all diagnoses in the U.S. However, males are more susceptible to ID than females and are often found to have severe outcomes. Mutations in Xchromosomal genes are thought to account for this male-biased phenomenon. KLHL15 was recently identified as a novel XLID gene. It encodes Kelch-like protein 15 (KLHL15), a substrate adaptor of a Cullin-3 (CUL3)-based E3 ubiquitin ligase complex that targets proteins, including the brain-enriched B′β regulatory subunit of protein phosphatase 2A (PP2A), for degradation by the ubiquitin/proteasome system (UPS). Several KLHL15 mutations have been found in the poorly characterized BACK domain, which is a "hotspot" for many deleterious variants of the other KLHL family members resulting in either Mendelian diseases or human cancers. We identified both loss-of-function (ΔFY241, ::ACOT9)

and gain-of-function (R249H) alleles, and we hypothesize that small deletions and point mutations in KLHL15's BACK domain lead to structural rearrangement that change the alignment between bound substrates and the ubiquitin transfer (E2/E1) complex to either slow or accelerate substrate ubiquitination and degradation, causing dysregulated protein turnover of CUL3KLHL15-targeted substrate(s) and eventually pathogenesis of ID.In addition, we applied bioinformatic approach coupled with mass spectrometry to identify other brain- and neuron-specific substrates also targeted by KLHL15 for polyubiquitination and proteaosomal degradation, which may uncover other molecular mechanisms underlying XLID and neurodevelopmental disorders (NDDs) in general.

Title: Characterization of a novel rat model of creatine transporter deficiency

Authors: *M. WRIGHT, K. POKSAY, A. TROTIER-FAURION, B. CASS, S. BROWN, K. JAYASHANKAR, M. ANDREWS, S. FYFFE-MARICICH;
Ultragenyx Pharmaceut., Novato, CA

Abstract: Creatine transporter deficiency (CTD) is a rare X-linked inherited disorder, caused by loss of function mutations in the *SLC6A8* gene which encodes the creatine transporter (CrT). CrT protein expression at the blood-brain barrier and in neurons helps supplement intraneuronal creatine pools in the brain as a source of ATP-energy. Without functional CrT, creatine pools become depleted, thus impairing the normal metabolic function in these cells. Patients with CTD experience global developmental delay, intellectual disability, autistic features, behavioral disorder, and delayed language development. There are no currently approved treatments for CTD.
Here we describe a rat model of CTD generated by deleting exons 2-4 from *SLC6A8* using CRISPR/Cas9 technology. The larger brain size of rats relative to mice allowed us to isolate intact neurons and analyze the intracellular creatine levels from individual $SLC6A8^{+/Y}$ (WT) and $SLC6A8^{-/Y}$ (CTD) rats. Brain histology, endogenous whole brain creatine levels, and a battery of behavioral phenotypes were also assessed. The brains of CTD rats showed no overt structural changes, consistent with previously published mouse models of CTD as well as patients with CTD. Endogenous creatine levels in both a whole brain homogenate, and in neuronally-enriched

cell isolates, were decreased by greater than 80% compared to WT. Additionally, whole brain homogenates from CTD rats dosed with d3-labeled creatine showed that exogenously delivered creatine was not quantifiable in brain tissue. Consistent with patients, *in vivo* ^{1}H- and ^{31}P-MRS analysis also demonstrated significantly decreased levels of endogenous brain creatine in the CTD rat brain (see poster by Lehtimäki and Fyffe-Maricich). The body weights of CTD rats were significantly lower than WT littermates possibly due in part to dental malocclusions that may have impacted food consumption. Behaviorally, CTD rats did not present with a strong behavioral phenotype compared to WT animals across a battery of motor and cognitive tests. This lack of a robust behavioral phenotype in the CTD rats is in contrast to what has been reported in mouse models of CTD, suggesting potential species-specific differences.
In summary, these data support the use of this CRISPR CrT KO rat as a model of CTD for evaluation of pre-clinical therapeutic candidates whose mechanism of action is defined by their ability to restore neuronal creatine concentrations.

Title: Longitudinal magnetic resonance spectroscopic (^{1}H and ^{31}P MRS) characterization of total and phosphorylated brain creatine in a novel creatine transporter deficient rat

Authors: *K. LEHTIMÄKI[1], B. SULLIVAN[2], K. JAYASHANKAR[2], M. ANDREWS[2], A. J. NURMI[1], S. FYFFE-MARICICH[2];

Abstract: Creatine transporter deficiency (CTD) is a rare X-linked inherited disorder, caused by loss of function mutations in the SLC6A8 gene which encodes the Creatine transporter. Loss of the Creatine transporter leads to low levels of creatine, resulting in a spectrum of disease manifestations including intellectual disability, delayed/absent speech and behavioral disabilities (Clark and Cecil, 2015, Pediatric Res). There are currently no approved treatments for this condition.
A novel SLC6A8 knock-out CTD rat model was generated, utilizing CRISPR/Cas9 technology, to evaluate pre-clinical therapeutic candidates (see poster by Wright and Fyffe-Maricich for full characterization details). The purpose of this study was to measure the longitudinal variability of Creatine (Cr) and Phosphocreatine (PCr) levels in the brain of live CTD rats by ^{1}H and ^{31}P-Magnetic Resonance Spectroscopy (MRS).

MRS experiments were performed using a 11.7T small animal system (Bruker BioSpin, Ettlingen, Germany), with high gradient strength and shims up to 4th order allowing high spectral resolution and narrow linewidths to distinguish the closely resonating PCr and Cr. ^{1}H MRS was acquired from a hippocampal voxel, while the ^{31}P MRS was acquired from a large forebrain voxel in order to increase the signal-to-noise ratio. MRS experiments were performed at three time points, each separated by 2 weeks. This study employed age-matched CTD rats of following genotypes: wildtype (WT) littermate male n=5, heterozygote (HET) female n=5 and hemizygote (HEMI) male n=5.
Repeat MRS measurements with multiple isoflurane anesthesia events were well tolerated by CTD rats of all genotypes. Both ^{1}H- and ^{31}P-MRS experiments demonstrated a gene-dose-dependent decrease of Cr and PCr (WT>HET>HEMI). The Cr levels measured by ^{1}H-MRS were significantly different between each group (WT = 8.64 +/- 0.51 mmol/kg, HET = 5.44 +/- 0.54 mmol/kg and HEMI = 1.71 +/- 0.13 mmol/kg; mean +/- stdev). ^{31}P-MRS demonstrated significantly lower PCr levels in the CTD rats compared to wild type (WT = 3.78 +/- 0.9 a.u., HET = 2.56 +/- 0.8 a.u. and HEMI = 0.66 +/- 0.1 a.u.; mean +/-stdev). The biologic variability over the three visits was <13.14%CV for Cr (measured by ^{1}H-MRS) and <41.67%CV for PCr (measured by^{31}P-MRS).
In summary, low levels of brain Cr and PCr measured by MRS in a novel rat model recapitulates observations from patients with CTD. This model has an adequate dynamic range and stability to be appropriate for future translational studies.

Title: Behavioural signatures of a developing neural code

Authors: *L. AVITAN, Z. PUJIC, J. MÖLTER, M. MCCULLOUGH, S. ZHU, B. SUN, A. MYHRE, G. J. GOODHILL;
The Univ. of Queensland, Queensland Brain Inst., Brisbane, Australia

Abstract: During early life, the neural code must develop to appropriately transform sensory inputs into behavioural outputs. However little is known about how developments in neural representations directly impact behaviour. To address this we used 2-photon calcium imaging of

GCaMP6s zebrafish larvae and and high speed recording of prey-capture behaviour at different ages. We showed behaviourally a spatial shift in prey detection in the visual field during early life, which is mirrored by a developmental shift in the locus of neural activity in the optic tectum. Decoding of spatial position from tectal activity improved with age at different rates across the tectum, and could predict individual differences in prey-capture behaviour. The dimensionality of evoked activity was higher than that of spontaneous activity, and some statistics of evoked activity became more distinct from those of spontaneous activity with age. Together these results show that developmental signatures of an emerging neural code can be directly related to observable properties of behaviour.

Title: Gene network control of cortical neuronal circuit assembly

Authors: *S. ZEPPILLI[1,2], A. BOYREAU[2], A. FLEISCHMANN[1], A. CROMBACH[3]; [1]Neurosci., Brown Univ., Providence, RI; [2]Col. de France, Paris, France; [3]Inria, Lyon, France

Abstract: A defining characteristic of the mammalian cortex is its enormous diversity of cell types. Earlier studies have provided insight into the genetic control of cell type specification in the neocortex (NCx). In contrast, the genetic mechanisms underlying the development of the olfactory cortex (piriform cortex, PCx), an evolutionarily old allocortical structure, remain poorly understood. Our lab has recently identified molecular signatures of PCx connectivity and discovered unexpected similarities and differences in the gene expression patterns in adult mouse NCx and PCx (Diodato et al., 2016). We here present recent results using single nuclei RNA sequencing that refine the molecular characterization of adult mouse piriform neuronal cell types. Based on these results we propose that NCx and PCx development is controlled by overlapping sets of transcription factors. To test this hypothesis we examine the expression of key transcription factors involved in neuronal lineage specification during development, employing immunohistochemistry in cleared brain preparations and light sheet microscopy. Furthermore, we use a computational approach to probe the mechanisms of interaction between the different transcriptional regulators. Genes and their interactions are encoded in a mathematical model of a gene network, and the regulatory structure of the network is inferred by

fitting to expression data obtained from whole-brain imaging experiments. Together, modeling and experiments will reveal the molecular mechanisms of PCx development, uncover key regulatory decision points of cortical neuronal lineage specification and identify similarities and differences between the gene network architecture of NCx and PCx.

Title: Characterization of novel starburst amacrine subtypes in zebrafish

Authors: *Y. LI[1,2], A. LEE[1], X. JIA[1], X. TANG[1], X. QIU[1], J. HE[1,2];
[1]Inst. of Neuroscience, Chinese Acad. of Sci., Shanghai, China; [2]Univ. of the Chinese Acad. of Sci., Beijing, China

Abstract: In mammal, starburst amacrine cells (SACs) have been reported to have two important functions. While their involvement of the generation of retinal waves that are critical, for the formation of visual circuits in the developing retina, SACs also provide the directional inhibition to retinal ganglion cells to generate centrifugal direction selectivity in the developed retina. Here we are exploring SAC subtypes in zebrafish (Danio rerio). Using single cell RNA sequencing and genetic labeling, we identified two subtypes of SACs, each of which exhibited on- and off-types, characteristic morphology, as well as expressing a specific set of transcription factors. CRISPR/CAS9 knockout assay revealed the genetic knockout of subtype-specific transcription factors led to the loss of both SAC subtypes, which further resulted in the disruption of the optical kinetic reflex in zebrafish.

Title: Deletion of melanopsin modulates the whole retina transcriptome during postnatal development

Authors: *J. A. LUCAS, S. FELDSTEIN, T. M. SCHMIDT;
Neurobio., Northwestern Univ., Evanston, IL

Abstract: Melanopsin-expressing, intrinsically photosensitive retinal ganglion cells (ipRGCs) respond directly to light and have been shown to mediate a broad variety of visual behaviors in adult animals. In addition to this, ipRGCs have been shown to be the first light sensitive cells in the developing retina, and have been implicated in a number of retinal developmental processes such as pruning of retinal vasculature and refinement of retinofugal projections. However, little is currently known about how melanopsin and ipRGCs drive such broad influences on retinal development or whether they modulate additional, unidentified aspects of retinal development. In order to more broadly understand the influence of ipRGCs on retinal development, we performed RNAseq to compare the retinal transcriptome of wildtype and melanopsin knockout mice at postnatal day (P) 8 and P14. We identified 66 and 374 differentially expressed genes at P8 and P14, respectively. We then cross-validated a subset of significantly differentially expressed genes with qPCR for both age groups, and identified multiple genes that were continued to be differentially expressed in adult retinas. Overall, our work shows that melanopsin expression alters the whole retinal transcriptome during development, and that some of these changes persist into adulthood. This work provides important insight to the diverse molecular impacts of melanopsin on the developing retina, and gene targets for further exploration in their role in retinal development.

Title: Origin and function of directionality in spontaneous retinal waves

Authors: *X. GE, A. GRIBIZIS, M. CRAIR;
Yale Univ., New Haven, CT

Abstract: Before the onset of visual experience, spontaneous retinal waves are the main source of activity in the developing superior colliculus (SC), thalamus and primary visual cortex in the mammalian visual system. Genetic and pharmacological manipulations of this spontaneous retinal activity suggest a causal link between retinal waves and circuit refinement. Previous studies found that Stage II (around the first week after birth in mice) spontaneous waves exhibit a strong directional bias. However, it remains unclear how this bias emerges, whether it changes over development and whether this spatiotemporal feature of spontaneous waves is critical for circuit refinement and the development of functional circuit properties. Here, we describe experiments that investigate the role and origin of spontaneous wave directionality during visual system development.
We used wide-field Ca^{2+} imaging of retinal ganglion cell (RGC) projections in the SC *in vivo* and optogenetic or light stimulation of the retina to examine spontaneous and stimulus induced wave direction bias. We observe that the directional bias emerges at the end of Stage II (~P8) waves and vanishes before the time of eye opening (~P12). The biased direction (temporal to nasal) is consistent between P8 and P12. Notably, the directional bias of wave propagation is not uniform across the retina, but rather resembles the pattern of optic flow in the retina generated by the animal's forward motion. To understand the origin of wave directional bias *in vivo*, we used selective optogenetic stimulation of starburst amacrine cells (SACs), or light stimulation after the onset of light response (~P10), to initiate waves at various locations in the retina. Our experiments suggest that starting from around P10, stimulated retinal waves propagate in a direction consistent with intrinsic waves, regardless of their nucleating sites. This suggests a

biased retinal circuit that favors the propagation of waves in a specific direction on the retina. In addition, we show that pharmacological blockade of inhibition *in vivo*, specifically $GABA_A$ mediated inhibition, diminishes wave directional bias. This result suggests that $GABA_A$ mediated inhibition plays an especially important role in establishing the strong directional bias of spontaneous retinal waves.
In summary, our results suggest a specific developmental stage in which spontaneous retinal waves exhibit a strong directional bias, and that this bias is a result of intrinsic asymmetry in the retinal circuit. This bias could potentially affect visual circuit refinement in the retina and other parts of the visual system during development.

Title: Cholinergic retinal waves are regulated by the dysbindin expression levels in developing retinal ganglion cells

Authors: *T.-L. CHENG[1], M.-H. LU[2], C.-T. WANG[1,3,4,5];
[1]Inst. of Mol. and Cell. Biol., [2]Sch. of Med., [3]Dept. of Life Sci., [4]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan; [5]Genome and Systems Biol. Program, Natl. Taiwan Univ. and Academia Sinica, Taipei, Taiwan

Abstract: Schizophrenia (SCZ) is an idiopathic disease with neurodevelopmental defects. One of the major SCZ susceptibility genes is Dystrobrevin-binding protein-1 (Dysbindin). Previous studies suggested that primary sensory processing, including visual processing, is often impaired in SCZ patients. However, the mechanism of Dysbindin in regulating visual system development remains unknown. During the first postnatal week in rodent, developing retinal neurons display retinal waves, which are essential for the refinement of retinogeniculate synapses. These retinal waves (also termed cholinergic waves) are initiated by starburst amacrine cells (SACs) spontaneously releasing acetylcholine (ACh) and γ-aminobutyric acid (GABA) to neighboring SACs and retinal ganglion cells (RGCs). Our preliminary results suggested that Dysbindin is important for regulating the spatiotemporal properties of cholinergic waves by using non-specific cell-type molecular perturbation. In this study, we aim to delineate the cellular mechanism underlying Dysbindin regulation of cholinergic waves. First, we used immunofluorescence staining to examine the localization of Dysbindin in developing rat retinas (P1-P15) and found

that Dysbindin is highly expressed in synapse layers, such as the inner plexiform layer. Next, we used the cell-type specific promoter (the Brn3b promoter for RGCs) to specifically overexpress or deplete Dysbindin in RGCs. By using live calcium imaging, we further analyzed the wave properties following molecular perturbation. We found that altering the levels of Dysbindin in RGCs specifically changed the interval of cholinergic waves. Therefore, Dysbindin regulation of cholinergic waves may be via RGCs. These results imply that Dysbindin may involve in SCZ pathogenesis through regulating the development of visual circuits.

Title: Neonatal neuronal activity of mouse visual structures in the absence of retinal drive

Authors: *M. S. BERNARDEZ SARRIA[1], N. D. FITZGERALD[2], M. C. CRAIR[2];
[1]Interdepartmental Neurosci. Program, [2]Neurosci., Yale Univ., New Haven, CT

Abstract: Early in the development of the mammalian visual system, retinal ganglion cells fire in a coordinated, synchronous spatiotemporal pattern. This activity spreads through the retina as retinal waves, and propagates along the ascending visual pathway to the thalamus (dLGN), superior colliculus (SC) and visual cortex (V1). A leading hypothesis in the field is that this spontaneous activity is key for the proper establishment of visual circuits. The developmental consequences of removing spontaneous retinal drive on central visual structures remains a topic of intense study, and how this activity affects the functional and anatomical development of the cortex in particular, is still poorly understood. Here, we use perinatal denervation (P0-1 enucleation) or neonatal inactivation (intraocular epibatidine) to assess chronic and acute effects of removing retinal input to visual circuit development. Our in-vivo widefield calcium imaging experiments reveal that cortical activity is robust in early postnatal life (P4). Neither acute nor chronic removal of retinal drive abolish activity in primary visual cortex (V1), but do change its properties dramatically. These results suggest that in the absence of retinal innervation or input, central visual structures use existing circuitry to drive activity in V1. Our studies also show that spatial properties of activity and correlations across visual structures are particularly affected by

these manipulations. The effects of denervation (chronic) and inactivation (acute) share important similarities, but they also show key differences that are likely driven by the effects of longer-term (days) homeostatic mechanisms. Generally, developmental neuroscience holds a retina-centric view with respect to activity-mediated assembly of visual circuits. Our results suggest the presence of important, non-peripheral inputs that may contribute to the development of the visual system, and in particular, V1.

Abstract: Rhythmic patterns of spontaneous activity are essential for the proper formation and maturation of sensory systems and have been described in several structures of the developing brain, including the retina or the thalamus. Previous work from our lab has demonstrated that waves of spontaneous activity in the embryonic thalamus are involved in the formation of cortical sensory maps. In the cortex, most studies of synchronized activity have been done *in vitro* or at postnatal stages when cortical maps are already formed. Here, we used *in vivo* wide-field imaging of calcium transients to identify patterns of activity in the embryonic and early postnatal cortex of the mouse. Using a stimulation paradigm of the whisker pad we were able to correlate the topography of the emerging somatosensory map with the spontaneous activity that occurs at these stages. In early sensory deprivation models, we found that the pattern of calcium activity that prefigures the formation of maps is altered already in the embryo, which unveils that cross-modal plasticity changes occur earlier than previously thought.

Title: Static and dynamic visual search in cerebral visual impairment using virtual reality and multi-modal neuroimaging paradigm

Authors: *C. R. BENNETT[1], E. S. BAILIN[2], C. M. BAUER[3], P. J. BEX[4], L. B. MERABET[5]; [1]Massachusetts Eye and Ear Infirmary, Boston, MA; [2]Mass. Eye and Ear -- Harvard Med. Sch., Boston, MA; [3]Harvard Med. School, Massachusetts Eye and Ear, Boston, MA; [4]Psychology, Northeastern Univ., Boston, MA; [5]MEEI- SERI Harvard Med. Sch., Boston, MA

Abstract: Background: Visual search of static and dynamic scenes involves higher-order visual processing brain regions. Developmental complications can impair the function of these areas and impact visuospatial performance. Evidence suggests that individuals with cerebral visual impairment (CVI) report difficulties with visual search tasks in complex environments. However, the neural correlates of impaired visual search in this population remain unclear. In this direction, we developed a static and dynamic virtual reality (VR) based visual search task and paired them with electroencephalography (EEG) and functional magnetic resonance imaging (fMRI) respectively.
Methods: A cohort of individuals with CVI (aged 16-25 years) and typically sighted controls (aged 14-28 years) underwent testing. Participants carried out visual search tasks in the static and dynamic VR environments, and were instructed to find a target (an object for the static task and a person in the dynamic task) among varying levels of distractors (i.e. other objects or moving people). Eye movement performance was captured with a Tobii 4C eye tracking system (90 Hz sampling). EEG signals were recorded using a wireless 20-channel system (Neuroelectrics) in response to viewing the static visual search task, and subjects underwent fMRI testing while viewing the dynamic visual search task (3T Philips Achieva system).
Results: Behavioral performance showed marked differences between the control and CVI groups for reaction time and quantified gaze data spread in the static and dynamic tasks. Individuals with CVI; (1) took longer to identify the correct target, (2) had notably wider search patterns, and (3) exhibited further impairment under conditions of higher task complexity, when compared to controls. Additionally, these impairments were more pronounced under the dynamic compared to the static task.

Collected EEG data and static visual search in CVI show (1) delayed timing and (2) differences in magnitude of early ERP brain responses (i.e. n170 and p300). fMRI data and dynamic visual search revealed that CVI participants demonstrated reduced activation in key visual processing regions (i.e., V1, hMT+, FFA, IPS). Furthermore, a pattern of increased frontal activation was observed for the CVI group.
Conclusions: Current results suggest that individuals with CVI have difficulty performing static and dynamic visual search. Increasing visual search demands (i.e. increased distractor levels) had a more detrimental effect in the CVI group. Furthermore, the temporal and spatial aspects of neurological responses within higher order visual processing areas reflected observed behavioral deficits.

Abstract: Calcium is an important ion involved in a wide array of physiological processes including regulation of key pathways involved in neuronal development. As such, temporal and spatial calcium dynamics are tightly regulated to accord specificity of signaling during development.In the current study, the vestibular end organs and cochlea were dissected out, incubated with anti-calretinin, anti-parvalbumin, and anti-calbindin antibodies overnight at room temperature and labeled with goat anti-rabbit serum conjugated with Alexa-Fluor 488 for two hours. Following wash, preparations were whole-mounted and examined under confocal microscope. In some preparations, Neuro Vue red nerve tracer was implanted in the vestibular nerve to highlight the brain areas receiving primary vestibular afferents to compare with areas expressing calcium binding proteins and vibratome-sectioned brainstems were then examined by confocal microscopy. At p7, there was robust expression of calretinin protein in all components of the inner ear; the hair cells of the canals' cristae, and in the maculae of the utricle and saccule. The supporting cells, axons neurons in spiral and vestibular ganglia expressed calretinin.

Parvalbumin expression was restricted to the inner hair cells in the basal turn of the cochlea, whereas, in the mid-turn and apical turns the three rows of hair cells expressed parvalbumin. In the vestibular end organs, only type 1 hair cells in the central zone of the cristae and striola regions of the utricle and saccule expressed parvalbumin. Both spiral and vestibular ganglia showed robust expression of parvalbumin. In the brain, calretinin was strongly expressed in the vestibular nuclei, dorsal cochlear nucleus, uvula and nodulus of the cerebellum. Parvalbumin was only expressed in the uvula and nodulus, whereas calbindin was expressed in Purkinje cells of the uvula and nodulus.Our study suggests that all sensory epithelium of the inner ear, including vestibular and cochlear components express at least two of the three calcium binding proteins analyzed. Similarly, all brain areas receiving primary vestibular and primary cochlear afferent express at least one calcium binding protein. We suggest that combinatorial code of the three calcium regulator control early stages of neurogenesis, and axon guidance in the cochleovestibular primary neurons, namely the acquisition of their central and peripheral synaptic targets.

Title: Development of serotonergic fibers and and perineuronal nets in the mouse auditory system

Authors: *K. VENABLE, C. C. LEE;
LSU Vet Sch., Baton Rouge, LA

Abstract: The serotonergic (5-HT) system is a highly conserved neurotransmitter system in mammals, and serotonergic disfunction is implicated in various pathological conditions. The 5-HT system is comprised of multiple receptor subtypes and is involved in crucial aspects of neural development, maintenance, and function, for example neuronal growth and migration, plasticity, and modulation. It is known that serotonin neurons originate in the brainstem and project rostrally and caudally to virtually the entire central nervous system. However, other basic morphological features are yet to be confirmed, e.g. whether serotonin neurons project divergently to multiple levels of the brain (i.e. midbrain and cortex). These features are critical for developing more accurate computational models of auditory processing. Here, we utilized a

mouse model to investigate: (1) the projection patterns and microarchitecture of the serotonergic system through different levels and developmental timepoints in the mouse auditory system, (2) the presence of single divergent 5-HT neurons that project to multiple auditory regions, and (3) the relationship between the serotonin system and perineuronal nets (PNNs). PNNs are critical structures of the extracellular matrix that affect the synaptic plasticity of the neurons they enclose and whose relationship in the auditory system is largely undefined. We utilized immunohistochemical (IHC) detection of serotonin transporters (SERT) and 5-HT for visualizing 5-HT fibers and wisteria floribunda agglutinin (WFA) to detect PNNs at the level of the midbrain to the cortex. Development of these structures were analyzed in male and female C57BL/6J mice at multiple timepoints during postnatal development and adulthood. The association of these structures varies in different auditory regions with age and likely underlies many of the physiological features associated with developing auditory system.

Title: Oxytocin modulates spontaneous activity patters in the developing sensory cortex

Authors: *P. P. MALDONADO[1], A. NUNO-PEREZ[1,2], J. KIRCHNER[3], E. A. HAMMOCK[4], J. GJORGJIEVA[3], C. LOHMANN[1];
[1]Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [2]Dept. of Fundamental Neuroscience, Fac. of Biol. and Medicine, Univ. of Lausanne, Laussane, Switzerland; [3]Max Planck Inst. for Brain Res., Frankfurt, Germany; [4]Psychology, Florida State Univ., Tallahassee, FL

Abstract: Spontaneous network activity occurs before birth and during early postnatal brain development. Specific patterns of spontaneous activity control the establishment and refinement of central sensory pathways that enable the brain to experience the environment. While neuromodulators and their receptors are highly expressed at this stage of development, it is unclear how they modulate spontaneous activity patterns. By combining *in vivo* and *in vitro*, Ca^{2+} imaging and electrophysiology, we investigated the effect of oxytocin on spontaneous neuronal activity of sensory cortices. Cortical oxytocin application strongly decreased the frequency of spontaneous activity events in the visual cortex (V1), but not in the somatosensory cortex (S1). Furthermore, in V1 oxytocin decreased interneuronal correlations. Voltage-clamp

recordings from layer 2/3 neurons in V1 slices revealed that oxytocin increased the frequency of spontaneous IPSCs but not of EPSCs. In contrast, oxytocin had a balanced effect in S1, increasing the frequency of both IPSCs and EPSCs. Oxytocin-induced inhibition was mediated by the activation of somatostatin$^+$ (SST^+) interneurons, since silencing SST^+ neurons pharmacogenetically blocked this effect fully. In addition, oxytocin specifically depolarized V1 SST^+ interneurons, increased their excitability and affected their action potential features. Thus, oxytocin increases the inhibition/excitation ratio and modulates specific features of V1 spontaneous activity patterns that are crucial for refining developing synaptic connections.

Title: SMAD4 mediated signaling is required for the precise formation of the vomeronasal somatosensory map to the accessory olfactory bulb

Authors: *A. NAIK[1], E. M. TAROC[2], R. KATREDDI[3], P. E. FORNI[4];
[1]Biol., Univ. at Albany, Albany, NY; [2]Biol., Univ. at Albany Biol. Dept., Albany, NY; [3]Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada; [4]Biol., SUNY, Univ. at Albany, Albany, NY

Abstract: The vomeronasal organ (VNO) contains two main types of vomeronasal sensory neurons (VSNs) that are located in different regions of neuroepithelium namely Apical and Basal. Apical VSNs express receptors of the V1R family of vomeronasal receptors(VR) and project to the anterior AOB, while basal VSNs express receptors of the V2R family and project to the posterior portions of the AOB. The basal neurons selectively express the transcription factors (TF) Tfap2ε while the apical neurons express the TF Meis2. Unlike the olfactory sensory neurons, VSNs expressing the same VR can innervate multiple glomeruli forming homotypic, heterotypic and mixed connections with dendrites of mitral cells in the AOB. What molecular mechanisms control this synaptic specificity remains largely unexplored. Here, we report BMP signaling gradient in the VNO with strong signaling limited to the basal VSNs. SMAD4 is a key player in TGFβ/BMP signaling pathway. By generating SMAD4 conditional knockouts(cKO) we abrogated the pathway in either immature basal VSNs (Tfap2εCRE; SMAD4flox/flox) or in mature VSNs of both populations (OMPCRE; SMAD4flox/flox). We found that conditional

disruption of SMAD4 mediated pathway in immature basal neurons leads to a progressive neuronal cell loss, however, we found SMAD4 mediated signaling to be dispensable once VSNs have reached maturity (OMP). Immunostaining against the presynaptic marker Vglut2, revealed that both models (Tfap2εCRE; SMAD4flox/flox and OMPCRE;SMAD4flox/flox) had significantly fewer and larger glomeruli only in the posterior region of AOB suggesting altered synaptic specificity for the basal VSNs. Transcriptome analysis from both mouse lines revealed misregulation of genes required for synapse organization and maturation. Moreover, immunostaining for immediate early gene cFOS and phosphorylated ribosomal protein S6, after male urine exposure, revealed loss of odor mediated activation of basal VSNs. Our results show, for the first time, a role for BMP signaling in synaptic specificity and functionality and survival of basal VSNs.

Title: Sensory feedback from myoclonic twitches during active sleep continues to activate sensorimotor structures beyond early infancy

Authors: *J. C. DOOLEY[1], G. SOKOLOFF[3], M. S. BLUMBERG[2];
[2]Dept Psychol, [1]Univ. of Iowa, Iowa City, IA; [3]Psychological and Brain Sci., The Univ. of Iowa, Iowa City, IA

Abstract: Myoclonic twitches, which are produced exclusively during active (REM) sleep, occur predominantly in the perinatal period but also persist into adulthood. In rats, sensory feedback from twitches drives neural activity in sensorimotor cortex from postnatal day (P) 2 through at least P12. However, it is not known whether they continue to drive activity in sensorimotor cortex beyond P12. Here, we recorded neural activity in both the forelimb representation of sensorimotor cortex and the ventral posterior nucleus (VP) of thalamus in unanesthetized preweanling rats from P12 through P20. Rats were head-fixed in a device that allowed them to locomote and cycle between sleep and wake. As expected, the quantity of active sleep decreased substantially from P12 through P20. Nonetheless, neurons in both sensorimotor cortex and VP continued to respond to sensory feedback from twitches; they also responded to sensory feedback from wake movements. That twitches drive thalamic and cortical activity

through at least P20 suggests that twitches continue to promote activity-dependent plasticity. In addition, at P16 and P20 but not P12, we observed prolonged periods of high-amplitude theta (5-6 Hz) oscillations in VP that was restricted to periods of active sleep. This thalamic theta may be related to the presence of continuous and coherent theta oscillations during active sleep in the red nucleus, a midbrain motor nucleus that contributes to the production of forelimb twitches, and hippocampus. All together, these findings suggest that active sleep promotes sensorimotor integration beyond the early neonatal period. Ongoing work is focused on such issues as whether theta influences the patterning of twitches and the processing of twitch-related reafference.

Title: Exploring the role of microglia and the perineuronal net as effectors of plasticity during barrel cortex development

Authors: A. C. BARRIENTOS[1], S. MROZIUK[2], A. LAHIJANI[2], ***J. C. BRUMBERG**[3]; [1]The Grad. Ctr., New York, NY; [2]Queens Col. , Cuny, Flushing, NY; [3]Queens Col. and The Grad. Center, Cuny, Flushing, NY

Abstract: To understand how tactile experience shapes the brain, it is necessary to study the interaction of the cellular and molecular constituents in the primary somatosensory cortex (S1) during critical period (CP) development. Using the mouse barrel cortex as a model system, we examined two key components in neural development and plasticity: Microglia (MG) and the Perineuronal Net (PNN). In early post-natal development, MG fine-tune the cortical wiring diagram in an experience-dependent manner by strengthening synapses while also removing weak or dying synapses while PNNs mature and emerge at the closure of developmental CPs, restricting plasticity into adulthood. Previously, we demonstrated that by altering the physiological state of MG with pharmacological agents, MG adopt morphological changes that correlate to pathological disturbances, and there is reduction of PNNs. Here, we continue to explore the relationship between MG and the PNN in CP development. C57BL/6 mouse litters underwent trimming in addition to random assignment of IP injections of saline (control), minocycline (a MG inhibitor) and lipopolysaccharide (LPS) to C57BL/6 mouse litters. Pups received chronic injections until post-natal day 30. MG morphology, density and PNN density

were examined using immunohistochemical and histochemical staining and stereology (Neurolucida and Stereo Investigator, MBF). We tested the following hypotheses: (1) trimming coupled with LPS injection will interact synergistically yielding in fewer PNNs, and (2) minocycline injection will synergize with trimming and further reduce PNN density and reduce MG density as it did in minocycline-treated mice with intact whiskers. MG density of trimmed LPS- and minocycline-treated mice do not differ from each other, but they both reduce MG density compared to that of trimmed saline-treated controls. We also report that trimming in conjunction with LPS and minocycline-injection reduce PNN density only in thalamo-recipient layers. A regression analysis shows that greater numbers of MG are related to fewer PNNs. Morphometric analyses of MG show differences between soma features of trimmed minocycline- and LPS-treated mice. Minocycline-treatment results in more complex soma contours and hyper-ramification within MG. Taken together, these studies suggest that sensory deprivation may render the developing brain more vulnerable to factors that influence MG activity and which may be related to PNN development.

Title: Disruption of the vomeronasal organ alters mRNA levels of dopamine receptors and steroid-related genes in sexually differentiated brain regions

Authors: *B. JACKSON[1], A. SWIFT-GALLANT[2], M. BREEDLOVE[1], C. JORDAN[1]; [1]Michigan State Univ., East Lansing, MI; [2]Psychology, Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: Mate preference in mice is profoundly affected by the disruption of pheromonal processing by the vomeronasal organ (VNO) when the signaling molecule “transient receptor potential cation channel” (Trpc2) is knocked-out. These knockout (KO) males readily mount same-sex partners and fail to display male-typical aggressive behaviors. KO females display male-typical sexual behaviors such as vigorous mounting towards both same and opposite-sex partners, and significantly reduced maternal aggression. These findings are striking given the well-established role of gonadal hormones in organizing such behaviors. Here, using real-time qPCR, we assessed whether Trpc2-KO males and females differ from same-sex wildtype (WT)

mice in mRNA levels of sex hormone receptors and dopamine receptors (DR) in the vomeronasal olfactory pathway. We find differences in estrogen receptors (ESR1 and ESR2) mRNA in the ventromedial hypothalamus (VMH), and nucleus accumbens (NA) in KO males compared to WT males. KO females show a downregulation of aromatase (Arom) and DR2 in the medial preoptic area (MPOA), and upregulation of DR2, DR3 and DR4 in the VMH compared to WT females. However, the most remarkable differences were that sex differences between KO males and KO females were exaggerated compared to WT males and WT females; while WT males and females differ in Arom mRNA in the bed nucleus of stria terminalis (BNST), medial amygdala and VMH, KO males and females also differ in DR1-5 and ESR2 in the NA, Arom in MPOA, ESR1 in BNST, and ESR1, DR2 and DR3 in VMH. These results suggest that impaired VNO functioning alters hormone and dopamine sensitivity in the vomeronasal olfactory pathway, which may contribute to the behavioral differences observed in Trpc2 KO mice.

Title: Role of Kiss1r in the cellular development of tongue of puberal Wistar rats

Authors: *A. M. JACINTO[1], A. MOLINA[1], B. PAIZ[1], V. ALATRISTE[2];
[1]Ctr. De Investigación Y Estudios Superiores En E, Puebla, Mexico; [2]BUAP, Puebla, Mexico

Abstract: The tongue is an organ that participate in important functions such as chewing, swallowing, language and sense of taste. In tongue, the cell development is regulated by several nervous fibers, growth factors, hormones, and others than nociceptive fibers that are not fully understood. Our objective was to study the role of Kiss1R in the epitheliums of tongue. We used 3 groups of rats, control, vehicle and treated with Kisspeptin-234 trifluoroacetate salt (p-234) 10 nM, n=5 for each group. At age of P24 by a surgical procedure, we injected vehicle (I.S.S. 100 µl) or p-234 (10 nM/ 100 µl of I.S.S.) in each horn of the uterus. Next we determinate the onset of puberty (FVO) when the vagina were completely open. For control, we only determinate the FVO. At the FVO we sacrificed the animals by CO_2 exposure and then we obtained the tongues. The tongues were fixed, and histologically treated to obtain 5 µm slides by microtome. Then some slides were stained with hematoxylin and eosin to determinate the changes in the different epitheliums, other slides were stained with Mason Trichromic to evaluate the connective tissue and finally we located the Kiss1r in the tongues by Immunohistochemestry. Our results show

that the inhibition of Kiss1r produces changes in the level of development of tissues such as mucous but not serous acini, muscle tissue, dorsal epithelium (germinative filiform papillae, lingual tonsils, filiform papillae and fungiform papillae) and the ventral epithelium (stratified smooth). And also, we determinate than there are differences in the Kiss1r expression in the vehicle and p-234 treated rats. We propose that Kiss1r participate in the development of the tissue probably through the regulation of nociceptive pathways.

Title: Inhibition of ventral tegmental area dopamine neurons rescues aberrant locomotor activity induced by prenatal cannabis exposure in male offspring

Authors: *S. ARONI[1], R. FRAU[2], M. MELIS[3], J. F. CHEER[4];
[1]Univ. of Maryland, Sch. of Med., Baltimore, MD; [2]Univ. of Cagliari, Cagliari, Italy; [3]Univ. of Cagliari, Monserrato, Italy; [4]Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Epidemiological studies report that prenatal cannabis exposure (PCE) increases the risk of developing schizophrenia in adulthood. Moreover, PCE predisposes to behavioral and cognitive deficits including hyperactivity, enhanced impulsivity, loss of sustained attention and increased sensitivity to drugs of abuse. These neuropsychiatric impairments are associated with dopaminergic signaling dysfunction, a phenomenon common in schizophrenic patients. However, the mechanisms through which PCE alters brain development leading to the manifestation of neuropsychiatric disorders are still unclear. Hence, we hypothesized that PCE induces behavioral dysfunction by enduringly altering the mesolimbic dopaminergic system. Long Evans dams expressing cre recombinase under the control of the TH promoter (TH::Cre) received Δ^9-tetrahydrocannabinol (THC) or vehicle (2 mg/kg/ml, daily) from gestational day 5 (GD5) to GD20. This low dose of THC does not elicit tolerance after repeated administration. A novel open field test was performed in male offspring at postnatal day 27-28 (PND27-28), corresponding to human pre-adolescence, under basal conditions and after an acute administration of THC (2.5 mg/kg/2 ml). Next, we evaluated the role of mesolimbic dopamine (DA) transmission by injecting a cre-dependent adeno-associated virus expressing an inhibitory DREADD (AAV5-DIO-hM4D(G_i)-mCherry) to target DA neurons in the ventral tegmental area

(VTA) of TH::Cre positive offspring. Open field testing was performed 30 minutes following systemic administration of clozapine-N-oxide (CNO, 3 mg/kg/2 ml i.p.) to activate VTA G_i-DREADDs . No differences were observed in spontaneous locomotor activity between vehicle and PCE offspring unless they were challenged with THC. Notably, acute THC paradoxically heightened the total distance traveled and the velocity (as opposed to canonical hypolocomotor response induced by acute THC) in PCE rats. Remarkably, THC-induced hyperlocomotion was curtailed in animals injected with G_i-DREADDs. These data suggest a causal involvement of VTA DA neurons in the paradoxical hyperlocomotor response to THC in PCE rats. Our findings improve the knowledge about the complex neurobiological processes underlying the pathophysiology of PCE-induced psychiatric disorders. We are currently running *in vivo* fiber photometry, to measure *nucleus accumbens* (NAc) DA transients in PCE-exposed adult animals, in order to further investigate the PCE-induced mesolimbic DA system disruption and the risk to develop compulsive drug-seeking behavior in adulthood.

Title: Examining the effects of early life SSRI antidepressant exposure on hippocampal metabolism and morphology

Authors: *K. A. UNROE[1], M. E. GLOVER[2], E. A. SHUPE[2], C. R. MCCOY[2], S. M. CLINTON[2];
[1]Translational Biology, Medicine, and Hlth., [2]Sch. of Neurosci., Virginia Tech., Blacksburg, VA

Abstract: Selective serotonin reuptake inhibitor (SSRI) antidepressants are commonly prescribed to treat pregnant and postpartum women suffering from depression. While SSRIs are generally considered safe to use in pregnancy, growing evidence shows that *in utero* SSRI exposure can elicit detrimental effects on offspring's emotional health, including increasing risk for depression. Rodent studies support these findings, showing that early life exposure to SSRIs alters brain development and leads to increased adult depression-like behavior. Work in our laboratory found that perinatal SSRI exposure triggered changes in DNA methylation and gene expression in the early postnatal hippocampus, with numerous alterations occurring in genes involved in neurodevelopment, metabolism, and synaptic plasticity. Based on these findings, we now hypothesize that perinatal SSRI exposure alters hippocampal circuit formation through

changes in dendritic spines and/or metabolic activity. To test this idea, we treated adult female Sprague Dawley rats with the SSRI citalopram (10 mg/kg/day) in drinking water (or vehicle - tap water) throughout pregnancy and the three-week postpartum period. Brains were harvested from male and female offspring at two developmental time points - postnatal day (P)14 when prominent perinatal SSRI-induced molecular changes were previously found and P75 when behavioral abnormalities are observed. A subset of the brains were processed for Golgi-Cox staining to evaluate dendritic spine density in subregions of the hippocampus (Cornu Ammonis, CA and dentate gyrus) of perinatal SSRI-exposed and control offspring. The remaining brains were processed for a histochemical assay to measure the activity of cytochrome c oxidase (COX), a proxy for basal metabolic activity. Our initial COX activity analysis focused on subregions of the hippocampus, but we later extended the assessment to the prefrontal cortex, habenula, and nucleus accumbens to test whether perinatal SSRI exposure affected metabolic activity beyond the hippocampus. Our results so far show that early life SSRI exposure increases COX activity in the adult male and female CA hippocampus and dentate gyrus. Ongoing analyses will determine whether these changes occur at earlier time points and whether other brain regions are affected. Likewise, the ongoing dendritic spine studies will test whether perinatal SSRI-related metabolic changes are associated with concomitant alterations of dendritic spine density and/or morphology. Together, these data will provide important information regarding the impact of perinatal SSRI exposure on brain development and emotional behavior.

Title: Multimodal identification of molecular layer neurons in the mouse hippocampal formation

Authors: *M. ANSTÖTZ[1], G. MACCAFERRI[2];
[2]Dept Physiol, [1]Northwestern Univ., Chicago, IL

Abstract: Information originating from the entorhinal cortex reaches the hippocampus via layer specific projections that reach the molecular layers. Here local circuits composed by GABAergic interneurons (INs) and glutamatergic Cajal-Retzius cells (CRs) integrate entorhinal input and produce physiologically-meaningful signaling. Therefore, the properties of specific and different types of local neurons in the molecular layers are important determinants of hippocampal

computations.
Unfortunately, several studies are based on a mistaken identification of the cells studied. For example, they often miss the important fact that the hippocampal molecular layers of adult rodents still contain CRs and consider every cell of the molecular layer as INs or, alternatively, they misidentify reelin-expressing INs for CRs by not considering that reelin is not a univocal molecular marker.
Here, we try to provide clear methodological criteria to allow an unambiguous distinction between these two different cell types.
First, we have used transgenic reporter mice and immunohistochemical experiments to show distinct spatio-temporal dynamics of these two neuronal populations. CR-cells appear clustered with a strong decrease in density during development. In contrast INs displayed a spatio-temporally homogenous distribution. Second, we have evaluated a series of molecular markers such as reelin, calretinin, CoupTF2, and p73 by quantifying the specificity of expression in both populations.
Third, we have used combined patch-clamp electrophysiology and post-hoc structural reconstructions to reveal key morphological parameters that could lead to the distinction of INs from CRs.
Lastly, we have taken advantage multivariate analysis to produce a clear and specific identification of distinct neuronal populations such as INs and CRs.
We hope that our new results and methodology will help avoid future ambiguity and potential mistakes in cellular investigations of the molecular layers.

Title: Foxp2 dependent formation of the social brain and sex specific function in social behaviors

Authors: *L. WANG[1], M. J. HERRERO[1], M. GOODRICH[1], T. SASAKI[1], C. LAZARSKI[2], Y. IMAMURA[3], A. PANIGRAHI[2], N. A. SMITH[1], K. HASHIMOTO-TORII[1], J. G. CORBIN[1]; [1]Ctr. for Neurosci. Res., [2]Ctr. for Cancer Immunol. Res., Children's Natl. Med. Ctr., Washington, DC; [3]Genome Sci. and Bioinformatics Core, Penn State Col. of Med., Hershey, PA

Abstract: The *Foxp2* gene encodes a transcription factor that is expressed in a variety of brain regions including the cerebral cortex, striatum, cerebellum and the amygdala. *Foxp2* is required for a variety of developmental processes including neuronal specification and dendrite formation. *Foxp2* mutations in humans are associated with language deficits and autism. One region of high expression of *Foxp2* is the medial subnucleus of the amygdala (MeA), which is involved in the regulation of social behaviors such as reproduction and defense. Our previous studies have revealed that Foxp2+ neurons in the MeA are a subclass of inhibitory output neurons and are activated in a sex-specific manner during mating and aggressive behaviors (Lischinsky et al., *eLife*, 2017). Based on these findings, we hypothesized that *Foxp2*-lineage neurons in the MeA express cohorts of genes/proteins involved in social behaviors and function in specification of neuronal circuits regulating social behaviors. To test this hypothesis, we first assessed expression of genes via biased and unbiased approaches in *Foxp2*-lineage neurons at both embryonic and postnatal stages. We further assessed *Foxp2*-lineage responses to application of different neuromodulators known to act in the MeA. We then conducted a wide battery of behavioral assessments in male and female *Foxp2+/-* mutant mice, including 3-chamber social interaction, olfactory discrimination, mating assays, resident-intruder aggression, predator odor aggression and maternal aggression. We found that *Foxp2+/-* mice displayed impaired social interaction and olfactory discrimination behaviors in a sex-specific manner. Correlating with these behavioral deficits were alterations in protein expression in the *Foxp2+/-* MeA. Thus our current results suggest that *Foxp2* may activate sex-specific genetic programs to regulate sex-specific social behaviors, which could help to better understand amygdala-linked and sex-biased developmental disorders, such as autism.

Title: Establishment of a mouse model carrying mutant DDP1 gene

Authors: *Y. HU, P. SONG;
Nanfang Hosp., Guangzhou, China

Abstract: Deafness-Dystonia-Optic Neuropathy (DDON) Syndrome, also known as Mohr-Tranebjaerg Syndrome (MTS; MIM 304700), is a rare progressive X-linked recessive disorder characterized by deafness, dystonia or ataxia and reduced visual acuity. *DDP1* (Deafness/Dystonia Peptide 1), which is also named as *TIMM8A* (Translocase of Inner Mitochondrial Membrane 8A) is the only causative gene. However, no DDON disease model mouse has been established and the molecular mechanism is still unclear. In the present study, we characterized a DDON patient with a novel hemizygous variation in *DDP1/TIMM8A* gene (NM_004085.3): c.82C>T (p. Q28X). Further, based on this variant, we generated a mouse line carrying hemizygous variation in *DDP1/TIMM8A* by clustered regularly interspaced short palindromic repeats (CRISPR)/Cas9 technology. *DDP1*$^{I23fs49X/y}$ mutant male mice exhibited reduced body weight, elevated hearing threshold, impaired learning ability, reduced forelimb grip strength, and impaired pain perception at early ages. However, balance and motor coordination and visual acuity were unaffected in mutant mice. On the molecular basis, immunofluorescence and electron microscopic analysis showed the distribution of variant DDP1 proteins (DDP1 Q28X or DDP1 I23fs49X) were changed. Variant DDP1 made mitochondria appeared rounder and swollen with broken cristae, especially in the primary auditory cortex (Au1) of mutant mice. In addition, Western blot analysis showed reduced levels of DDP1 do not affect biogenesis of mitochondrial oxidative phosphorylation system (OXPHOS) protein and soluble matrix protein SOD-2. Taken together, we have successfully generated the a first mouse model with DDP1 gene frame shift mutation , which recaptured many symptoms or signs of DDON syndrome. DDP1 variations result in changes in the localization and mitochondrial morphology.

Title: Dose dependent anxiogenic effect of levetiracetam during pregnancy on an epilepsy model in Wistar rats and its relationship with SV2A in hippocampus of the offspring

Authors: *M. F. PINTO-GONZÁLEZ[1], N. A. MOY-LÓPEZ[1], J. GUZMÁN-MUÑIZ[1], N. Y. CORTÉS-ÁLVAREZ[1], O. P. GONZÁLEZ-PÉREZ[1], J. L. COLLÁS-AGUILAR[1], C. M. GAITÁN-VAZQUEZ[2], M. FLORES-RAMIREZ[3];

Abstract: During pregnancy, both maternal epilepsy and classic anticonvulsive use may have teratogenic effects over the development of the central nervous system. By other hand, use of new generation anticonvulsive drugs, as Levetiracetam (LEV) may be a safe option for seizure control during pregnancy without affecting the development of the progeny, such as changes in the expression of synaptic vesicle protein 2A (SV2A), LEV binding site. Our aim was to analyze the anxiogenic effect of growing doses of LEV during pregnancy on an epilepsy model and its relationship with SV2A expression in the hippocampus of the offspring. 12 nulliparous female rats at 90 days of age were divided in 6 groups with different conditions: 1) negative control, saline solution (SS); 2) Positive control LEV 25 mg/kg in SS (LEVSS); 3) LEV 25 mg/kg with previous exposition to Picrotoxin (LEV25); 4) 50 mg/kg LEV-PTX (LEV50); 5) 100 mg/kg LEV-PTX (LEV100); and 6) Exposure to PTX with SS only (PTX). 1.5 mg/kg of PTX or saline solution for 10 days were given for the epilepsy model. Resulting female and male pups were considered as the study subjects (n=120, 20 per group). Anxiety evaluation was made on P42 using the elevated plus maze (EPM), results from EPM were analyzed by anxiety index. To see if there was an effect over mobility, open field test was also applied to identify changes in total distance moved and speed. Tissue was obtained also in P42 to measure Hippocampal expression of SV2A by immunohistochemistry and evaluated with optic density. According to data normality, Kruskall-Wallis was applied. Results from the anxiety index showed significant differences according to treatment ($H=11.526$, $gl=5$, $p=0.009$), while posterior contrast analysis showed that LEVSS group presented a decreased anxiety index compared with control group (SS). By other hand, mobility also showed significant differences in distance traveled ($H=9.276$, $gl=5$, $p=0.026$), and velocity ($H=9.211$, $gl=5$, $p=0.027$), which in the contrast analysis were also related to differences between SS and LEVSS groups, having LEVSS pups an increased mobility compared to SS. There were no differences between control group and the ones with other conditions in behavioral test. While in SV2A hippocampal expression, there was no statistical difference between control group and those who were administered LEV, PTX group showed a significant increased SV2A expression in C3 and DG areas, compared with the rest of the groups ($p<0.05$). Results suggest that LEV exposure during critical periods of brain development without PTX exposure may lead to an anxiolytic effect, while preventing changes on SV2A expression when dams are previously exposed to a PTX epilepsy model.

Title: Early life exposure to the SSRI citalopram alters limbic expression of Brain-specific angiogenesis inhibitor 3 (Bai3) and associated ligands in a sex-dependent manner

Authors: *E. A. SHUPE[1], M. E. GLOVER[1], K. A. UNROE[2], S. M. CLINTON[1];
[1]Sch. of Neurosci., [2]Translational Biology, Medicine, and Hlth., Virginia Tech., Blacksburg, VA

Abstract: Selective Serotonin Reuptake Inhibitors (SSRIs) are the mainstay antidepressant treatment for the 10-20% of pregnant and postpartum women who suffer from major depression. Although maternal antidepressant use is considered generally safe, producing minimal risk for pregnancy complications or teratogenic effects, *in utero* exposure may elicit enduring effects on neurodevelopmental and neuropsychiatric outcomes in the offspring. Clinical and basic scientific research both suggest that early-life SSRI exposure may increase risk of depression in adulthood. Consistent with clinical findings, studies in rodents demonstrate that perinatal exposure to SSRIs disturbs multiple behavioral domains relevant to depression, contributing to increased anhedonia, behavioral despair, and anxiety. Recent data by our laboratory have replicated these findings to show that perinatal citalopram exposure increases anhedonia and behavioral despair in both male and female adult rat offspring. In addition, our laboratory has demonstrated that signaling of Brain-specific angiogenesis inhibitor 3 (Bai3), an adhesion G-protein coupled receptor involved in regulating synaptogenesis and dendritic spine formation, is altered by perinatal exposure to multiple SSRIs in rats. The present study tests the working hypothesis that perinatal exposure to the SSRI citalopram alters neurodevelopmental and behavioral outcomes in part through disruptions in Bai3 signaling. To test this, we examined mRNA expression of Bai3 and associated signaling molecules, including C1ql1-3 and Elmo2, during early development (postnatal day (P)14) and in adulthood (P60) in limbic brain regions of male and female rat offspring exposed to the SSRI citalopram from gestation through weaning. At P14, expression of the Bai3 ligand C1ql3 in the dorsal CA of the hippocampus is increased in female, but not male, offspring exposed to citalopram. By P60, C1ql3 expression in control female offspring is elevated relative to male offspring, but female perinatal SSRI-exposed offspring show decreased levels compared to control females. Further, in the prefrontal cortex, Bai3 and C1ql3 expression are enhanced in perinatal SSRI-exposed female, but not male, offspring at P14, an effect which does not persist at P60. Altogether, these findings raise important considerations for the use of SSRIs during pregnancy and suggest a possible role of the Bai3 signaling pathway in the

etiology of depression-like behavior in SSRI-exposed offspring, as functional changes during development in limbic structures including the hippocampus likely contribute to increased vulnerability for depression in adulthood.

Title: Small molecules to correct the alternative splicing of human mutant ELP1 transgene in mouse models of familial dysautonomia

Authors: *X. ZHAO[1], J. NARASIMHAN[1], A. DAKKA[1], V. GABBETA[1], S. JUNG[1], A. MOLLIN[1], N. ZHANG[1], J. WANG[1], S. ZHANG[1], E. MORINI[2], P. DIETRICH[3], M. SALANI[2], I. DRAGATSIS[3], S. A. SLAUGENHAUPT[2], G. KARP[1], N. A. NARYSHKIN[1], M. WEETALL[1];
[1]PTC Therapeutics, Inc., South Plainfield, NJ; [2]Mass Gen. Res. Inst., Boston, MA; [3]Dept. of Physiol., Univ. of Tennessee, Memphis, TN

Abstract: Introduction: Familial dysautonomia (FD) is an autosomal recessive inherited disorder of the nervous system that affects the development and survival of autonomic and some sensory neurons. Originally reported by Riley et al in 1949, FD is now recognized as one of several hereditary sensory and autonomic neuropathies. More than 98% of patients have been of Ashkenazi Jewish descent.
FD is caused by a mutation that results in a change in the mRNA splicing mutation resulting in the tissue-specific skipping of exon 20 and a corresponding reduction of the Elongator complex protein 1 (ELP1).
Methods and Results: Through chemical screening and optimization, we identified orally available small molecules that correct the ELP1 mRNA splicing resulting in full-length mRNA. These compounds are able to increase full length ELP1 mRNA and ELP1 protein in patient fibroblasts . Oral administration of these compounds to mice that express the human mutant ELP1 transgene, led to an increase in ELP1 protein in multiple PNS and CNS tissues in a dose dependent manner .
A phenotypic mouse, TgFD9; ELP1Δ20/flox carries the human mutant IKBKAP transgene and expresses extremely low levels of endogenous ELP1 (ELP1Δ20/flox). It recapitulates many phenotypic features and same tissue-specific mis-splicing defect seen in FD patients, including reduced growth rate, reduced number of fungiform papillae, spinal abnormalities, sensory and sympathetic impairments .

We hypothesized that a small level of ELP1 elevation during the early development in brain or in peripheral nerve system may lead to phenotypic improvements in our animal models. We observed that TgFD9; ELP1Δ20/flox have a reduced birth rate (less than the expected ratio). We found that ELP1Δ20/Δ20 mice, expressing less ELP1 protein resulted in 100% embryonic lethality. On the contrary, the survival of a milder line (TgFD9; ELP1flox/flox) was close to 100% and achieved almost normalized body weight. The correlations between total ELP1 and survival and phenotypic severities in these mice will be needed for further investigations. Conclusions: Small molecule splicing modifiers of the human mutant ELP1 mRNA associated with FD have shown efficacy in both cellular and animal models of familial dysautonomia.

Abstract: Cabin1, an inhibitor of calcineurin and MEF2 activity, is enriched in developing neurons and neural crest tissues. Previously we discovered that knockdown of Cabin1 gene expression resulted in diminished sensorimotor responses and craniofacial abnormalities. To further validate our preliminary findings, we have established zebrafish strains with Cabin1 gene knockout using CRISPR/Cas9 genome editing. In the knockout strains, we recover half of the expected rate of Cabin1 homozygous mutants based on Mendelian inheritance, with the loss occurring during larval stages. Furthermore, the surviving mutants are significantly smaller in size than their wild type and heterozygous siblings. Behavioral testing of mutant fish revealed a

specific defect in response to visual stimuli. As previously observed in the Cabin1 knockdown fish, Cabin1 homozygous mutants also display abnormal jaw morphology. We are currently testing the hypothesis that defects in visual behavior and jaw morphology impact feeding capability, ultimately leading to the observed decrease in larval growth and survival.

Title: Developing a modifier screen for novel regulators of the hippo tumor suppressor pathway in *Drosophila*

Authors: *W. R. MEARA, J. RISTER;
Univ. of Massachusetts Boston, Boston, MA

Abstract: Carefully regulated gene expression creates an enormous variety of neurons. Signaling pathways are often repurposed to differentiate sensory neurons, however the mechanistic details of this process are not fully understood. One example is the highly conserved Hippo tumor suppressor pathway, which is used to differentially express color sensitive Rhodopsin (Rh) proteins in a subset of Drosophila photoreceptors. This results in a mutually exclusive decision to either express blue-sensitive Rh5 (~35%) or green-sensitive Rh6 (~65%). Reuse of the Hippo pathway in photoreceptors offers an exciting new context to screen for tumor suppressors and growth regulators using the binary readout of Rh5 (Hippo off) vs. Rh6 (Hippo on). We established a paradigm to identify genotypes with abnormal Rh5:Rh6 ratios in a high throughput manner using water immersion microscopy and an Rh5>gfp reporter. We have found multiple genotypes that exhibit increased or decreased ratios of Rh5:Rh6 that can serve as genetic backgrounds in modifier screens for novel Hippo regulators. We also discovered an Rh6 derepression phenotype that was analyzed using complementation tests. These findings will further our understanding of the Hippo pathway and photoreceptor differentiation.

Title: Alterations in patterns of gene expression in the Brazilian short-tailed opossum (Monodelphis domsetica) due to early loss of vision

Authors: *M. ENGLUND[1], R. T. BOTTOM[2], R. F. PEREZ, JR[2], K. J. HUFFMAN[3], D. S. STOLZENBERG[1], L. A. KRUBITZER[4];
[1]Psychology, Univ. of California Davis, Davis, CA; [2]Neurosci., [3]Psychology/Neuroscience, Univ. of California, Riverside, Riverside, CA; [4]Neurosci., UC Davis, Davis, CA

Abstract: Spontaneous activity from the periphery and experience-dependent mechanisms work in concert during development to generate the functional organization and connectivity of the neocortex. Early loss of sensory input dramatically alters how this developmental program unfolds. To study the effects of vision loss, we used the Brazilian short-tailed opossum (Monodelphis domestica), which has a well-developed visual cortex and is highly altricial at birth. Previous work in our laboratory has shown that when visual input is lost very early in development, neurons in would-be visual cortex respond to somatosensory and auditory stimulation. In addition, V1 receives input from both the primary auditory (A1) and the primary somatosensory (S1) areas. To appreciate how the developmental program is altered to produce these observed changes, we bilaterally enucleated opossums at postnatal day (P) 4, prior to the onset of spontaneous retinal activity and before thalamocortical axons have reached the cortex. We then took micropunches from V1 and S1 just after eye opening at P36, when experience-dependent pruning of visual cortex is underway, and used qPCR to test for differences in gene expression levels within fields, and in-situ RNA hybridization (ISH) to assess expression patterns across the cortex. Data from qPCR experiments show that experimental P36 animals enucleated at P4, have significant decreases in the expression of patterning genes within the region corresponding to visual cortex in controls. These genes, Id2 and RZRβ, are involved in areal and laminar patterning and regulate the development of intraneocortical connections. Additionally, we observed a relative reduction in GABAa receptor and Ephrin A5 expression in V1 of early blind animals. Utilizing our newly developed in-house, Python based toolbox for quantifying gene expression gradients across the entire cortex from raw ISH data, we found that the expression of Id2 and RZRβ were shifted medially in P36 animals enucleated at P4 compared to control P36 animals. Futhermore, lateral to the V1/V2 boundary, Id2 expression was significantly increased in P36 animals enucleated at P4 compared to sighted controls.

Interestingly, this heightened expression co-registers with the previously defined 'Area X,' a heavily myelinated region observed in adult early blind animals. In sum, our data suggests that the early loss of vision results in cortex-wide alterations to gene expression patterns in areas that process both the spared and lost senses.

Title: ErbB2 signaling drives cochlear supporting cell and GER cell proliferation *in vitro* and hearing improvement after noise *in vivo*

Authors: *J. ZHANG[1], L. SHAH[1], J. LIU[2], K. S. HENRY[3], P. WHITE[1];
[1]Dept. of Neurosci., [2]Dept. of Pathology, [3]Dept. of Otolaryngology, Univ. of Rochester, Rochester, NY

Abstract: Hearing is the ability to detect and perceive sound, an important quality in human activities. Hearing loss follows when cochlear hair cells (HCs) are damaged or lost due to various factors, such as ototoxic insults and exposure to noise. In mammals, HCs are not regenerated once they die, resulting in permanent hearing impairment. Moreover, some insults drive hearing loss even though HCs persist, suggesting cochlear dysfunction. Here we report on the effects of expressing constitutively activated ERBB2 receptors (CA-ERBB2) in mouse cochlear SCs. We used a Tet-On transgenic strategy to achieve ERBB2 gain-of-function at different stages.
Perinatally, CA-ErbB2 activation in cochleae can be accomplished by crossing a Tet-On CA-ErbB2 line with an inner ear specific rtTA line, Sox10-rtTA. Such expression is under temporal control by doxycycline application to cochlear culture from postnatal age day 2 (P2). Significant proliferation was observed in SCs and in the cochlear greater epithelial ridge (GER) region upon CA-ErbB2 activation. HC damage in combination with CA-ERBB2 treatment may deliver different effects, which are under investigation both *in vivo* and *in vitro*.
In young adults, we adopted a similar transgenic approach to activate CA-ErbB2 in SCs. To assess the potential therapeutic effects from CA-ERBB2, we exposed mice with strong noise,

consisting of an 8-16 kHz band at 110 dB for two hours. This noise exposure drove temporary thresholds shifts of an average of 30 dB and permanent threshold shifts of 25 dB across all auditory frequencies. Here we report significantly improved auditory thresholds in mice that endured such level of noise but were treated with CA-ERBB2 expression in their cochlear SCs. Cochlear HCs, as the primary sound transducers, were largely preserved in both control and CA-ERBB2 groups. Synapses between HCs and auditory nerves, the connecting parts from the cochlea to the brain, are currently under investigation.
Previous studies suggested the potential roles of EGF family ligands in promoting regeneration. We report that the expression of a constitutively active receptor, ERBB2, involved in this signaling pathway correlates with proliferation in cochlear SCs at early stage and improved hearing after noise damage at young adulthood. The underlying mechanisms for this improvement will be the focus of future study.

Title: Kappa-opioid receptor regulated dopamine clearance is linked to dopamine transporter phosphorylation

Authors: ***S. RAMAMOORTHY**[1], D. RAGU VARMAN[1], A. E. MORITZ[2], R. HORTON[3], M. VITELA[3], L. C. DAWS[3], J. D. FOSTER[2], L. D. JAYANTHI[1], R. A. VAUGHAN[2], T. SHIPPENBERG[4];

Inst. on Drug Abuse/IRP, Baltimore, MD

Abstract: Dynorphin (DYN), its receptor, the kappa opioid receptor (KOR), and mesolimbic dopamine (DA) neurotransmission systems are implicated in the pathogenesis of depression and addiction. DYN-fibers synapse onto DA terminals, and KOR are expressed on these same DA terminals. This anatomical co-presence of Dyn/KOR structures on DA neurons suggests that the presynaptic DYN/KOR system may modulate DA transmission. Indeed, KOR agonists decrease

DA release and extracellular DA concentrations. Effective clearance of released DA from the extracellular space by the DA-transporter (DAT) is one of the critical factors regulating dopaminergic neurotransmission. Previously, we demonstrated that KOR agonists upregulate DAT activity by increasing surface DAT expression through extracellular signal-regulated kinase1/2 activation (ERK1/2) (PMC4188751). DAT is a phosphoprotein, and whether DAT phosphorylation is involved in KOR- mediated DAT regulation and trafficking is unknown. In the current study, we investigated the role of DAT phosphorylation in mediating acute KOR regulation of rat DAT (rDAT). KOR agonist U69,595 increased DAT activity in cells coexpressing KOR and rDAT. We discovered that the N-terminal region (amino acids 23-55) of rDAT is involved in KOR-mediated rDAT upregulation. Immunoblot studies using a phosphoThr53-DAT antibody revealed that U69,593 treatment stimulated Thr53 phosphorylation of rDAT in cells coexpressing KOR, which was blocked by the KOR antagonist nor-binaltorphimine (nor-BNI). U69,593 mediated Thr53 phosphorylated rDAT was predominantly found on plasma membrane-resident rDAT. Mutation of Thr53 to Ala53 in rDAT prevented U96,593/KOR-enhanced DAT activty and Vmax, as well as surface expression and phosphorylation. Increased Thr53 phosphorylation of native rDAT was observed in rat nucleus accumbens and caudate putamen following systemic administration of KOR agonist U69,593. Furthermore, *in vivo* high-speed chronoamperometry studies demonstrate that while KOR-agonist U69,593 accelerate DA clearance, KOR-antagonist nor-BNI prolonged DA clearance from extracellular space. In conclusion, our findings provide the first evidence that phosphorylation of Thr53 in DAT protein is required for KOR mediated DAT upregulation in the central nervous system.

Title: Dopamine transporter as a master regulator of functional connectivity and network topology of dopaminergic and GABAergic networks

Authors: *D. R. MILLER[1], D. T. GUENTHER[2], J. J. LEBOWITZ[1], A. J. REFOWICH[1], C. A. HANSEN[1], A. P. MAURER[2], H. KHOSHBOUEI[1];
[1]Neurosci., [2]Evelyn F. McKnight Brain Inst., Univ. of Florida, Gainesville, FL

Abstract: Dopamine neurotransmission plays a significant role in a plethora of behaviors from learning and memory, to motivation and addiction. Dopaminergic information is transmitted by consensus through synchrony (Beeler and Dreyer, 2019). The spatial temporal kinetics of dopamine signaling, comprising diffusion and synaptic transmission, are heavily regulated by dopamine transporter. Therefore, we hypothesized that perturbations in dopamine transporter activity will induce aberrant synchrony between dopaminergic neurons that alters the structure of local dopaminergic and GABAergic networks. To examine dopamine transporter regulation of GABAergic networks in the ventral midbrain regions, neurons were transduced with an AAV5 containing the genetically encoded calcium indicator GCaMP6f. Neuronal somas were segmented, and time resolved calcium signals were used as a proxy for neuronal activity. Networks were constructed by the top 15% strongest temporal functional connections at baseline (aCSF) before and after dopamine transporter activation through Spearman's rank correlation coefficient. In GABA networks, methamphetamine (a dopamine transporter activator) exposure produced a D2 receptor-sensitive network suppression and induction of subsets of strongly connected neurons to drop out from the network. Furthermore, methamphetamine altered the time course of network assortativity of GABA networks ($n = 71$ to 134 neurons, 6 independent experiments, one-way ANOVA with Tukey's post-hoc multiple comparisons, $p < 0.05$). To examine dopamine transporter regulation of dopaminergic networks, 200 μm coronal slices were prepared from the ventral midbrain comprising both the dopaminergic neuron rich regions substantia nigra pars compacta and ventral tegmental area of male and female mice. In both regions and sexes, dopamine transporter activation by methamphetamine increased the variance of functional connectivity that persisted even after blockade of GABA, glutamate and dopamine receptors signaling but sensitive to dopamine transporter blockade ($n = 5$ to 11 slices from 1-3 animals per group, one-way ANOVA with Tukey's post-hoc multiple comparisons, $p < 0.05$). Since this preparation is devoid of input from other brain regions, the induction of functional connectivity spikes is likely due to the intrinsic properties of dopaminergic neurons to self-organize their activity. Therefore, dopamine transporter is a fundamental regulator of dopaminergic synchrony, exhibiting cascading effects across both local dopaminergic and GABAergic networks. Our data reveal the central role of dopamine transporter activity in functional network modulation.

Abstract: Introduction: Parkinson's disease (PD) is characterized by loss of substantia nigra (SN) dopaminergic neurons, resulting in reduced CNS dopamine transmission. PD is widely thought to start in the periphery; however, whether and how PD affects peripheral dopamine transmission remains unknown. Peripheral immune cells express key dopaminergic proteins, including dopamine transporter (DAT) and tyrosine hydroxylase (TH). Therefore, it is possible that the peripheral dopamine system is affected by PD pathology. Objective: We hypothesized that peripheral immune cells of PD patients exhibit dysregulated dopamine homeostasis. Methods/Results: Using flow cytometry we found human peripheral blood mononuclear cells (PBMCs) constitutively express DAT and TH with 90% of CD14+ cells expressing both markers. Upon examining PBMCs of PD patients receiving a variety of treatments, we found that DAT/TH positive PBMCs are elevated in PD patients compared to healthy controls (n=67 independent biological replicates, $P<0.05$) irrespective of the treatment modality applied. Importantly, in drug naïve patients diagnosed with PD we observed the highest increase in DAT/TH positive monocytes (n=5, $P<0.05$) compared to both treated PD patients and healthy individuals, suggesting observed changes correlate with disease pathology and not treatment interventions. Collectively, these data suggest a system-wide dysregulation of the dopamine system on peripheral immune cells in PD. To further understand the functional consequences of increased DAT+/TH+ PBMCs, we asked if DAT function was altered on PD monocyte-derived cells. Live cell fluorescence microscopy and biochemical analysis confirmed healthy human

monocyte-derived macrophages (MDM) express membrane-localized, canonically functional DAT (Km=3.2mM). Surprisingly, relative to healthy age-matched controls, PD patients' MDMs exhibited dramatically elevated DAT-mediated substrate uptake and increased membrane localization ($p<0.0001$, n=5 biological replicates). Conclusions: Taken together, these data are consistent with the interpretation that in PD peripheral dopamine homeostasis is dysregulated. Importantly, this presents PBMC DAT/TH as a potential biomarker for PD and suggests the peripheral dopamine system is functionally linked to the CNS dopamine system. Future work will aim to validate this biomarker and investigate the mechanistic connection between peripheral-CNS dopamine systems to elucidate the pathophysiological role of dysregulated monocyte dopamine transmission in PD.

Title: Exposure to ambient fine and ultrafine particles alters dopaminergic transmission *in vitro*

Authors: *M. A. ANDRADE OLIVA[1], Y. DEBRAY-GARCIA[2,4], J. ESCAMILLA-SANCHEZ[1], R. GONZALEZ-PANTOJA[1], M. URIBE-RAMIREZ[3], A. DE VIZCAYA-RUIZ[3], J.-A. ARIAS-MONTANO[1];

Abstract: Parkinson's disease, depression and schizophrenia have been associated with alterations in dopaminergic transmission and exposure to environmental pollutants, such as fine (FP < 2.5 μm) and ultrafine particles (UFP < 0.1 μm). The striatum is a neuronal nucleus with extensive dopaminergic afferents and a target of particle toxicity, which results in oxidative stress, inflammation, astrocyte activation and modifications in dopamine content and D_2 receptor (D_2R) density. In this work, FP or UFP were collected and characterized from the air of Mexico City. In striatal synaptosomes, exposure to FP and UFP inhibited [^{3}H]-dopamine uptake and increased depolarization-evoked [^{3}H]-dopamine. In membranes from rat striatum or CHO-K1 cells transfected with the long isoform of the human D_2R ($hD_{2L}R$), FP and UFP exposure increases D_2R affinity for dopamine, measure by displacement of [^{3}H]-spiperone binding. In

striatal slices and CHO-K1-hD_{2L}R cells, exposure to FP and UFP increased the potency of dopamine to inhibit forskolin-induced cAMP formation. The effects were more notorious by exposure to UFP than FP showing that factors such as size and composition could be involved. These results indicate that exposure to FP or UFP directly affect dopaminergic transmission.

Title: Projection-specific diversity of dopamine neurons within the medial substantia nigra

Authors: *N. HAMMER, S. STOJANOVIC, N. FARASSAT, J. ROEPER;
Goethe Univ. Frankfurt, Frankfurt, Germany

Abstract: Midbrain dopamine (DA) neurons are not only subdivided by their location within the midbrain, residing either in the ventral tegmental area (VTA) or the substantia nigra pars compacta (SNc), but also by their different axonal projection targets, e.g. the dorsomedial striatum (DMS), dorsolateral striatum (DLS), or distinct regions within the nucleus accumbens (NAcc) [1, 2]. DA neurons located in the medial SNc project either to DMS, DLS or the lateral shell of NAcc [2, 3]. These distinct projections of DA neurons are associated with distinct electrophysiological properties *in vitro* [1, 2]. Recently, we also identified significant *in vivo*differences between mSNc DA neurons projecting to the dorsal striatum (DMS/DLS) and lNAcc [3]: mSNc DA neurons projecting to lNAcc displayed more burst firing events per minute while they also possessed more pauses, longer periods of electrical silence. In contrast, mean in vivo frequencies and the coefficient of variations were not different between dorsal and ventral striatum projecting mSNc DA neurons [3]. When studying the different, retrogradely identified DA subpopulations within the mSN of adult C57Bl6 mice in more detail in vitro, we found that those DA neurons projecting to DMS showed the lowest intrinsic firing frequencies (DMS_{mSNc}= 1.6 ± 0.1 Hz, n = 27; $lNAcc_{mSNc}$ = 2.0 ± 1.7, n = 19; DLS= 2.5 ± 0.2 Hz, n = 20) and longest rebound delays (DMS_{mSNc}= 673.6 ± 82.1 ms, n = 24; $lNAcc_{mSNc}$= 426.8 ± 51.6 ms, n = 19; DLS_{mSNc}= 215.3 ± 37.6 ms, n = 20). As differences neuromodulatory control are expected to contribute to the *in vivo*activity of DA neurons in addition to their intrinsic excitability, we are currently investigating potential projection-specific differences in D2R-mediated inhibition of

mSNc DA neurons.

Title: Distinct subthreshold activity of projection-specific dopamine neurons revealed by *in vivo* whole cell recording

Authors: *K. OTOMO[1,2], S. STOJANOVIC[1], N. FARASSAT[1], C. PALADINI[3], J. ROEPER[1]; [1]Inst. of Neurophysiol., Goethe Univ. Frankfurt, Frankfurt, Germany; [2]Intl. Max Planck Res. Sch. for Neural Circuits, Max Planck Inst. for Brain Res., Frankfurt, Germany; [3]UTSA Neurosciences Inst., Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Ventral tegmental area (VTA) dopamine (DA) neurons play critical roles in motivation and reward- or aversion-based learning, as well as drug addiction and schizophrenia, by encoding environmental information to reinforce behavior. In the past decade, an increasing number of studies have demonstrated the heterogeneity of the midbrain DA neurons. Upon presentation of a rewarding or aversive stimulus, DA neurons can either be excited or inhibited depending on the subpopulation, which is associated with distinct axonal projection targets. In order to better understand DA subtype-specific computations, direct analysis of *in vivo* subthreshold properties of VTA DA subpopulations will be mandatory. As a first step, we recorded subthreshold activity from midbrain DA neurons in intact brains with the whole-cell configuration, using our recently-developed deep brain *in vivo* patch-clamp technique. Of the 132 putative DA neurons recorded with internal solution containing neurobiotin, 74 were successfully recovered and demonstrated to be dopaminergic, i.e., immuno-positive for tyrosine hydroxylase. These identified DA neurons displayed large variations in sag amplitudes during an injection of hyperpolarizing current, as well as differences in post-inhibition rebound behavior, ranging from transient rebound bursting to long pausing, resembling our previously published *in vitro* data. Additionally, our burst-triggered average analysis revealed two distinct subthreshold pre-burst signatures; one that directly entered a burst mode from the baseline membrane potentials, and another where the burst onset was preceded by a strong hyperpolarization. To define subthreshold behavior in distinct projection-defined VTA DA subpopulations, we are

currently evaluating different methods to record from projection-identified DA neurons, by combining *in vivo* patch clamp recordings either with highly-diluted fluorogold-mediated retrograde tracing or with GFP plasmid labeling.

Title: Modeling the role of T-type calcium channels and their functional coupling to SK channels in projection-specific rebound properties of nigral dopamine neurons

Authors: *C. J. KNOWLTON[1], S. STOJANOVICH[2], J. ROEPER[2], C. C. CANAVIER[1]; [1]Cell Biol. and Anat., Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA; [2]Inst. of Neurophysiol., Frankfurt am Main, Germany

Abstract: The electrical activity of midbrain dopamine (DA) neurons was long thought to homogeneously signal reward prediction errors. However, distinctions between DA subpopulations are now becoming increasingly clear; DA neurons might also provide start/stop signals for actions and signal salient and even aversive events. A morphologically realistic, multi-compartmental model calibrated by projection-specific *in vitro* electrophysiology data of DA neurons (see abstract by Stojanovic et al.) was used to propose mechanisms for axonal projection-specific responses of dopamine neurons in the substantia nigra (SN) during a prolonged hyperpolarization and the subsequent rebound phase. The model predicts that the degree to which the T-Type (CaV3) Ca^{2+} channels are de-inactivated controls whether DA SN neurons projecting to the dorsolateral striatum (DLS) exhibit a short latency rebound spike or longer latencies due to the presence of a subthreshold oscillation. Deeper hyperpolarizations favor the latter, because the larger Ca^{2+} influx activates SK channels sufficiently to prevent an action potential on at least one cycle of a subthreshold oscillation. Setting the SK or T-type conductance to zero eliminated subthreshold oscillatory responses and produced substantial transient increases in rebound spike frequency, consistent with experimental observations using SK and T-Type channel selective pharmacology. Another important result was that simply increasing conductance density of A-type (Kv4.3) K+ channels in the model eliminated both the fast rebound responses and the subthreshold oscillation; instead, the model produced only delayed post-inhibitory responses associated with a continuum of ramp-like subthreshold

responses consistent with observations in DMS-projecting DA neurons. Increased A-type conductance in DMS is shown to be consistent with more ramp-like interspike intervals in DMS projecting cells, deeper after-hyperpolarizations and a lower basal frequency relative to DLS projecting cells. Setting the SK conductance to zero in both simulated DLS and DMS projecting cells elicited rebound bursts mediated by the H current in the model. In the model, sustained rhythmic bursting could be obtained with SK block, an elevated L-type calcium conductance and a slowly activating Ca^{2+}-independent potassium current to repolarize the bursts. Distinct rebound properties and spike latencies after hyperpolarizing firing pauses are present between different DA projections and well captured by computer modeling implementing both realistic channel biophysics and calcium dynamics that control functional coupling.

Title: T-type calcium channels mediate fast rebound bursting in dorsolateral striatum projecting dopamine neurons in the lateral substantia nigra

Authors: *S. STOJANOVIC[1,2], K. OTOMO[1], C. J. KNOWLTON[3], J. SHIN[1], C. C. CANAVIER[3], S. LAMMEL[2], J. ROEPER[1];
[1]Inst. of Neurophysiol., Frankfurt am Main, Germany; [2]Dept. of Mol. and Cell Biol. and Helen Wills Neurosci. Institute, Univ. of California, Berkeley, CA; [3]Cell Biol. and Anat., LSU Hlth., New Orleans, LA

Abstract: T-type calcium channels (LVA) are prominent in substantia nigra (SN) dopaminergic (DA) neurons, but their functional roles are not entirely understood. Previous studies have shown that LVA are being recruited through dopamine D2-receptor inhibition (Evans et al., 2017) and are involved in activation of SK potassium channels (Wolfart et al., 2002). To study the biophysical properties of LVA in DA SN neurons, we conducted comprehensive measurements of their biophysical properties *in vitro* in acute brain slices using patch-clamp recordings. This revealed a functional gradient throughout the medio-lateral axis of the SN, where lateral SN DA neurons showed a significantly greater LVA current amplitudes in comparison to those in medial SN DA neurons. In our next set of experiments, we retrogradely traced dorso-lateral striatum (DLS), as lateral SN preferentially projects to this striatal region (Lerner et al., 2015; Farassat et

al., unpublished), and compared it with other projection-specified DA subpopulations. After a hyperpolarizing current injection, DLS-projecting lateral SN DA neurons displayed strikingly faster rebound excitation, quantified as shorter latencies to the first spike and subthreshold oscillations, that were not observed in other DA subpopulations projecting to dorsomedial or ventral striatum. Selective pharmacological inhibition of LVA decreased rebound excitability and abolished the oscillations. In addition, application of SK-channel blockers led to high-frequency rebound bursting with shortened rebound delays. We are currently modelling the calcium dynamics of the flexible coupling between LVA and SK channels. Finally, *in vivo* patch-clamp whole-cell recordings of lateral SN DA neurons confirmed that the high rebound excitability is also present in the intact brain. We currently aim to identify synaptic inputs that might recruit this neuronal behavior in lateral SN DA neurons.

Title: Social interactions are dependent on Ntrk2 signaling in the dopaminergic neurons

Authors: *M. SAHU[1], Y. PAZOS-BOUBETTA[1], M. PALMISANO[1], V. VOIKAR[1,2], E. CASTREN[1];
[1]Neurosci. Center, HiLIFE, Univ. of Helsinki, Helsinki, Finland; [2]Lab. Animal Ctr., Helsinki, Finland

Abstract: Dopamine in the vertebrate brain executes its functions via two prominent pathways; the nigrostriatal and the mesocorticolimbic pathway. The dopaminergic nigrostriatal pathway is essential for the control of voluntary motor behavior, while the mesocorticolimbic pathway is involved in controlling emotion-based behavior such as motivation and reward. Neurotrophin, brain derived neurotrophic factor (BDNF) signals through its high affinity receptor tyrosine kinase B (Ntrk2/TrkB). Both BDNF and Ntrk2 are widely expressed in the mid-brain dopaminergic neurons. BDNF can facilitate stress and drug induced neuro-adaptaion in the mesocorticolimbic pathway. Common pathological changes due to insufficient trophic support of BDNF via Ntrk2 on dopamine systems have been linked to psychosis, schizophrenia, attention deficit/hyperactivity disorder (ADHD), depression and addiction. Furthermore, antidepressants activate BDNF/Ntrk2 signaling and are concomitantly linked with increased dopamine levels in

the brain. Most of the studies have focused on region specific deletion of Ntrk2 from the dopaminergic subset of neurons. Previous studies have found BDNF signaling is highly crucial in the mesolimbic pathway during periods of chronic stress (Wook Koo et al 2016) but in the nigrostriatal pathway Nrtk2 deletion had no effect on neurodegeneration (Kramer et al 2007). This study investigates function of Ntrk2 in the dopaminergic neurons using a DAT-icre (Parlato et al 2006) mediated conditional knockout mouse. We used a tDtomato reporter to confirm the DAT expression patterns. These transgenic animals survive until adulthood without any morphological deformities. However, they are overweight compared to the control littermates and are innately aggressive. Absence of the Ntrk2 signaling hinders social recognition in three compartment sociability tests. These animals show memory impairment in novel object recognition task. Interestingly, the general motor behavior was found to be unaltered. Thus, Ntrk2 signaling is highly crucial in the mesocorticostriatal dopamine pathway. Further investigations on the reward circuitry and dopamine neuron development in these mice would dissect the potential target regions of Ntrk2 in the dopamine neurotransmission.

Title: Aging increases microglia senescence in the midbrain

Authors: *L. PHAN, F. SHAERZADEH, J. LEBOWITZ, M. DACQUEL, A. BECHTLE, W. HACHMEISTER, D. R. MILLER, W. J. STREIT, T. C. FOSTER, A. KUMAR, H. KHOSHBOUEI;
Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Microglia are responsible for maintaining tissue homeostasis, neuronal support and protection. Since aging is the major risk factor for neurodegenerative diseases, including Parkinson’s disease, we hypothesized that the ratio of microglia to dopaminergic neurons as well

as microglial heterogeneity change with aging in the substantia nigra pars compacta (SNc) and ventral tegmental area (VTA). To address this hypothesis, we conducted stereological analyses to measure age-dependent changes in the number of microglia and dopaminergic neurons in the SNc and VTA of 1-, 6-, 9-, 18- and 24- month- old C57BL/J6 male mice. For quantification of the anatomical features of microglia, we stained coronal sections of the midbrain with tyrosine hydroxylase (TH) and Iba1, and performed stereological image analysis. In both brain regions, microglia increased in aged mice, whereas the number of TH+ cells reached a plateau after 1 month. Quantitative morphometry analyses revealed microglial complexity and projection area declined with aging while cell body size increased. Surprisingly, the contact sites between microglia and dopaminergic neurons in both regions increased in aged mice, suggesting an aging-dependent increase in microglial support of dopamine neurons. Furthermore, to assess for gait deficits with aging, ventral plane imaging (DigiGait) was utilized. Gait analysis indicates aging-dependent changes in mice gait indices. In conclusion, increases in microglial cell number, ratio of microglia to dopamine neurons, and physical contact sites suggest these innate biological mechanisms may compensate for the aging-dependent decline of microglia complexity (senescence) for continued neuronal support in aging within the SNc and VTA.

Title: Involvement of astrocytes and volume regulated anion channels (VRACs) in the ethanol-induced increase of nucleus accumbens taurine in rats

Authors: *L. ULENIUS[1], K. ADEMAR[1], A. ANDRÉN[1], R. STOMBERG[1], L. ADERMARK[1], B. SÖDERPALM[1,2], M. ERICSON[1];
[1]Inst. of Neurosci. and Physiol., Univ. of Gothenburg, Gothenburg, Sweden; [2]Beroendekliniken, Sahlgrenska Univ. Hosp., Gothenburg, Sweden

Abstract: The harmful use of alcohol constitutes one of the leading factors for the total burden of disease and injury. Regarding the dopamine (DA) elevating properties of the drug, alcohol's

primary site of action appears to be within the nucleus accumbens (nAc), a central area of the mesolimbic dopamine system. We have previously shown that in order for ethanol to increase nAc DA levels, a simultaneous increase in endogenous taurine is required. The endogenous amino acid taurine exert a number of effects, including osmoregulation, and we hypothesize that taurine is released following ethanol exposure in order to re-equilibrate the osmotic pressure. Supporting this theory we have previously shown that inhibition of cell swelling, or manipulation of extracellular osmolarity, antagonizes ethanol-induced taurine and DA release in the nAc. The aim of the present study was to identify whether the ethanol-induced taurine increase originates from neurons or astrocytes and if the release is mediated via volume regulated anion channels (VRACs). Adult male Wistar rats were equipped with a microdialysis probe in the nAc and received acute treatment with the Na+ channel blocker tetradotoxin (TTX), the glial metabolic inactivator fluorocitrate or the VRAC inhibitor DCPIB alone, and together with ethanol (2.5 g/kg, i.p. or 300 mM locally perfused in the nAc) or vehicle. In all experiments extracellular levels of taurine and DA were examined in the dialysate every 20 minutes using HPLC. We found the ethanol-induced elevation of taurine to occur independently of TTX-administration, whereas the DA release was substantially decreased. Metabolic inactivation of astrocytes by fluorocitrate suppresses both the ethanol-induced increase in taurine, as well as the increase in DA. Furthermore, local perfusion with DCPIB attenuates ethanol-induced taurine release and prevents ethanol from increasing DA. We conclude that the ethanol-induced elevation of extracellular taurine in the nAc derives mainly from astrocytes and that taurine is likely released via VRACs. This strengthens the hypothesis that taurine acts as an osmotic regulator to antagonize ethanol-induced swelling of astrocytes.

Abstract: Cocaine (COC) is a main psychostimulant that acts by increasing catecholaminergic neurotransmission mainly due to its effects on dopamine transporter (DAT). However, other transmitter systems may also be regulated by COC, including GABAergic circuits. Since the role of COC in modulating GABA reuptake is not defined, we investigated the molecular mechanisms related to the increase in GABA uptake induced by acute cocaine exposure and its effects on locomotor activity in adolescent mice. Behavioral experiments showed that COC increased locomotor activity and its effects were prevented by a previous treatment with SCH23390. A single COC exposure reduced both GABA uptake and GAT-1 protein levels. On the other hand, cAMP levels were increased after COC challenge. The major changes induced by acute COC on neurochemical assays and behavioral tests were avoided by blocking dopamine D1-like receptors. Our findings suggest that dopamine D1-like receptors are key players in the regulation of extracellular GABA levels through a single COC exposure in adolescent mice.

Title: Repeated methamphetamine exposure alters the baseline firing activity of ventral tegmental area dopamine neurons

Authors: *D. O. SAMBO[1], M. LIN[1], J. LEBOWITZ[1], D. MILLER[1], H. KHOSHBOUEI[2]; [2]Box 100244, [1]Univ. of Florida, Gainesville, FL

Abstract: Repeated exposure to low to moderate doses of methamphetamine have been shown to induce behavioral sensitization, including increased locomotor responses to the same dose of drug. While the exact mechanism of methamphetamine-induced behavioral sensitization is less clear, increased sensitivity of dopaminergic signaling including decreased activity of inhibitory D_2 autoreceptors (D_2R) is one proposed mechanism. We and other have shown acutely administered methamphetamine increases the frequency of firing activity of dopamine neurons and stimulates dopamine efflux via the dopamine transporter. Increased extracellular dopamine in the ventral tegmental area (VTA) in turn activates the inhibitory D_2Rs resulting in feedback inhibition and decreased activity of dopamine neurons. In this study, we investigated the effect of repeated methamphetamine exposure (2mg/kg/7days) on the baseline activity of VTA dopamine neurons. Whole-cell slice recordings in VTA dopamine neurons of methamphetamine vs. saline treated mice revealed that sub-chronic, systemic exposure to methamphetamine increased the *baseline* excitability of VTA dopamine neurons, such that methamphetamine-treated animals showed a more depolarized membrane potential and increased spontaneous firing activity. To our surprise, the "sag" current, as measured by the I_h-mediated current after application of hyperpolarizing current pulses, showed no change of methamphetamine vs. saline treated animals, suggesting no changes in the inhibitory function of the neurons. Analysis of current-evoked single action potential (AP) properties revealed that sub-chronic methamphetamine exposure narrowed the AP width, increased the AP amplitude, and decreased the depolarization input resistance. Further analysis revealed that these changes in basal neuronal activity were coupled to increased activity of Ca^{2+} channel activity as well as the frequency and amplitude of intracellular Ca^{2+} transients in VTA dopamine neurons. These findings suggest that in the absence of D_2R activation by high levels of dopamine, sub-chronic exposure methamphetamine exposure also alters the intrinsic, baseline firing activity of dopamine neurons in a Ca^{2+}-dependent manner.

Antec Scientific, Zoeterwoude, Netherlands

Abstract: Ultra-High Performance Liquid Chromatography (UHPLC) is a rapidly growing separation technique based on the application of LC columns with sub-2 µm particles operating at higher linear velocities and high back pressures. UHPLC offers advantages in chromatographic resolution, analysis speed, and sensitivity over conventional HPLC systems. The combination of Electrochemical Detection (ECD) with UHPLC can be a powerful solution to increase the sample throughput and sensitivity of neurotransmitter analysis in microdialysates, brain homogenates and other sample matrices. The versatile UHPLC ALEXYS Neurotransmitter Analyzer based on the DECADE Elite detector with SenCell is based on a flexible and scalable approach to offer an analysis solution for various neurotransmitter applications (biogenic amines and acidic metabolites, amino acid neurotransmitters and acetylcholine). A fast and sensitive method is presented for the analysis of the amino acid neurotransmitters GABA and Glutamate in microdialysates based on the new ALEXYS neurotransmitter analyzer (figure 1). Separation is achieved on a sub-2 µm particle column after automated pre-column derivatization with o-phthaldialdehyde (OPA). A step-gradient is used for clean-up of late eluting amino acid neurotransmitters present in microdialysate samples at the end of the run. With this approach excellent detection sensitivity can be achieved with minimal sample consumption. Other amino acids e.g. histamine, and large neutral nmino acids (LNAAs: Tyr, Val, Met, Orn, Leu, Ile, Phe, Lys, Trp) can be analyzed too using this method.
Method features:
• Automated odorless in-needle OPA-sulphite derivatization.
• Small sample use per analysis: 5 uL only (injection volume 1.5 µL)
• Fast and efficient separation using sub-2 µm particle column
• Post separation step-gradient to eliminate late eluting components
With this approach, a high sample throughput and low detection limit of around 10 nmol/L (15 fmol, 6 pg on column) for GABA is achievable.

Title: Glycogen synthase kinase-3ß regulates the serotonin transporter function and trafficking in a phosphorylation-dependent manner

Authors: *D. RAGU VARMAN, L. D. JAYANTHI, S. RAMAMOORTHY;
Pharmacol. and Toxicology, Virginia Commonwealth Univ., Richmond, VA

Abstract: The serotonin (5-HT) transporter (SERT) plays a critical role in the regulation of serotonergic transmission in the central nervous system. While increasing evidence has shown that several protein kinases act as modulators in SERT regulation, the precise molecular mechanisms are mostly incomplete. In this study, the molecular mechanisms of glycogen synthase kinase-3ß (GSK3ß)-mediated SERT regulation and the site of transporter phosphorylation were investigated. We found that GSK3α/ß inhibitor CHIR99021 produced a time and dose-dependent elevation of SERT function with a concomitant increase in the SERT Vmax and surface expression. Moreover, while genetic interference of GSK3α/ß increased SERT function, coexpression of constitutively active GSK3ß-S9A decreased SERT function. The site-specific mutagenesis study revealed that mutation of serine 48 to alanine in SERT (SERT-S48A) not only completely abolished CHIR99021-mediated stimulation of 5-HT transport, but also the inhibitory effect caused by the active GSK3ß-S9A. Coexpression of GSK3ß-S9A with wild-type SERT reduced 5-HT transport, Vmax, and the surface SERT levels while enhancing SERT phosphorylation. However, coexpression of active GSK3ß-S9A with SERT-S48A did not change 5-HT transport, Vmax, surface SERT expression or SERT phosphorylation. Unlike wild-type SERT, SERT-S48A mutant did not exhibit functional stimulation following siRNA silencing of GSK3α/ß. Furthermore, Akt inhibitor AktX was effective in inhibiting both wild-type SERT and SERT-S48A mutant suggesting that GSK3 ß regulates SERT independent of Akt activation. Collectively, these findings are the first to reveal Ser-48 in SERT as a GSK3ß-dependent phosphorylation site, and that this site is required for GSK3ß-mediated SERT functional regulation.

Title: Neurokinin 1 and noradrenergic interplay in stress-mediated affective disorders and psychostimulant abuse: Studies from amphetamine-insensitive norepinephrine transporter mutant mouse model

Authors: *L. D. JAYANTHI[1], J. J. WINDLE[2], P. MANNANGATTI[1], S. RAMAMOORTHY[1]; [1]pharmacology and Toxicology, [2]Human and Mol. Genet., Virginia Commonwealth Univ., Richmond, VA

Abstract: Altered noradrenergic transmission and presynaptic norepinephrine (NE) transporter (NET) expression have long been associated with depression and drug addiction. Stress-related neuropeptides, including substance P, play an important role in drug abuse and relapse to drug-taking behavior. We have shown that neurokinin-1 receptor (NK1R) activation by substance P downregulates NET via PKC phosphorylation of the T258/S259 motif and that the same motif is required for AMPH-mediated NET downregulation (PMID:16740633; PMC3789959, PMC2939970). Our more recent studies show that AMPH-induced NET regulation and behavior are sensitive to NK1R antagonists and to manipulations targeting the NET-T258/S259 motif (PMC5266628; PMC5714664). To identify the neurobiological consequences of T258/S259-dependent in-vivo NET regulation, we have developed a prototypical mutant mouse model where the T258/S259 motif in the NET is replaced with an A258/A259 motif. Preliminary studies on the NET-T258A/S259A knock-in mice showed reduced NET functional expression in brain regions implicated in stress- and psychostimulant- mediated behaviors. Compared to WT males, NET-T258A/S259A males exhibit more anxiety-like behavior while such genotype-specific difference was not observed in the females. Compared to respective sexes of WT mice, male and female NET-T258A/S259A mice exhibit similar levels of basal locomotor activity. However, while AMPH-induced locomotor activation was similar in female T258A/S259A and WT mice, it was significantly reduced in male NET-T258A/S259A mice compared to WT males. AMPH-induced CPP was intact in both male and female T258A/S259A mice compared to WT male and females. While NK1R antagonist aprepitant attenuated AMPH-induced CPP in both sexes of WT and in T258A/S259A males, it failed to attenuate AMPH-induced CPP in T258A/S259A females. The data from T258A/S259A mice suggest that T258/S259-dependentNET regulation contributes to affective disorders and AMPH reward via NE-NK1 interplay. Thus, by expanding our appreciation of NK1R-mediated molecular events in AMPH-

mediated NET regulation, further studies on T258A/S259A mice will be extremely important and impactful in understanding NET regulatory mechanisms that are usurped by AMPH in the context of NE-NK1 interplay.

Title: Role of inhibitory interneuron in the locus coeruleus in startle and pre-pulse inhibition behavior in mouse

Authors: *H.-C. TSAI[1], M.-Y. MIN[1], C.-C. KUO[1], H.-J. YAU[1], H.-W. YANG[2];
[1]Natl. Taiwan Univ., Taipei, Taiwan; [2]Chung-Shan Med. Univ., Taichung, Taiwan

Abstract: The locus coeruleus (LC) consists of noradrenergic (NA) neurons that have global axonal projection to the forebrain. LC-NA neurons exhibit two activation patterns, tonic and phasic. Tonic LC activation is correlated to the transition of wakefulness and alertness. In contrast, phasic LC activation is responding to changes in environmental contingencies and is able to modulate cognitive processes on a trial-by-trial basis. Nevertheless, the cell mechanism underlying the regulation of phasic and tonic LC activation remains largely unknown. The pre-pulse inhibition (PPI) is a commonly used operational measurement of sensorimotor gating, a fundamental and preattentive form of information-processing allowing organisms to filter information from external and internal domains. Previous study has shown that pharmacological activation of tonic LC activity decreased PPI. In this study, we reported an enhancement of PPI by suppression of local inhibitory interneurons in the LC with designer-receptor- exclusively-activated-by-designer-drug (DREADD). Male vesicular GABA transporter (VGAT)-Cre knock-in mice aged 5 weeks were injected with 20 nl adeno-associated virus (AAV) carrying a double-floxed inverted open reading frame hM4Di-mCherry into the LC. After 3 weeks of infection, we found that intraperitoneal administration of 1mg/kg of clozapine-N- oxide (CNO) to the mice 30 minutes before behavior test significantly increased PPI (PPI = 57.06 ± 3.22%, n=26), compared to those administered with vehicle (PPI = 42.14 ± 3.78%, n=26; p=0.0842556364685233, pair t test). On the contrary, the effect on PPI of CNO was neither observed in mice receiving the AAV injected to other pontine areas (n=9) nor in mice receiving control AAV injected into the LC (n=13). Besides, the unconditioned exploratory behaviors were unaltered in mice showing

increased PPI (n=14); linear regression analysis showed no significant relation between startle response and PPI. The results demonstrate that the mice showed more attentive possibly due to the enhanced phasic activation when local inhibitory interneurons in the LC were suppressed.

Title: Investigating the localization and functional role of GABA receptors at neuromuscular synapses of the earthworm Lumbricus terrestris

Authors: M. J. ILGENFRITZ, K. M. SHERRY, D. N. GALA, ***W. L. COLEMAN**;
Biol. and Allied Hlth. Sci., Bloomsburg Univ. of Pennsylvania, Bloomsburg, PA

Abstract: The balance of excitatory and inhibitory signaling is critical for normal nervous system function, and is a key component of synaptic integration within the central nervous system. Synapses at the earthworm body wall muscle involve both excitatory and inhibitory components, which provides a useful model system for investigating these features. While a general inhibitory role of GABAergic signaling at the earthworm muscle has been established, the exact localization of the receptors and their individual functions are poorly understood. This study confirmed the presence of both GABA-A and GABA-B receptors at the body wall synapses using immunohistochemistry and confocal microscopy. The receptors localized to the same synaptic structures that were co-labeled for the presynaptic protein synapsin I. The GABA receptors could be presynaptic, postsynaptic, or both. To test the possibility that GABAergic receptors have presynaptic function, we performed an exploratory experiment using synaptogreen C4 dye (also called FM1-43), which stains synaptic vesicles through compensatory endocytosis. Following anesthesia in 10% ethanol saline solution, earthworms were dissected and cleaned to expose the ventral nerve cord and body wall muscles. Tissue sections were then loaded with 5uM synaptogreen C4 dye in an elevated K+ solution for 10 minutes. The loading solution for the experimental group also contained 5uM GABA. Following rinses and treatment with 200uM ADVASEP-7 for five minutes to reduce background fluorescence, staining of synaptic structures was assessed using confocal microscopy. Average fluorescence intensity was

quantified using measurement tools in Zen Blue software. To ensure that any differences in intensity were due to the treatment, all images were acquired using the same laser power and detector gain voltage. The average fluorescence intensity was not significantly different between the two groups (p=0.68, two tailed paired t-test with equal variance, control n = 40 structures analyzed, from 5 microscopic fields, from two worms; GABA treatment n = 130 structures analyzed, from 27 microscopic fields, from three worms). Under the tested conditions activation of GABAergic receptors had no effect on the presynaptic loading of synaptogreen, which suggests that these receptors may only have postsynaptic function. Future experiments will be aimed at elucidating specific GABA receptor functions at these synapses using electrophysiological techniques.

Title: Modulation of anion channel gating by C-terminal domains in excitatory amino acid transporters

Authors: *E. G. NEUREITER[1], D. TORRES-SALAZAR[1], M. H. CHENG[2], A. M. KARA[1], A. D. GONZALEZ-SUAREZ[1], C. GLASSER[1], J. GARCIA-OLIVARES[1], I. BAHAR[2], S. G. AMARA[1];

Abstract: Glutamate is the major excitatory neurotransmitter in the brain. The Excitatory Amino Acid Transporters (EAATs) are responsible for clearing excess glutamate released at synapses through uptake; excess extracellular glutamate leads to excitotoxicity and cell death. EAATs couple the influx of a molecule of glutamate, 3 sodium ions, and one proton with the counter transport of one potassium ion. In addition, EAATs function as anion selective channels. Although recent studies have been instrumental in beginning to understand the structural elements involved, the precise mechanisms and the structural links between glutamate transport and anion channel function are not fully understood. This exploratory study combines molecular dynamics simulations and electrophysiological techniques to elucidate the relationship between anion channel gating and glutamate transport in EAATs. A large body of evidence has supported a role for C-terminal domains in the gating mechanism of voltage-dependent chloride channels. In EAATs specifically, several studies have implicated C-terminal residues in cellular

trafficking, localization, and functionality. We constructed a computational model of EAAT4 including the C-terminal region in order to examine this region's effects on anion channel gating. This model suggests potential interactions between charged residues in the C-terminus in EAAT4 and in transmembrane domain 3 (TM3). We tested this potential relationship using electrophysiological recordings in *Xenopus* oocytes expressing different point mutations in TM3 (K119D, R123D, and R127D) and the C-terminus (E523, E528, and E530) as well as different truncations in the C-terminus of EAAT4. Glutamate uptake was measured using radiolabeled glutamate in uptake assays on transfected cells and oocytes. Our results show that a full truncation of the C-terminus (Q521X) disrupts anion channel gating and significantly reduces glutamate transport, indicating that the C-terminal domain plays a critical role in modulating the structural coupling between substrate transport and anion channel opening. Mutations in both the C-terminus and TM3 result in altered anion permeability ratios and anion channel permeation. These data demonstrate that the interaction of the C-terminus and TM3 is required for gating the anion channel. Our results help elucidate the molecular determinants underlying the structural coupling between anion channel gating and substrate translocation in EAATs.

Title: The effects of D-serine on tectal cell dendritic morphology and retinotopic map development

Authors: *Z. CHORGHAY[1], V. LI[1], A. SCHOHL[1], E. S. RUTHAZER[2];
[2]Montreal Neurolog. Inst., [1]McGill Univ., Montreal, QC, Canada

Abstract: The N-methyl-D-aspartate type glutamate receptor (NMDAR) is essential for precise neural circuit refinement during development, through its effects on arbour morphology, synaptic stability, and plasticity. Our lab previously demonstrated that the gliotransmitter D-serine, an endogenous co-agonist for NMDARs, promotes glutamatergic synapse maturation, and stabilizes axonal structural and functional inputs in the developing visual system of the Xenopus tadpole. In this model, retinal ganglion cells (RGC) from one eye send contralateral projections to the optic tectum, allowing us to parse out presynaptic (RGC axons) from postsynaptic (tectal

dendrites) effects. Here, we further investigate the role of D-serine in circuit refinement, focusing on the postsynaptic side, by examining its effects on tectal cell dendritic morphology and the retinotopic map. To study morphology, we co-electroporated Cre-dependent GFP and dilute Cre plasmids into the tectum to stochastically label recently-differentiated single cells. We performed in vivo two-photon imaging every 24 hours for 4 days to detect morphological changes in these cells, following rearing of tadpoles in D-serine versus control. To extract retinotopic maps, we microinjected RNA into one blastomere at the two-cell stage, expressing the genetically-encoded calcium sensor GCaMP6s in half the animal i.e. tectal cells in one hemisphere and contralaterally projecting RGC axons in the other. We presented these animals with monocular visual mapping stimuli while performing rapid 4D calcium imaging of the tectum, then correlated fluorescence intensity changes to the positions of visual stimuli. The consequences of NMDA receptor signal enhancement on map refinement were tested by comparing maps in tadpoles reared in D-serine versus control. We find that D-serine does not interfere with the emergence of coarse retinotopic maps, but does decrease the complexity of dendritic morphology and produce alterations in overall map organisation. Overall, these findings provide support for the potential role of D-serine in neural circuit refinement, through its action on NMDAR-mediated neurotransmission, which has been implicated in neural circuit development, plasticity, and visual processing.

Title: Cysteine transporter compensation occurs in the brains of system x_c^- null mice

Authors: H. SOSNOKSI, M. M. MORGAN, ***S. J. HEWETT**;
Syracuse Univ., Syracuse, NY

Abstract: To avoid excitotoxicity and oxidative stress, the concentration of extracellular glutamate in the brain must be tightly regulated and antioxidants, such as the tripeptide γ-glutamyl cysteinyl glycine [aka glutathione (GSH)], must be dynamically produced. Several transporters, including excitatory amino acid transporters (EAATs) and system x_c^-, work to maintain extracellular glutamate levels by balancing its uptake and release, respectively.

Additionally, system x_c^- is known to import cystine, an amino acid fundamental to the production and maintenance of cellular GSH. Yet, mice that are null for system x_c^- appear healthy and, in previous studies, we found their brains are protected from, rather than more vulnerable to, glutamate excitotoxicity and oxidative stress. These data indicate that system x_c^- null mice may employ alternative glutamate or cystine/cysteine transport mechanisms [e.g., Excitatory Amino Acid Transporters (EAATs) 1-3, the Alanine-Serine-Cysteine-Transporters (ASCTs) 1 or 2, and/or the Large Neutral Amino Acid Transporter (LAT) 2] to regulate glutamate and/or sustain GSH levels *in vivo.* Thus, the objective of this work was to determine whether loss of system x_c^- leads to compensatory changes in the aforementioned transporters in brain. Toward this end, we measured and compared the striatal, hippocampal and cortical plasma membrane protein levels of EAAT1, 2, and 3, ASCT-1 and LAT-2 between system x_c^- null and wild-type mice via Western Blot Analysis. Mouse null for system x_c^- showed a significant increase in EAAT1 and EAAT3 expression over levels measured in wild-type control brains in the striatum only. Expression of LAT-2 increased significantly in all three brain regions ─striatum, hippocampus and cortex ─ of the system x_c^- null mouse tested, whereas no change in either EAAT2 or ASCT1 was measured in any brain region as compared to wild-type control brain. Thus, compensatory changes in transporter expression occurs in brains of mice null for system x_c^- in both a transporter type and brain region specific manner.

Abstract: Glycine is a major inhibitory neurotransmitter in the vertebrate central nervous system where the extracellular levels are controlled by two glycine transporters (GlyT1 and GlyT2). GlyTs belong to the solute carrier 6 family that group secondary active transporters dependent of

sodium and chloride to transport their substrates. While glycine transporters are essential for survival in mammals, their homologues and expression patterns in invertebrates are features not known. By sequence homology, Stuart et al., 2006 identified the gene CG5549 in *Drosophila melanogaster* to have the highest sequence homology with the vertebrate glycine transporters and later, in a separate study Ceriani et al., 2017, confirm that the gene CG5549 (Dmel-GlyT2) can transport glycine. However, neither report provided evidence of the specificity and kinetic analysis. In this study, we subjected the CG5549 to homology modelling and docking using the atomic coordinates of close relatives, the serotonin and dopamine transporters. We obtained a 3D model of the transporter that show the possible binding cage for glycine and ion binding sites. Initial biochemical characterization suggest that CG5549 is a more general amino acid transporter with low affinity for glycine. Further analysis should elucidate the substrate specificity and kinetic properties of this transporter.

Title: Bidirectional control of neuronal activity using light-activated potassium channels

Authors: *O. M. CONSTANTIN[1], S. GAO[2], J. YU-STRZELCZYK[2], S. YANG[2], G. NAGEL[2], T. G. OERTNER[1], C. E. GEE[1];

Abstract: Optogenetic stimulation of neurons is a powerful approach that allows light evoked depolarization and firing of neurons. The number of genetically encoded tools for neuronal excitation has greatly increased in the last years, whereas the toolbox available for reversibly silencing neuronal activity is limited. Considering the importance of K^+ for setting the membrane potential, light-activated K^+ channels would allow rapid inhibition of individual neurons or populations with little effect on other ion gradients. Here we present an improved version of a novel light-gated K^+ selective channel (Beck et al., Frontiers in Neuroscience 2018). The new

optogenetic tool is a tandem construct developed by fusing bPAC, a bacterial photo-activated adenylyl cyclase to a cyclic nucleotide-gated channel with high permeability for K^+. The high light sensitivity of bPAC and the channel's high K^+ permeability allow for strong hyperpolarization of the plasma membrane even with short pulses of low intensity light. Rat hippocampal neurons expressing the fusion construct are strongly hyperpolarized (~20 mV) when blue light is applied (50 ms, 470 nm, 1 mW/mm^2). This hyperpolarization completely blocked action potentials induced by up to 2 nA somatic current injections, an effect which lasted around 40 s. This blockade of firing could be easily extended to 5 minutes by repeatedly flashing blue light at 30 s intervals. The ability of bPAC to integrate light over time as well as its narrow activation spectrum allows for this new fusion construct to be used for dual color excitation-inhibition experiments. Using prolonged 400 nm light at extremely low intensity (0.001 mW/mm^2), action potentials generated by red-light activation of co-expressed Chrimsons were fully blocked without any cross-activation. By expressing both the fusion potassium channel and a Chrimson in presynaptic CA3 neurons, we could bi-directionally control synaptic transmission to postsynaptic CA1 neurons. The improved light-gated potassium channel is a new tool that expands the inhibitory optogenetic toolbox and allows for precise and potent manipulation of membrane potential and when combined with a Chrimson variant allows precise spiking or inhibition of presynaptic neurons with blue and red light.

Title: Altered excitability in a mouse model of multiple sclerosis: Role of voltage gated potassium channels

Authors: *L. FAZIO[1], M. CERINA[1], V. NARAYANAN[1], T. BUDDE[2], S. G. MEUTH[1]; [1]Neurol. Dept. with Inst. of Translational Neurol., [2]Inst. of Physiol. I, Univ. of Muenster, Muenster, Germany

Abstract: Multiple sclerosis (MS) is an inflammatory disease of the central nervous system, characterized by the appearance of randomly distributed brain lesions, involving both white and gray matter structures. These lesions are accompanied by episodes of de- and remyelination along with neuroaxonal degeneration. Recent findings pointed out that the early phase of

remyelination is characterized by a cortical hyperexcitability, suggesting an altered expression of certain ion channels along demyelinated neurons. Voltage-gated potassium channels (K_v) play a pivotal role in shaping neuronal excitability. The opening of these channels elicits and outward current repolarizing the cell and therefore, pharmacological targeting of these channels represents an appealing strategy for the treatment of various diseases. However, the role of these channels in autoimmune disorders still requires further investigations. To address this issue, we induced an experimental autoimmune encephalomyelitis in C57Bl6 mice, a widely used experimental model of MS. Furthermore, to mimic the appearance of lesions characteristic of MS, we focally injected a cocktail of the cytokines tumor necrosis factor alpha and interferon gamma in the primary auditory cortex. To investigate the contribution of K_v channels to cortical hyperexcitability, we electrophysiologically characterized cortical neurons in vitro. We therefore performed whole cell recordings on acute living brain slices from mice with a focal lesion and respective controls, at different stages of the disease. In current clamp, neurons from perilesional areas showed increased number of action potentials both in the acute (+100%) and late (+284%) phase of the disease in comparison to controls. However, specific K_v channel modulators were still efficient in limiting their excitability. In voltage clamp, measuring the outward current generated by these channels in the acute and late phase of the disease showed a reduced current amplitude (-40% and -41%, respectively) in accordance with an increased excitability. Taken together, our results suggest the involvement of K_v channels in generating and sustaining cortical hyperexcitability in our MS model and that the pharmacological modulation of K_v channels can partially rescue the normal phenotype.

Title: Ion channel mechanism of phenylephrine induced spontaneous firing in DRN 5-HT neurons

Authors: *J. WANG[1], Y. WANG[2], X. DU[3], H. ZHANG[4];
[1]Dept. of Pharmacol., Shijiazhuang, China; [2]Hebei Med. Univ., Shijiazhuang, China; [4]Pharmacol., [3]Hebei Med. Univ., Hebei, China

Abstract: Abstract
Over the years accumulated evidence implicate serotonergic (5-HT) system originating in the dorsal raphe nucleus (DRN) in the pathogenesis and treatment of psychiatric disorders. The firing activity of DRN 5-HT neurons is the key determinant in controlling the serotonin transmission and the emotion-related behaviors. 5-HT neurons are not intrinsic pacemakers but rather depend on extrinsic inputs to drive their firing, mainly the noradrenergic input trigger from the locus coeruleus (LC). Accordingly, noradrenergic agonist, e.g. phenylephrine (PE) could induce spontaneous firing of 5-HT neurons in brain slices which otherwise are quiescent. However, it is not clear how exactly PE induces this spontaneous activity, although some ion channels, e.g. A-type potassium channels have been suggested to play a role. In this study, we attempted to study the ion channel mechanism of phenylephrine-induced spontaneous firing in DRN 5-HT neurons. We found that the A-type potassium channels, the calcium-activated small-conductance potassium channels (SK channels) and the M-type potassium channels are likely the targets of PE modulation which contribute to the PE-induced spontaneous activity of DRN 5-HT neurons.

Title: Dopamine D2 receptor-mediated modulation of rat retinal ganglion cell excitability

Authors: ***N. YIN**, Y.-L. YANG, S. CHENG, H.-N. WANG, Y. MIAO, F. LI, Z. WANG; Inst. of Brain Science, State Key Lab. of Med. Neurobio. and MOE Frontiers Ctr. for Brain Science, Fudan Univ., Shanghai, China

Abstract: Retinal ganglion cells (RGCs) are output neurons in retinal circuity. Modulation of RGC excitability may affect the retinal visual information integration and processing. Here, whether and how dopamine D2 receptor modulate RGC excitability were explored in acutely isolated rat RGCs using whole-cell patch-clamp techniques. Extracellular application of quinpirole (10 μM), a selective D2 receptor agonist, significantly suppressed outward K^+ currents of the cells, which was reversed by sulpiride (10 μM), a selective D2 receptor antagonist. We further showed that quinpirole selectively suppressed glybenclamide- and 4-aminopyridine-sensitive K^+ current components, but had no effect on the tetraethylammonium-sensitive one. In addition, quinpirole significantly and selectively enhanced Nav1.6 voltage-

gated Na^+ currents. The effects of quinpirole on K^+ and Na^+ currents were mediated by intracellular cAMP/protein kinase A (PKA), mitogen-activated protein kinase (MAPK)/extracellular signal-regulated kinase (ERK), and calcium/calmodulin-dependent protein kinase II (CaMK II) signaling pathways, but not by phospholipase C (PLC)/protein kinase C (PKC) signaling. Under the current-clamp conditions, extracellular application of quinpirole significantly increased the numbers of action potentials evoked by positive current injections in RGCs, suggestive of enhanced cell excitability. Our results indicate that D2 receptor activation increases rat RGC excitability by suppressing glybenclamide- and 4-aminopyridine-sensitive outward K^+ currents and enhancing Nav1.6 currents through the intracellular cAMP/PKA, CaMKII and MAPK/ERK signaling pathways.

Title: Interaction between HCN and slack channels regulates mPFC pyramidal cell excitability and working memory function

Authors: *L. EL-HASSAR[1,3], D. DATTA[2], M. CHATTERJEE[1], A. F. ARNSTEN[2], L. K. KACZMAREK[1];

Abstract: Neuronal networks of the prefrontal cortex (PFC) subserve working memory (MW), the ability to retain short-term neuronal information in absence of sensory stimulation. This aspect of mental representation has been extensively studied in monkeys and rats using spatial working memory tasks and has been shown to depend on persistent firing of layer III dPFC pyramidal cells. Persistent firing of these neurons for a period of up to several seconds is therefore considered to be the cellular basis for spatial working memory. Disruption of dPFC pyramidal cell firing during stress or mental illness leads to working memory deficits and to inappropriate behavior. One mechanism by which stress can disrupt WM performance is through excessive release of catecholamines, which activate cAMP signaling to influence the activity of ion channels and alter PFC pyramidal cell firing. For example, increased open probability of hyperpolarization-activated cyclic nucleotide-gated (HCN) channels in response to elevated

cAMP during stress alters WM performance by decreasing firing rate. This finding raises the question of how activation of HCN channels, which normally produces depolarization and increased firing, reduces the firing of PFC pyramidal cells. We are testing the hypothesis that Na^+ influx through HCN channels activates Na^+-activated K^+ (K_{Na} or Slack) channels to hyperpolarize the membrane and raise spike threshold. Slack channels are highly expressed in the frontal cortex and human Slack mutations produce severe intellectual disability. We have tested interactions between HCN1 and K_{Na} channels in PFC pyramidal neurons using immunoelectron microscopy, co-immunoprecipitation, patch-clamp recordings and behavior. First, we found that ZD7288, a specific blocker of HCN channels reduces K_{Na} current in pyramidal cells but has no effect on Slack current in an HEK cell line stably expressing this K_{Na} channel, demonstrating that ZD7288 does not interact with Slack directly. Second, we found that Slack channels co-immunoprecipitate with HCN1, and, using immunoelectron microscopy, that HCN1 and Slack channels colocalize on the same dendritic spine of PFC pyramidal cells. Third, we have found that blockers of Slack channels (and of HCN1 channels) improve working memory performance and that the actions of Slack and HCN channel blockers occlude each other in the working memory test. Our ongoing results suggest that a common pathway between HCN and Slack channels exists to regulate the excitability of dPFC pyramidal neurons and WM performance

Abstract: ATP signaling and surface P2X4 ATP-gated receptor channels are upregulated in various neurological disorders including chronic pain, epilepsy and neurodegenerative diseases such as Alzheimer's disease (AD) or amyotrophic lateral sclerosis (ALS). P2X4 displays a widespread distribution in CNS neurons and glial cells as well as in multiple peripheral cell types throughout the body. A key question regarding the role of purinergic signaling in health and disease is the function of this upregulated surface P2X4 state observed in specific cell types. To elucidate the cell-specific functions of P2X4 in a pathological context, we created a conditional transgenic knock-in P2X4 mouse line (floxed P2X4mCherryIN) allowing the Cre activity-dependent genetic swapping of the internalization motif of P2X4 by the fluorescent protein mCherry to prevent constitutive endocytosis of P2X4. We describe and characterize two distinct knock-in mouse lines expressing non-internalized P2X4mCherryIN either in excitatory forebrain neurons (CamK2) or in all cells natively expressing P2X4 (CMV). The genetic substitution of wild-type P2X4 by non-internalized P2X4mCherryIN in both knock-In mouse models does not alter the sparse distribution and subcellular localization of P2X4 but leads to a cell-specific increased surface P2X4 expression mimicking the pathological upregulated P2X4 state. Floxed, CamK2- and CMV-P2X4mCherryIN mice were viable, normal in size, reproduced normally and displayed no obvious physical or behavioral abnormalities. We provide evidence using a battery of behavioral tests that the increase in P2X4 at the surface of excitatory neurons decreases anxiety and impairs memory processing. In addition, we demonstrate that increased surface P2X4 expression blocks long-term potentiation (LTP) and alters LTD at hippocampal CA1 synapses. These effects are more pronounced when surface P2X4 expression is specifically increased in forebrain excitatory neurons. The key finding of this study is that the increased surface expression of P2X4 in forebrain excitatory neurons is a major regulator of hippocampal synaptic plasticity, learning and memory and anxiety functions. Overall, we provide an innovative knock-in P2X4 model to study the functional contributions of upregulated P2X4 in specific cells of the nervous system but also in peripheral tissues throughout the body.

Title: Insulin regulates P2x4 receptor function and promotes its rapid delivery to the cell surface

Authors: E. BERTIN[1], A. MARTINEZ[1], A. R. ASE[2], E. EISELT[1], P. A. SEGUELA[2], M. EMERIT[3], *E. BOUE-GRABOT[1];
[1]IMN, CNRS UMR 5293, Univ. de Bordeaux, Bordeaux, France; [2]Dpt of Neurol. and Neurosurg., Montreal Neurolog. Institute, McGill Univ., Montreal, QC, Canada; [3]Inst. de Psychiatrie et Neurosciences de Paris, INSERM U1266, Univ. Paris Descartes, Paris, France

Abstract: P2X receptors (P2X) are ATP-gated non-selective cation channels highly permeable to calcium widely expressed in many tissues. In the central nervous system (in neurons and glia), macrophages, epithelia tissues, vascular endothelial cells they participate in synaptic neuromodulation and neuroglial communication, inflammation, chronic pain or vascular tone. P2X4 are constitutively internalized by dynamin-dependent endocytosis and mainly retained intracellular in basal conditions. P2X4 have been shown to be upregulated at the surface of cells in various pathophysiological contexts such as ischemia, chronic neuropathic pain or neurodegenerative diseases, indicating the importance of the regulation of P2X4 function and trafficking. Insulin was previously shown to modulate the trafficking and function of GABA-A and AMPA receptors in CNS neurons. Here we show that insulin induces a rapid (2-min incubation) and long-lasting increase of the amplitude of ATP-evoked currents in *Xenopus* oocytes expressing mammalian P2X4 receptors. Insulin blocks also the rundown of P2X4 responses observed during repeated application of ATP. In contrast, no change in ATP responses from oocytes expressing P2X2 or P2X3 receptors is observed in the presence of insulin. Internalization-deficient P2X4 mutants (P2X4Y378A, P2X4FlagIN or P2X4mCherryIN) responses are potentiated in a similar manner by insulin. In addition, western blot analysis of surface biotinylated and total protein fractions from oocytes shows that insulin increases the number of surface wild-type and internalization-deficient P2X4 mutants. Furthermore, ATP-evoked P2X4 currents and surface number of native P2X4 are significantly increased by insulin in mouse microglia as well as in native peritoneal macrophages from wild-type or knockin P2X4mCherryIN mice. The insulin-mediated increase of surface and function of P2X4 is abolished in presence of tyrphostin or TeTN, two blockers of insulin receptors and exocytosis, respectively. By real-time imaging on live cortical neurons expressing P2X4-pHluorin123 or P2X4Y378A-pHluorin123, we show that application of insulin causes a rapid and strong increase in fluorescence intensity of both constructs revealing the increase of insertion of P2X4 at the surface. Altogether, these results show that insulin potentiates P2X4 receptors in various cell types (neurons, microglia and macrophages) very likely via delivery of new P2X4 channels to the surface.

Title: Identification of hyperforin binding site at TRPC6 channels

Authors: *Y. EL HAMDAOUI, K. FRIEDLAND;
Pharmacy/Biochemistry, Mainz, Germany

Abstract: Depressive disorders are ranked on the second place of all known psychiatric diseases in humans and affect currently 300 million people of all ages worldwide according to the WHO. Extracts of St. John's wort plant (Hypericum perforatum) have turned out to be a clinical effective alternative to classical antidepressants to treat mild to moderate depression. The antidepressive active constituent of St. John's wort is the phloroglucinol hyperforin, which has been described as a potent uptake inhibitor of several neurotransmitters like serotonin, dopamine and norepinephrine and for the first time in 2007 as a selective activator of canonical transient receptor potential (TRPC) channel 6. However, the binding mode of Hyperforin to TRPC6 is still unknown. TRPC6 is a plasma membrane located nonselective cation channel permitting the uptake of mono- and divalent cations such as sodium and calcium. TRPC6 channels play an important role in neuronal Ca^{2+} signaling. Moreover, studies have already demonstrated that activation of TRPC6 channel via hyperforin regulate synaptic plasticity which is negatively changed in depression. Based on their amino acid sequences and functional similarities, the TRPC family can be divided into 4 groups: TRPC1, TRPC2, TRPC4/5, and TRPC3/6/7. As previously mentioned, hyperforin is a selective activator of TRPC6, which shows no activation of the TRPC6 homologues TRPC3 and TRPC7, respectively. Therefore, we screened several TRPC6 mutants by exchanging amino acids in TRPC6, which differed from TRPC3 or TRPC7 to evaluate the binding site of hyperforin. Afterwards, we started to focus on a TRPC6 mutation which showed no activity towards hyperforin. To demonstrate that this amino acid sequence is responsible for hyperforin mediated TRPC6 activation and selectivity over TRPC3, we exchanged the corresponding amino acids in TRPC3 with the respective amino acids of TRPC6. In single cell Ca^{2+} imaging experiments and patch clamp experiments, hyperforin now also activates mutated TRPC3 channels. Taken together, we identified the putative binding site of hyperforin at TRPC6 channels.

Title: TRPM2 regulates NPAS4 activity in the mouse hippocampal neurons

Authors: *S. KO[1,2], M. CHOI[1], H. SON[1,2];
[1]Hanyang Biomed. Res. Inst., Seoul, Korea, Republic of; [2]Hanyang Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Transient receptor potential melastatin type 2 (TRPM2) is an oxidative stress-sensing calcium-permeable channel that is abundantly expressed in the brain. TRPM2 signaling has been linked to several pathophysiological processes in the brain and proposed as a potential therapeutic target for neurological diseases. We previously demonstrated that *Trpm2* knockout mice had an antidepressant-like phenotype. Here we show that genetic ablation of TRPM2 increased phosphorylation of histone deacetylases 5 (HDAC5) and its nuclear export in mouse hippocampus. In addition, TRPM2 deficiency increased expression of neuronal PAS domain protein 4 (NPAS4), a neural activity-dependent transcriptional factor, which is negatively regulated by HDAC5. Conversely, H_2O_2-induced TRPM2 activation decreased NPAS4 expression in a dose-dependent manner in mouse hippocampal neuron. These results suggest that NPAS4-dependent gene expression might be altered in *Trpm2* knockout mice. We are currently investigating a role of NPAS4 in the antidepressant-like behavior of *Trpm2* knockout mice.

Title: Cholinergic receptors activate TRPM4 in pyramidal cortical neurons at mice mPFC layer 2/3

Authors: *E. LEIVA-SALCEDO, F. NAVARRO, F. A. PERALTA, D. RIQUELME;
Dept. of Biol., Univ. de Santiago, Santiago, Chile

Abstract: Medial prefrontal cortex receives cholinergic inputs from basal forebrain and local inputs from interneurons in the layer 1 which shapes its electrical properties. This cholinergic modulation specifically targets different cortical layers, the neurons wherein express different cholinergic receptors, giving an increasing processing and control capabilities of the cortical excitability. Intracellular Ca^{2+} is critical for this process and is actively involved in the setting of the resting membrane potential and particularly in medial prefrontal cortex layer 2/3, pyramidal neurons express TRPM4, a non-selective cation channel permeable to monovalent cations and activated by intracellular calcium with a somatic and proximal-dendritic distribution. Using slice electrophysiology and local perfusion of pharmacological modulators of TRPM4 and cholinergic receptors, we study the participation of TRPM4 in modulation of local membrane potential in response to cholinergic modulation and how this impact the EPSP transmission. We found that somatic carbachol perfusion depolarizes layer 2/3 neurons, TRPM4 inhibition reduces this effect. Furthermore, the application of TRPM4 inhibitor obliterates the effect of carbachol on mEPSP. Additionally, after a train of synaptic stimulation, the application of TRPM4 inhibitors in the soma or in the distal dendrites obliterates the effect of carbachol in the eEPSP amplitude and slope. Altogether, our results suggest that TRPM4 participates in the cholinergic control local excitability with ensuing effects on synaptic transmission.

Title: NALCN channel is essential for pacemaking activity and burst discharges in substantia nigra dopamine neurons

Authors: *S. HAHN, M. PARK;
Sungkyunkwan Univ. Sch. Of Med., Suwon-City, Korea, Republic of

Abstract: Dopamine neurons in the substantia nigra pars compacta (SNc) exhibit two major firing patterns: slow tonic firing and high-frequency phasic (burst) firing. Tonic pacemaking occurs spontaneously and regularly to maintain basal dopamine level, while phasic burst firing is evoked by glutamatergic afferents to increase dopamine transients in target areas *in vivo*. However, it is not elucidated whether NALCN ion channel is involved in these specific firing patterns in dopamine neurons. Since NALCN appears to be essential for the establishment of RMP and neuronal excitability, we investigated whether NALCN channels contribute to generation of tonic and phasic firings in nigral dopamine neurons. We observed that most dopamine neurons endogenously express NALCN mRNA. Replacement of extracellular Na^+ greatly influenced background leak currents and membrane potential. Despite the usage of TTX and Cs^+ which block Na_V and K_V channels, the substantial amount of Na^+ leak conductance remained, which was attenuated by inhibition of NALCN channels. NALCN inhibition also hyperpolarized membrane potential about 10 mV under the presence of TTX and ZD7288 which block Na_V and HCN channels. In addition, we found that, when NALCN was blocked, pacemaking was completely abolished and it can be reinstated by current injection. However, in this condition, glutamate-evoked burst firing was almost not generated. These results suggest that NALCN could play an important role not only in generation of pacemaker activity, but also in regulation of evoked burst discharges in nigral dopamine neurons.

Title: Prolonged bursting evoked by reactive oxygen species in *Aplysia* neuroendocrine cells

Authors: *A. K. CHAUHAN, N. S. MAGOSKI;
Dept. of Biomed. and Mol. Sci., Queen's Univ., Kingston, ON, Canada

Abstract: Ion channels are essential for regulating the excitability and plasticity of neurons. In particular, non-selective cation channels (which pass Na^+ and K^+, and sometimes Ca^{2+}) elicit plateau potentials and persistent spiking in neurons responsible for learning, sensory processing, motor output, or neuroendocrine function. The bag cell neurons of the mollusc, *Aplysia*, have been used extensively to examine the regulation of secretion and excitability. Upon synaptic stimulation, these neuroendocrine cells undergo a prolonged period of enhanced excitability, known as the afterdischarge, during which hormones are released into the blood to initiate

reproduction. In part, a Ca^{2+}-permeable, Ca^{2+}-activated, voltage-dependent cation channel provides the depolarizing drive to sustain the afterdischarge. Furthermore, the afterdischarge is associated with both the activation of phospholipase C, which hydrolyzes phosphatidylinositol-4,5-bisphosphate into diacylglycerol (DAG), and the production of reactive oxygen species. As such, we tested if hydrogen peroxide (H_2O_2) impacts afterdischarge generation and if this is influenced by DAG. Under whole-cell voltage-clamp, perfusion of micromolar to millimolar concentrations of H_2O_2 resulted in an inward current in single cultured bag cell neurons. Preventing H_2O_2 reduction with mercaptosuccinate enhanced the current, while the reducing agent, dithiothreitol, lowered the response. In current-clamp, H_2O_2 resulted in depolarization followed by a burst, similar to a genuine afterdischarge. Treatment with cation channel blockers, 9-phenanthrol or clotrimazole, as well as the classical Na^+ channel antagonist, tetrodotoxin, largely attenuated both the H_2O_2-induced current and action potential firing. Moreover, in *ex vivo* desheathed bag cell neuron clusters, sharp-electrode current-clamp recording showed that H_2O_2 evoked a *bona fide* afterdischarge, implying that H_2O_2 may activate the cation channel that maintains the afterdischarge. Our lab recently published that 1-oleoyl-2-acetyl-sn-glycerol (OAG), a DAG analogue, potentiates this cation channel in cell-free patches. In the present study, bath-application of OAG enhanced the H_2O_2-induced current in whole-cell voltage-clamped cultured bag cell neurons. This would suggest that reactive oxygen species and phosphoinositol metabolites may function synergistically, and contribute to reproductive behaviour by promoting long-term bursting.

Title: Mechanosensitivity of the bacterial voltage-gated sodium channel NaChBac

Authors: *P. R. STREGE[1], A. MAZZONE[1], C. ALCAINO[1], C. A. AHERN[2], G. FARRUGIA[1], A. BEYDER[1];
[1]Mayo Clin., Rochester, MN; [2]Univ. of Iowa, Iowa City, IA

Abstract: Voltage-gated Na^+ channels (Na_Vs) are critical determinants of cellular electrical excitability. Na_Vs are present in tissues that have primary mechanical functions, such as the

heart, skeletal muscle, and gastrointestinal tract. Indeed, eukaryotic Navs are mechanosensitive, but the molecular mechanism of their mechanosensitivity is poorly understood due to their fast kinetics, large size, and limited structural information. Prokaryotic Navs are emerging as excellent models of eukaryotic Navs. One such prokaryotic Nav channel from *Bacillus halodurans*, NaChBac, is structurally, pharmacologically, and functionally similar to eukaryotic Navs. Further, NaChBac mutant T220A inactivates 70-fold slower than wild-type (WT), which allows for a close examination of its activation mechanism. We aimed to investigate NaChBac mechanosensitivity at the whole cell and single channel levels. We transiently expressed WT or T220A NaChBac in Piezo1 knockout (P1KO) HEK293 cells to exclude contribution from the mechano-gated channel. We next recorded Na^+ currents either by whole cell voltage clamp or as single channels in cell-attached patches with mechanical stimulation by shear stress or pressure clamp, respectively. Similar to eukaryotic Navs in previous studies, shear stress of WT and T220A NaChBac increased peak Na^+ current (ΔI_{PEAK}: WT +58.7±10.1%, T220A +39.0±6.8%), accelerated the activation kinetics ($\Delta\tau_A$: WT -39.3±3.8%, T220A -42.1±5.6%), and hyperpolarized the voltage-dependence of activation ($\Delta V_{1/2A}$: WT -4.4±0.6 mV, T220A -3.7±0.9 mV) and WT inactivation ($\Delta V_{1/2I}$: -3.7±1.1 mV) (n=7 cells each). At the single channel level, negative pressure (-30 mmHg) significantly increased T220A NaChBac open channel probability (P_O) when the voltage-dependent P_O was 0.2-0.3 (ΔP_O: +142.3±22.3%), but not at P_O <0.2 (+19.8±6.3%) or >0.3 (+9.4±5.1%). The pressure-induced P_O increase was due to an increase in the number of open events (+116.7%) alongside a decrease in the average duration of the closed events (Δt_{CLOSED}: -19.1%). In conclusion, bacterial Navs are good models of eukaryotic Nav mechanosensitivity, and our results support a Nav mechanosensitivity model in which force increases P_O by destabilizing the closed state. Title: Aminoglycosides differentially modulate acid sensing ionic channels (ASIC) depending on subunit composition of the channel

Authors: *E. SOTO[1], A. ORTEGA-RAMÍREZ[3], R. FELIX[4], R. VEGA[2];
[1]Inst. of Physiol., Benemerita Univ. Autonoma De Puebla, Puebla, Pue., Mexico; [2]Benemerita

Univ. Autonoma De Puebla, Puebla, Mexico; [3]Benemerita Univ. Autonoma de Puebla, Institute of Physiology, Mexico; [4]Cinvestav-IPN, Mexico City, Mexico

Abstract: Acid-sensitive ion channels (ASICs) are involved in various processes such as epilepsy, cerebral ischemia pain perception, memory and learning among others, thus making them targets of interest. Aminoglycoside antibiotics were previously shown to inhibit ASIC currents in dorsal root ganglion neurons (DRGn) of the rat. In this work we report the effect of three aminoglycosides: gentamicin (Gen), tobramycin (Tbr) and kanamycin (Kan), on the ASIC currents. The experiments were performed using the patch clamp technique in the whole cell configuration to record native ASICs on DRGn and recombinant ASICs of different subunits (1a, 1b, 2a and 3) expressed in CHO K-1 cells. For the ASIC current activation a puff of acid pH (6.1, 5s) was used. In the co-application protocol both the acid pH and the drug were applied together during 5 s. In the pre-application the drug was applied 15s before the acid puff. In the pre-application channels interact with the drug in the closed state. In contrast, in the co-application the drug interacts with the channels in the open state. We found that in native ASICs, the co-application of Tbr, Gen and Kan produced a dose dependent inhibition of the ASIC currents, whilst during the pre-application Gen and Kan also produced an inhibition of the ASIC current whilst the Tbr increased the peak ASIC current up to 200% at 100 μM. Since the effect of Kan is of very low potency it was not further studied. In the heterologous expression system, Gen co-application has an inhibitory action in the peak of the current in ASIC2a and ASIC3 homomers. In both of them Gen also produced an increase in desensitization rate. Gen showed no action in ASIC1a homomers. In ASIC1a homomers the co- and pre-application of 100 μM Tbr produces an inhibition of the peak current. In ASIC1b tobramycin co-application has no effect but the pre-application inhibits the peak current and slows the desensitization rate. In ASIC2a homomers Tbr co-application produced an inhibition of the peak current, and a tendency to increase the peak current in the pre-application. In ASIC3 Tbr showed no action although a tendency to slow the desensitization rate was observed with the pre-application. In ASIC2a and ASIC2b heteromeric channels the co-application of Tbr inhibits the current and the pre-application produced an increase of the current. Our results showed that AG exerted a selective action depending on the subunit composition of the ASICs with a potentiating action while interacting with ASIC2a homomers and heteromers. The effect depends also on channels state. Thence analogues of these molecules could constitute new and valuable tools for the modulation of ASICs.

Title: Histological examination at A11 of rat

Authors: *H. OZAWA[1], T. YAMAGUCHI[2], S. HAMAGUCHI[1], S. YAMAGUCHI[1], S. UEDA[2];
[1]Anesthesiol., Dokkyo Med. Univ., Mibu, Japan; [2]Dept. of Histology and Neurobio., Dokkyo Med. Univ. Sch. of Med., Mibu, Japan

Abstract: The A11 dopaminergic (DA)cell group is the only group that includes neurons innervating the spinal cord among the A8-A16 dopaminergic cell groups. Adysfunction of A11 dopaminergic systemis thought to contribute to the pathogenesis of restless legs syndrome. However, little is known regarding the neuronal composition, distributions, neurocircuitries of the A11 region. Revealing these histochemical properties of A11 neurons is being expected to elucidatethe mechanisms of regulating the spinal dopaminergic system.To determine the neuronal composition in the A11 region of adult male rat, we performed immunohistochemistry for neuronal markers such as tyrosine hydroxylase (TH), calcium binding proteins (CaBP) including calbindin (Calb) and parvalbumin (PV), and also for calcitonin gene-related peptide (CGRP), androgen receptor (AR), and estrogen receptors. To determine innervations of the A11 region, we also performed immunohistochemistry for dopamine beta hydroxylase (DBH) and corticotrophin-releasing factor (CRF).We found at least three types of neurons in the A11 region regarding expression of CaBP:TH(-)/ Calb(+), TH(+) /Calb(-), or TH(+) /Calb(+), whereas there were no PV-immunoreactive (IR) cell bodies. In combination with a tracer experiment using retrograde tracer Fluorogold (FG), we found FG-positive (FG(+)) neurons with a variety of neurochemical properties: FG(+)/TH(+)/Calb(+), FG(+)/TH(+)/Calb(-), FG(+)/TH(-) /Calb(+), FG(+)/TH(-)/Calb(-). In addition to these neuronal populations expressing CaBP, we also found CGRP positive cells, AR positive cells in the A11 region.For neuronal innervations of the A11 region, both Calb- and PV-IR processes were found throughout the entire A11 region, extending in varied directions depending on the level relative to bregma. We also found CRF-IR processes and DBH-IR processes with characteristic distributions within the A11 region. These findings indicate that the A11 region is composed of a variety of neurons that are distinct in their neurochemical properties, and suggest that the diencephalospinal dopamine system may be regulated at the A11 region by Calb-IR, PV-IR, DBH-IR, and CRF-IR processes,and at the terminal region of the spinal cord by Calb-IR processes derived from the A11 region.

Title: The role of zinc in glycinergic synaptic transmission and hyperekpleixa

Authors: *D. WU[1], N. ZHOU[2];
[1]China Med. University, Grad. Inst. of Biomed. Science,, Taichung, Taiwan; [2]Grad. Inst. of BioMedical Sci., China Med. Univ., Taichung, Taiwan

Abstract: The free Zn^{2+} is not only a contributing factor of neuronal death after stroke, but also plays an important role in regulating synaptic transmissions by modulation of synaptic receptors and ion channels. Zn^{2+} modulates different channel receptors, such as NMDA receptors, GABAA receptors, glycine receptors (GlyRs), and voltage-gated Ca2+ channels. Among these, GlyRs are bidirectionally modulated by Zn2+: low concentrations (from nanomolar to low micromolar levels) of Zn^{2+} potentiate GlyR currents, whereas high concentrations (>~10 micromolar) inhibit GlyR functions. GlyRs mainly mediate the fast inhibitory synaptic transmission in the spinal cord and brain stem. The deficits of GlyR functions are directly associated with human hyperekplexia, which is characterized by exaggerated startle responses upon the unexpected stimuli. It has been reported that the $Glra1^{D80A}$ knockin mice, in which the potentiation of GlyR was supposed to be eliminated, showed only mild symptoms resemblance to the human startle diseases. However, more recent studies argued that the D80A mutation failed to affect Zn2+-mediated potentiation on GlyR functional, making it inconclusive whether Zn2+ modulation is critical for GlyR-mediated functions and synaptic transmission.Our recent study has found that the human hyperekplexia missense mutation in the GlyR α1 subunit, W170S, caused almost complete loss of Zn2+-mediated potentiation, and these results have been confirmed by several other groups. Based on our previous studies, we generated W170S knockin mice. The phenotypes of W170S mice appeared from 14 days to 16 days after birth. They showed reduced the right reflex abnormal gait and tremor. A sudden sound from a clap by the observer led to the generalized muscle contractions and the fall over. The severity of symptoms gradually increased since the initiation. Usually, the homozygous died in 4 to 5 postnatal weeks even with intensive care. The mRNA level of Glra1 in the cortical cortex and spinal cord from WT, heterozygous and homozygous Glra1(W170S) mice from the same litters were not significantly different by performing Q-PCR assay. We further detected the protein expression levels of GlyRs α1 in the neocortex and spinal cord. The preliminary results indicated that the

expression level of GlyRs α1 in the spinal cord showed a mild decrease in homozygous but not heterozygous Glra1(W170S) compared with their WT littermates. Taking advantage of this knock-in mouse model, we will unveil whether Zn2+ modulates synaptic transmission in glycinergic synapses and how these modulations are linked to human diseases.

Title: Dendritic localisation and exocytosis of NAAG in the rat hippocampus

Authors: K. NORDENGEN[1,4], ***C. MORLAND**[2,1], B. S. SLUSHER[5], V. GUNDERSEN[6,1,3]; [1]Dept. of Mol. Med., [2]Dept. for Pharm., [3]Inst. of Clin. Abstract: While a lot is known about classical, anterograde neurotransmission, less is known about the mechanisms and molecules involved in retrograde neurotransmission. Our electron microscopic immunogold data suggests that N-acetylaspartylglutamate (NAAG), the most abundant dipeptide in the brain, act as a retrograde transmitter in the hippocampus. NAAG was predominantly localised in dendritic elements of glutamatergic synapses, where it was present in close proximity to synaptic-like vesicles. In hippocampal slices, NAAG was depleted from postsynaptic dendritic elements during neuronal stimulation induced by depolarising concentrations of potassium or by exposure to glutamate receptor agonists. The depletion was completely blocked by botulinum toxin B, and strictly dependent on extracellular calcium, indicating exocytotic release. In contrast, NAAG levels in presynaptic glutamatergic nerve terminals and GABAergic pre- and postsynaptic elements were very low. In these compartments depolarisation or glutamate receptor agonists, did not affect the levels of NAAG, indicating that NAAG was released exclusively from postsynaptic elements of glutamatergic synapses. Together these data suggest a possible role for NAAG as a retrograde signalling molecule at glutamatergic synapses via exocytotic release.

Title: Cell-type specific serotonergic modulation of the claustrum

Authors: *K. L. L. WONG, G. J. AUGUSTINE;
Lee Kong Chian Sch. of Med., Nanyang Technological Univ., Singapore, Singapore

Abstract: The claustrum is a thin, long structure that forms dense and reciprocal connections with many other brain regions. Although serotonergic inputs to the claustrum have been reported (Histochem J. 28:747; J Comp Neurol. 526:2428), the role of serotonin in claustral function is unknown. To address this question, we performed whole-cell patch clamp recordings from claustral neurons in brain slices, while either applying serotonin by pressure application or releasing endogenous serotonin by photostimulating serotonergic terminals via Channelrhodopsin-2. Six different types of claustral neurons were classified according to their intrinsic electrical properties. Approximately 75% of all these neurons responded to serotonin application, even in the presence of blockers of glutamate receptors (kynurenic acid; 100 μM) and GABA receptors (GABAzine; 10 μM) to eliminate potential upstream synaptic responses. In all three types of claustral projection neurons, serotonin evoked a long-lasting outward current (V_h = -60 mV) that was caused by a potassium conductance increase. Photostimulation-induced release of endogenous serotonin evoked a similar outward current response from claustral projection neurons. This response was mediated by at least in part by 5HTR-2C serotonin receptors, because it was reduced by a specific blocker of this receptor (RS1002221; 5 μM). Claustral interneurons exhibited a heterogenous mix of responses to serotonin application. VIP interneurons produced an inward current at -60 mV. This response was mediated by 5HTR-3A receptors, because it was eliminated by the 5HTR-3A blocker granisetron (1 μM). In contrast, SST and PV neurons showed either inward or outward current responses. We conclude that serotonin produces a diversity of postsynaptic actions within the claustrum: projection neurons are largely inhibited by serotonin, while local interneurons are either excited or inhibited by serotonin. On balance, the net effect of this serotonergic modulation is to inhibit claustral output. Thus, serotonin could play a prominent role in gating claustrum function *in vivo*.

Title: Neuronal cFOS activation in response to amphetamine and methamphetamine identified with whole brain clearing

Authors: *T. P. WIGSTROM[1], S. M. UNDERHILL[1], M. S. COLT[1], S. WILLIAMS AVRAM[2], T. USDIN[2], S. G. AMARA[1];
[1]Lab. of Mol. and Cell. Biol., Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Systems Neurosci. Imaging, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Acute exposure to amphetamine (AMPH) and methamphetamine (METH) has been extensively linked to the activation of mesocorticolimbic circuits through their ability to modulate dopaminergic and glutamatergic neurotransmission. The two drugs differ in their elicited behavioral outcomes, therapeutic utility, and potential for addiction despite only differing by a single methyl group. Upon entry into dopamine neurons, both drugs activate similar G-protein-linked signaling pathways through the activation of an intracellular GPCR for trace amines, TAAR1. However, we have recently observed that METH can activate these same signaling pathways in cell types which lack the dopamine transporter (DAT), suggesting that METH can enter cells through a different mechanism that does not involve transport by the DAT. To further investigate this hypothesis, we examined the anatomical distribution of activated neurons in the brains of mice exposed to AMPH and METH using the whole brain clearing technique iDISCO (immunolabeling-enabled 3D imaging of solvent-cleared organs). We identified activated neurons in the brain by immunostaining for activated cFos, an immediate early gene transcription factor that is highly responsive to membrane depolarization and thus provides a readout of neuronal activation. Saline, AMPH (2 mg/kg), or METH (2 mg/kg) solutions were administered by i.p. injection into adult (12-24 w) C57/bl6 male and female mice. At 2 hrs, the mice were anesthetized and perfused with 4% paraformaldehyde. The whole brains were immunolabeled for cFOS and then cleared with dichloromethane and dibenzyl ether. We imaged the brains with a light sheet microscope and analyzed the images with Arivis software. We identified eighteen regions of interest, with the majority involved in either basal ganglia or limbic circuits. Differences in cFos activation were observed between vehicle control and AMPH brains. Furthermore, METH brains exhibited new regions of activation compared to the AMPH brain. These data highlight the divergent circuit activation mediated by these closely-related psychostimulants that may contribute to the differences in the pharmacological and behavioral profiles observed for AMPH and METH.

Title: Methamphetamine sensitization facilitate inhibitory currents in pyramidal neurons from the medial prefrontal cortex

Authors: *M. ARMENTA-RESÉNDIZ[1], A. LAVIN[2];
[1]MUSC, Charleston, SC; [2]Dept Neurosci, Med. Univ. South Carolina, Charleston, SC

Abstract: Background: Chronic methamphetamine (METH) exposure has become a serious problem throughout the world and has been connected to several harmful medical complications, particularly hypofrontality and deficits in cognition. Here we propose that METH sensitization increases inhibitory transmission in the prefrontal cortex (PFC) through a D1R activation of fast-spiking parvalbumin-positive interneurons. The outcome of interneuron over-activation will be an imbalance in excitation/inhibition homeostasis resulting in hypofrontality and cognitive deficits.Methods: We use whole-cell recordings to determine the effects of METH sensitization (1 mg/kg 1st and 7 or 14 day and 5 mg/kg 2-6 or 2-13 days) on the inhibitory activity in prelimbic (PL) layer 5 pyramidal neurons of slices from medial prefrontal cortex (mPFC) in Cre+ PV Long-Evans male and female rats. We evaluate cognitive activity with Novel Object Recognition (NOR) and working memory tests (WM). Results: Neurons from animals repeatedly exposed to METH show a significant increase in the amplitude of sIPSCs after 7 or 14 days of METH. Also, they show a significant increase in frequency at 14 days as well as significant increases in the current needed for evoking a minimum response. Moreover, bath administration of the antagonist D1 SCH 23390 blocks the METH effect in amplitude but not in the frequency of the events. We also found that METH causes significant deficits in the NOR test for temporal order memory.Conclusions: In summary, METH sensitization enhances the inhibitory transmission in PL layer 5 pyramidal neurons of the mPFC and causes cognitive impairments. D1 antagonism is able to reduce the postsynaptic effects mediated by METH exposure.

Title: Is it time to rename the neuropeptide processing enzyme Neurolysin (EC3.4.24.16)?

Authors: *K. D. PHILIBERT[1], X. SHAO[1], M. J. GLUCKSMAN[2];
[1]Ctr. for Proteomics and Mol. Therapeut., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL; [2]Biochem. & Mol. Biol., Chicago Med. School/RFUMS, North Chicago, IL

Abstract: Neuropeptides modulate intercellular communication for proper metabolic activity, cell differentiation and growth in a neurobiological context. Alterations in expression or processing of neuropeptides produces deleterious neuropathophysiologic processes. It is the neuropeptide processing enzymes that form a nexus in the synapse for regulating signaling in the extracellular milieu through its control of peptide neurotransmitters. Though originally assigned numbers by the Enzyme Commission, more descriptive names were assigned ~25 years ago when fewer neuropeptides were known but today these names are misnomers and do not adequately convey function. Two closely related neuropeptide processing enzymes that cleaved 6-9 different substrates at the same location, EC3.4.24.15 (EP24.15; thimet oligopeptidase) and EC3.4.24.16 (EP24.16; neurolysin), were distinguished solely by an alteration in the bond hydrolyzed in neurotensin; hence, the designation Neurolysin. Through our neuromics discovery pipeline to unveil new substrates for processing enzymes, the repertoire of neuropeptide regulation has expanded beyond the initial six to nine observations in the past. Utilizing biochemical, structural, and systems-based proteomic approaches including in silico molecular modeling, mass spectrometry, enzyme kinetics, and X-Ray crystallography, we have demonstrated substrates for EP24.16 that differ substantially from the closely related EP 24.15 both in the detailed cleavage sites as well as whether a peptide can be degraded and thus is a true substrate. Several examples include the neuroprotective, hybrid neuropeptide substrate Colivelin and the EP 24.15 cleaved reproductive peptide Phoenixin while gonadotropin inhibitory neuropeptide RFRP-3 exhibits different cleavage sites. Interestingly, Xenin 8, a gut peptide, with a C-terminal sequence very similar to Neurotensin, is cleaved at the same site by both EP24.15 and EP24.16 enzymes. This has further ramifications as several processing enzymes can act upon the same neuropeptide and a given neuropeptide can be a substrate for several neuropeptide processing enzymes. Furthermore, the fragments produced by the action of these enzymes themselves can have varied and novel functions such as the degradation of the decapeptide GnRH responsible for reproduction; the GnRH1-5 fragment produced has a different receptor

and downstream signaling from it's parent peptide. With the discovery of novel neuropeptides and their functions coupled with advanced technological methodologies, one must be cautious with utilizing older, misleading enzyme names for neuropeptide processing enzymes.

Title: Sigma-1 receptor control of cocaine-induced endocannabinoid signaling via inhibition of extracellular vesicle release in the ventral tegmental area

Authors: *D. I. DRYANOVSKI[1], Y. NAKAMURA[2], T.-P. SU[3], C. R. LUPICA[4];
[1]Natl. Inst. On Drug Abuse, NIH, Baltimore, MD; [2]Pharmacol., Hiroshima Univ., Hiroshima, Japan; [3]Cell. Pathobiology Section Integrative Neurosci. Br., NIDA-IRP, NIH, Baltimore, MD; [4]Electrophysiology Res. Section, NIH/NIDA-IRP, Baltimore, MD

Abstract: Endogenous cannabinoids (eCB) are signaling lipids released from neurons that retrogradely activate cannabinoid CB1 receptors (CB1R) on axon terminals to limit neurotransmitter release. 2-arachidonoylglycerol (2-AG) is an eCB that is synthesized from membrane phospholipids by the enzyme diacylglycerol lipase-α (DGLα). Our previous work has demonstrated that cocaine stimulates 2-AG synthesis in rat midbrain dopamine neurons to increase their activity via inhibition of GABAergic synapses, or disinhibition. However, mechanisms for 2-AG release are unknown. Here, we confirm that cocaine stimulates the synthesis of 2-AG in the mouse midbrain dopamine neurons and identify a mechanism whereby 2-AG is localized to non-synaptic extracellular vesicles (EVs) that are released when cocaine binds to the Sigma-1 receptor (σ1R). The σ1R resides on the mitochondria-ER interface membrane, serving as a protein chaperone, and plays a role in controlling calcium signaling from the ER to the mitochondria. Under basal conditions, the σ1R is bound to ADP-ribosylation factor 6 (ARF6), a small GTPase. Cocaine binding to the σ1R leads to dissociation of the σ1R/ARF6 complex and activation of myosin light chain kinase (MLCK), which is permissive to EV release. Genetically eliminating or pharmacologically inhibiting σ1Rs prevented cocaine-induced 2-AG release. However, pharmacological inhibition of σ1Rs had no effect on depolarization-induced suppression of inhibition (DSI) at GABAergic synapses on midbrain dopamine neurons, and experiments are planned to determine whether DSI is disrupted in σ1R knockout mice. We also found that the synthesis and tonic release of 2-AG is not altered in σ1R knockout mice,

suggesting specificity for cocaine-facilitated 2-AG release. Our results demonstrate that cocaine-mediated 2-AG signaling is controlled by the σ1R-ARF6-MLCK pathway and shed new light on the mechanisms through which cocaine promotes eCB release. These results could lead to potential novel treatments for cocaine addiction.

Abstract: Extracellular vesicles (EVs) are specialized organelles that extrude and transfer proteins and RNAs between cells. Neuronal EVs have been identified, but their properties and functional relevance remain poorly understood. We performed transcriptomic and proteomic analyses and unexpectedly identified EVs as critical regulators of the early molecular events underlying NMDAR-dependent synaptic strengthening. Rapidly after NMDAR activation the core EV proteins Alix and Tsg101 are synthesized, localize to synapses, and promote EV release from neurons. Synaptic activity-induced EVs have similar properties to EVs produced by other cells types, and proteomic analysis revealed they contain phosphorylated CamKII and other synaptic proteins. EVs can be taken up by nearby neurons and induce bi-directional synaptic signaling via subsequent phosphorylation of CamKII in unstimulated neurons. Blocking ceramide production, which is required for EV biogenesis, inhibited the enhancement of mEPSC amplitudes after glycine treatment. Taken together, EVs appear to play an active role in the process of synaptic strengthening.

Abstract: The extracellular matrix (ECM) regulates neural development and activity of neural and immune cells in mature brains. Paradoxically, ECM attenuation is reported either to enhance or to impair synaptic plasticity. Here, we uncover molecular mechanisms behind this dual action. We demonstrate that enzymatic attenuation of ECM by chondroitinase ABC (ChABC) decreases CA1 pyramidal cell excitability and thus restrains long-term potentiation (LTP) in CA3-CA1 synapses. This effect is mediated by a loss of ECM proteoglycan brevican, triggering increased cell surface expression of small conductance (SK) Ca^{2+}-activated K^+ channels through a mechanism involving metabotropic glutamate receptors ($mGluR_{III}$) and protein kinase A. Blocking this mechanism restores principal cell excitability and LTP in brevican knockout mice, and leads to supranormal signaling through β1 integrins and NMDA receptors, which augment LTP after enzymatic attenuation of ECM. Thus, ECM molecules - enriched in perineuronal nets associated with fast-spiking perisomatic interneurons, but also broadly expressed as the perisynaptic ECM enveloping principal neurons - homeostatically control the excitability of the latter cells and predisposition of excitatory synapses to undergo functional modifications.

Title: The role of Itgβ3 in nucleus accumbens function

Authors: *A. N. JAMESON[1], A. CARNEIRO[2], D. G. MCMAHON[3,2,1], B. A. GRUETER[4,2,1]; [1]Vanderbilt Brain Inst., [2]Pharmacol., [3]Biol. Sci., [4]Anesthesiol., Vanderbilt Univ., Nashville, TN

Abstract: Stress disorders, like depression, anxiety, and substance use disorder, are regulated by serotonin (5-HT). The dorsal raphe nucleus (DRN), the major site for neuronal 5-HT synthesis, sends projections to the nucleus accumbens (NAc). Synaptic adaptations in the NAc correlate with changes in mood and reward, key components of stress disorders. A subpopulation of DRN projection neurons express the β3 subunit of the integrin αvβ3 receptor (Itgβ3). Itgβ3 regulates extracellular 5-HT concentration by modulation of 5-HT transporters. Mice lacking Itgβ3 have increased vulnerability to chronic stress, implicating a role for Itgβ3 in behavior. Furthermore, the Itgβ3 receptor contributes to cocaine-reinstated drug-seeking by regulating AMPAR surface expression in the NAc. However, how Itgβ3 regulates 5-HT and excitatory transmission in the NAc, and contributes to maladaptive reward behaviors is unknown. Itgβ3 is only expressed in a subpopulation of 5-HT neurons, suggesting that it confers a specific function to this neuronal population. Using a mouse line with selective deletion of Itgβ3 within 5-HT neurons, we are investigating its role in the DRN to NAc circuit. Using acute brain slice whole-cell patch-clamp electrophysiology, we have characterized how Itgβ3 contributes to 5-HT synaptic transmission as well as glutamatergic transmission. Our data suggests that Itgβ3 in 5-HT neurons modulates both excitatory and 5-HT synaptic transmission in the NAc. Behavioral assessment of the contribution of Itgβ3 within this circuit is ongoing. Taken together, the behavioral and electrophysiological assessment will provide an understanding of the mechanistic contribution of Itgβ3 within the 5-HT circuit to stress disorders.

Title: Acetylcholine differentially modulates cortical and thalamic input to the basolateral amygdala

Authors: *S. C. TRYON[1], J. X. BRATSCH-PRINCE[1], J. W. WARREN[1], G. C. JONES[1], M. A. WILSON[1,2], A. J. MCDONALD[1], D. D. MOTT[1];

Abstract: The basolateral amygdala (BLa) receives glutamatergic input from cortical and subcortical regions and cholinergic input from the basal forebrain. Acetylcholine, released by this cholinergic input, can modulate emotional memory encoding and consolidation. We have previously reported that pharmacological activation of muscarinic receptors (mAChRs) suppresses cortical input to the BLa and that the extent of this muscarinic inhibition varies between individual rodents. Furthermore, differences in muscarinic inhibition correlate with individual differences in cued fear learning and extinction in rats, suggesting that differences in cholinergic signaling may underlie individual variation in the susceptibility to fear memory disorders. To further explore the mechanism of cholinergic inhibition we used brain slice electrophysiology and optogenetics to investigate the effect of optogenetically released ACh at prelimbic (PL) and thalamic (THAL) inputs to BLa. Released ACh significantly suppressed both cortical and thalamic input to BLa. Theta burst stimulation of cholinergic input was effective at producing inhibition, in line with the reported firing pattern of basal forebrain neurons. ACh-mediated inhibition of cortical input was blocked by atropine, indicating that it was muscarinic receptor-mediated. To investigate inhibition at specific input pathways, we optogenetically stimulated PL or THAL input and pharmacologically activated mAChRs with muscarine. Muscarine produced significantly stronger inhibition of PL than THAL input. Furthermore, inhibition in these two pathways was mediated through different mechanisms. Inhibition of PL input was directly produced by presynaptic M3 mAChRs, whereas inhibition of THAL input was mediated by retrograde endocannabinoid signaling engaged by postsynaptic M3 mAChRs.

Reflecting these distinct mechanisms, muscarinic inhibition in these two pathways displayed distinct frequency dependence. During low frequency stimulation (1-10 Hz) of input pathways, muscarinic inhibition remained intact throughout the 10 pulse stimulus train. However, during high frequency stimulation (20-40 Hz), inhibition of THAL input strengthened, whereas inhibition of PL input was relieved. Furthermore, at PL inputs we found that postsynaptic mAChRs enhanced NMDA currents, suggesting that the PL input that overcomes muscarinic inhibition may selectively enhance plasticity. Overall, these findings suggest a mechanism through which ACh can specifically enhance signaling and plasticity during high frequency (gamma) activity at PL input and regulate fear memories.

Title: Ethanol modulation of inhibitory circuits in the basolateral amygdala

Authors: *S. MUNSHI, J. G. TASKER;
Tulane Brain Institute, Dept. of Cell and Mol. Biol., Tulane Univ., New Orleans, LA

Abstract: Both clinical and pre-clinical studies have shown an effect of alcohol consumption on fear conditioning. The basolateral amygdala (BLA), which consists of both glutamatergic projection neurons and GABAergic interneurons, is known to play an important role in the development and regulation of fear memory formation. The overall excitatory activity of the BLA is tightly regulated by GABAergic interneurons, which play an important role in fear memory regulation. Thus, determining the effect of alcohol on the activity of local GABA circuits in the BLA is crucial to understanding the neuronal basis for the neurophysiological and fear-related behavioral effects of alcohol consumption. The alcohol regulation of GABAergic interneuron circuits of the adult BLA is not well understood. Therefore, in the present study, we used *ex vivo* whole-cell patch-clamp recordings from BLA pyramidal neurons in amygdala slices of adult male Wistar rats (8 - 10 weeks of age) to investigate the effects of acute ethanol application on GABAergic inhibitory postsynaptic currents (IPSCs). Our exploratory findings showed that ethanol increases the frequency of both spontaneous and miniature IPSCs without affecting IPSC amplitude or decay time. Preliminary experiments suggest that the ethanol response is specific to parvalbumin neurons. These data suggest that ethanol causes a spike-

independent, presynaptic modulation of GABA inhibitory inputs from parvalbumin interneurons to BLA principal neurons in the adult male rat.

Title: Astroglial role in synchronized persistent neuronal activities

Authors: *R. KUMAR[1], Y.-T. HUANG[2], S.-F. TZENG[3], C.-K. CHAN[1];
[2]Inst. of Physics, [1]Inst. of Physics, Academia Sinica, Taipei, Taiwan; [3]Dept. of Life Sciences, Natl. Cheng Kung Univ., Tainan, Taiwan

Abstract: Cognitive processes are related to synchronization and propagation of firing activities in neuronal systems. These temporal coordinations in the form of burst-firings occur by sequential activation of cell assemblies (1) and are widely observed *in vivo* and *in vitro* brain tissue conditions. This process of sequential cell assembly could be physiological (2) or pathological (3). Still, the underlying mechanism behind such coordinated behavior remains unclear. Lines of evidence indicate astroglial network could extend neuroglial interplay by allowing information processing and integration in large number of neurons. It is now conceivable that origin and sustenance of coordinated temporal dynamics in neurons may not solely ruled by neuron-neuron interaction. Recent findings on neuron-astrocyte synaptic interaction (4) further supports, neuro-glial networking could be the effective mechanism behind such coordinated activities. However, the collective dynamics interplay between the two cell types had been speculative due to absence of robust astrocyte-specific tools so far. Current advancement in genetically encoded indicators specifically designed for studying astrocytes enables us to investigate their interactions more closely. Here we report our findings obtained from cortical cultures developed on a multi-electrode arrays (MEA) system. Employing astrocyte-specific genetically encoded calcium indicators(GECI) with MEA, we found that astroglial network respond to neuronal persistent synchronized activities through synchronized calcium elevation. Based on previous studies (5), positive feedback from synaptic glutamate release mediates persistent neuronal activities. Through pharmacological manipulation of glutamate transporters, it was found that persistent activities are tightly regulated by astrocytic glutamate transporters (GLT-1). Therefore, it is indicative that neuron-astrocyte interaction through astroglial glutamate transporter system could be an important regulatory mechanism

whose function/dysfunction could contribute to context-dependent/abnormal information integration in neuronal circuits.

Title: Persistence of neuronal representations through time and damage in the hippocampus

Authors: *W. G. GONZALEZ, H. ZHANG, A. HARUTYUNYAN, C. LOIS;
Caltech, Pasadena, CA

Abstract: It is not known how neurons encode memories that can persist up to decades. To investigate this question, we performed long-term simultaneous bilateral imaging of neuronal activity in the hippocampus of freely moving mice. From one day to the next ~40 % of neurons changed their responsiveness to cues; however, thereafter only an additional 1 % of cells changed for each additional day. Despite the apparent instability between days, field responses of CA1 neurons are very resilient to lack of exposure to the task or lesions to CA1. Although a small fraction of individual neurons retain their responses over weeks, groups of neurons with inter- and intrahemispheric synchronous activity had stable responses. Neurons whose activity was synchronous with a large group of neurons were more likely to preserve their responses across multiple days. These results suggest that although information stored in individual neurons is relatively labile, representations of a familiar environment can be stable in networks of synchronously active neurons.

Title: Interneuronal control of early oscillatory activity in the olfactory bulb of neonatal mice

Authors: ***J. K. KOSTKA**, I. L. HANGANU-OPATZ;
Developmental Neurophysiol., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Precisely-tuned interplay between pyramidal neurons and interneurons during early development enables the maturation of neuronal networks and their coordinated activity as well as behavioral performance at adulthood. In the olfactory bulb (OB), oscillatory activity in different frequency bands is considered to be important for odor sampling, discrimination, and learning. However, while the sense of olfaction is already functional from birth, the OB network activity at this age differs substantially from adult patterns. Recently, we have shown that in the developing OB, pyramidal neurons, i.e mitral and tufted cells (MTCs), play a crucial role in the generation of neonatal continuous respiration-driven oscillations (2-4 Hz) and discontinuous theta bursts (4-12 Hz). In addition, odor sampling induces beta band (15-30 Hz) activity in the neonatal OB, while gamma oscillations (30-100 Hz), linked to odor discrimination, are still absent during the first postnatal weeks. The role of interneurons for the generation of oscillatory patterns in the OB during development remains largely unknown. To close this knowledge gap, we combine optogenetic manipulation of genetically-defined interneuron subtypes in the OB of neonatal mice (postnatal day (P) 8-10) with extracellular recordings of single unit activity and local field potentials *in vivo*. Optogenetic stimulation of $Gad2^{+}$ interneurons leads to a strong decrease in MTC firing as well as a decrease of oscillatory activity in the theta and beta band in the OB. In contrast, inhibition of the same cell populations increases theta band activity as well as the power of the respiration-related rhythm. These results indicate an important role of local interneuron-MTC interactions in shaping coordinated activity in the developing OB.

Title: Cholinergic induced slow wave oscillation in the claustrum *in vitro*

Authors: *T. J. BAL, C. MONIER, G. OUANOUNOU;
Integrative and Computat. Neurosci., Paris-Saclay Inst. of Neurosci. (NeuroPSI), CNRS/Paris-Sud University, UMR9197, Gif Sur Yvette, France

Abstract: The claustrum (and the endopiriform nucleus) form a complex containing a small proportion of interneurons and a majority of far-projecting excitatory claustrocortical neurons that lay deep below the insular cortex. It is the most reciprocally connected structure in the brain and receives cholinergic and a variety of neuromodulatory inputs from subcortical structures (Goll et al., 2015). Its functional role remains largely unknown. The claustrum has been proposed to be a central integrator for the unified sense of cognition (Crick & Koch, 2005), a hub for attention (Atlan et al., 2018), for multi-sensory binding, and may modulate the synchronization of neocortical slow-wave activity (Narikiyo et al., bioarXiv 2018) or enhance synchronized oscillations between cortical areas (see Vidyasagar & Levichkina, 2019). Little is known on the claustrum circuit properties or on its cell-types: the membrane and synaptic properties, the sensitivity to neuromodulation, and spontaneous states of activities. We use techniques that preserve recurrent slow oscillations (resembling the in vivo up & down states) in cortical circuits in mouse brain slices. In a slice that contains parts of the claustrum and neocortex, we found that the claustrum generates two different types of activities. i) A spontaneous and moderate spiking discharge in principal neurons and interneurons generated by background synaptic activity appears randomly, can last hundreds of milliseconds to seconds, and returns to quiescent periods. ii) Application of the cholinergic agonist carbachol induces in about half of the experiments a robust 0,3-1 Hz rhythmic recurrent network oscillation characterized by the occurrence of compound excitatory and inhibitory postsynaptic potentials and spike discharge. We are exploring the mechanisms of this claustrum slow-wave activity: Does it result solely from the interactions of neurons within the claustrum, although there are few direct connections between its principal cells (Kim *et al.*, 2016), and/or is it due to synaptic loops between the claustrum and neocortex, such as the adjacent insular cortex, or the entorhinal cortex that spontaneously generates Up & down states in the same slice?

Title: Conditions for and detectability of extremely fast oscillations in neuronal activity

Authors: R. HELIN[1], S. ESSINK[2], H. BOS[3], E. HAGEN[4], M. HELIAS[2], J. SENK[2], T. TETZLAFF[2], S. J. VAN ALBADA[2], M. DIESMANN[2], S. GRÜN[2], ***H. E. PLESSER**[1,2];

Abstract: While validating a biologically motivated network model [1] against some 150 simultaneously recorded experimental spike trains [2] we observed qualitative differences in the raster plots and power spectra of the two. The network model exhibits extremely fast oscillations at over 200 Hz visible as a peak in the power spectrum and as narrow, closely spaced vertical stripes in the spike raster plot, which are not visible in raster plots of the experimental data. We wondered if the extremely fast oscillations may be overlooked in experimental data due to lack of data or if they only exist due to specific properties of the network model.
Early theoretical studies of simple random networks identified the inhibition-dominated excitatory-inhibitory loop as the origin of these oscillations and proposed parameter regimes avoiding the oscillations [3]. Today, both analytical and simulation tools are available to investigate more complex multi-layered network models.
This allows us to investigate extremely fast oscillations in a well-established cortical microcircuit model [1,4] comprising four cortical layers with an excitatory and inhibitory population each.

After confirming that the extremely fast oscillations are not simulation artifacts, we explored how the number of spike trains sampled from simulations affects the detectability of gamma-band and of extremely fast oscillations. We further found that extremely fast oscillations do not occur for certain distributions of synaptic delays.

Title: Hippocampal fast-spiking interneurons are functionally more vulnerable to acute hypoxia-ischemia and reperfusion in comparison with pyramidal cells

Authors: *D. HEFTER, P. GRUBE, A. DRAGUHN, M. BOTH;
Inst. of Physiol. and Pathophysiology, Heidelberg Univ., Heidelberg, Germany

Abstract: Fast-spiking interneurons (FSI) are considered to be more vulnerable to metabolic insults than pyramidal neurons (PYR) due to their high energy demand. As FSI orchestrate synchronous network activity such as gamma and sharp-wave ripple oscillations (SPW-R), impairment of their function following hypoxia-ischemia (HI) implies disturbed network function and excitatory-inhibitory balance, which may lay the basis for development of neuropsychiatric diseases. However, the acute effects of HI on FSI function and the consequences for network activity remain elusive. Therefore we employed a model of oxygen-glucose deprivation (OGD) and reperfusion in acute brain slices exhibiting spontaneous SPW-R and performed tetrode recordings from the hippocampal CA3 and CA1 regions. OGD was maintained until a hypoxic spreading depression occurred; then the tissue was allowed to recover for one hour under normoxic perfusion. Several spike sorting and clustering techniques were systematically tested to yield the optimal separation between putative FSI and PYR units. Despite potential tissue and cellular swelling during OGD, stable unit recordings were feasible throughout the experiment. Gaussian mixture models clustering based on the firing distribution

of the units (inter-spike intervals, bursting) yielded the best separation between FSI and PYR which appeared as clearly distinct clusters. Putative FSI showed an impaired functional recovery from OGD as compared to PYR (decreased firing frequency and bursting, reduced coupling to SPW-R). Furthermore, analysis of the functional connectivity revealed distinct changes in the inhibitory and excitatory connections between units. Following reperfusion, SPW-R recovered partially. Taken together, in this study we show increased functional impairment of putative FSI after OGD as compared to PYR. These findings are in support of the hypothesis that interneurons may be particularly severely affected following a metabolic insult which may cause an imbalance between excitation and inhibition.

Title: The development of pyramidal neurons - interneurons interactions in the mouse prefrontal cortex

Authors: *M. CHINI, I. L. HANGANU-OPATZ;
Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: GABAergic interneurons are indispensable for the generation of different brain rhythms and the establishment of functional neuronal circuits. While their role in this regard has been subject to extensive research in the adult brain, little is known about their developmental contributions. Understanding how the embedment of interneurons into local circuits occurs is critical, as they are thought to be crucial for the generation of prefrontal beta/gamma rhythms related to cognitive processing, and their dysfunction has been reported for several neurodevelopmental disorders. To fill this knowledge gap, we used a combination of cre-lines and viral approaches to express inhibitory and excitatory light-sensitive opsins in a pan-interneuronal line (Gad^{2+}) and a line targeting interneurons derived from the medial ganglionic eminence ($Dlx5/6^{+}$). Combining *in vivo* extracellular recordings from the prelimbic subdivision of prefrontal cortex from non-anesthetized mice of 4-12 days of age with subtle and layer-specific optogenetic manipulations, we report that interneurons are critical mediators of early prefrontal oscillatory activity. Surprisingly, even at 4 days of age interneurons display adult-like characteristics and effects. They exert a strong inhibitory effect on the spiking of pyramidal

neurons and on local field potentials. As mice age, the quality of the effect does not change, but the magnitude, reliability, and dimensionality of the response robustly increase. Moreover, we used a variety of statistical methods to analyze more than 200.000 pairs of single unit spike trains and show that the blueprint of the functional architecture of the prefrontal cortex is already present in the first postnatal week. The maturation of inhibitory connectivity selectively shapes fast-scale synchrony between pairs of neurons, enhancing local and within-column connectivity, while pruning spurious and less specific connections. These data give first insight into the developmental mechanism of interneuronal wiring within prefrontal circuit.

Title: Specialized frontal cortical control over the anterior thalamic reticular nucleus

Authors: *N. HÁDINGER[1], E. BőSZ[1], G. VANTOMME[2], B. TÓTH[1], A. LÜTHI[3], L. ACSÁDY[4];
[1]Lab. of Thalamus Res., Inst. of Exptl. Medicine- Hungarian Acad. of Sci., Budapest, Hungary; [2]Univ. of Lausanne, Lausanne, Switzerland; [3]DNF, Univ. of Lausanne, Lausanne, Switzerland; [4]Inst. Exp. Med. Hung Acad Sci., Budapest, Hungary

Abstract: It has long been known that the neocortex is organized into areas with different cognitive functions. However, we are only beginning to understand the importance of regional specializations in cortico-thalamic interactions. Since basically all cortical functions involve cortico-thalamic communication, regional specialization of this loop according to the functional requirements is of high interest. In this study we describe a novel component in the cortico-thalamic pathway which is specific for the frontal cortices and innervates the thalamic reticular nucleus (TRN).
The entire TRN is under cortical control via inputs from the layer 6 (L6) of the neocortex. L5 cortical output, which otherwise exerts profound control over thalamic activity, was thought to reach thalamus without innervating TRN, mainly based on data from the sensory areas. In this study conditional viral tracing from the frontal but not parietal cortical areas in the L5-specific Rbp4-Cre mouse revealed dense, topographically-organized projection to the antero-ventral TRN. Compared to L6-TRN synapses the L5-TRN synapses showed distinct ultrastructural properties at the electron microscopic level. *In vitro* electrophysiological experiments

demonstrated that in contrast to the L6-TRN pathway the L5-TRN pathway displays short term depression instead of short term facilitation and that L5-TRN EPSCs has higher NMDA/AMPA ratio. Optogenetic activation of L5 cells in anesthetized mice elicited action potentials in anterior TRN with short latency and high fidelity. During spontaneous activity single spike activity of L5-recipient TRN cells showed low correlation with the ongoing frontal cortical oscillations, while high frequency longer TRN burst were tightly coupled with fast high amplitude cortical events indicating efficient control in case of cortical synchrony. Confirming this, optogenetically recruiting progressively more L5 cells converging on the TRN neurons resulted in TRN bursts with higher spike number and intra-burst frequencies. L5 driven TRN sectors innervated thalamic nuclei with frontal cortical connections. The data together suggest powerful and temporally precise cortical control specifically in frontal cortico-thalamic circuits via strong coupling of TRN cells to synchronized L5 outputs.

Title: Temporal dynamics of alternating current stimulation

Authors: *B. ASAMOAH[1], A. KHATOUN[1], M. MC LAUGHLIN[2];
[2]Neurosci., [1]KU Leuven, Leuven, Belgium

Abstract: Rationale
Neural spiking can phase lock to transcranial alternating current stimulation (tACS) provided the generated electric field in the brain is strong enough (transcranial mechanism). Recently we showed that there is also a transcutaneous mechanism where peripheral nerves are stimulated. They then give a rhythmic input to the brain. In tACS studies the stimulation duration is relatively long (~ 10 minutes). Supposedly, longer stimulation allows for more neuromodulation. This should then give a stronger behavioural effect. It is, nevertheless, not yet clear how neurons respond to these alternating currents (both transcranial and transcutaneous) over time.
Objective

We set out to understand this temporal aspect of the alternating current stimulation. Therefore we investigated the ongoing interaction between the neuron and the applied alternating current when the generated electric field is strong enough to affect neurons. We also investigated this interaction for the transcutaneous mechanism of tACS. Our main objective was to determine how long a decision maker would need to detect a change in neural entrainment caused by the stimulation. This is an important question as it is an indicator of the type of behavioural tasks which may be successful in humans.

Methods

In 7 anaesthetised male Wistar rats we opened the scalp and inserted a multichannel recording probe into the motor cortex via a craniotomy. We then recorded neural activity during 3 consecutive minutes. During the second minute of recording we also stimulated with a sinewave waveform. We stimulated either directly on the skull or on a limb. For the transcranial as well as transcutaneous condition we stimulated with 3 amplitude levels. This design allowed us to assess neural activity before, during and after stimulation. Also we were able to assess effects for different stimulation strengths.

Conclusions

Analysis shows that when stimulation (transcranial as well as transcutaneous) is turned on, neurons respond immediately. This response sustains over time and disappears rapidly when the stimulation is turned off.

We found that detection of neural entrainment effects at the neuron level depends on two factors: observation time and stimulation strength. Low stimulation levels produce entrainment effects which only become detectable over longer observation periods (tens of seconds). Higher stimulation levels produce entrainment effects that can be detected in shorter observation periods (seconds).

These results suggest that to observe behavioural neural entrainment effects in humans, tasks that rely on accumulation of information over longer periods of time are more likely to be successful.

Title: Scale-invariant neuronal activity in primary visual cortex of awake mice

Authors: *E. CAPEK, D. PLENZ;
Section on Critical Brain Dynamics, Natl. Inst. of Mental Health, NIH, Bethesda, MD

Abstract: Brains must solve large information processing challenges in an efficient manner. It is well known that being in the critical regime can maximize certain computational capabilities of a network. Critical dynamics have been demonstrated in neural networks *in vivo*, suggesting that criticality may be a strategy brains adopt to improve their information processing efficiency. What is not known is to what extent different networks in the mammalian brain occupy this regime. In particular, it isn't known what cell subtypes and what layers of visual cortex participate in critical dynamics, and whether different visual stimuli can alter this participation. Here we study the scale-invariant aspects of neuronal activities as a proxy for critical network dynamics. We analyze the activity of select excitatory and inhibitory neuron populations in mouse visual cortex from a 2-photon imaging dataset made publicly available through the Allen Brain Observatory. We find specific aspects of scale-invariance in select groups of pyramidal neurons of V1 across a variety of stimulation patterns. Our results are in line with the idea that visual processing in V1 occurs at criticality.

Title: Integrated information generated by cortico-striatal-thalamic circuits correlates with level of consciousness

Authors: *M. AFRASIABI[1], M. J. REDINBAUGH[1], N. A. KAMBI[1], J. M. PHILLIPS[1], S. MOHANTA[1], A. RAZ[2,4], A. M. HAUN[3], Y. B. SAALMANN[1];

Abstract: A prominent model of the neural correlates of consciousness (NCC: minimal brain mechanisms sufficient to produce conscious states), Integrated Information Theory, proposes that consciousness depends on integrated information (Φ), the information generated by a system above and beyond the information generated by its parts. Such integration must be supported by

reciprocal interactions between neural populations. While cortico-cortical and thalamo-cortical interactions are thought to contribute to the NCC, the basal ganglia are often disregarded. However, the thalamus provides often overlooked direct input to the striatum, allowing for thalamo-striatal interactions. To investigate the NCC status of cortico-striatal-thalamic circuits, we compared their integrated information across conscious states.
We used laminar probes to simultaneously record from the frontal eye field (FEF), lateral intraparietal area (LIP), caudate nucleus (CN) and central lateral thalamus (CL) in 2 macaques during general anesthesia (propofol or isoflurane) and wakefulness (resting state). Structural MRI of probes *in situ* verified positioning, and we identified cortical layers using current source density. To manipulate cortico-striatal dynamics and arousal, we electrically stimulated CL across 16 probe contacts (200 μA at 50 Hz). We analyzed data during stable eye epochs at baseline and with CL stimulation. To monitor consciousness level, we used EEG, EMG, eye position, and vitals. Recordings occurred in the dark with the animal's head stabilized.
We used a measure of integrated information based on cross-covariance of simultaneously recorded local field potentials (LFPs) over a short time window (200 ms). We compared the self-information I of a multi-channel system (mutual information across a time lag of 5 ms) with an estimate of the self-information I* of a *partitioned* version of the system, forcing independence of partitioned channels. The integrated information is the minimal difference of these quantities over all possible partitions ($\Phi^*=I-I^*$). We evaluated Φ^* for every subsystem of 6 cortical components (superficial, middle, deep layers of FEF and LIP) plus CN.
We found greater Φ^* during wakefulness versus (propofol and isoflurane) anesthesia. Moreover, Φ^* correlated with the increased level of arousal induced by electrically stimulating CL. During wakefulness the full cortico-striatal system had the largest Φ^*. Subsystems including the deep cortical layers tended to have higher Φ^*, especially those involving CN.
These results suggest that circuits involving not only cortical and thalamic components, but also striatal mechanisms, contribute to the NCC.

Title: Collective activity of ventral CA1 neuronal populations in awake mice

Authors: *U. CHOCKANATHAN, E. WARNER, K. PADMANABHAN;
Neurosci., Univ. of Rochester, Rochester, NY

Abstract: The ventral CA1 (vCA1) region of hippocampus is implicated in an array of behaviors including spatial navigation and memory, anxiety, social recognition, and social memory. This constellation of behaviors arises from the unique connectivity of vCA1, which includes afferents from entorhinal cortex, amygdala, and piriform cortex and efferents to nucleus accumbens, prefrontal cortex, and main olfactory bulb. Furthermore, within vCA1, molecular, cellular, and biophysical diversity influence the heterogeneity in neural responses and their links to behavior. While each of these features, and the single-neuron responses associated with them, has been extensively studied, the manner in which vCA1 neurons collectively participate in guiding behavior remains largely unknown. Importantly, the structure of vCA1 population activity, the implications of this activity for neural coding, and the ways in which this activity is disrupted in diseases is not well understood. To address this, we made extracellular recordings from large populations of neurons in vCA1 in awake mice running on a linear wheel in a virtual reality environment by stereotactically targeting a 128-channel silicon electrode array to vCA1 (coordinates relative to bregma: -3.15mm AP, 3.25mm ML, 4.00mm DV). To understand this activity, we calculated the entropy, a measure of the diversity of network states, of ensembles of neurons (N = 3-40 neuron subpopulations) in two states: while the animal was running and while it remained stationary. Next, to understand the organizational principles of the population, including the functional coupling between neurons, we fit the population activity to a class of maximum entropy models derived from statistical physics. These models capture the global structure of activity using a minimal set of assumptions, such as the probability of firing of individual neurons and the functional coupling between pairs of neurons. We compared the predicted network states from the model with that of the recorded population to understand how individual firing rates and pairwise interactions govern overall population states. Finally, we considered the role that higher order interactions between neurons (triplet and quadruplet interactions, for instance) play in governing the activity of vCA1 networks. This study will determine how vCA1 neurons function collectively to drive network activity.

Title: Dendritic properties of parvalbumin interneurons enhance robustness of gamma oscillations

Authors: *K. VERVAEKE, H. HU, B. KRIENER;
Univ. of Oslo, Oslo, Norway

Abstract: Network oscillations in the gamma range (40-100 Hz) are important for many cognitive tasks by coordinating the temporal organization of neural ensembles. Parvalbumin (PV)-expressing inhibitory neurons that form reciprocal synaptic connections tend to fire action potentials at gamma frequencies, suggesting an important role in generating gamma oscillations. However, the circuit mechanisms underlying gamma rhythms remain poorly understood. A consistent problem of inhibitory network models is that synchrony is not robust against heterogeneities in the excitatory synaptic drive. Fast and strong inhibitory synapses and shunting inhibition increase robustness, but when exposed to biologically realistic heterogeneities, network synchrony in these models still fails. Classic work performed network simulations using 'point-neuron' models that lump the morphology of cells into a single compartment. Here, however, we hypothesized that the dendritic morphology of PV neurons could be essential to generate robust gamma rhythms. Using dual patch clamp recordings of the soma and dendrites of PV neurons in the dentate gyrus, we show that the slope, or gain, of the input-output relationship is much lower for dendritic input compared to somatic input. Thus the dendrites scale down the sensitivity of a PV neuron to changes in its input. This is due to the unique properties of PV neuron dendrites that express a high density of K^+ channels and a low density of Na^+ channels. Using biologically realistic network models composed of PV cells with reconstructed dendrites, we tested how their dendritic properties affect network synchrony. We found that the low gain of the input-output relationship homogenizes the firing rates of cells in the network, thereby not only allowing much higher input heterogeneities, but also relaxing the requirement for strong inhibitory coupling. This demonstrates that the unique properties of PV neuron dendrites are essential to produce gamma oscillations and support the many cognitive tasks correlated with this brain rhythm.

Title: Variability in response to electrical stimulation changes with brain state in humans

Authors: *R. ZELMANN[1], P. KAHALI[2], A. C. PAULK[1], B. CROCKER[1], L. A. SANTA CRUZ[2], F. TIAN[2], G. R. COSGROVE[4], Z. WILLIAMS[3], P. L. PURDON[2], S. S. CASH[1]; [1]Neurol., [2]Anesthesia, Critical Care, and Pain Mgmt., [3]Neurosurg., Massachusetts Gen. Hosp., Boston, MA; [4]Neurosurg., Brigham and Women's Hosp., Boston, MA

Abstract: Since sleep or loss of consciousness has long been known to alter underlying brain dynamics, the human brain's response to electrical stimulation likely also change in these altered brain states. We investigate the variability of the response to single-pulse direct electrical stimulation (SPES) in the intracranial EEG (sEEG) while participants are awake, asleep, or under anesthesia.

Working with patients with pharmaco-resistant complex partial seizures implanted for clinical reasons who voluntarily participated after fully informed consent (N=4), we performed SPES (pulse: 7uA, inter-stimulation interval 2+/-0.25s) across 5 brain regions during wake and anesthesia. In a subset, we repeated the experiment during sleep (N=2). We analyzed 20 (or 12 during sleep) bipolar pairs of intracranial channels near stimulation electrodes with cortico-cortical evoke potentials (CCEP) responses to stimulation during wake. Up to 15 SPES pulses were selected per state per channel, resulting in 300 total events (sleep: 149) for analysis. We compared CCEP between wake in the epilepsy monitoring unit (wakeEMU), sleep, wake in the operating room before anesthesia induction (wakeOR), and anesthesia. We found increased variability in CCEPs peak time and amplitude during sleep and anesthesia in individual bipolar pairs. To quantify this observation, we selected three intervals corresponding to CCEP peaks (N1: 5-50ms; N2: 50-200ms; Long: 200-1000ms) and computed the standard deviation (STD) of the absolute response amplitude. Paired t-tests of log10(STD) between states were performed. The mean variability across channels was higher during anesthesia and sleep than for wake (EMU & OR) for N1, N2 and Long intervals. We found significant differences ($p<0.01$) between wake and anesthesia for N1 and Long intervals. Importantly, similar results were obtained when normalizing by the baseline variability at each state.

We then asked if peak-time and amplitude of the largest peak for each interval changed during each state, defined as the maximum absolute amplitude of the sEEG z-score normalized to baseline (30s before first stimulation). We found that peak amplitudes during the anesthesia state were smaller for all intervals. Significant differences ($p<0.05$) were found between wakeEMU and sleep for all intervals and between wake (EMU & OR) and anesthesia for N1 and N2 intervals. For peak-time, significant differences ($p<0.05$) were found between wake and anesthesia for N2 and long intervals.

Our results suggest an increase in variability in the response to stimulation when consciousness is lost, paving the way for a potential new electrographic biomarker of consciousness.

Title: Functional disruption of intracranial EEG dynamics during subanesthetic ketamine-induced dissociative state

Authors: *F. TIAN[1,3], L. D. LEWIS[7], O. JOHNSON-AKEJU[1], D. W. ZHOU[4], R. A. PETERFREUND[1], E. N. ESKANDAR[8], S. S. CASH[2], E. N. BROWN[1,3,4,5,6], P. L. Surgery, Albert Einstein Col. of Med., Bronx, NY

Abstract: Ketamine is a widely used anesthetic. At higher doses, ketamine induces unconsciousness and immobility, whereas at lower or subanesthetic doses, it produces a dissociative state, which includes altered sensory perception and a sense of disembodiment. The mechanism whereby subanesthetic doses of ketamine disrupts functional brain activity to produce the dissociated state remains unclear. The objective of this study is to investigate in humans the effects of subanesthetic doses of ketamine on brain dynamics and the dissociative state.

Five epilepsy patients were implanted with intracranial depth, surface, and strip electrodes for detection of seizure foci. We recorded during a ketamine infusion administered just prior to the electrode removal surgery. Baseline signals were recorded for 5 minutes. Then each patient

received an infusion of a subanesthetic dose of ketamine (0.5 mg/kg over 14 minutes). During ketamine administration, the patients performed an auditory task consisting of interleaved verbal and click stimuli presented every 3.5-4.5 seconds. Patients completed an abbreviated version of the Clinician-Administered Dissociative States Scale (CADSS) questionnaire at the conclusion of the ketamine infusion.

The responses on the CADSS questionnaire and the intermittent responses to the auditory stimuli confirmed that our subanesthetic ketamine administration paradigm induced a dissociative state. This state was associated with decreased of alpha oscillation power in precentral gyrus, similar to a prior report showing that subanesthetic doses of ketamine induces a dissociative state by disrupting multisensory integration in the precuneus and temporal-parietal junction that are modulated by alpha waves. Patients also exhibited an increase of gamma oscillation power in both frontal and temporal lobes under subanesthetic ketamine. Additionally, global coherence analysis demonstrated that administration of a subanesthetic ketamine dose leads to the onset of broadband low gamma/high beta coherence. Finally, phase amplitude coupling between slow (0.1-1Hz) and beta oscillations displayed a transition from coupling in which beta oscillations are larger in the troughs of the slow oscillation ("trough-max") at baseline, to another form of coupling in which beta is largest at the peaks of the slow oscillation ("peak-max") after the ketamine infusion. Collectively, these findings indicate that disruption of the dynamic coordination between brain regions may play an important role in mediating the ketamine-induced dissociative state.

Title: Slow oscillatory activity across neocortex and hippocampus is at least partially coordinated by the thalamic nucleus reuniens

Authors: *B. E. HAUER[1], S. PAGLIARDINI[2,1], C. T. DICKSON[3,1,2];
[1]Neurosci. and Mental Hlth. Inst., [2]Physiol., [3]Psychology, Univ. of Alberta, Edmonton, AB, Canada

Abstract: Synchronized activity across the brain is a hallmark of sleep, a phenomenon which has physiological relevance for a host of functions. In particular, coordinated activity between medial prefrontal cortex (mPFC) and hippocampus (HPC) has been suggested to be critical for some mnemonic processes during both wakefulness and sleep. One of the most ubiquitous and physiologically relevant activity patterns occurs during slow-wave states, a ~1 Hz rhythm known as the slow oscillation (SO). However, it is currently unclear how the SO is coordinated between mPFC and HPC. Here, we examined the nucleus reuniens (RE), a midline thalamic body with direct, reciprocal projections to both mPFC and HPC, for its possible role in synchronizing the SO between these disparate sites. We used a rat model under urethane anesthesia because of how closely and dynamically it models natural sleep, in terms of alternations of forebrain state and corresponding physiological measures. We first characterized RE neuronal activity using single- and multi-unit recordings, determining that RE units rhythmically fire during, and are phase synchronized with, the mPFC SO. Optogenetic excitation of the RE reliably produced an evoked response in the HPC. Similarly, exciting the mPFC produced a similar evoked response in the HPC, with longer latency. Chemogenetically inhibiting the RE blocked this mPFC-mediated evoked potential in the HPC, suggesting that the RE is a critical and functional excitatory intermediary between mPFC and HPC. Importantly, during RE inactivation, we observed a robust decrement in mPFC-HPC coherence at SO frequencies. Critically, this diminished synchrony was not a consequence of decreased SO power, which was unchanged pre- and post-RE inhibition. Our results demonstrate a decisive role for the RE in at least partly mediating mPFC-HPC SO coordination, a phenomenon which has marked implications for sleep-dependent memory consolidation.

Title: Differences in thalamocortical synchronization during sleep and anesthesia-induced unconsciousness

Authors: *J. B. BRISCOE[1,2], J. HARROD[2], M. A. WILSON[2], P. L. PURDON[1], E. N. BROWN[1,2], F. J. FLORES[1,2];
[1]Anesthesia, Critical Care and Pain Med., Massachusetts Gen. Hosp., Boston, MA; [2]The Picower Inst. of Learning and Memory, Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Drug-induced unconsciousness, as observed during general anesthesia, is characterized by cortical activity exhibiting high amplitude, low frequency oscillations. The physiological state of unconsciousness observed during sleep displays a similar pattern of cortical activity, but it is fundamentally different from the unconsciousness observed during anesthesia. During sleep, the subjects can easily wake up in response to mild-intensity sensory stimuli, while during anesthesia the subjects are unresponsive even in the presence of severe tissue damage. We have previously shown, by simultaneously recording extracellular activity in frontal cortex and anterior thalamus, that the unconscious state induced by propofol dosing is characterized by frontal thalamocortical synchronization in both delta (1-4 Hz) and spindle/alpha (10-15 Hz) frequency bands. We wondered if the stark differences in responsiveness between sleep and anesthetic-induced unconsciousness is due to differences in the degree of thalamocortical synchronization. We implanted male Sprague-Dawley rats, weighing 500 to 700 g, with silicon probes aimed at prefrontal cortex and anterior thalamus, and recorded cortical and behavioral activity while the animals were allowed to freely behave in a box. To identify the periods of wakefulness and non-REM sleep, we fed the electrophysiological and behavioral recordings into a deep belief artificial neural network, consisting of a linear classifier on the top and a structure of 100 x 100 hidden layers based on restricted Boltzmann machines. We observed

that while the power of cortical and thalamic signals in the delta and spindle/alpha bands increases during non-REM sleep, the thalamocortical coherence observed during non-REM sleep it is not significantly different from the thalamocortical coherence observed during wakefulness. However, different classes of anesthetic drugs produce an increased level of thalamocortical coherence in the delta and alpha frequency bands. The lack of sustained frontal thalamocortical coherence during non-REM sleep may provide a plausible mechanism to explain the stark difference between sensitivity to external stimuli observed during sleep-related unconsciousness and anesthetic-induced unconsciousness.

Abstract: Propofol-induced anesthesia produces reproducible oscillatory dynamics that can be recorded at the scalp: the loss of posterior sensory alpha (~10 Hz) rhythms and rise of coherent anterior alpha rhythms. Thalamocortical circuits are thought to underlie both alpha rhythms; however, the spatiotemporal and functional properties of alpha networks and the roles of thalamic nuclei in organizing them are not fully deciphered. We hypothesized that regional cortical alpha dynamics would reflect specific connectivity patterns to thalamic nuclei. We studied neurophysiological recordings from 11 patients with intracranial depth and electrocorticography (ECoG) electrodes as they received propofol general anesthesia while performing a behavioral task. Using multitaper spectral and global coherence analyses to track spatiotemporal dynamics of alpha, we estimated each channel's contribution to alpha coherence before and after loss of consciousness (LOC). We then selected two subsets of the channels with the greatest increase and decrease in alpha coherence, respectively. For each patient, we found 3 matched surrogates from the Human Connectome Project WU-Minn diffusion-weighted imaging dataset and performed probabilistic tractography from regions of interest representing the two channel groups to individual thalamic nuclei using a probabilistic atlas. Finally, we mapped both channel groups to their corresponding resting-state functional networks, using the Yeo atlas. After LOC, alpha coherence showed the strongest decrease in the visual, auditory and somatosensory cortices and the strongest increase in the anterior cingulate, orbitofrontal cortex, and medial temporal lobe. These two alpha networks are associated with connections to distinct thalamic nuclei. First, the posterior sensory cortices showing the greatest decreases in alpha power after LOC are connected to the pulvinar and ventral posterolateral nuclei. The frontal and midline structures showing increased alpha rhythms after LOC are connected to the mediodorsal and ventral anterior nuclei. These results suggest that loss of posterior (sensory) alpha is associated with impairment of processing of external stimuli, whereas alpha coherence in the frontal regions, belonging to the ventral attention functional network, would impair self-awareness and internal consciousness and impede responsiveness to external stimuli.

Title: Identifying convergent components of unconscious brain state dynamics in sleep and anesthesia

Authors: *R. WARD-FLANAGAN, A. LO, M. SOBEY, C. T. DICKSON;
Univ. of Alberta, Edmonton, AB, Canada

Abstract: The unconscious state produced by natural sleep is unique and dichotomous. It consists of spontaneous, cyclical alternations between an activated state known as rapid-eye movement (REM; characterized by low-voltage, fast EEG activity) and deactivated state known as non-REM (NREM; characterized by large amplitude, slow oscillatory activity). These physiologically discrete states and the recurring fluctuations between them have made it difficult to model the complete neurophysiological spectrum of natural sleep without using sleep itself. Our aim in the current study is to characterize how select common anesthetics promote specific electrophysiological components of natural sleep in order to find a reliable pharmacological proxy for natural sleep.
We assessed a number of commonly used anesthetics as potential candidates for a pharmacological model of sleep, including isoflurane, ketamine-xylazine, pentobarbital, chloral hydrate, and propofol. Sprague-Dawley rats were randomly assigned to one of the anesthetic groups for acute electrophysiological recordings in the cortex and hippocampus. All anesthetics were delivered intravenously, except isoflurane which was delivered continuously via nosecone. Dosage was consistently monitored and adjusted to maintain a surgical plane of anesthesia.
At a surgical plane, electrophysiological activity in rats in the ketamine-xylazine, and chloral hydrate anesthesia groups exhibited a unitary state of large amplitude, slow oscillatory activity resembling NREM sleep. In the isoflurane, pentobarbital, and propofol anesthesia groups we observed a burst-suppression pattern of activity, which is consistent with the electrophysiological activity archetypically observed in a coma state. Interestingly, rats in the urethane anesthesia group exhibited an pattern of activity with cyclic and spontaneous alternations between an activated state of low-voltage fast cortical activity concomitant with theta (~ 4 Hz) in the hippocampus, and a deactivated state of large-amplitude, slow oscillations (~ 1 Hz) in both the

cortex and hippocampus. These changes in brain state corresponded with modulation of physiological functions, including respiratory activity, heart rate, and temperature, which are all typically observed in natural sleep during transitions between REM and NREM. Subsequently, our data suggests that only urethane anesthesia exhibits the full neurophysiological spectrum of natural sleep in terms of components, dynamics and time frame. Consequently, urethane is the most viable pharmacological proxy for the spontaneous cyclic alternations of sleep that we have assessed at present.

Title: Phase coupling versus amplitude coupling; two associated but distinct modes of neural connectivity

Authors: *P. MOSTAME[1,2], A. BABAJANI-FEREMI[3], S. SADAGHIANI[1,2];

Abstract: While communication across distant neural populations is critical for all cognitive processes, researchers use fundamentally different measures to assess such functional connectivity (FC). Some neurophysiological studies use phase coupling (*PhC*) defined as coupling between the phases of two signals, reflecting the synchronization of rhythmic oscillation cycles. Others use amplitude coupling (*AmpC*) defined as coupling between the envelopes of two signals, reflecting synchronization of activation amplitude. PhC and AmpC thus quantify different neurobiological mechanisms, yet the relationship of the two remains elusive. In addition, task-based studies of neurophysiological data commonly use PhC, while AmpC has been mostly used for resting state data. Therefore, investigating correspondence between PhC and AmpC not only clarifies to what extent and how these two neural mechanisms relate to each other, but also provides an informative link between findings of task-based and resting state studies. We assessed spatial and temporal correspondence between PhC (measured by Phase Locking Value) and AmpC over 5 canonical frequency bands using intracranial Electrocorticography (ECoG) in 10 patients undergoing presurgical evaluation. In each

frequency band, spatial correspondence was estimated as correlation across the static FC matrices of PhC and AmpC. Subsequently, temporal correspondence in each frequency band was evaluated using temporal correlations between PhC and AmpC dynamics for each electrode pair. Significant correspondence between the spatial pattern of PhC and AmpC was detected during stimulus processing in all subjects and all frequency bands ($R \approx 0.48$ for delta, progressively decreasing with increasing frequency). This spatial correlation vanished almost entirely ($|R| < 0.07$) when accounting for FC already present prior to stimulus onset, suggesting that the spatial correlations reflected intrinsic FC independent of stimulus processing. Regarding the temporal relationship between PhC and AmpC dynamics, we not only observed a considerable proportion of connections with positive correlations across the dynamics (~28%), but also substantial proportions of connections with anti-correlated (~24%) or uncorrelated dynamics (~48%). We conclude that PhC and AmpC reflect intrinsic FC in a similar fashion across space, while they expose both interrelated and divergent stimulus-related FC changes across time. Consequently, PhC and AmpC constitute two distinct but associated modes of neural communication.

Title: Dynamical evolution of spatiotemporal patterns of cortical activity under different brain states

Authors: *A. CAMASSA[1], M. DASILVA[1], M. MATTIA[2], M. V. SANCHEZ-VIVES[1,3]; [1]IDIBAPS (Institut D'Investigacions Biomediques August Pi I Sunyer), Barcelona, Spain; [2]Inst. Superiore di Sanità, Roma, Italy; [3]ICREA, Barcelona, Spain

Abstract: Conscious and unconscious states are associated with specific characteristics based on the spatiotemporal dynamics of ongoing brain activity. In this study we aimed to characterize different brain states by studying the changes occurring to the spatiotemporal dynamics of slow-wave propagation in multichannel cortical data. During the sleep-like slow oscillations (SO, < 1Hz) regime, activation waves spontaneously emerge and propagate across the cortical network both *in vitro* and *in vivo* in anesthetized animals (Sanchez-Vives and McCormick, Nat Neurosci., 2000; Ruiz-Mejias et al., J Neurophysiol., 2011). Here, we varied the brain states *in vivo* by

varying the anesthesia levels, without departing from the slow-wave activity regime: the emergent oscillatory activity ranged from lower (0.12 Hz) to higher (1.15 Hz) frequency for high to low anesthesia levels respectively. We recorded the extracellular local field potential (LFP) with a superficial 32-channel electrode-array placed on the surface of the brain of eight mice anesthetized at three different levels and developed a phase-based method to reconstruct the spatiotemporal dynamics of propagating waves in multichannel recordings. The instantaneous phase at each electrode and the latency were computed as in Muller et al., Nat. Commun., 2014. As a result, we were able to define the patterns of propagating activity under each anesthesia level, to study their dynamical evolution over time, and estimate for each brain state the overall dynamical richness and sequence predictability. Overall, our findings allowed us to characterize the evolution of the cortical dynamics under different brain states within the SO regime, revealing that the wave propagation patterns change together with the brain state showing richer spatiotemporal dynamics in lighter anesthesia states, supporting the idea of an increasingly complex brain activity that varies when we move from deeply unconscious states towards wakefulness.

Abstract: Broadband High-frequency Activity (BHA; 70-150 Hz), also known as "high gamma," a key analytic signal in human intracranial recordings is often assumed to reflect local neural firing (multiunit activity; MUA). Accordingly, BHA has been used to study neuronal population responses in auditory, visual, language, mnemonic processes and cognitive control. BHA is the electrophysiological measure best correlated with the Blood Oxygenation Level Dependent (BOLD) signal in fMRI. Although critical for interpreting intracranial signals in human and non-human primates, the neuronal populations and physiological processes generating BHA remain unknown. Here, we show that BHA dissociates from MUA in primary visual (2 monkeys) and auditory cortex (2 monkeys). Using laminar multi-electrode data, we found a bimodal distribution of stimulus-evoked BHA across depth of a cortical column: an early-deep, followed by a later-superficial layer response. Only the early-deep layer BHA had a clear local MUA correlate, while the more prominent superficial layer BHA had a weak or undetectable MUA correlate. In many cases, particularly in V1 (70%), supragranular sites showed strong BHA in lieu of any detectable increase in MUA. Due to volume conduction, BHA from both the early-deep and the later-supragranular generators contribute to the field potential at the pial surface, though the contribution may be weighted towards the late-supragranular BHA. Our results demonstrate that the strongest generators of BHA are in the superficial cortical layers and show that the origins of BHA include a mixture of the neuronal action potential firing and dendritic processes separable from this firing. It is likely that the typically-recorded BHA signal emphasizes the latter processes to a greater extent than previously recognized. The ongoing work aims to test whether these dissociations are also observed during active visual exploration.

Title: Excitatory and inhibitory regulation of cortical network complexity

Authors: A. BARBERO-CASTILLO[1], P. MATEOS-APARICIO[1], L. PEREZ-MENDEZ[1], S. CALDAS-MARTINEZ[1], ***M. V. SANCHEZ-VIVES**[1,2];

Abstract: The cortical network is composed of thousands of units interacting in different ways throughout different brain states, resulting in a variety of cortical dynamic patterns. From the awake state to deep sleep, anesthesia or coma states, there are profound changes in cortical interactions both in the temporal and the spatial domains. As a result, the awake state is characterized by complex patterns of causal interactions, whereas this complexity collapses in deep sleep or anesthesia. An understanding of the mechanisms that enable the emergence of complex brain states is critical for the development of reliable monitors of brain state transitions and of consciousness levels during anesthesia and in brain-injured patients, and for devising mechanistically-based interventions to promote state transitions and recovery of function. To this end, in a previous study we adapted a measure of cortical complexity, the perturbational complexity index, originally devised for human EEG (Casali et al., *Sci Trans Medicine* 2013), to the *in vitro* cortical network (D'Andola et al, *Cerebral Cortex*, 2017). We demonstrated that complexity was low during slow oscillations, and increased in awake-like states induced by cholinergic and noradrenergic agonists. In the current study, we explore the role of $GABA_A$ and $GABA_B$ inhibition on the modulation of cortical spatiotemporal complexity during both synchronous (slow oscillations) and asynchronous (awake-like) regimes while recording from the surface of the slice with 16-channel multielectrode arrays. Our experiments demonstrate that progressively blocking either fast or slow inhibition decreases complexity, even when network excitability increases. This illustrates that complexity varies independently of excitability as we have previously found while varying excitability by means of electric fields (Barbero-Castillo et al., *Brain Stimulation*, 2019). Our results demonstrate that an orchestrated participation of excitatory and inhibitory components is required for the maintenance of cortical complexity.

Title: Differential roles of three distinct pyramidal cell subpopulations during ongoing gamma oscillation in mouse hippocampal area CA3 *in vitro*

Authors: *H. BALLEZA-TAPIA, A. FISAHN;
Neurogeriatrics, NVS, Karolinska Institutet, Stockholm, Sweden

Abstract: Gamma oscillations in hippocampus emerge from the synchronous firing of action potentials (AP) of different neuronal classes as a result of the coordinated interaction between excitation and inhibition in a neural network. In the past years, a few studies have described distinct pyramidal cell (PC) subpopulations in hippocampal area CA3 with differing electrophysiological and morphological properties. However, the role of each PC subpopulation for CA3 neural network function is poorly studied.
By performing whole-cell patch-clamp recordings in mouse hippocampal slices we described 3 electrophysiological distinct subtypes of PCs in area CA3 with a specific anatomical distribution within the stratum pyramidale (s.p.). We found that PCs located close to the edge of s.p. and stratum oriens displayed a burst-like firing pattern (BF-PCs) of APs. In contrast, PCs located within the s.p. could be divided according to their AP adaptation rates into strong adapters (A-PCs) and weak- or non-adapters (WA-PCs).
To study the involvement of PC subpopulations during the initial- and stable-phase of gamma oscillations we performed simultaneous patch-clamp and local field potential (LFP) recordings in hippocampal slices activated with kainate. We found that while A- and WA-PCs firing was involved both in the initial- and stable-phase, BF-PCs did not participate in gamma oscillations since none or few APs were fired.
We also studied the excitatory/inhibitory input to PCs by recording the EPSCs and IPSCs. We found that EPSC frequency of A-PCs was higher than in WA- and BF-PCs only during the initial-phase of gamma oscillations. EPSC amplitude of A-PCs was higher than in BF-PCs only in the stable-phase. Compared to BF-PCs, IPSC amplitude of both A- and WA-PCs was higher in the initial- and stable-phase of gamma oscillations. IPSC frequency of WA-PCs was higher than in A- and BF-PCs only in the initial-phase.
Finally, to further evaluate the relationship between gamma oscillations and the excitatory/inhibitory input to PCs we calculated the cross-correlation between the whole-cell and LFP signals and found that EPSC-LFP cross-correlation peak (XC-Peak) and lag (XC-Lag) were similar between the 3 PC subpopulations. In contrast, IPSC-LFP XC-Peak of A- and WA-PCs was significantly higher compared to BF-PCs in both the initial- and stable-phase of gamma oscillations. XC-Lag of WA was higher than BF-PCs only in the stable-phase. In conclusion, our data support the hypothesis that CA3 PCs are organized into distinct subpopulations with differential roles in cognition-relevant neuronal network dynamics and provide new insights in the physiology of the hippocampal circuitry.

Title: Factors determining theta phase preference across CA1 sublayers

Authors: *A. NAVAS-OLIVE[1], M. VALERO[2], A. DE SALAS-QUIROGA[3], T. JURADO-PARRAS[1], E. CID[1], L. M. DE LA PRIDA[1];

Abstract: Hippocampal pyramidal cells fire selectively to build abstract representations of a contingency of visual, auditory, somatosensory and behavioural events. While moving around these “spaces”, sequences of hippocampal “place cells” are activated in an orderly manner coordinated by the theta rhythm (4-12 Hz). One mechanism determining these sequences is theta phase precession, which occurs anytime the animal traverses a “place field”. However, hippocampal cells also exhibit a specific phase preference, which can be influenced by the global brain state. Here, we aim to study factors underlying theta phase preference across deep and superficial CA1 pyramidal sublayers during theta oscillations. First, we obtained juxtacellular and multi-site recordings in awake head-fixed mice and freely-moving rats. We found a characteristic bimodality in the distribution of the preferred firing phases of CA1 pyramidal cells. In order to understand the underlying factors, we built a biophysically realistic model that includes most of the known excitatory and inhibitory inputs converging in deep and superficial cells. The sublayer location was one factor explaining firing bimodality, but we found other influencing axes as well such as entorhinal and intra-hippocampal inputs. We tested some of the model predictions using cell-type specific chemogenetic approaches and unsupervised dynamical analysis of LFP activity. We discuss on the multiple dimensions determining phase preference and speculate about their potential role in defining episodic memory function.

Title: Phase-specific intra-cortical microstimulation in a brain-machine interface environment differentially modulates beta oscillations in motor cortex and affects behavior

Authors: *O. PELES[1,2], U. WERNER-REISS[1,2], H. BERGMAN[1,2], Z. ISRAEL[3], E. VAADIA[1,2];
[1]Edmond and Lily Safra Ctr. for Brain Sci. (ELSC), [2]Dept. of Med. Neurobio., Hebrew Univ., Jerusalem, Israel; [3]Dept. of Neurosurg., Hadassah Univ. Hosp., Jerusalem, Israel

Abstract: It is widely accepted that oscillatory activity in the beta-band, prevalent in the motor cortex, plays a major role in complex tasks such as planning and execution of sensorimotor behavior. Thus, being able to modulate these neuronal patterns in behaving animals may impact our understanding of cortical dynamics. In order to experimentally manipulate oscillations, we trained monkeys, implanted with arrays of 96 electrodes in the motor cortex, to volitionally enhance local field potential (LFP) beta-band (20-30Hz) activity at selected sites by neural operant conditioning, using a real time brain machine interface (BMI) environment. Subsequently, we applied intra-cortical microstimulation (ICMS), precisely timed to oscillation phases.
We demonstrate that beta oscillations of LFP and single-unit spiking activity increased dramatically following the BMI training, and that pre-movement beta-power was positively correlated with the reaction times, and negatively correlated with task success rate. Furthermore, we show that phase-specific ICMS modulated the power and phase of the oscillations, shifting local networks between oscillatory and non-oscillatory states. Lastly, these stimuli induced phase-dependent effects on the animal's behavior.
Our findings may contribute to unraveling the functional role of cortical oscillations. In addition, this research can pave the way for the use of an advanced BMI platform for a wide range of neurological and psychiatric disorders where volitional control (biofeedback) aided by fine-tuned electrical stimulations can restore normal activity whenever abnormal patterns are identified.

Title: Phase-dependent closed-loop modulation of neuronal oscillations

Authors: ***C. G. MCNAMARA**, M. ROTHWELL, A. SHAROTT;
MRC Brain Network Dynamics Unit, Dept. of Pharmacol., Univ. of Oxford, Oxford, United Kingdom

Abstract: Closed-loop modulation, whereby features of ongoing brain signals are used to control the timing of electrical or optical stimulation, has the potential to provide targeted manipulation of functional and dysfunctional neuronal activity. Field potential oscillations provide an attractive input signal for such modulation, providing a robust signal to inform the timing of stimulation. Normal brain function is associated with an assortment of oscillations of various frequencies having different properties across brain networks, each reflecting the timing of separate computational processes and levels of synchronization between and within associated brain areas. As such, stimulation accurately delivered on a specified phase of a given oscillation provides the opportunity to target individual aspects of brain function. To this end, we have developed a highly responsive closed-loop system using a digital circuit to produce a continuous online phase-estimate. In addition to stable oscillations, the system is capable of tracking the early cycles of short, transient oscillations across the full described frequency range (from 4 to 250 Hz and above). The system is implemented as a hardware description in Verilog and can be added to any recording system where electrophysiology data is routed through an FPGA, making it widely applicable. We deployed the system on an Intan USB interface board and used it to test the effect of phase-dependent closed-loop stimulation using two experimental setups. Firstly, we used behaving, parkinsonian rats that had received a 6-OHDA hemi-lesion to the substantia nigra pars compacta producing robust high-beta frequency oscillations (28 - 40 Hz) across the cortex and basal ganglia. A phase-estimate was calculated from an electrocorticogram above motor cortex to control the timing of pulsatile electrical stimulation of basal ganglia nuclei. Within individual animals, target phases that led to amplification and suppression showed different stimulation delivery characteristics suggesting stimulation worked in a truly closed-loop manner. Secondly, we drove optogenetic stimulation of the motor thalamus based on the phase of

different oscillation frequencies recorded from the reciprocally-connected motor cortex. These experiments demonstrate that both electrical and optical closed-loop phase-dependent stimulation can be used to modulate transient oscillatory activity across forebrain networks. Such approaches could provide a powerful tool for modulating neuronal oscillations associated with brain disorders and investigating the functional role of various rhythmic activities in normal brain function.

Title: Ketamine-induced impairment in hippocampal network gamma oscillation: Reversal by the mGlu2/3 receptor agonist LY379268

Authors: *T. GAO, H. CRUCES_SOLIS, H. ROSENBROCK, N. SCHUELERT;
CNS Dis. Res., Boehringer Ingelheim Pharma GmbH & Co. KG, Bibrach an der Riss, Germany

Abstract: Cognitive deficits are a core feature of schizophrenia. Network gamma oscillations (20-80 Hz) in prefrontal cortex and hippocampus are crucial for healthy cognitive function. In schizophrenia patients, as well as in animal models related to schizophrenia, abnormal gamma oscillations has been observed correlating with impaired cognitive function. Glutamate hypothesis of schizophrenia suggested that NMDA receptors in GABAergic interneurons are hypofunctional resulting in disinhibition of the glutamatergic efferent neurons and hence increased glutamate release and gamma oscillations indicative of excitatory/inhibitory (E/I) imbalance. Activation of metabotropic glutamate receptor 2/3 (mGluR2/3) by its agonist LY379268 suppresses presynaptic glutamate release and further, reversed the impairment of PCP-induced attention [1] and ketamine-induced increase of gamma oscillations [2]. In present study, we used mouse hippocampal slices to evaluate the effect of LY379268 on pharmacologically induced gamma oscillations in CA3 region. Local filed potential were recorded in CA3 region of acute hippocampal slices from 6-8 weeks old male C57BL6/J mice. Induction of gamma oscillations were produced by either 20 µM carbachol or 150 nM kainate. Then, we used 10 µM ketamine, a non-competitive NMDA receptor antagonist, to induce an E/I imbalance, and LY379268 was co-infused to evaluate effects on leading frequency and total

power of the 20-80 Hz gamma band. After induction of gamma oscillations by carbachol or kainate, the leading frequencies in ketamine-infused hippocampal slices were significantly lower compared to control slices. Co-infusion with LY379268 reversed the ketamine-induced alteration of gamma oscillation. We conclude that ketamine can change the network gamma oscillation in hippocampus and its effect can be reversed by co-administration of the mGlu2/3 agonist LY379268. These results provided new in-vitro evidence corroborating previous findings that mGluR2/3 might be a potential therapeutic target for cognitive deficits related to schizophrenia. Title: Pre-ictal limbic coherence outside of the seizure onset zone: Considerations for the selection of normal EEG in epilepsy patients

Authors: *I. BALZEKAS, V. KREMEN, P. NEJEDLY, G. A. WORRELL;
Mayo Clin., Rochester, MN

Abstract: Epilepsy is associated with well-established changes in network activity, especially at the onset of seizures. The extent to which non-seizure onset zone (SOZ) contacts exhibit pathological changes in the hours preceding a seizure is unclear. It is possible that seizure-related, network alterations extend beyond the SOZ and begin well before seizure onset, warranting careful consideration of which brain regions and intracranial EEG (iEEG) time series can be deemed “normal” for cognitive neuroscience studies. The goal of this study was to determine if coherence between non-SOZ limbic electrode contacts change in the pre-ictal period. We identified 3 subjects undergoing iEEG monitoring for epilepsy surgery who had electrode contacts in at least two, non-SOZ limbic structures and who experienced at least one, 10-hour, seizure-free period during recording. In total, 16 electrode contacts were identified in the amygdala, hippocampus, insula, and lateral orbitofrontal cortex. The start times of 6 seizures were used to designate a one hour pre-ictal period, ending 5 minutes prior to seizure onset, and a

one hour inter-ictal period ending five hours prior to seizure onset. We calculated 3 main spectral features (delta-beta power ratio as a proxy for sleep/wake state, zero-phase lag coherence, and variance of coherence (1 minute moving window)) for each ipsilateral pair of limbic contacts using 10 second segments and frequency bands of 1-3 Hz, 3-7 Hz, 7-13 Hz, and 13-30 Hz. Features during the pre-ictal and inter-ictal periods were averaged for each subject. Wilcoxon rank-sum test was used to identify subject-specific and region-specific differences between groups. When pooled across all subjects, the pre-ictal period showed a significant decrease in beta coherence ($p < 0.01$, $n = 37$ per group). Amygdala-hippocampal alpha coherence and variance of beta coherence were significantly decreased in the pre-ictal period ($p < 0.01$, $n = 6$ per group) as was insula-hippocampal beta coherence ($p = 0.01$, $n = 8$ per group). These differences were not associated with a difference in delta coherence or delta-beta ratio between the pre-ictal and inter-ictal samples, although this study was underpowered to evaluate an interaction between coherence and brain state. In summary, these findings suggest that limbic coherence between non-SOZ contacts is altered in the pre-ictal period. Careful characterization of or omission of pre-ictal (1 hour +) iEEG may be warranted in analyses using non-SOZ contacts to investigate limbic network physiology.

Abstract: D-amphetamine (d-AMPH), which causes the direct release of dopamine and norepinephrine from synaptic terminals, produces emergence from propofol and isoflurane anesthesia in rats. Dexmedetomidine (DEX) is an α_{2A}-adrenoreceptor agonist, whereas ketamine is an anesthetic that acts primarily by inhibiting N-methyl-D-aspartate (NMDA) type glutamate

receptors. These drugs produce loss of consciousness (LOC) by different mechanisms from GABAergic agents such as propofol and volatile anesthetics. In this study, we tested the efficacy of d-AMPH for accelerating recovery from DEX- and ketamine-induced LOC and recorded local field potentials (LFPs) to reveal how d-AMPH modulates neural activities in rat prefrontal cortex (PFC). LOC was defined by loss of righting, and the time to recovery of consciousness (ROC) was defined as the time from onset of saline/d-AMPH to return of righting.
After DEX (50 μg/kg IV) infusion, d-AMPH (3 mg/kg IV) administration significantly decreased the mean times to ROC from 87.2 min to 1.7 min ($p < 0.001$). When the D_1 dopamine receptor antagonist SCH-23390 (0.2 mg/kg IV) was administered prior to d-AMPH (1 mg/kg IV), the mean time to ROC increased significantly from 5.1 min to 80.3 min ($p < 0.001$). However, after ketamine infusion (50 mg/kg IV), d-AMPH (3 mg/kg IV) significantly increased the mean time to ROC from 6.3 min to 11.6 min ($p = 0.017$). When SCH-23390 (0.2 mg/kg IV) was administered prior to d-AMPH (1 mg/kg IV), the mean time to ROC increased significantly from 6.3 min to 24.6 min ($p < 0.001$). After ketamine (50 mg/kg IV) infusion, the mean time to ROC in rats that received SCH-23390 (0.2 mg/kg IV) alone was 28.7 min.
Spectral analysis of PFC LFP recordings revealed that, compared to the awake state, DEX (50 μg/kg IV) produced a sustained increase in δ (0.1-4 Hz) power that coincided with LOC. However, the administration of d-AMPH (1 mg/kg IV) after DEX promptly decreased δ power and restored an awake LFP pattern that coincided with ROC. The administration of SCH-23390 (0.2 mg/kg IV) prior to d-AMPH blocked this effect. In contrast, ketamine increased δ and γ (40-50 Hz) power, and d-AMPH administration did not affect the ketamine-induced changes in LFP power.
In conclusion, d-AMPH rapidly restores consciousness and an awake LFP pattern after DEX infusion. This effect is blocked by the D_1 antagonist SCH-23390, suggesting that the arousal effect is mediated by dopamine. However, d-AMPH does not induce behavioral or neurophysiological reversal of ketamine-induced unconsciousness. These results demonstrate that the D_1 dopamine receptor-mediated arousal effect of d-AMPH is anesthetic-dependent.

Title: Nasal respiration drives 80-130 Hz oscillations in the olfactory bulb of ketamine-xylazine anesthetised rats: Implications for the NMDA receptor hypofunction model of schizophrenia

Authors: *W. SREDNIAWA[1], J. WROBEL[2], M. WHITTINGTON[3], D. K. WOJCIK[1], M. J. HUNT[4];

Abstract: NMDA receptor hypofunction is used widely to model psychosis in humans and experimental animals. The neural networks which underlie the psychotomimetic actions of NMDA receptor antagonists, such as ketamine, remain poorly understood. Over the past decade we, and other groups, have shown that NMDA receptor antagonists are associated with abnormal high-frequency oscillations (HFO; 130-180 Hz) in local field potentials (LFP) recorded of awake rodents. Although HFO have been reported in multiple brain regions, the olfactory bulb (OB) appears to be particularly important for the generation of this activity. Here, we report that under ketamine (100 mg/kg) and xylazine (10 mg/kg) anesthesia (KX) a slower HFO rhythm (80-130 Hz) can be recorded from the rat OB which is comparable to that recorded in awake rats. Similar to the awake state, KX-HFO occurred as bursts that were coupled on a cycle-by-cycle basis to slower frequencies, were attenuated by unilateral naris blockade, and reversed phase close to the mitral layer. Simultaneous thermocouple (used to measure nasal respiration) and LFP recordings revealed that KX-HFO and slower oscillations, mainly delta (<2 Hz), were coupled to specific phases of nasal respiration. Further, using 32 channel silicon probes, we spatially profiled KX-HFO and delta in the OB and found HFO current sources/sinks close to the mitral layer and a large delta current source/sink more ventrally (in the extraplexiform/glomerular layers) that preceded KX-HFO occurrence. We suggest that KX-HFO emerge, due to enhanced current flow across the extraplexiform/glomerular layers, as a result of the strong delta sinks produced by nasal respiration. We conclude that KX anesthesia appears suitable for investigating aberrant HFO relevant to the awake state, which is also likely to be driven by natural breathing.

Title: Dynamics of *in vivo* cortical network activity and local field potentials in a Huntington's disease mouse model

Authors: *M. D. SEPERS[1], J. P. MACKAY[2], E. KOCH[2], D. XIAO[1], T. H. MURPHY[1], L. A. RAYMOND[3];

Abstract: Huntington's disease (HD) is a hereditary neurodegenerative disease characterized by profound degeneration of the striatum and cortex, with patients showing progressively disordered movement and cognition. Before the onset of motor symptoms and cell death, mutant huntingtin (mHtt) expression causes abnormalities in synaptic and neuronal activity. Although the striatum is well studied in HD models, fewer studies have examined cortical neuron function in HD and in particular *in vivo* cortical network connectivity. Preliminary *in vivo* data from our labs with mesoscopic imaging using voltage-sensitive dyes (VSDs) showed a more extensive spread of evoked sensory signals across the cortical surface in YAC128 HD mice. To further examine mHtt-induced changes in the cortex, here we used tetrodes chronically implanted across various cortical areas in 6 month-old YAC128 vs. wild-type mice to measure local field potential (LFP) oscillations, and in some cases single neuron activity. Consistent with the VSD imaging experiments, our preliminary data suggest that YAC128 mice show an augmented response to evoked sensory input by limb stimulation. In multiple cortical areas instantaneous LFP power remained elevated in YAC128 longer than wild-type, particularly in beta frequencies. We also repeatedly tested awake-behaving mice to correlate spectral densities and coherence across cortical areas and used video analysis to differentiate between behavioural states: at rest, whisking, grooming and running on a wheel. The work presented here extends our knowledge of the impact of mHtt beyond *ex vivo* studies of individual neurons to the function of the intact cortical network in HD.

Title: High-gamma amplitude is coupled to low-gamma phase in sensorimotor cortical activity

Authors: *M. W. SLUTZKY[1], R. D. FLINT, III[2];
[2]Neurol., [1]Northwestern Univ., Chicago, IL

Abstract: Phase-amplitude coupling (PAC) in brain oscillations consists of the modulation of high-frequency amplitude according to low-frequency phase. Many studies have described PAC between low-frequency rhythms (delta, theta, or alpha bands) and high-gamma band (70-200 Hz) activity in multiple areas of the cerebral cortex, basal ganglia, and hippocampus. Here, we examined a new form of coupling between the phase of low-gamma (30-60 Hz) oscillations and high-gamma amplitude.
We computed low-gamma - high-gamma PAC in two ways: the height ratio of the phase-amplitude histogram and the mean vector length (MVL). We computed these measures on data from two monkeys and 2 human subjects. We recorded intracortical LFPs from primary motor cortex in 2 monkeys (and primary somatosensory cortex in 1 monkey) during center-out reaching tasks. We recorded subdural electrocorticography (ECoG) from the motor and premotor cortices in two humans performing grasping movements while undergoing monitoring for epilepsy. We computed the phase and amplitude of the signals using the Hilbert transform on bandpass-filtered data.
Overall, we found gamma-gamma coupling in many sites of both monkey LFPs and human ECoG. In monkey LFPs, we found that this coupling was higher in the resting position than during the first 500 ms of reaching movement (mean height ratio of 0.072 vs. 0.027, respectively, over all 96 electrodes in 2 monkeys, p=0.03, paired t-test). MVL measures also revealed substantial gamma-gamma coupling in both monkeys that decreased during movement over all electrodes.
These results point to a novel form of phase-amplitude coupling in the sensorimotor cortices. This coupling appears to be larger during idle state and smaller during movement.

Title: Functional connectivity of the cortico-thalamo-cortical circuit after interrupting spike and wave discharges with closed-loop stimulation in rats

Authors: *F. SANTOS-VALENCIA, E. URBINA-TREJO, S. ALMAZÁN-ALVARADO, A. RUBIO-LUVIANO, D. MARTÍNEZ-VARGAS;
Inst. Nacional De Psiquiatría Ramón De La Fuente Muñiz, Mexico City, Mexico

Abstract: High frequency electrical stimulation to deep brain nuclei has shown to be an effective way to control seizures in some forms of human epilepsy and animal models; however the way it modulates the epileptic circuits to achieve this effect is not clear. We sought to investigate this process by stimulating the cortico-thalamo-cortical circuit in an animal model of spike and wave discharges (SWD). To do this, we implanted 2 stimulation electrodes and 1 recording electrode in the right basoventral thalamus and four electrodes in bilateral motor and somatosensory cortices of Wistar rats. After 7 days post-surgery Pentylenetetrazol was injected at a single dose of 30 mg/kg of weight to induce SWDs, local field potentials (LFP) were recorded for an hour and the thalamus of half of the animals was stimulated (train duration 1s, 130Hz, biphasic squared wave 0.1ms pulses) immediately after the detection of a SWD. To deliver closed-loop stimulation band passed filtered (5-10Hz) recordings of the somatosensory cortex were input to a MATLAB program that implements the Line Length algorithm for the real time detection of SWDs (moving window 2s, time steps 0.01s). The total number of SWDs was the same in both groups and the mean percentage of interrupted SWDs in stimulated animals was 77.4%. To reveal changes in the functional connectivity of the circuit we employ wavelet coherence analysis using Morlet as the mother wavelet with 12 voices per octave. A 1s epoch following the stimulation train of interrupted SWDs was chosen for analysis; coherence was computed between the LFPs of the thalamus and the 4 cortices. We found less synchronization in the total analysis band (1-50 Hz) between the thalamus and both somatosensory cortices and in the delta (1-4Hz) and theta (4-7Hz) bands between the thalamus and both motor cortices when SWDs were interrupted. Thus, closed-loop high frequency electrical stimulation modulates the epileptic cortico-thalamo-cortical circuit by halting its intrinsic recurrent connectivity that allows the maintenance of SWDs.

Title: State-dependent variability in hierarchical phase-amplitude coupling of neural oscillations

Authors: *R. B. JOSHI[1], D. C. KLORIG[1], H. P. ZAVERI[2], D. W. GODWIN[1];
[1]Wake Forest Sch. of Med., Winston-Salem, NC; [2]Dept. of Neurol., Yale Univ., New Haven, CT

Abstract: Objective: A number of prior studies suggest that cross-frequency coupling between neural oscillations is functional and ubiquitous across a range of spatiotemporal scales. In this study, we studied phase-amplitude coupling (PAC) in baseline mouse local field potential (LFP) recordings over frequencies ranging from infraslow activity (below 0.2 Hz) to ripple frequencies (200 Hz). We additionally determined how PAC varied with sleep-wake state.
Methods: We computed PAC over logarithmically-distributed frequency bands ranging from 0.06 to 400 Hz in prefrontal cortex (PFC) and the CA1 region of the hippocampus in both ripple-locked and spontaneous, ongoing data. Ripple data was derived from 42, 30-minute baseline recordings across 18 animals. The spontaneous data included three 8-hour recordings from one animal. In our spontaneous data, we further determined whether sleep-wake state, as measured by the ratio of theta power to large irregular activity (LIA) power, affected the expression of PAC.
Results: In our ripple-locked data, we observed significantly nonzero ($p<0.0001$) coupling between delta and spindle frequencies, delta, and ripple, infraslow and subdelta, and infraslow and delta in all regions. In our spontaneous recordings, we found significantly nonzero ($p<0.0001$) coupling between infraslow and subdelta, and infraslow and delta activity. The magnitude of the coupling did not vary significantly by theta/LIA ratio (i.e., sleep-wake state). However, we did find spatially variable shifts in the phase of infraslow activity where subdelta and delta activity amplitude peaked.
Conclusions: We observed a hierarchical organization of PAC between infraslow, delta, spindle, and ripple activity. We speculate that the phase shifts observed in PAC with sleep-wake state in spontaneous data do not reflect shifts in the timing properties of oscillatory coupling, but rather dynamic, state-dependent spatial variability of engagement and disengagement of these oscillations.

Title: Local kainate receptor expression provokes synchronous network activity in hippocampal slices

Authors: *T. KAARELA[1], W.-C. CHANG[1], T.-K. KUKKO-LUKJANOV[1], S. E. LAURI[2], T. P. TAIRA[1];
[1]Vet. Biosci., [2]Mol. and Integrative Biosci. Res. Programme, Univ. of Helsinki, Helsinki, Finland

Abstract: Kainate type glutamatergic receptors (KARs) modulate synaptic transmission and neuronal excitability depending on their subunit composition and localization. Developmental expression of KARs in the immature hippocampus is suggested to promote activity-dependent synchronization of neuronal networks, yet the exact mechanisms are still unclear. Here we asked how local manipulation of KAR subunit GluK1 modulates synchronous network activity in postnatal hippocampi *in vitro*. Multichannel recordings were used to study the spatio-temporal profile of network activity in organotypic hippocampal slice cultures. Slices were extracted from P7 male rats and cultured on multielectrode array probes with 64 planar microelectrodes (MED64). Gene expression in the CA3 pyramidal neurons was modified with injection of lentiviruses, carrying either a control (EGFP, n=12) or GluK1c over-expressing (OE, n=7) construct. Cultured hippocampi spontaneously presented alternating synchronous activities resembling ictal and interictal epileptiform discharges (IEDs) after 6 days in culture. When compared to control slices GluK1 OE did not alter the ictal activity period duration or spiking frequency. Interictal periods, however were significantly shorter ($p<0.05$, Student´s t-test), resulting in more frequent ictal discharges. In control slices, IEDs preceded the ictal discharges with increasing frequency. Interestingly, networks with GluK1 OE presented significantly fewer IEDs ($p<0.01$, Student´s t-test) which were mainly detected right before the ictal activity without the steady increase in frequency. Early IEDs originated at the CA3 and the depolarization propagated locally in the CA3 region. Prior to the onset of ictal activity, IEDs were associated with synchronous depolarizations between the CA3 and the CA1. In GluK1 OE the recruitment of the CA1 was faster, provoking the ictal initiation. Our data suggests that facilitated spatial propagation of IEDs promote synchronization of network activity in KAR expressing slices, supporting the notion that these receptors might play essential role in the functional integration of neurons in hippocampal circuitries.

Title: Increased local field potential beta power in cerebral cortex of a model of Dup15q

Authors: *M. VALLEJO[1], D. TRAN[1], V. SARAVANAPANDIAN[2], J. FROHLICH[1], M. C. JUDSON[4], B. D. PHILPOT[5], S. S. JESTE[3], P. GOLSHANI[1];
[1]UCLA Dept. of Neurol., Los Angeles, CA; [3]A7-469, [2]UCLA Semel Inst. of Biobehavioral Sci., Los Angeles, CA; [4]The Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [5]Cell Biol. and Physiol., Univ. North Carolina, Chapel Hill, NC

Abstract: Duplications of 15q11.2-q13.1 (Dup15q syndrome) are a frequent cause of autism spectrum disorder, intellectual disability, and epilepsy (Finucane et al. 2016). Recent studies using EEG spectral power show that children with Dup15q syndrome have dramatically increased beta band power (beta1=12-20Hz, beta2=21-30Hz) compared to typically developing children and children with non-syndromic intellectual disabilities and autism (Frohlich et al. 2016). Yet, it is poorly understood which of the many duplicated genes in the region lead to the EEG phenotype. Candidate genes include Ube3a, which is paternally imprinted and the non-imprinted α5/γ3/β3 $GABA_A$ receptor subunit gene cluster, which has been implicated in the generation of pharmacologically-induced beta oscillations (Christian et al.2015). Understanding the EEG mechanism will be critical to link this biomarker to specific molecular pathways and, furthermore, may suggest new therapies. To dissect the contribution of different duplicated genes to the beta EEG phenotype, we have performed silicon probe multielectrode array electrophysiological recordings from the parietal cortex of three Dup15q syndrome animal models during adulthood. Mice with maternally inherited 15q duplication (*mat*DP/+) overexpress Ube3a, $GABA_A$ receptor subunits genes, as well as other genes in the region (Nakatani et al. 2009,) while mice with paternally inherited 15q duplication (*pat*DP/+) do not have overexpression of Ube3a (which is imprinted) but do have overexpression of the other genes in the region (Nakatani et al. 2009). We also compared these mice to mice that exclusively express Ube3a but no other regions (generated by the Philpot lab). Similar to EEG recordings from humans, local field potential recordings from parietal cortex of *mat*DP/+ animals showed increases in both beta1 power and beta2 power, but only during locomotion [beta1:~39% 11.81 (=0.01) beta 2: ~28% 11.81 (=0.018). Two-Way ANOVA & Multiple comparison]. On the other hand, *pat*DP/+ and Ube3a overexperssor mice showed no significant changes in beta power. These results suggest that a combination of increased copy number of Ube3a and non-imprinted genes in the region (including $GABA_A$ receptor subunits) may be responsible for the abnormal beta oscillations observed in humans. Current studies are probing whether beta oscillations recruit specific populations of cortical neurons to fire in synchronization with the abnormal oscillation in Dup15q syndrome mice.

Title: Computational models and phantom validation of transcranial electrical stimulation techniques for deep brain targets

Authors: *B. TESSLER[1], S. E. FOX[2];
[1]SUNY - Downstate Med. Ctr., Brooklyn, NY; [2]Dept Physiol & Pharmacol, State Univ. of New York Downstate Med. Ctr., Brooklyn, NY

Abstract: Hippocampal theta is the largest amplitude rhythmic local field potential (LFP) in the mammalian brain. It is often associated with learning and memory due to its involvement in the timing of place cell firing. In the literature, anti-epileptic effects have been seen during theta with a dramatic reduction of epileptic discharges. Transcranial electrical stimulation (tES) techniques may provide for an advantageous method to elicit or modulate theta at low-cost and low-risk, allowing it to be easily translatable. In our lab, we tested tES methods that optimize the injected currents to target the CA1 of the hippocampus in a rat model. With 3-D reconstructions generated from MRI data that are inserted into powerful physics solvers, various electrode placements are iterated through to maximize the ratio of electric field intensity in the CA1 relative to the rest of the brain. We then validate these results by using phantom models of cleaned rat skulls filled with agar that have NaCl concentrations appropriate for the equivalent brain electrical conductivity. We have found our physics simulation results to be comparable to our phantom model results. One of the tES methods we tested is intersectional pulsing (ISP) stimulation, which is proposed to focus electric fields on deep targets by a rotation of the bipolar current injection. However, we have found ISP electric fields to be equal to the equivalent electrode placements without any rotation. The optimal tES method we have validated is temporal interference (TI) stimulation that uses two pairs of electrodes, one injecting a current of slightly higher frequency than the other causing an amplitude maximum at the difference frequency near the midline of the two pairs, thus properly targeting deeper structures. These results will guide us and other researchers to maximize the efficacy of their tES techniques when attempting to modulate neuronal oscillations of deep structures.

Nijmegen, Nijmegen, Netherlands; [8]Swammerdam Inst. for Life Sciences, Ctr. for Neuroscience, Fac. of Science, Univ. of Amsterdam, Amsterdam, Netherlands; [9]Wellcome Trust Ctr. For Neuroimaging, London, United Kingdom

Abstract: The Communication-through-Coherence (CTC) hypothesis proposes that flexible effective communication among neurons depends on their coherence (Fries, Neuron 2015). Indeed, when two visual stimuli induce two local gamma rhythms in macaque V1, only the gamma induced by the attended stimulus entrains gamma in V4 and establishes coherence (Bosman et al, Neuron 2012). Additionally, attended V1 gamma shows higher peak frequency, potentially causing the selective V1-V4 coherence. Here, we investigate whether and which local modulations within V1 can result in the observed attentional effects. We used Dynamic Causal Modeling (DCM) for Cross-Spectral Densities (Friston et al, NeuroImage 2012) to fit a canonical microcircuit (Bastos et al, Neuron 2012) to macaque electrocorticographic data. DCM allows investigating the causes of the attentional effects at the microcircuit level, which is challenging to access experimentally. The data consists of triplets of two V1 sites with non-overlapping receptive fields, sending converging inputs to a V4 site. To fit the complex, non-linear models to the dataset and overcome local minima, we used Variational Laplace, introducing multiple re-initializations with stochastic updates of parameters. This novel scheme allowed us to 1) identify models with higher evidence than achieved with the conventional method, 2) show that the nature of the attentional effects in the winning model is robust across neighboring local minima and 3) show that there is an optimal level of noise that both overcomes local minima and avoids poor fitting. We find that modulation of V1 connectivity is sufficient to model the observed

attentional effects. We used Parametric Empirical Bayes to identify attentional modulations conserved over the selected triplets. The winning model suggests that attention primarily regulates inhibitory pathways within V1: Attention 1) increases the self-inhibition of superficial pyramidal cells (likely related to PV-interneuron activity), 2) increases the feed-forward excitation from layer-4 excitatory neurons to superficial pyramidal cells, 3) decreases the self-inhibition of layer-4 excitatory neurons and 4) decreases the feedback inhibition of superficial pyramidal cells onto layer-4 excitatory neurons. The latter two inhibitory effects can be mediated by local inhibitory interneurons in layer 4. The probability of those attentional modulations across the top 5% of models is 0.88, 0.94, 0.87 and 0.93, suggesting their crucial role. Thus, attentional modulations within the V1 circuitry, primarily of inhibitory connections, can explain increased V1 gamma frequency and enhanced V1-V4 gamma coherence.

Title: Amplitude-modulated high-frequency electric field stimulation of gamma oscillations *in vitro*

Authors: *Z. ESMAEILPOUR[1], G. KRONBERG[2], L. C. PARRA[3], M. BIKSON[4];
[1]City Col. of New York (CCNY), New York, NY; [2]Biomed. Engin., The City Col. of New York, New York, NY; [3]Biomed. Engin., [4]Dept of Biomed. Engin., City Col. of New York, New York, NY

Abstract: It has been suggested that amplitude-modulated high-frequency (>1 kHz) electrical stimulation has special biophysical or neurophysiological features that can be leveraged in neuromodulation, including applications of transcranial electrical stimulation (tES) and inferential stimulation (IF). Explaining the cellular mechanism of amplitude-modulated high-frequency stimulation is thus of interest in neuromodulation. Yet, the well-established low-pass filtering by neuronal membranes suggests minimal neuronal polarization in response to continuous charge-balanced high-frequency stimulation, regardless of any underlying modulation. The hippocampal brain slice model is among the most characterized systems in neuroscience and exhaustively characterized in screening the effects of electrical stimulation. Effect of amplitude-modulated high-frequency electric fields on ongoing network activity was evaluated in carbachol-induced gamma oscillation in CA3a region of rat hippocampal slices. Extracellular local field potentials were recorded and analyzed before, during and after 2 s of

stimulation. We tested kHz frequency carriers with low-frequency modulation such that the resulting waveform alternates between low and high amplitude phases every tens of ms, with tens of kHz oscillations per modulated phase. The hippocampal brain slice model of gamma oscillation provided a rapid experimental system to test the degree of modulation produced by amplitude-modulated high-frequency stimulation as well as control waveforms of fixed amplitude kHz stimulation and simple low-frequency sinusoidal stimulation. We further developed a computational model of excitatory/inhibitory neuronal network with conductance-based synaptic interactions. kHz oscillations in the high phase driving singe neuron activity, with loss of efficacy determined by linear membrane low-pass characteristics and accommodation. The inter-phase period drives oscillations determined by non-linear network characteristics. These simple rules explain a broad range of findings. Inferential waveforms require significantly more intensity than simple low-frequency sinusoids (as used in transcranial Alternating Current Stimulation, tACS), may be ineffective at intensities relevant for clinical transcranial stimulation (compared to tACS), and would be increasingly ineffective with higher kHz carriers (e.g. 2 kHz). The lack of response to continuous fixed amplitude kHz stimulation does not reflect a special sensitivity to the modulation, but rather accommodation to steady stimulation.

Title: Communication through coherence: Analysis of the optimal phase shift and the importance of waveform shape

Authors: *E. NOZARI[1], J. CORTES[2];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Univ. of California San Diego, La Jolla, CA

Abstract: According to the communication through coherence hypothesis, the causal effect of one oscillatory circuit on another is maximized if the two are phase-locked and their phase shift is "optimal", i.e., such that the sender signal arrives at the receiver at the peak of its excitability. It is often postulated that this optimal phase shift is the same as the stable phase shift, i.e., the

phase shift that the two oscillators naturally converge to in the steady state. However, the computation of the stable phase shift often requires (accurate) computational models of the underlying dynamics. Furthermore, even though it has been long known that heterogeneity can alter the stable phase shift of coupled oscillators, analyses have been primarily focused on synchronous and anti-phase relationships (phase shifts of 0 and 180 degrees) modulo the effects of delays. In this work, we seek to characterize the stable phase shift of pairs of heterogeneous and non-sinusoidal coupled oscillators in terms of their waveform shapes.
We first define a waveform synchronization centroid (WSC), computed independently for each oscillator, which coincides with the peak of sinusoidal waveforms but may be significantly off-peak for general ones. We then show that the stable phase shift of same-frequency weakly-coupled oscillators is equal to the difference of the phases of their WSC, i.e., the oscillators slide with respect to each other until their WSCs are aligned. The computation of WSC, however, still requires knowledge of the computational model of each oscillator. We thus analyze the optimal phase shift that maximizes the cross-correlation function (closely related to coherence index) and the linear-threshold causal effect (as a deterministic measure of information transfer), which depend only on the waveforms. We analytically prove that, for sinusoidal oscillators, correlation and causal effect are maximized exactly when the two oscillators are phase-locked with zero phase shift. However, neither this direct relationship between cross-correlation and causal effect nor the optimality of zero phase shift are generally true for oscillators with non-sinusoidal waveforms. In the latter case, we observe that the difference in WSC is better explained by the phase shift maximizing the causal effect rather than the one maximizing cross-correlation.

Title: Intrinsic gamma mechanisms differ in model lateral and basal amygdala networks

Authors: ***F. FENG**[1], D. HEADLEY[2], D. PARE[2], S. NAIR[1];
[1]Univ. of Missouri-Columbia, Columbia, MO; [2]Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: The basolateral amygdala (BLA) is recognized as being important for mediating learned emotional behaviors. Consistent with this view, *in vivo* LFP recordings from rodent BLA during states of emotional arousal reveal gamma oscillations (30-100 Hz) that are thought to

facilitate communication with downstream targets and coordinate local activity. However, BLA is heterogeneous with distinct lateral (LA), basal (BL) and accessory-basal (AB) subdivisions, and the role of these distinct nuclei in generating and supporting gamma oscillations is presently unclear.
We have recently found that gamma in LFP recordings differ significantly between LA and BL regions. For instance, spontaneous gamma oscillations were prominent in BL but not in LA. However, gamma power in LA was found to be significantly higher during task-related events. Differences in microcircuitry and extrinsic inputs between the regions might explain these observations. For instance, although it is known that gamma oscillations emerge from reciprocal interactions between pyramidal cells (PNs) and parvalbumin-expressing fast spiking inhibitory interneurons (FSIs), it is also recognized that subtle changes in the connectivity and synaptic strengths of this microcircuit affects the properties of gamma. The link between microcircuitry differences and gamma properties is difficult to explore experimentally. Hence, we used large-scale biophysical computational models of LA and BL that incorporate known connectivity as well as cellular and synaptic neurophysiology to explore this question.
In vivo extracellular recordings from LA and BL revealed differences in cell proportions of PNs and FSIs, connectivity between the cell types, and firing rates during different states. Furthermore, it is also known that LA and BL differ in their afferent connections. After incorporating data related to connectivity and cell proportions, model synaptic strengths were tuned to replicate the firing rates and gamma characteristics of the specific region, LA or BL. The new network parameters also reproduced what was found *in vivo* and in earlier models. We found that the sparser connectivity in LA, compared to BL, necessitates significantly higher inhibitory synaptic strengths (FSI-PN) in the LA model to match *in vivo* firing rates. These models provide a path forward to understanding the mechanisms underlying gamma oscillations in the BLA and exploring how they affect local computations.

Title: Alpha oscillations rhythmically modulate large-scale functional connectivity in the human cortex

Authors: *J. I. CHAPETON, R. HAQUE, J. H. WITTIG, JR, S. K. INATI, K. A. ZAGHLOUL;
NIH, Bethesda, MD

Abstract: Neural oscillations are ubiquitous in the human cortex and appear at multiple temporal and spatial scales, however, the functional significance of these rhythms continues to be a topic of intense debate. Recent evidence has suggested that coherent neuronal oscillations may serve as a gating mechanism for flexibly modulating communication between brain regions. Given that a brain region may send and receive connections from multiple other regions, synchronized oscillations could allow for communication between brain regions to be modulated without requiring substantial changes to the underlying structural connectivity. This is the basic principle behind models of oscillation-mediated communication such as communication through coherence and communication through resonance.

Alpha oscillations are the canonical example of rhythmic neural activity in the human brain and appear to be particularly well suited for mediating large-scale synchronization. This is because they are robust in terms of power and frequency and can be readily observed throughout the human cortex. Here, we test the hypothesis that large-scale communication in the human brain is modulated by coherent oscillations in the alpha band by investigating human intracranial EEG (10 participants) and micro-electrode recordings (2 participants) captured from awake, freely behaving participants as they were being monitored for seizure activity. Based on theoretical considerations related to the implementation of communication schemes that depend on oscillatory entrainment or resonance, we identified a set of constraints which must be satisfied if alpha oscillations are to modulate large-scale communication. By analyzing functional connectivity in both the time and frequency domains, we demonstrate that alpha oscillations satisfy these constraints and are well suited for modulating communication over large spatial scales in the human brain.

Specifically, we find robust alpha oscillations that are coherent between brain regions with center frequencies that are specific to each individual participant. Regions demonstrating coherent narrowband oscillations also exhibit time-locked broadband correlations with a consistent time delay, as required for an efficient communication channel. The phase lags of the coherent alpha oscillations match the time lags of the correlated components, and importantly, both broadband correlations and neuronal spiking activity are modulated by the phase of the oscillations. These results are specific to the alpha band and provide evidence that large scale communication in the human brain may be rhythmically modulated by alpha oscillations.

Title: Enhancing the synchronization of coupled gamma rhythms through intrinsic network heterogeneity

Authors: *X. XU, H. RIECKE;
Applied Mathematics, Northwestern Univ., Evanston, IL

Abstract: The synchronization of gamma rhythms in different brain areas has been implicated in some cognitive functions. Here, we focus on the effect of neural heterogeneity on the synchronization of such rhythms, which are associated with PING (pyramidal-interneuronal network gamma) rhythms or ING (interneuronal network gamma) rhythms. The synchronization properties of rhythms depends on their phase response to external input. Therefore, we determined the macroscopic phase-resetting curve for finite-amplitude perturbations (fmPRC), using numerical simulation of all-to-all coupled networks of integrate-and-fire neurons exhibiting gamma (either PING or ING) rhythms. Importantly, the delayed coupling between excitatory (E) and inhibitory (I) cells or between I and I cells was strong. We show that the intrinsic neural heterogeneity can strongly modify the fmPRC. While the infinitesimal mPRC is strictly positive, for sufficiently large perturbations the fmPRC can become biphasic. Thus, for PING rhythms, an external excitation to the E cells can not only advance but also delay the network depending on the time when it is applied, even though the same excitation would only lead to an advance when applied to uncoupled neurons. The delay arises when the excitation causes additional spikes of inhibitory neurons, whose delaying impact outweighs the external excitation. These results explain how the intrinsic heterogeneity allows the PING rhythm to become synchronized (either accelerated or decelerated) to a periodic external excitatory force and, by extension, to another PING rhythm. The persistent relationship between two coupled phase-locking rhythms then can be understood as the stable point on the fmPRC. Based on the dependence of the fmPRC on the heterogeneity, we numerically show that for larger intrinsic heterogeneity, coupled PING rhythms can be synchronized for a wider range in the mismatch of their frequencies. A similar mechanism is found for the synchronization of ING rhythms. Our results identify a potential function of neural heterogeneity in the synchronization of coupled gamma rhythms, which may play a role in neural information transfer via communication through coherence.

Title: Dynamics in oscillatory waveform shape revealed by empirical mode decomposition

Authors: *A. J. QUINN[1], V. LOPES-DOS-SANTOS[1], W.-K. LIANG[2], C.-H. JUAN[2], J.-R. YEH[2], N. HUANG[3], D. DUPRET[1], A.-C. NOBRE[1], M. WOOLRICH[1];

Abstract: The waveform shape of the hippocampal theta oscillation shows large variability between cycles, though the physiological and behavioural relevance of this is not well understood or accounted for in current models of hippocampal theta function. Changes in theta waveform shape that prolong the duration of a particular theta phase may facilitate the gamma oscillations and cell spiking nested within that theta-phase. As such, waveform shape variability may be a relevant feature for computations within the Hippocampus. Here, we characterise waveform shape with the Instantaneous Frequency (IF) of an oscillation isolated by masked Empirical Mode Decomposition (EMD). IF is estimated from the differential of the phase and quantifies how quickly an oscillation is progressing through a cycle at a given point ie how quickly or slowly the cycle is progressing at that point. Crucially, this may be estimated at the full sampling rate of the observed data allowing measurement of within-cycle variation of IF. Differences in cycle duration and timing between features are normalised across cycles by interpolating each cycle's IF to a regularly sampled phase grid. This phase-aligned IF allows for direct comparisons at each point in the phase despite variations in their absolute and relative timing of each cycle. The variance of phase-aligned IF is taken as a summary of waveform shape. This method is applied to LFP data recorded from CA1 in the Hippocampus of 8 mice across 46 open field recording sessions. The waveform shape across all theta cycles is explored in a 2d space coding each cycles peak and edge asymmetry revealing a tendency towards high-frequency ascending edges and low frequency descending edges. In contrast, there is a wide variety in peak asymmetry with both fast peak cycles and fast troughs cycles occurring with

similar prevalence. A two-level multivariate GLM was used to quantify the relationship between waveform shape, movement speed and novel/familiar environment, with covariates of theta cycle amplitude and theta cycle average frequency. This shows that theta waveform shape is differentially modified by both movement speed and environment novelty. Finally, change in theta waveform shape modulates higher-frequency theta nested oscillations whiles covarying out the effects of movement speed, theta amplitude and theta frequency. Shape analysis through phase-aligned IF shows that theta waveform-shape is a measurable and relevant feature showing rapid dynamics and strong covariance with movement speed and theta-nested oscillations.

Title: Hierarchy of cortical population characteristic timescales inferred from field potentials

Authors: *R. GAO[1], B. VOYTEK[2];
[1]Univ. of California San Diego Dept. of Cognitive Sci., La Jolla, CA; [2]Dept. of Cognitive Sci., Univ. of California San Diego, La Jolla, CA

Abstract: Neuronal populations across the macaque cortex exhibit intrinsic characteristic timescales in their spiking fluctuations. Specifically, sensory areas have shorter timescales of spiking autocorrelation (i.e., faster decay), while frontal areas have longer timescales [1]. Importantly, these regional differences predict working memory function, suggesting possible physiological mechanisms for how populations temporally maintain information [2]. Extending measurements of population timescales across many brain regions would considerably broaden our understanding of neurodynamics and how they support behavior. However, it is prohibitively expensive and technically challenging to record single units across the whole macaque cortex under different tasks, and impossible in the human brain due to the scarcity of single-unit recordings, even in rare clinical settings.
Here we infer neuronal population timescales from field potentials recorded via

electrocorticography (ECoG) grids across the macaque and human cortex. In frequency domain, the power spectral density (PSD) of field potentials often have a 'knee' [3] connecting two distinct power law-like regimes. The frequency at which this knee occurs corresponds mathematically to the time constant of autocorrelation decay in time domain. Applying a spectral parameterization tool we developed on 8 whole-cortex ECoG recordings from 2 monkeys [4,5], we find that ECoG timescales are tightly correlated with the reported spiking fluctuation timescales in select cortical areas from [1]. Furthermore, we extend the analysis to resting ECoG recordings from 106 human patients (1772 electrodes total) undergoing epilepsy monitoring [6]. We find that intrinsic timescale of electrode groups in each brain region increases with distance from the respective primary sensory (or motor) area, and that frontal lobe timescales, in particular, decreases with age. We validate the method with simulation of varying timescales, and discuss results pertaining to the scale-free nature of neuronal activity. In summary, this work offers a method for characterizing neuronal population timescales without single-unit measurements, which can be extended to M/EEG and field potential data in humans and other model organisms. Title: Assessing how periodic oscillation properties influence estimates of aperiodic neural activity

Authors: *A. HOHIL[1], R. GAO[2], B. VOYTEK[3];
[1]Cognitive Sci., Univ. of California at San Diego, La Jolla, CA; [2]Cognitive Sci., Univ. of California San Diego Dept. of Cognitive Sci., San Diego, CA; [3]Cognitive Sci., Univ. of California San Diego Dept. of Cognitive Sci., La Jolla, CA

Abstract: In this work, we investigate if nonstationarity and nonsinusoidality (i.e., the waveform shape) of oscillations can cause a change in the estimate of the aperiodic component. Since these components are not independently controllable in real data, we simulate data in the time series, and independently vary periodic and aperiodic parameters in the simulation, while observing changes in the retrieved parameters of the power spectrum in analysis. This allows us to see which periodic oscillatory parameters confound estimates of aperiodic components, enabling us

to make more reliable claims about the physiological processes that generate oscillatory and aperiodic signals in the brain.
Mesoscale electrophysiological signals recorded in the brain, such as the local field potential (LFP), reflect postsynaptic current fluctuations that are largely aperiodic. However periodic neural oscillations can wax and wane, are often bursty, nonstationary, and nonsinusoidal (Cole and Voytek, 2017). These aperiodic and periodic components can be separated in the frequency domain representation of the signal (power spectrum), a 1/f-like signal with narrowband oscillatory peaks rising above it. Notably, recent research demonstrates that these different components likely index different physiological properties. In particular, the aperiodic exponent (slope) correlates with the excitation and inhibition ratio of the local circuit (Gao et al., 2017). Behaviorally, the aperiodic component correlates with task engagement, cognitive load, and aging, in which the slope of the aperiodic component in older adults has shown to flatten with age.
However, these interpretations assume that the aperiodic and periodic components arise from separate and independent processes, which has not been explicitly examined. Under this assumption, features of the oscillation such as frequency shift, nonsinusoidality, etc. do not impact the estimate of the slope. But it is currently unknown if and how changes in oscillatory features can also bias the slope estimate of the aperiodic component in the frequency domain, thus confounding interpretations of oscillatory vs. aperiodic processes in the brain.

Title: Phase-amplitude coupling mediates sensory-motor integration in the macaque visual cortex

Authors: M. B. KHAMECHIAN[1], S. TREUE[2], ***M. ESGHAEI**[2], M. R. DALIRI[1];
[1]Iran Univ. of Sci. and Technol., Tehran, Iran, Islamic Republic of; [2]German Primate Ctr., Goettingen, Germany

Abstract: Visually-guided behavior requires the integration of information across several brain areas, to generate motor responses based on visual inputs. For this, sensory information encoded in the visual areas needs to be transmitted to the motor cortex. However, the neural mechanisms underlying this integration have remained elusive.
We recorded extracellular activities from the middle temporal area (MT) of two macaques while they performed a change detection task, requiring them to report a subtle change in the direction of a coherently moving random dot pattern (RDP). Based on the monkey's response time (RT) in each trial we divided the trials into a fast and a slow subset. We next extracted the local field potentials (LFP) and calculated the phase-amplitude coupling (PAC) for the period before the direction change, and compared the PAC between fast and slow trials in different frequency pairs. Our data show that fast trials have a significantly higher PAC between the beta band's phase (10-25 Hz) and high-gamma band's amplitude (180-220 Hz) for the interval preceding the animal's response. This indicates that local neural activities in visual cortex (reflected in high-gamma oscillations) more likely occur at a specific phase of the beta band oscillations in fast trials. This suggests that an enhanced beta high gamma PAC helps transferring the sensory signals to higher level sensorimotor areas, including the motor cortex. Our data propose a novel neural mechanism through which the information transfer from sensory to motor areas could be enhanced via synchronizing neural activities in different frequencies.

Title: Probabilistic characterization of Fast ripple parameters in a temporal lobe epilepsy model by Bayesian inference

Authors: *M. A. NUÑEZ-OCHOA, G. CHIPRÉS-TINAJERO, N. GONZÁLEZ-DOMÍNGUEZ, L. G. MEDINA-CEJA;
Univ. De Guadalajara, Zapopan, Mexico

Abstract: Epilepsy represents a global public health problem, in particular, temporal lobe epilepsy (TLE) is a subtype of the pathology that is highly refractory to pharmacological treatment and therefore, generally referred to surgical intervention and it is very important to develop new paradigms of approach to the diagnosis and treatment of this disease. The high-

frequency oscillation in the range of 250 to 600 Hz, also known as Fast ripple (FR), is becoming increasingly important as a biomarker for detecting epileptogenic zones, since they are observed exclusively in epileptic foci, both in experimental models and in patients with TLE. The origin of this activity is strongly associated with synaptic modifications related to the pathological process of TLE and characterizing the properties of the FR signal between different regions of the brain could explain intrinsic characteristics of the underlying neuronal circuits; in addition, once characterized, the parameters could be used to evaluate pharmacological or surgical interventions contrasting changes in these. The aim of the present study was to construct the probability distributions of means and standard deviations of the following FR parameters: Peak to peak voltage, power frequency, power and duration between three different regions of the trisynaptic circuit. Six adult male Wistar rats (210 - 300g) were used for this study to induce the epilepsy model; the rats were injected into the right lateral ventricle (AP: -4.5 mm, ML: -5.2 mm y DV: -7 mm) with a single dose of pilocarpine hydrochloride (2.4 mg/2µl) through a needle connected to an injection pump attached to the stereotaxic framework (Stoelting Co. IL. USA); these animals were video-monitored 24 hours/day in order to detect spontaneous and recurrent seizures, once detected, rats were oxygen-isoflurane anesthetized and fixed to the stereotactic frame. Fixed-recording tungsten wire electrodes (60 µm outer diameter), consisting of pairs with a 500 µm vertical tip separation, were implanted into the Dentate Gyrus, CA3, and CA1, all microelectrodes were implanted ipsilateral to the pilocarpine injection; a total of 346 FR were recorded, then Bayesian inference was used to estimate the joint posterior probability distributions of the parameters. In a satisfactory way, we constructed the credibility regions (joint posterior probability distributions) of the studied parameters between the different regions of the trisynaptic circuit according to our inclusion criteria used in the present study.

Title: Exercise acutely increases the coupling between hippocampal and neocortical ripples in humans

Authors: A. RAMIREZ-CARDENAS[1], C. K. KOVACH[1], J. F. RAMIREZ-VILLEGAS[3], R. C. COLE[2], A. GROSSBACH[4], P. E. GANDER[1], H. KAWASAKI[1], J. D. GREENLEE[1], M. A. HOWARD, III[1], ***M. W. VOSS**[5];

[1]Dept. of Neurosurg., [2]Neurol., Univ. of Iowa Hosp. and Clinics, Iowa City, IA; [3]Inst. of Sci. and Technol. Austria (IST Austria) Am Campus 1, 3400, Klosterneuburg, Austria, Austria; [4]Ohio State Univ., Columbus, OH; [5]Dept. of Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: Physical exercise improves hippocampal-based learning and memory in rodents and humans. Recent data highlight the importance hippocampal circuits to these performance benefits. Beyond improvements in long-term potentiation and synaptic plasticity mechanisms in rodents, the electrophysiological basis for exercise-induced effects on human hippocampal-cortical circuits is unknown.

However, there is a growing understanding of electrophysiological mechanisms supporting hippocampal-based learning and memory. Slow field potential deflections and high frequency oscillations in the hippocampus, known as 'sharp wave-ripple' (SWR) complexes, are thought to play a critical role in memory consolidation and retrieval across sleep and awake states. More recently the occurrence and functional role of ripples in the neocortex has also been recognized (Frauscher et al. 2018; Guragain et al. 2018). In both rodents and humans the coupling between hippocampal and neocortical ripples has been observed in association with learning and memory retrieval (Khodagholy et al. 2017; Vaz et al. 2019). These recent findings relate ripples to acute modulation of coupling between the hippocampus and association cortices. Further, physical exercise has been shown to increase hippocampal-cortical functional connectivity both immediately and after months of training (Voss et al., 2019). Yet, the data from exercising humans depends exclusively on hemodynamic measures of functional connectivity and cannot speak to the electrophysiological mechanisms.

Thus, we obtained electrocorticographic and depth-electrode recordings in 13 epileptic surgical candidates with coverage of both hippocampal-entorhinal and medial-prefrontal regions during awake resting state, before and after acute exercise. Heart rate, respiratory frequency and skin conductance were continuously monitored. Contacts in seizure onset zone and those where epileptic events were determined were excluded.

Results show, for the first time, that hippocampal-cortical coupling associated with ripples in humans is altered in the awake resting state acutely after exercise. Specifically, synchrony between high-frequency oscillations in the hippocampus and medial prefrontal cortex increased and was maintained when using a variety of signal-referencing and ripple detection methods. We also show that low frequency-gamma phase-amplitude coupling between pairs of hippocampal contacts is increased after acute-exercise. These findings elucidate potential electrophysiological mechanisms by which physical exercise could improve human memory.

Title: Dynamics of state transitions in local laminar circuits

Authors: *N. KHARAS, S. R. DEBES, A. R. ANDREI, V. DRAGOI;
Univ. of Texas at Houston Dept. of Neurobio. and Anat., Houston, TX

Abstract: Spontaneous fluctuations in neuronal firing are observed at the timescale of milliseconds. Traditionally, synchronized neural activity was characterized as ON and OFF state transitions during sleep, whereas desynchronized activity was viewed as a hallmark of wakefulness. However, recent studies have indicated that ON and OFF states are present during wakefulness, but the prevalence of synchronized activity and its dependence of behavioral state remain unclear. To determine whether synchronized fluctuations in ON and OFF states occur in different behavioral states, we recorded single- and multi-unit activity along a cortical column in monkey visual cortex (areas V1 and V4) while animals performed a behavioral task or were sleeping. We subsequently employed a hidden Markov model to identify ON and OFF response states in neuronal populations, and measured the frequency of transitions between the two states within a column. The number of transitions per second between states was significantly greater in sleep than in wakefulness. The trial-by-trial frequency of the transitions was negatively correlated with the global brain state measured by arousal. We further examined the presence of synchronized state transitions in the supragranular, granular, and infragranular layers of V1 and V4 during wakefulness, and discovered that synchronized fluctuations in population activity were rare events across layers. Furthermore, we induced ON and OFF state transitions using optogenetics stimulation in one cortical layer to determine whether synchronized fluctuations spread towards adjacent layers. However, the rapid fluctuations in cortical activity caused by light did not propagate to other layers despite strong inter-layer connectivity. Our findings indicate that cortical laminar networks operate in a desynchronized mode during wakefulness and switch to synchronized activity during sleep.

Title: Computational changes in the hippocampus and entorhinal cortex in TLE

Authors: *W. P. CLAWSON, P. P. QUILICHINI, C. BERNARD, D. BATTAGLIA;
Inst. de Neurosciences des Systemes, Aix-Marseille Univ., Marseille, France

Abstract: Neural computation occurs within large neuron networks in the dynamic context of varying brain states. In our previous work (Clawson et al., Science Advances 2019) we have shown that during both anesthesia and sleep specific subsets of "computing hub neurons" perform well defined information processing operations (storage and sharing) in a brain state-dependent manner. Different sets of computing hubs are recruited in different computing substates, a multitude of which exist within each global brain state. Furthermore transitions between different substates occur spontaneously, forming complex sequences whose syntax is neither regular nor random but complex, i.e. standing between order and disorder. We generalize here our novel analysis framework to the new case of Temporal Lobe Epilepsy (TLE). TLE is associated with a variety of functional deficits. However, how TLE effects the underlying algorithmic behavior of neuronal ensembles is unknown. Using acute high-density recordings in the hippocampus and entorhinal cortex in the induced TLE rat model we identify computing substates using a similar approach as our previous work. The aim is to compare the properties of hub neurons as well as the computational substates of the recorded regions to previously reported results in control animals. We find that the likelihood that a neuron assumes the role of a computational hub is decreased while the identified sequences of substates expressed are on average, less complex. We propose that the underlying biological changes which occur during status epilepticus disrupt the algorithmic patterns in such a way that may cause functional deficits. However, applying these methods to behavioral data would be needed to further test this hypothesis.

Title: Are there discrete gamma sub bands in hippocampal networks during spatial navigation?

Authors: *V. DOUCHAMPS[1], S. FERTE[1], D. BATTAGLIA[2], R. GOUTAGNY[3];
[1]Univ. of Strasbourg, Strasbourg, France; [2]INS, Univ. Aix-Marseille, Marseille, France; [3]CNRS UMR7364, Strasbourg, France

Abstract: Theta and gamma oscillations are believed to organise hippocampal activity. The classic view suggested that two gamma sub-bands, occurring at different theta phases, are related to encoding and retrieval of spatial information. Recent evidence suggested that there is in fact a wider repertoire of theta-gamma patterns of coupling, indicating that, in the CA1 area of the hippocampus, each theta cycle has an individual profile of gamma features. We thus aimed at investigating whether the dentate gyrus shows a similar pattern of theta-gamma coupling dynamics during the learning of a spatial reference memory task. To do so, we developed a new task based on a radial maze presenting marked decision points (exit/entry of each arm). We examined the difference between the CA1 and dentate gyrus cellular layers across learning of the task by CD1 mice implanted with a linear multielectrode in the right dorsal hippocampus (n=3). We extracted, without a priori, the dominant gamma frequencies from the LFPs using an unsupervised ensemble empirical mode decomposition method. We reliably found two intrinsic mode frequencies with a peak power around 45 and 80 Hz, corresponding broadly to the gamma sub-bands classically described. The power of these intrinsic mode frequencies increased with training, although more strongly in CA1. We further performed a theta cycle-by-cycle analysis of the gamma (30-200 Hz) power in the composite gamma signal (from the intrinsic mode frequencies with a frequency within gamma range). We used an unsupervised algorithmic approach to identify typical gamma bursting patterns during theta cycles. Strikingly, we found that a continuum of gamma burst types exist, with the peak gamma frequency being strongly correlated with the running speed, in both CA1 and the dentate gyrus. However, this continuous repertoire is sampled in an "edge-of-chaos" manner, giving rise to sequences of bursts with fast switching frequencies, despite the lack of gaps between sub-bands. In conclusion, our results contrast with scenarios proposing only a discrete number of mostly mutually-exclusive gamma

types. We are now investigating how the theta-gamma oscillatory bursting dynamics (statistics of temporal sequences...) evolve across learning and as a function of the behavioral strategy employed by the animal to solve the task.

Title: Temporal network analysis of hippocampal computing hubs and state sequences

Authors: *N. PEDRESCHI[1], W. CLAWSON[1], C. BERNARD[1], P. P. QUILICHINI[1], A. BARRAT[2], D. BATTAGLIA[1];
[1]Aix-Marseille University, INS, Marseille, France; [2]CPT, Univ. Aix-Marseille, Marseille, France

Abstract: Neural computation occurs within large neuron networks in the dynamic context of varying brain states. In our previous work (Clawson et al., Science Advances 2019) we have shown that during both anesthesia and sleep specific subsets of "computing hub neurons" perform well defined information processing operations (storage and sharing) in a brain state-dependent manner. Different sets of computing hubs are recruited in different computing substates, a multitude of which exist within each global brain state. Furthermore transitions between different substates occur spontaneously, forming complex sequences whose syntax is neither regular nor random but complex, i.e. standing between order and disorder. In our previous work, however, we have not analyzed in detail the temporal variability of functional connectivity networks between single units, occurring both within consistent computing substates and across substates.
Here we use a sliding window approach to estimate time-dependent networks of information sharing among tens of single units in hippocampus and enthorinal cortex during anesthesia. We adopt then a temporal network formalism, generalized from analyses first introduced in social network studies, to characterize the "style" of temporal variability of these networks.
We find first that these functional connectivity networks have at any time a characteristic core-periphery structure, in which segregated units are connected as network leafs to an integrated assembly of more tightly functionally interconnected units. However the exact units participating to the core or to the periphery substantially change across time-windows, with new units entering

and other leaving the core in a "liquid" way.
Furthermore in such a temporal network description framework, new notions of hubness can be introduced. Some cells can share information with a multitude of other units but only in a quite intermittent manner, as "activists" in a flash mob. Other cells can on the contrary share information with a smaller number of other units, but do so in a more steady manner, as "whisperers" to influential nodes. Through an unsupervised classification approach we extract different types of temporal hubness styles and assign them to each different cell, showing that: anatomical localization only poorly influence the style of temporal connectivity that a cell can have; a cell can change style of temporal connectivity across different computing substates. Altogether our study reveal the potential unleashed by upgrading from a static to a temporal network perspective current functional connectivity analyses of multichannel electrophysiological recordings.

Title: The effect of subthreshold and threshold stimulation of the vagal nerve on hippocampal formation theta rhythm in anaesthetized rats

Authors: ***J. KONOPACKI**[1], A. BRONCEL[2], R. BOCIAN[1], P. KŁOS-WOJTCZAK[2]; [1]Dept. of Neurobio., Univ. of Lodz, Lodz, Poland; [2]Med. Technol. Ctr., Natolin, Poland

Abstract: Just recently it was demonstrated that vagal nerve stimulation (VNS) is capable of inducing hippocampal formation (HPC) theta rhythm (Broncel et al., 2017). The neuronal substrate underlying this novel phenomenon is poorly known. The cholinergic and GABAergic profile of VNS-induced theta rhythm in anesthetized rats has just recently been addressed (Broncel et al., 2018, Broncel et al., 2019). In a present study we extended our earlier observation concerning VNS-induced theta oscillations. Specifically, the purpose of the present study was to compare the subthreshold and threshold stimulation of the vagal nerve on HPC theta rhythm. The advantage of using model of VNS-induced theta rhythm is that it allows analysing the effects of subthreshold stimulation and the effects of threshold stimulation. The definition of subthreshold stimulation of vagal nerve adopted in a present study concerns the

delayed effect that could be observed when low VNS intensity (0.4-2.0 mA) is applied a few times in strictly defined intervals. This kind of VNS protocol allows registration of well-developed theta rhythm which appears with a delay of even a dozen min. The definition of threshold stimulation of vagal nerve concerns the effect of VNS applied with higher intensity (6-8 mA). In this case HPC theta appears directly and only during stimulation. These results have some clinical implication. VNS is indicated in patients with pharmacotherapy resistant epilepsy. The existence of VNS-responders and VNS non-responders may reflect direct and delayed neural processes of stimulation of vagal nerve fibres.

Title: Several distinct types of VIP-expressing GABAergic neurons reside in the stratum lacunosum moleculare of the mouse CA1 hippocampal region

Authors: *B. MARINO, L. TOPOLNIK;
Laval Univ., Quebec City, QC, Canada

Abstract: The vasoactive intestinal peptide-expressing (VIP+) GABAergic neurons in the CA1 hippocampus provide a widespread control over local circuit inhibition. The hippocampal VIP+ neuronal population is highly heterogeneous, comprising cells with distinct properties, connectivity and recruitment to network activity *in vivo*. The cellular architecture, regulation and function of hippocampal VIP+ cells remain still largely unknown. Here, we examined the cellular diversity of the type II VIP+ interneuron-specific interneurons that have soma located within the CA1 *stratum lacunosum moleculare* (LM) and have been suggested to contact several distinct types of interneurons in *stratum radiatum* (RAD). Using whole-cell patch-clamp recordings in combination with morphological and neurochemical analysis of VIP+ LM cells in acute slices obtained from VIP-Cre;Ai9 mice, we identified several distinct cell types. The majority of VIP+ LM cells had an axon projecting to the oriens/alveus with collaterals in the RAD. The second main population comprised VIP+ neurons that, in addition to innervating CA1, had projections to other cortical areas, including subiculum. The third type included VIP+ interneurons with local dense innervation of the CA1 LM and RAD. Unsupervised cluster analysis of membrane properties of VIP+ LM cells confirmed the existence of several cell types

with distinct action potential and firing properties, including the regularly-spiking, rapidly-adapting and irregularly-spiking cells. The majority of VIP+ LM cells co-expressed calretinin. Taken together, these data elucidate the structural and functional diversity within hippocampal VIP+ disinhibitory circuits, with different cell types likely playing distinct roles in hippocampal mnemonic processing and executive functions.

Title: Gap junction are involved in modulation of hippocampal theta rhythm induced by vagal nerve stimulation in anesthetized rats

Authors: *R. BOCIAN[1], A. BRONCEL[2], P. KŁOS-WOJTCZAK[2], J. KONOPACKI[1]; [1]Dept. of Neurobio., Univ. of Lodz, Lodz, Poland; [2]Res. Dept., Med. Technol. Ctr., Natolin, Poland

Abstract: INTRODUCTION: Vagal nerve stimulation (VNS) is currently approved for treatment of both pharmacologically resistant seizures and severe refractory depression. In addition, VNS is used for treatment of Alzheimer disease, schizophrenia and central inflammation. Interestingly, VNS has also been demonstrated to enhance long-term potentiation in the hippocampal formation (HPC) and improve memory in rats and humans. Just recently it was demonstrated that VNS is capable of inducing hippocampal theta rhythm (Broncel et al., 2017). The neuronal substrate underlying this novel phenomenon is poorly known. To note, the cholinergic and GABAergic profile of VNS-induced theta activity in anesthetized rats has just recently been addressed (Broncel et al., 2018, 2019). AIM: In a present study we extended our earlier observation concerning pharmacological profile of VNS-induced theta oscillations. Specifically, the purpose of the present study was to test the hypothesis that the VNS-induced hippocampal theta rhythm could be modulated by local HPC gap junctions (GJs) transmission. ANIMALS AND METHODS: Male Wistar rats were implanted with cuff stimulating electrode on left vagus nerve and tungsten recording electrode into HPC. The VNS was applied using following square pulse parameters: pulse duration 1 ms, train duration 10 s, frequency 10 Hz and a current intensity of 8 mA. These VNS parameters were previously found to induce a direct effect on HPC field potential i.e. theta rhythm appearing during vagal stimulation. Two GJs

agents carbenoxolon, the nonspecific GJs blocker and trimethylamine, the nonspecific opener of gap junction were injected into HPC. Two parameters (power and frequency) of VNS-induced theta rhythm were evaluated. RESULTS: It was demonstrated that carbenoxolone slowly inhibits VNS-induced theta while trimethylamine slowly facilities it. Injection of both agents evoked changes in VNS-induced theta power and were without any effects on frequency. CONCLUSIONS: These observations indicate that HPC electrical coupling mediates the theta rhythm induced by VNS.

Title: Validation of spiking sorting methods with paired recordings from awake mice

Authors: *L. M. F. KLAVER[1], R. C. BULLINS[1], K. C. ARNDT[1], E. GILBERT[1], M. FRICKE[1], P. HANNA[1], J. J. JUN[2], D. F. ENGLISH[1];

Abstract: Extracellular single unit recording in behaving animals is rapidly increasing in popularity throughout the neuroscience community. The advent of large-scale devices, such as Neuropixels, in addition to existing silicon-probe and tetrode technologies, has led to more investigators using this method in an increasing array of behavioral setting and different brain areas. A critical step in the processing of data obtained with any of these devices is spike-sorting: the assignment of spikes to individual neurons. This process has evolved from largely manual cluster cutting methods to near-automated algorithms. While processing speed has increased dramatically, it is unknown whether the accuracy has followed a similar trajectory. A primary impediment to benchmarking the performance of any spike sorting method is the lack of ground-truth data. Such data consists of the same neuron(s) being recording with an unambiguous technique (i.e. juxtacellular or patch electrode) and an extracellular probe. To date there is a very limited set of such data, primarily obtained from a limited set of brain regions (hippocampus and neocortex) in anesthetized animals. There is a current need for high-quality, long-duration ground-truth recordings in multiple brain areas in awake animals.To generate a ground-truth dataset for spike sorting validation across multiple brain areas in awake mice, we developed a hybrid juxtacellular/silicon probe in which the glass electrode tip is positioned ~20 microns from the nearest silicon probe recording site. The proximity of these recording sites allows us to obtain an extracellular response of the juxtacellularly recorded unit with a sufficiently high signal-to-

noise ratio (SNR ranging from ~3-9). Preliminary data suggest that these devices produce stable recordings in multiple brain areas of awake, head-fixed mice for ~20-60 minutes. The combination of multiple brain areas, suitable recording length, and high SNR, in awake behaving mice, makes this dataset ideal for spike sorting validation. We will evaluate the performance of multiple spike sorting algorithms and determine their failure points relative to: population synchrony, bursting, spike waveform similarity and noise events including movement artifacts.To facilitate this process in a transparent and open-source manner, this project will be integrated into the SpikeForest framework, a public spike sorting evaluation website created and hosted by the Flatiron Institute.

Title: Dynamics of glutamatergic transmission onto CA1 neurons in awake mice

Authors: *E. GILBERT[1], K. C. ARNDT[1], L. M. KLAVER[1], R. BULLINS[2], M. FRICKE[1], P. HANNA[1], D. F. ENGLISH[1];
[1]Sch. of Neurosci., [2]Virginia Tech., Blacksburg, VA

Abstract: Pyramidal neurons in hippocampus area CA1 receive excitatory glutamatergic afferent inputs from the entorhinal cortex and CA2/3, while interneurons additionally receive such inputs from local pyramidal neurons. During wakefulness, the hippocampus alternates between two states, each with identifiable correlates in the local field potential (LFP): active behaviors are accompanied by theta oscillations, while quiet wakefulness and consummatory behaviors are accompanied by large-irregular activity (LIA) in the LFP, including sharp-wave ripples (SWR). Excitatory inputs during both states are believed to shape these local field potential signatures. During theta oscillations, entorhinal and CA3 inputs arrive at distinct phases of theta, which is believed to support phase precession of place cells, while during LIA, CA2/3 glutamatergic input provides the excitatory drive to initiate SWRs. These findings have been primarily based upon analysis of single unit spiking across brain areas and corresponding LFP in hippocampal subfields and layers. While these measures have been invaluable in determining the functional relationships between these structures, they are insufficient to examine the dynamics of inputs to individual neurons across brain states.
To investigate the dynamics of excitatory inputs to identified single neurons in CA1 during different states, we are using an awake mouse preparation which combines local field potential

recording with two-photon imaging of extracellular glutamate. Local field potentials are recorded with standard methods, while glutamate is visualized using the genetically encoded glutamate sensor iGluSnFR *(1)*. As expected from known anatomy, during quiet wakefulness we observed coincident glutamate transients surrounding many dendritic shafts in the stratum radiatum layer, and less so surrounding somas in the pyramidal layer. Additional experiments will investigate the dynamics of these events in different cell types across multiple states and behaviors.

Title: Mechanisms of ripple oscillations in cortical regions

Authors: *K. C. ARNDT[1], L. M. KLAVER[1], E. GILBERT[1], M. FRICKE[1], R. BULLINS[1], P. HANNA[1], S. A. MCKENZIE[2], D. F. ENGLISH[1];
[1]Sch. of Neurosci., Virginia Tech., Blacksburg, VA; [2]NYUMC, New York, NY

Abstract: Sharp-wave associated ripple oscillations (~100-200 Hz) in the CA1 region of the hippocampus are a key component of hippocampal function *(1)*. Replay of place cell sequences occurs during ripples, and interruption of ripples during sleep and wakefulness impairs memory consolidation. The proposed significance of the speed of the ripple oscillation is to enable plasticity in downstream cortical targets, although ripple oscillations are not observed in most cortical areas. Recently, studies in rodents *(2)* and humans *(3)* have found restricted areas of cortex exhibiting ripple oscillations, temporally correlated to hippocampal ripples and related to learning.
The mechanisms of ripple oscillations in the hippocampus have been characterized at the synaptic and cellular level, and involve interactions between excitatory and inhibitory neurons, with inhibition setting the pace of the oscillation. Optogenetic stimulation of excitatory neurons in CA1, dentate gyrus and layer 5 of the somatosensory cortex has been demonstrated to evoke ripple-like oscillations, termed induced high frequency oscillations (iHFOs). This suggests that such oscillations may be an inherent property of circuits composed of excitatory and inhibitory

neurons, and that sufficient excitatory drive may evoke such oscillations in a variety of structures. Alternatively, different circuit architectures across cortical areas and layers may be more or less suited to supporting ripple generation, which may explain why ripples are not observed in all cortical areas and layers.
Using electrophysiological and optogenetic approaches in awake mice, we are investigating the ability for multiple cortical areas and layers to support ripple oscillations and iHFOs. Preliminary data suggests that in the retrosplenial cortex, a hippocampal target which exhibits ripple oscillations in layer 2/3, iHFOs may be preferentially generated in superficial layers. This would suggest that in addition to an excitatory drive of sufficient magnitude, the generation of ripple oscillations in extra-hippocampal cortical areas may also rely on specialized single cell physiology and/or local circuit interactions.

Title: First insight into the connectome of the octopus learning and memory system

Authors: *F. BIDEL[1], Y. MEIROVITCH[2], R. SCHALEK[2], X. LU[2], A. PELEG[2], T. FLASH[3], J. W. LICHTMAN[2], B. HOCHNER[1];
[1]Dept. of Neurobio., Hebrew Univ., Jerusalem, Israel; [2]NWL 249.50, Harvard Univ., Cambridge, MA; [3]Dept. of Computer Sci. and Applied Mathematics, Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Cephalopod molluscs like *Octopus vulgaris* have the most highly evolved nervous systems of any invertebrate group and exhibit sophisticated cognitive abilities which depend on a

pivotal brain structure: the vertical lobe (VL). The VL shows an anatomical connectivity organization typical of learning and memory network like the insect mushroom body and vertebrate hippocampus and cerebellum. However, previous anatomical considerations, supported by more recent physiological experiments have suggested that the VL is organized in a simple "fan-out fan-in" connectivity scheme with a robust NO-mediated LTP at the fan-out synaptic connections and a rich neuromodulation. More specifically, our current understanding of the VL circuitry and ultrastructure relies on the ground breaking work of J. Z. Young and E. G. Gray which suggests that ~ 1.8 million afferents from the medial superior frontal lobe are mediated to the ~ 60K large VL output neurons by a computationally thick intermediate and local layer of ~ 25 million small interneurons, called amacrine cells. The aim of this work is to get a better understanding of the function of the learning and memory circuitry of the octopus by producing the first detailed description of the synaptic and neuromodulatory connections of the various neurons comprising the VL, using recent progress of volume electron microscopy imaging. Accordingly, we collected and fixed *O. vulgaris* VL and subsequently serially sliced, imaged at 4 nm pixel resolution and aligned 1,000 30nm-sections from the VL using Automatic Tape-Collecting Lathe Ultramicrotome and a Scanning Electron Microscope (SEM). Extraordinary rich and highly dense synaptic profiles, with various type and combinations of synaptic vesicle types, are observed across the VL neuropil. Based on vesicles characteristics, filaments and organelles types and density, we have identified at least six different types of neuronal compartments in this circuitry. At least five categories of large repeating synaptic structures are found between those neuronal compartments, suggesting a possibly more elaborate circuitry than the one so far documented. Remarkably, whereas many of the synaptic categories we characterize are abundant in other invertebrates, at least one category shows greater similarity to a pyramidal spiny synapse. This work establishes the foundations for future connectomics work that will attempt to fully reconstruct the circuitry of the VL. We believe that a high-resolution connectome map of the VL will play a key role in understanding the network properties that have independently evolved in the complex learning and memory system of this advanced invertebrate.

Title: Protease-activated receptor 1 rescues impaired synaptic plasticity and anxiety-related behavior but does not affect spatial learning deficit in juvenile rat after status epilepticus

Authors: *O. ISAEVA[1], M. SEMENIKHINA[1], R. BOHOVYK[1], M. FEDORIUK[1], O. NIKOLAIENKO[1], L. T. ALKURY[2], A. SAVOTCHENKO[1], O. KRISHTAL[1];
[1]Bogomoletz Inst. of Physiol., Kiev, Ukraine; [2]Col. of Natural and Hlth. Sciences, Zayed Univ., Abu Dhabi, United Arab Emirates

Abstract: Brain injuries are often accompanied by the disruption of blood-brain barrier (BBB) integrity. Consequences of BBB dysfunction can greatly affect neuronal excitability and induce epileptic seizures. Inhibition of protease-activated receptor 1 (PAR1), a major thrombin receptor in the brain, produces an anti-epileptogenic and neuroprotective effects in an experimental model of temporal lobe epilepsy (TLE). Since serine proteases and PAR1 are implicated in the synaptic plasticity and memory formation, the aim of the present study was to evaluate the involvement of PAR1 in synaptic plasticity and behavior deficits following SE. Using lithium-pilocarpine model of TLE in juvenile rat, we demonstrate that inhibition of PAR1 rescues SE-induced synaptic plasticity deficits in CA1 region of hippocampus. Although treatment with PAR1 antagonist does not ameliorate spatial learning deficits, it attenuates an anxiolytic-like behavior in juvenile rats after SE. Taken together; our data suggest an important role of PAR1 in SE-induced synaptic and behavioral alterations and provide a new insight into the cellular mechanisms underlying behavioral impairments associated with epilepsy.

Title: Impact of seizure activity on apoptosis and epileptogenesis in a guinea pig model of mesial temporal lobe epilepsy

Authors: *D. VILA VERDE, A. CATTALINI, F. COLCIAGHI, M. DE CURTIS;
Epilepsy Unit, Fondazione Inst. Neurologico "Carlo Besta", Milan, Italy

Abstract: Seizures are observed in several neurological disorders and are associated with social stigma and co-morbidities. Sustained seizure activity is thought to be responsible for altering both neuronal and glial function, thus influencing the process of epileptogenesis and ictogenesis. This has not been definitively demonstrated since seizures and brain damage develop in parallel in many epilepsies. The present study aims to evaluate if seizure activity *per se* could be sufficient to induce the expression of brain damage biomarkers and consequently worsening of epileptogenesis. To achieve this, we used an animal model in which focal non-convulsive status epilepticus (ncSE) was evoked in guinea pigs by unilateral injection of kainic acid (KA) in the hippocampus (Hpc) with continuous video-EEG recording for 3 days (n=10). Moreover, to differentiate the effects of KA alone, another group was added, in which KA-injected animals were treated with diazepam (DZP, n=5) which markedly reduce seizures during SE. KA animals exhibited a non-convulsive SE with seizures lasting from 6 up to 12 hours. The advantage of this model is to have a contra-lateral Hpc that has as much seizures as the ipsi-lateral side, but without the cytotoxic effects of KA and, in fact, 57,3 ± 4,2 % of all seizures were focal but bilateral. Immunohistochemical analysis on neuronal markers NeuN and MAP2, Tunel and Fluoro-Jade (FJ) showed a significant reduction in the number of neurons in the Hpc (n=8) ipsi-lateral to KA injection, compared to sham controls (n=6) in CA1/CA3; with DZP this reduction was less severe. In the Hpc contra-lateral to KA injection, no reduction of neurons was found in sham, KA- and DZP-injected animals. In KA-injected animals, the ipsi-lateral Hpc had a significant increase in Tunel and FJ positive cells, compared to controls and the contra-lateral side. DZP-treated animals showed a statistical increase in the ipsi-lateral Hpc compared to controls but not as incremented as the KA-injected animals. As expected, injecting KA induced neuronal death in the ipsi-lateral Hpc in CA1 and CA3. When animals were administered with DZP this damage was still present but in a less aggressive fashion. This suggests a possible synergy between KA and seizures to induce apoptosis and cell loss. However, we observed that seizures *per se* were not sufficient to induce neuronal death. These findings hint to the possibility that seizures are not responsible for inducing brain damage through apoptosis, but coupled with a previous insult (trauma, infection, etc) they may exacerbate the effect of the preceding malady.

Title: Circadian rhythmicity in vulnerability to seizure induced death

Authors: *B. S. PURNELL[1], G. F. BUCHANAN[2];
[2]Neurol., [1]Univ. of Iowa, Iowa City, IA

Abstract: Over 50 million people worldwide live with epilepsy. The leading cause of epilepsy related death is sudden unexpected death in epilepsy (SUDEP). More years of potential life are lost to SUDEP than any other neurological disease with the exception of stroke. There is a great deal which is not known about SUDEP; there are no known ways of preventing it, predicting when it will happen, or identifying patients at the greatest risk. What is known is that SUDEP typically happens during the night following some form of seizure-induced cardiorespiratory failure. Many aspects of mammalian physiology and behavior are subject to regulation by circadian rhythmicity in ways that might make seizures that occur during the night more dangerous. The goal of this investigation was to test the hypothesis that circadian rhythmicity alters vulnerability to seizure induced death. Our approach was to induce seizures at different circadian phases and monitor seizure severity, mortality, and respiratory sequelae. Male C57BL/6J mice (7-10 weeks old) were singly housed in cages equipped with running wheels in a 12:12 light-dark schedule and allowed to entrain normally to the ambient lighting conditions for 7-10 days. Mice were then housed in conditions of constant darkness (DD) until their free-running period could be easily determined using running wheel activity. Maximal electroshock seizures were induced at six circadian time points (circadian time [CT] 2, 6, 10, 14, 18, and 22. n = 9 per time point). Seizures were monitored using infrared video for quantification of motor seizure severity. Whole body plethysmography was recorded before during and after the seizure to quantify the respiratory outcome of the seizure. We found that seizure induced death was not uniformly distributed across the experimental time points with an increased rate towards the end of the subjective night ($p = 0.04$, V test for circular uniformity). These results indicate that circadian rhythmicity alters vulnerability to seizure induced death. Circadian differences in vulnerability to seizure induced death may contribute to the increased nocturnal incidence of SUDEP. Future investigations into the mechanistic underpinnings responsible for circadian differences in vulnerability to seizure induced death may inform the development of preventative strategies for SUDEP.

Title: Stimulation of DRN serotonin neurons decreases PGES length and reduces seizure-induced mortality

Authors: *A. N. PETRUCCI[1], J. CHOU[1], K. VENCER[2], G. F. BUCHANAN[1];
[1]Dept. of Neurol., [2]Dept. of Hlth. and Human Physiol., Univ. of Iowa, Iowa City, IA

Abstract: Sudden unexpected death in epilepsy (SUDEP) is the leading cause of death in individuals with uncontrolled epilepsy. The exact etiology of SUDEP is unknown. A potential risk marker for SUDEP is post-ictal generalized EEG suppression (PGES), a period of low amplitude EEG activity following some seizures. The cause of PGES is unknown, but PGES duration may correlate with SUDEP risk. Our lab has demonstrated that PGES can occur after maximal electroshock (MES) and kindled seizures in mice and that pharmacologically increasing 5-HT tone reduces PGES duration. We hypothesized that the dorsal raphe nucleus (DRN) may be involved in PGES. The DRN sends 5-HT projections broadly to regions associated with arousal and its firing is reduced by seizures. Therefore, stimulating the DRN may reduce PGES duration and mortality. Six C57BL/6J (3 male/3 female; 8-12 weeks old) and eight *Pet1-Cre* and WT mice (4 male/4 female per genotype; 8-12 weeks old) were implanted with EEG and EMG electrodes and a bipolar stimulating/recording electrode in the right basolateral amygdala (AP: -1.3 mm; ML: -2.8 mm; DV: -4.7 mm). C57BL/6J mice were additionally instrumented with a microdialysis cannula directed toward the DRN (AP: -4.6 mm; ML: 0 mm; DV: -3.0 mm) and *Pet1-Cre*/WT mice received a microinjection (500 nl) of AAV-ChR2 and implantation of a fiberoptic cannula into the DRN. After recovery, afterdischarge threshold determination, and kindling, animals underwent seizure inductions (120-500 µA, 1 sec train of 1 msec square wave pulses at 60 Hz) during wake or sleep following focal chemical (45 µl/min, 6.8 pH artificial cerebrospinal fluid, 10 min) or optogenetic (473 nm, 4 Hz, 10 mW, 2% duty, 10 s ON / 10 s OFF, 10 min) DRN stimulation. Seizure severity and PGES duration was assessed. In a separate set of experiments, twelve (5 male, 7 female; 8-12 weeks old) C57BL/6J mice were implanted with EEG/EMG electrodes and a microdialysis cannula into the DRN. Mice underwent seizure induction via MES (60 mA, 0.2 s, 60 Hz sine wave pulses) following chemical DRN stimulation as above. Mortality, seizure duration, and seizure severity were determined off-line by post hoc video review. After experimentation, animals were intracardially perfused and implant placements were verified histologically. Pre-seizure focal chemical and optogenetic stimulation of the DRN decreased PGES length. Identical chemical DRN stimulation reduced mortality in the MES model. These data suggest that the DRN may be implicated in PGES generation and in seizure-induced mortality. In the future we will determine the downstream circuitry and 5-HT receptor subtypes underlying the effect of DRN stimulation on PGES generation.

Title: Gabapentin treatment reduces status epilepticus-induced neocortical injury

Authors: *M. B. PEREZ-RAMIREZ[1], I. PARADA[2], R. MOEIN[2], D. A. PRINCE[3];
[1]Neurol. and Neurolog. Sci., [2]Stanford Univ., Palo Alto, CA; [3]Stanford Hosp. and Clinics, Stanford, CA

Abstract: Status epilepticus (SE) is a seizure that can last more than 5 minutes and it increases the probability for subsequent seizures. For instance, prolonged febrile seizures in children, are associated with a risk of subsequent temporal lobe epilepsy. The mechanisms by which neocortical SE induces chronic sequella, including epileptogenesis, are not yet fully understood. Furthermore, there is no available therapy to prevent epileptogenesis or other morbidities following SE. Gabapentin is an antiallodynic and anticonvulsant drug known to inhibit the interaction between TSPs and α2δ-1, and it is also known to have anti-synaptogenic effects. We focus on studying focal neocortical seizures to understand what types of potentially epileptogenic chronic synaptic changes may occur following 10 and 30 days of a single episode of SE in the neocortex and whether or not gabapentin can rescue the abnormalities following SE. In the present study we use immunohistochemistry (ICC) and electrophisiology techniques, to assess structural and functional changes after a focal episode of SE, and Gabapentin treatment to prevent these changes. Our results show increased immunoreactivity for putative excitatory synapses and for astrocytic proteins. Additionally, SE provoked abnormal local field potentials and increased miniature excitatory postsynaptic currents (mEPSCs) in the affected neocortex. Gabapentin can reduce the increased excitatory connections as well as decrease the astrocytic proteins. Further studies need to be done to address the gabapentin effects on the functional modifications.

Title: Changes in the homeostatic roles of microglia induced by cannabidiol (CBD) in a translational model of epilepsy

Authors: *T. R. VICTOR[1], M. W. ELMES[2], D. G. DEUTSCH[2], S. E. TSIRKA[1];

Abstract: Epilepsy is a chronic neurological disorder due to abnormal activity in neuronal circuits and characterized by repeated seizures. It affects 1% of people worldwide and considerably impacts the quality of life of both patients and caregivers. There are currently over 25 anti-epileptic drugs (AEDs) available, however these drugs only relieve seizure symptoms and can have severe adverse effects. Even with the variety of AED's available, approximately one-third of patients with epilepsy are unresponsive to the available drugs. Cannabidiol (CBD), a non-psychotropic component of *Cannabis sativa,* was recently approved by the FDA for use for intractable epilepsies, and provides a well-tolerated therapeutic option for those who do not respond to traditional AEDs. CBD has neuroprotective properties and lessens the severity of experimentally induced seizures in animals and suppresses neuroinflammation in culture. While effective, the mechanism CBD utilizes to achieve its anti-epileptic effects is still poorly understood. Our lab has shown that microglia, the immune cells of the central nervous system (CNS), act as important mediators of seizure severity. We postulate that CBD exerts positive effects that affect microglial roles. Our data suggest that CBD is effective as a therapeutic agent in a kainate model of induced epilepsy. Administered late after the onset of seizures, it suppresses successive seizure events and modulates microglial activation. This study evaluates the effects of CBD on microglia-mediated processes, which include inflammation, apoptosis, and neurogenesis post seizure. The results of this study will provide insights the mechanism of CBD action and help identify potential targets for the future medications that can aid in the optimal performance of neuronal circuits. This work was partially supported by an NSF Predoctoral Fellowship and SBMS funds to TRV.

Title: Transcriptome investigation of the mechanisms involved in preconditioning induced by electrical stimulation of the perforant pathway in the rat

Authors: G. G. ZANETTI[1], E. V. DIAS[2], I. LOPES-CENDES[1], ***A. S. VIEIRA**[3];
[1]Univ. Estadual de Campinas, Campinas, Brazil; [2]State Univ. of Campinas - Unicamp, Campinas, Brazil; [3]Univ. Estadual De Campinas, Campinas, Brazil

Abstract: The most frequent neuroimage finding in mesial temporal lobe epilepsy (MTLE) patients is Mesial Temporal Sclerosis, that has hippocampal atrophy as one of its main components. The electrical stimulation of the perforant pathway for a period of 8 hours in awake rats reproduces hippocampal lesion with a morphology that resembles the human condition without the induction of an episode of status epilepticus (SE). In order for animals to survive such a long period of stimulation in this model it is necessary two days of 30 minutes preconditioning sessions by electrical stimulation of the perforant pathway. Therefore, the objective of the present study is to explore the biological processes, and the molecular components involved in the preconditioning of the hippocampus employing transcriptomic analysis of the different hippocampal sub-regions.Electrodes were implanted bilaterally in the dentate girus (DG) and in PP of control (n=5) and experimental rats (n=5). After one week the PP of experimental rats were electrically stimulated for 30 minutes in two subsequent days. 24h following stimulation rats were euthanized and the brains processed for laser microdissected using Zeiss PALM LCM. Dorsal (dDG) and Ventral DG (vDG) were collected from each rat, total RNA was extracted, and libraries for RNAseq in Illumina Hiseq platform were prepared. A total of 1,895 genes were differentially expressed ($p<0,05$) when comparing the control Dentate Gyrus with the stimulated Dentate Gyrus, 908 genes were at the Dorsal region (DDG) and 459 were ventral region (VDG), and 528 genes at both regions. Pathway enrichment analysis indicated that both DDG and VDG presented differently expression genes related with inhibitory pathway, showing up regulation with GABAA receptors, GABA biosynthesis, and down regulation of genes in cAMP pathway and GAT, indicating a coordinated increase of inhibition. The cholesterol biosynthesis pathway was up-regulated exclusively in VDG. The transcriptome data explored in this study suggest different functions depending the region of Dentate Gyrus. The transcriptome data also indicates a marked increase in inhibition in the DG after pre-conditioning, a observation consistent with previous physiological data.

Title: TrkB-Shc signaling protects against hippocampal injury following status epilepticus

Authors: Y. Z. HUANG[1], X.-P. XIAO[1], K. KRISHNAMURTHY[1], ***J. O. MCNAMARA**[2]; [1]Dept. of Neurobio., [2]Dept. of Neurobiology, Med. (Neurology), Pharmacol. and Mol. Cancer Biol., Duke Univ. Med. Ctr., Durham, NC

Abstract: Temporal lobe epilepsy (TLE) is a common and commonly devastating form of human epilepsy for which only symptomatic therapy is available. One cause of TLE is an episode of *de novo* prolonged seizures (status epilepticus, SE). Understanding the molecular signaling mechanisms by which SE transforms a brain from normal to epileptic may reveal novel targets for preventive and disease-modifying therapies. SE-induced activation of the BDNF receptor tyrosine kinase, TrkB, is one signaling pathway by which SE induces TLE. While activation of TrkB signaling promotes development of epilepsy in this context, it also reduces SE-induced neuronal death. This led us to hypothesize that distinct signaling pathways downstream of TrkB mediate the desirable (neuroprotective) and undesirable (epileptogenesis) consequences. We subsequently demonstrated that TrkB-mediated activation of PLCγ1 is required for epileptogenesis. Here we tested the hypothesis that the TrkB-Shc-Akt signaling pathway mediates the neuroprotective consequences of TrkB activation following SE. We studied measures of molecular signaling and cell death in a model of SE in mice of both sexes, including wild-type and *TrkB*$^{Shc/Shc}$ mutant mice in which a point mutation (Y515F) of TrkB prevents the binding of Shc to activated TrkB kinase. Genetic disruption of TrkB-Shc signaling had no effect on severity of SE yet partially inhibited activation of the pro-survival adaptor protein Akt. Importantly, genetic disruption of TrkB-Shc signaling exacerbated hippocampal neuronal death induced by SE. We conclude that that therapies targeting TrkB signaling for preventing epilepsy should spare TrkB-Shc-Akt signaling and thereby preserve the neuroprotective benefits.

Title: The status of immune complement cascade activation in epilepsy

Authors: A. L. SOMMER[1], N. D. SCHARTZ[2], A. AROOR[1], *A. L. BREWSTER[1];
[2]Psychological Sci., [1]Purdue Univ., West Lafayette, IN

Abstract: Individuals with refractory epilepsy have drug-resistant seizures. Surgical resection of the seizure focal point is often the preferred remaining treatment option for refractory epilepsy, but not all patients are candidates. Thus, our objective is to identify novel therapeutic targets for drug-resistant epilepsy focusing on signaling cascades that modulate neuroimmune interactions such as the classical complement pathway (C1q-C3) of the immune complement system. Histopathological features of drug-resistant epilepsy include a decline in synaptodendritic elements and neurons, along with microgliosis. Through characterizations of brain samples derived from human refractory epilepsy we previously reported alterations in complement proteins C1q and C3 (Wyatt et al. Experimental Neurology. 2017; 295:184-193). These proteins are associated with the regulation of inflammatory and phagocytic responses, as well as microglial synaptic pruning in the developing brain and in neurodegenerative disorders. In this study we investigated the status of immune complement activation by determining the extent to which C1q and C3 signaling is associated with the downstream activation of C5 in a large pool of brain samples from patients with refractory epilepsy (n=17). Because complement C3 is linked to synaptic loss of PSD95, we determined the correlation between complement and PSD95 levels within the same samples.
Western blots (WB) with antibodies against C1q, C3, C5, and PSD95 were done in whole tissue homogenates containing a mix of gray and white matter.
Results from the WBs showed a correlation between the protein levels of C3 and C5 ($p<0.0001$), as well as between C3 and PSD95 ($p=0.076$) within the samples. However, there was no significant correlation between proteins C1q and C5 ($p=0.1085$) or between C1q and C3 ($p=0.5165$).
Based on these results, we speculate that the significant correlation between levels of complement proteins C3 and PSD95 may indicate a close association complement activation and

synaptic remodeling in epilepsy. Mechanistic studies are currently underway to determine the role of complement proteins in pathological synaptic remodeling in epilepsy.

Title: A role for microgliosis in the neuropathology of prolonged seizures

Authors: *S. K. JOHNSON, A. L. SOMMER, S. LAM, A. L. BREWSTER;
Psychological Sci., Purdue Univ., West Lafayette, IN

Abstract: Evidence from experimental models of epilepsy support that prolonged seizures (status epilepticus, SE) promote pathological hippocampal synaptodendritic remodeling that contributes to the development of unprovoked seizures and cognitive decline. One potential mechanism underling the SE-induced sequelae is proliferation and activation of microglia (microgliosis). Previously we reported that inhibition of SE-induced microgliosis with rapamycin attenuated the loss of the dendritic protein Map2 in the hippocampus, as well as the associated hippocampal-dependent spatial learning and memory deficits (Brewster et al. PLoS One. 2013; 8(3):e57808). To further investigate the role of microgliosis in the SE-induced synaptodendritic pathology we tested the efficacy of a more selective inhibitor of microglia, PLX3397 (PLX), in our experimental model of epilepsy. PLX binds to colony stimulating factor 1 receptor on microglia and inhibits the downstream signaling responsible for survival and proliferation.
The pilocarpine model of SE was used to generate epileptic male rats. Those that reached seizure level 6 in the Racine scale were used for this study (n=8-11 per group). SE was induced with pilocarpine (1hr) and controls were given saline. PLX (50mg/kg in chow) or Vehicle (Veh; regular chow) were given immediately after SE for up to 3 weeks. Brains were processed for immunohistochemistry using antibodies against IBA1 to determine levels of hippocampal microgliosis. Four groups were evaluated: Control+Veh (n=9), SE+Veh (n=8), Control+PLX (n=6), and SE+PLX (n=11). Microglia were counted in 40x images, from 6 sections per animal. First we found that the PLX treatment significantly decreased microgliosis in Control+PLX rats compared to Control+Veh rats ($p<0.0001$; t-test). As expected, we found a significant increase in the number of microglial cells in hippocampi of SE+Veh rats compared to Control+Veh rats

($p<0.0001$; two-way ANOVA). Interestingly, in the PLX-treated SE group we observed two distinctive groups which we categorized as responders and non-responders when compared to the SE+Veh group. The SE+PLX responders (n=8) had significantly decreased microgliosis compared to the SE+Veh group ($p<0.0001$; two-way ANOVA). The SE+PLX nonresponses (n=3) had higher levels of microgliosis compared to the SE+Veh group ($p<0.0001$; two-way ANOVA).
These data indicate that PLX treatment suppresses microgliosis in our control and SE groups. Our findings support that PLX may be a useful tool to study whether suppression of microgliosis attenuates the synaptodendritic and cognitive decline following SE. Ongoing studies are testing this hypothesis.

Title: Inhibition of complement C3 activation attenuates pathological cognitive and synaptic changes in a rat model of status epilepticus

Authors: *N. D. SCHARTZ[1], A. L. BREWSTER[2];
[2]Psychological Sci., [1]Purdue Univ., West Lafayette, IN

Abstract: Epilepsy is characterized by spontaneous recurrent seizures and comorbid conditions such as cognitive dysfunctions. In individuals with epilepsy, this pathophysiology can be exacerbated by episodes of prolonged continuous seizure activity (status epilepticus; SE). In an otherwise healthy system, SE provoked by adverse events including head trauma or stroke results in hippocampal injury and an increased risk for the subsequent development of epilepsy and cognitive decline. We previously reported that this pathophysiology correlates with SE-induced hippocampal dendritic instability, microgliosis, and complement C3 hyperactivation in both human and experimental epilepsy. Thus, in this study we tested the hypothesis that C3 inhibition after SE will attenuate memory deficits and synaptic protein loss in the hippocampus.
To eliminate C3 in rats we used the complement C3 inhibitor cobra venom factor (CVF). Male rats were injected with pilocarpine (300mg/g, i.p.) to induce SE or with saline (controls). Behavioral seizure severity to levels 5-6 (SE) was scored using the Racine scale. One week after SE, rats were injected with CVF (100ng/g, i.p.) or equal volume saline. Four groups were

investigated: Veh-C, Veh-SE, CVF-C, CVF-SE. Two weeks after SE, the novel object recognition (NOR) test was used to assess recognition memory. After NOR, hippocampi were processed for western blot with antibodies against the synaptic proteins PSD95 and VGat.
In the NOR test trial, rats from the Veh-C and CVF-C groups spent significantly more time exploring the novel object compared to the familiar object ($p<0.05$). In contrast, rats from the Veh-SE group spent a similar amount of time exploring both objects ($p=0.09$) while the CVF-SE rats spent significantly more time exploring the novel object ($p<0.001$), suggesting improved memory in the CVF-SE rats. After NOR, protein levels of PSD95 and VGat were determined in the hippocampus. We found a significant reduction in the protein levels of PSD95 ($p<0.01$) and Vgat ($p=0.04$) in the Veh-SE compared to Veh-C. However, there was no difference in PSD95 ($p=0.33$) or Vgat ($p=0.67$) between CVF-C and CVF-SE groups, suggesting that CVF attenuates the SE-induced loss of these synaptic proteins.
Taken together, these findings support that SE-induced C3 activation contributes to hippocampal synaptic remodeling and impairments in memory, and suggest that C3 may be a therapeutic target for the treatment of some memory deficits in epilepsy.

Title: Noise assisted memd based phase connectivity analysis to personalize closed-loop DBS therapy in epilepsy patients

Authors: S. FARAHMAND[1], ***T. SOBAYO**[2], D. J. MOGUL[2];
[1]BioSig Technologies, Inc., Los Angeles, CA; [2]Biomed. Engin., Illinois Inst. of Technol., Chicago, IL

Abstract: Deep brain stimulation (DBS) is a treatment that has been explored for controlling seizures in patients with intractable epilepsy. Many clinical and pre-clinical studies using DBS therapy determine stimulation parameters through trial and error. The same stimulation parameters are often applied to the whole cohort, which consequently produces mixed results of responders and non-responders. In this study, an adaptive non-linear analytical methodology is proposed to extract stimulation frequency and location(s) from endogenous brain dynamics of epilepsy patients, using phase-synchrony and phase-connectivity analysis, as seizures evolve. The proposed method was applied to seizures recorded using depth electrodes implanted in both

hippocampus and amygdala in three patients. A reduction in phase-synchrony was observed in all patients around seizure onset. However, phase-synchrony started to gradually increase from mid-ictal and achieved its maximum level at seizure termination. This result suggests that hyper-synchronization of the epileptic network may be a crucial mechanism by which the brain naturally terminates seizure. Stimulation frequency and locations that matched the network phase-synchrony at seizure termination were extracted using phase-connectivity analysis. One patient with temporal lobe epilepsy (TLE) had a stimulation frequency ~15 Hz with the stimulation locations confined to the hippocampus. Another two patients with extra-temporal lobe epilepsy (ETE) had stimulation frequency ~90 Hz with at least one stimulation location outside of the hippocampus. These results suggest that DBS parameters may vary based on the patient's underlying pathology. The proposed methodology provides an algorithm for tuning DBS parameters for individual patients in an effort to increase the clinical efficacy of this therapy.

Abstract: Objective: Atypical language laterality, secondary to refractory epilepsy, presents complications to surgical planning and cognitive outcomes. The present study examined relationships between 1) the differences in language representation between mesial temporal sclerosis (MTS) and non-lesional epilepsy and 2) language laterality, as determined through functional Magnetic Resonance Imaging (fMRI), and performance on single trial learning and delayed memory (California Verbal Memory Test 2nd-edition (CVLT) and Rey Auditory Verbal Learning Test (RAVLT), phonemic verbal fluency (Controlled Oral Word Association Test (COWAT), and confrontation naming (Boston Naming Test 2nd Edition, BNT) in a sample of patients with intractable epilepsy.
Methods: Retrospective data was compiled on patients with refractory epilepsy undergoing interdisciplinary pre-surgical workup (N=101) with mean age of 37.2 (SD=11.9) and education of 12.3 (SD=3.7). The sample was then stratified by non-lesional (n=48) and mesial temporal

sclerosis (n=53). Language dominance as determined by voxelwise analysis of task-based functional MRI was stratified as unilateral, mixed bilateral, and pure bilateral.
Results: Analyses showed greater bilateral language dominance, as determined through fMRI, was negatively correlated with single trial learning on CVLT and RAVLT (rs = -0.45, p = 0.048) in patients with mesial temporal sclerosis (MTS); whereas no significance was found in non-lesional patients. No significant correlations were found across memory or language measures irrespective of lesional status.
Conclusions: Individuals with non-lesional epilepsy, demonstrated no significant association between bilateral language dominance and performance on cognitive measures. Patients with MTS and bilateral language dominance evidenced reduced performance on single trial verbal learning. Interestingly, the non-lesional epilepsy patients demonstrated an almost identical base rate of bilateral language dominance as compared to the patients with MTS. Therefore, these findings demonstrate the need for further examination of the interaction of atypical language dominance and lesional status in patients with epilepsy.

Title: Alterations of resting state functional brain connectivity in the early period of epileptogenesis - An EEG-fMRI combined study

Authors: L. LI[1], L. HE[3], C. BOU KHALIL[1], H. YEH[1], J. STERN[1], N. G. HARRIS[4], R. STABA[1], J. ENGEL, Jr.[1,2], *A. BRAGIN[1];

Abstract: The current study aims to investigate the alterations of resting-state functional brain connectivity (rsFC) during an early period of epileptogenesis using combined EEG and fMRI modalities. Sprague-Dawley rats were injected with kainic acid in the left CA3 area to induce

status epilepticus (SE). One week before and 2 weeks after SE, 10 minutes of BOLD data were acquired using a single-shot, gradient-echo, echo-planar, fMRI sequence (TR/TE=2000, 35ms with voxel sizes of 0.27×0.27×0.75mm) from rats under a bolus of medetomidine sedation (0.5 mL / 0.1mg/kg). We performed an independent component analysis to identify the resting-state networks (RSNs), and to guide the selection of regions-of-interest (ROIs) for electrode implantation. As a result, a total 16 bilateral ROIs representing the key structures of RSNs were selected. After the second fMRI session at 2 weeks post-SE, depth electrodes were implanted in the ROIs including left/right Prelimbic cortex, left/right Anterior Cingular cortex, left/right Motor cortex and left/right Dorsal/Ventral Hippocampus. Wide-band electrical activity was recorded continuously for 8 weeks. A total 9 sham control rats and 12 rats that later develop spontaneous epilepsy (E+) were selected for a combinatorial analysis of fMRI and EEG data. Our results demonstrated (a), the BOLD-rsFC was stable across a one-week window period in both sham and E+ rats; (b) compared to the sham rats, increase of the intra-network connectivity and decreased of the inter-network connectivity was observed in the E+ rats**;** (c) pairs of ROIs with increased rsFC were associated with stronger EEG coupling (70-170Hz) and increased synchrony of multiunit discharges. These results suggest after an epileptogenic injury regional network dysregulation could produce local areas containing abnormal FC and hyperexcitability that support the development of epilepsy. Future work will investigate whether sites of increased BOLD rsFC correspond with pathological HFOs, which could provide a non-invasive approach to study the formation of PIN clusters during epileptogenesis.

Title: Minimum spanning tree characteristics of refractory epilepsy patients

Authors: J. FIEL[1], E. M. MELO[1], R. NAVEGANTES[1], F. L. GOMES[2], ***A. PEREIRA**[3]; [1]Federal Univ. of Pará, Belém, Brazil; [2]Ophir Loyola Hosp., Belém, Brazil; [3]Federal Univ. of Pará/Institute of Technol., Belém, Brazil

Abstract: Network analysis has been successfully used to describe the topological and spatial organization of the human connectome. In the present work, we combined two approaches, the debiased weighted phase-lag index (dWPLI) and the minimum spanning tree (MST), to compare

the EEG functional connectivity network of refractory epilepsy (RE) patients and healthy subjects. The MST is considered being an unbiased method that allows a common frame of reference to compare brain networks. We recorded nine minutes of resting-state EEG from patients diagnosed with RE (N=7) and from sex- and age-matched healthy control participants (N=7). Functional Connectivity (FC) between pairs of electrodes was estimated with the dWPLI method and based on four frequency ranges: theta (4-8Hz), alpha (8-12Hz), beta (13-30Hz), and Low gamma (30-45Hz). We calculated a connectivity matrix for each subject and for each frequency range. Subsequently, the minimum spanning tree (MST) was measured in order to obtain the fundamental network properties. The normalized leaf fraction characterized the MSTs. We also calculated kappa value to get the degree distribution and thus the resilience to attacks against the network. We found key differences in network topology between the two experimental groups, specifically both the leaf fraction and divergence of resting state networks were notably larger in the RE group. These results suggest the MST organization of the RE patients presents a more random organization in comparison with the controls. Deviation towards randomization implies a suboptimal resting-state network organization of RE patients, which undermines the efficiency of information exchange across different brain regions

Title: Interictal epileptiform discharges shape large-scale intercortical communication

Authors: ***P. DAHAL**[1], N. GHANI[2], A. FLINKER[3], P. DUGAN[4], D. FRIEDMAN[4], W. DOYLE[4], O. DEVINSKY[4], D. KHODAGHOLY[1], J. GELINAS[2];

Abstract: Dynamic interactions between remote but functionally specialized brain regions enable complex information processing. This intercortical communication is disrupted in the neural networks of patients with focal epilepsy, and epileptic activity can exert widespread effects within the brain. However, the mechanisms by which epileptic activity shapes large-scale

neural networks remain mostly unknown, and have broad implications for understanding coordination of distributed network activity in the human brain. Using large-scale human intracranial electroencephalography (iEEG) recordings, we have determined that interictal epileptiform activity in the human brain affects large-scale cortical networks through establishment of dynamic, pathologic oscillatory coupling. We show that interictal epileptiform discharges (IEDs) are significantly coupled with spindles in discrete, individualized brain regions outside of the epileptic network, establishing communication between the conventionally defined epileptic network and the rest of the brain. We ascertained that a substantial proportion of these localized spindles travel across the cortical surface, a property that has not previously been demonstrated for these oscillations. Brain regions that participate in this IED-driven oscillatory coupling express spindles that have a broader spatial extent and higher tendency to propagate than spindles occurring in uncoupled regions. These altered spatiotemporal oscillatory properties could identify areas at risk for recruitment into the epileptic network independent of IED or seizure detection. Our findings have key implications for understanding how dynamic oscillatory coupling can be established in the human brain, specifically focusing on how focal neural patterns can modulate properties of large-scale cortical networks. Furthermore, we hypothesize that these IED-driven, spatiotemporally specific patterns of abnormally coordinated brain activity could provide a mechanism for large-scale disruption of neural network function in focal epilepsy. Such patterns could contribute to impairment of processes that heavily rely upon intercortical communication, such as cognition and memory. Consequently, this coupling may represent a therapeutic target for closed-loop therapy to address cognitive comorbidities and disease progression in these patients.

Title: Fmri functional connectivity predicts brain regions of interictal epileptic discharges

Authors: *J. SU[1,2], H. KHOO[3], N. V. ELLENRIEDER[1], L.-L. ZENG[2], D. HU[2], F. DUBEAU[1], J. GOTMAN[1];
[1]Montreal Neurolog. Institute, McGill Univ., Montreal, QC, Canada; [2]Col. of Intelligence Sci. and Technol., Natl. Univ. of Def. Technol., Changsha, China; [3]Dept. of Neurosurg., Osaka Univ. Grad. Sch. of Med., Suita, Japan

Abstract: Objective: We aim to examine whether regions of Interictal epileptic discharges (IEDs) in intracerebral EEG (iEEG) can be predicted non-invasively by fMRI functional connectivity (FC).
Methods: We studied 38 focal epilepsy patients who underwent simultaneous EEG/fMRI scanning and subsequent intracerebral stereo-EEG investigation. Their scalp IEDs were labelled. In EEG/fMRI analysis, different spatial distributions of IEDs were considered independent studies and IED-related maximal BOLD responses were evaluated using generalized linear model. Studies in which there were iEEG electrodes inside the maximal responses were selected and divided into three groups: Studies with 1. distinct maximal BOLD with t-value clearly higher than other clusters and concordant with seizure-onset-zone (SOZ); 2. Moderate maximal BOLD concordant with SOZ; 3. maximal BOLD discordant with SOZ. Using maximal BOLD as seed, the functionally connected zone (FCZ) was determined. We then use automatic IED detection to label IEDs in iEEG data. IED rates in iEEG channels inside and outside the FCZ were compared in the three groups. The effect of laterality (whether channels are in the same hemisphere as maximal BOLD) and distance between channels and maximal BOLD were considered. Correlation between functional connectivity values and IED rates were also analyzed.
Results: 36 studies in 25 patients were included. IED rates inside the FCZ were higher than outside in Group 1 ($p=2.6\times10^{-6}$) and Group 2 ($p=0.001$) and the inside-outside difference remained after regressing distance and laterality factors (Group 1, $p=1.5\times10^{-6}$; Group 2, $p=0.013$). In Group 1, FC values were correlated with IED rates in channels inside the FCZ ($p<0.05$).
Conclusions: Our results demonstrate a higher probability of finding IEDs in the FCZ of SOZ-concordant maximal BOLD responses than in other regions, regardless of distance and laterality. In studies with distinct maximal BOLD, functional connectivity values can partially predict IED rates. It is thus feasible to non-invasively infer probable brain regions exhibiting IEDs.

Title: Activation of the instrinsic apoptotic pathway in the cerebellum of kindled rats

Authors: *E. M. TADDEI LIZÁRRAGA[1], C. R. OSORNIO[1], M. RUBIO[2], C. MENDOZA[1], C. TREJO[3], V. CUSTODIO[1], L. HERNANDEZ[1], E. GONZALEZ[1], C. PAZ[1];

Abstract: The signaling cascades that lead to apoptosis are divided in two main categories: the intrinsic and extrinsic pathways. Experimental studies in epilepsy models have demonstrated the presence of extrinsic apoptotic neuronal death in the cerebellum, with the loss of Purkinje cells. However, the exact mechanism by which apoptosis occurs in the cerebellum has not yet been

elucidated. The intrinsic pathway results in activation of either anti-apoptotic (Bcl-2) or pro-apoptotic proteins (Bid, Bax and cytochrome C), and has been shown to play a role in a number of neurodegenerative diseases. Therefore, we hypothesize that epileptic activity will modify the intrinsic apoptotic pathway as well. We performed Western blot and immunohistochemistry determinations in the cerebellar tissue of rats exposed to amygdaloid kindling. An increase in protein activation of caspases 8 and 9, as well as a decrease in the expression of Bcl-2 was observed. In addition, we found a cytosolic immunopositivity for cytochrome C and mitochondrial immunolocalization of truncated Bid and Bax. Caspase-8 activates the intrinsic pathway releasing Bid, which performs mitochondrial translocation of Bax, inactivating Bcl-2 and allowing the release of cytochrome C through the mitochondrial permeability transition pore, promoting the activation of caspase-9, which in turn activates caspase-3, the main executor caspase of apoptosis. Therefore, we conclude the intrinsic apoptotic pathway is involved in cerebellar neuronal death. These results give us a broader perspective on the mechanisms underlying neuronal loss following epileptic seizures and are an important contribution to the pathophysiology of epilepsy.

Title: Using Epileptogenicity Index to quantify the characteristics of the epileptic network in a diverse clinical dataset

Authors: *G. SMITH[1], W. C. STACEY[2];
[1]Pediatrics, Pediatric Neurol., [2]Neurol., Univ. of Michigan, Ann Arbor, MI

Abstract: Objective and Rationale
When clinicians analyze intracranial EEG, they rely on both interictal and ictal biomarkers of the location of seizure onset. Quantitative research has revealed several quantitative measures of the behavior of the epileptogenic network. One such measure is the Epileptogenicity Index (EI). In the current study, we applied EI to the EEG of patients in a database of clinical intracranial EEG recordings to test the feasibility of applying this method in a diverse clinical dataset.
Methods

We used clinical data from intracranial EEG recordings from pediatric and adult patients evaluated at our institution. Using the method of calculation of EI previously described, we first calculated a measure of the ratio fast to slow energy spectra at each sample in a snippet of EEG surrounding a seizure. This calculation was performed on up to 5 of each of the types of seizures captured for each patient. Next, the EI was calculated using the Page-Hinckley algorithm to detect the moment when the energy ratio changed to favor high frequency activity at the start of seizure in each channel. Finally, we counted the frequency with which this algorithm produced a robust measure of EI.

Results

This analysis was performed in a total of 61 seizures from 14 different patients taken from a consecutive cohort including all patients who underwent intracranial EEG monitoring at the University of Michigan. Patients were included if clinical data and intractanial EEG data were available at the time of analysis. In 4/14 patients this algorithm did not yield a reliable EI value; in 7/14 patients the algorithm yielded consistently reliable EI values, and in 3/14 patients the algorithm did not yield a reliable EI value in a subset of seizures or seizure types. In 46/61 seizures the algorithm yielded a reliable measurement of EI.

Discussion

These results show that calculation of EI, which depends on a transition from low-frequency to high-frequency spectral power at seizure onset, is a robust measure of epileptogenicity in 75% of the patients tested. This analysis also shows that a subset of seizure onset is characterized by some other pattern. For instance, rhythmic spiking less than 12 Hz at seizure onset causes a decrease in energy ratio, leading to an inability to accurately detect seizure onset with the algorithm. Thus, EI is a robust measure in the majority of seizures detected by intracranial EEG in this cohort; however, some patients have seizures that are not amenable to this method. Further research should be aimed at developing quantitative measures of seizure onset that capture the diversity of seizure onset types.

Title: Upregulation of Fstl1 and Ifitm3 in astrocytes mediate neurodevelopmental impairment induced by innate immune activation

Authors: *T. NAGAI, N. ITOH, S. YAMADA, K. YAMADA;
Nagoya Univ. Grad Sch. Med., Nagoya, Japan

Abstract: Immune activation in the CNS is associated with the pathophysiology and/or etiology of psychiatric disorders. Polyriboinosinic-polyribocytidylic acid (polyI:C) triggers a strong innate immune response that mimics immune activation by viral infections. Induction of interferon-induced transmembrane 3 (Ifitm3) in astrocytes has a crucial role in polyI:C-induced neurodevelopmental abnormalities. We previously identified follistatin-like 1 (Fstl1) in polyl:C-induced neurodevelopmental impairment. In the present study, we characterized the Ifitm3-dependent inflammatory processes focusing on astrocyte-derived Fstl1 following polyI:C treatment to assess the neuropathologic role of Fstl1. Astrocytes were treated with PBS (control) or polyI:C. The conditioned medium was collected 24 h after the polyI:C treatment and used as astrocyte condition medium (ACM). The expression of Fstl1 mRNA and extracellular Fstl1 protein levels were analyzed by quantitative PCR and western blotting, respectively. For functional studies, neurons were treated with ACM and the effects of ACM on dendritic elongation were assayed. To examine the role of Fstl1, recombinant Fstl1 protein and siRNA for Fstl1 were used. To investigate the expression of Fstl1 in vivo, neonatal mice were treated with vehicle or polyI:C on postnatal day2 to 6. ACM prepared with polyI:C (polyI:C ACM) contained significantly higher Fstl1 protein than control ACM, but no increase in Fstl1 was observed in polyI:C ACM derived from Ifitm3-deficient astrocytes. We found that the production of Fstl1 involves the inflammatory responsive molecule Ifitm3 in astrocytes and influences neuronal differentiation. The levels of Fstl1 increased in the hippocampus of polyI:C-treated neonatal mice. COS7 cells co-transfected with both Fstl1 and Ifitm3 had higher extracellular levels of Fstl1 than the cells transfected with Fstl1 alone. Treatment of primary cultured hippocampal neurons with recombinant Fstl1 impaired dendritic elongation, and the deleterious effect of polyI:C ACM on dendritic elongation was attenuated by knockdown of Fstl1 in astrocytes. These results suggest that the extracellular level of Fstl1 is regulated by Ifitm3 in astrocytes, which could be involved in polyI:C-induced neurodevelopmental impairment.

Title: Astrocyte Panx1 prevents status-induced social behavior deficits

Authors: A. CIBELLI[1], P. OBOT[2], J. VELISKOVA[2], L. VELISEK[2], *E. SCEMES[2];
[1]Neurosci., Albert Einstein Col. of Med., New York, NY; [2]Cell Biol. and Anat., New York Med. Col., Valhalla, NY

Abstract: Early life seizures can lead to cognitive and behavioral deficits with several reports indicating a strong association between epilepsy and autism spectrum disorder (ASD). Pannexin 1 (Panx1) is an ATP release channel present in astrocytes as well as in neurons with strong relation to seizures. Our previous work showed that, in juvenile mice, Panx1 promotes status epilepticus (SE) induced by kainic acid (KA). More recently, by using conditional knockout mice, we showed that astrocyte but not neuronal Panx1 has protective effects in the KA model, delaying the onset of SE and improving seizure outcome. To determine the extent to which astrocyte Panx1 protects against behavioural impairments resultant from KA-induced seizures, we evaluated the mice 5 weeks following KA-induced seizures for possible sociability deficits (a hallmark of ASD). Three weeks old male and female Panx1$^{f/f}$, GFAP-Cre:Panx1$^{f/f}$, NFH-Cre:Panx1$^{f/f}$, and Panx1-null mice were i.p. injected with KA (20mg/kg). Mice that developed SE for at least 60 min were then evaluated for sociability 5 weeks later. We used the automated three-chambered apparatus to assess social interaction of KA-exposed and age-matched naive mice. The software (Any-Maze) quantifies direct social approach behavior when a subject mouse is presented with the choice of spending time with either a stranger mouse (A) or an object (O). Sociability was defined as the subject mouse spending more time in contact with *A* than with *O*. Repeated measures one-way-ANOVA was used for statistical analysis and significance set at $P< 0.05$. Six to 8 mice per group were used. The mice of all genotypes not exposed to seizures spent more time with the stranger mouse (~ 145 sec) than with the object (~45 sec). Five weeks after KA-induced seizures, Panx1$^{f/f}$ and GFAP-Cre:Panx1$^{f/f}$ mice displayed social deficits, spending comparable time with *A* (~ 70 sec) and *O* (~50 sec), while the NFH-Cre:Panx1$^{f/f}$ and Panx1-null mice did not show the social deficits, spending more time (~140 sec) with *A* than with *O* (~60 sec). Thus, the global deletion of Panx1 or the presence of Panx1 in astrocytes have protective effects on seizure-induced social behaviour deficits. These results not only indicate that Panx1 might be a potential therapeutic target to treat seizures and associated social deficits, but also highlight the importance that astrocyte Panx1 plays in preventing seizure-induced behavioural sequels.

Sci., Univ. of Missouri - Kansas City Sch. of Med., Kansas City, MO

Abstract: Clinical evidence suggests a pathological role of increased levels of oxidative stress in many neurodegenerative diseases, including glaucoma. In all subtypes of glaucoma, optic nerve head astrocytes (ONHAs) undergo reactive astrocytosis, which is the mechanism underlying the clinically observed optic nerve head remodeling. Metalloporphyrin superoxide dismutase (SOD) mimetics are potent antioxidants with a well-documented safety profile. The purpose of this study was to determine whether the metalloporphyrin SOD mimetic, manganese(III) tetrakis(1-methyl-4-pyridyl) porphyrin (Mn-TM-2-PyP), exerts glioprotective effects against reactive astrocytosis-induced sensitization to oxidative stress. We have previously shown that reactive astrocytosis results in a significant increase in celluar oxidative stress levels, as quantified using dichlorofluorescein and CellROX®fluorescence. Primary adult rat optic nerve head astrocytes (ONHAs) were pre-treated for one hour with 0.005% Mn-TM-2-PyP or vehicle. ONHAs were then exposed to ambient or hyperbaric pressure (25 mmHg above ambient) to induce reactive astrocytosis and subsequently to chemically-induced oxidative stress using *tert*-butyl hydroperoxide (tBHP; 0 to 1 mM). 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) uptake and lactate dehydrogenase (LDH) release assays for cell viability and proliferation were performed to determine glioprotective potential. Reactive astrocytosis shifted both the $IC_{50}$for tBHP in the MTT assay and the EC_{50} for tBHP in the LDH assay by > 80 μM.

Mn-TM-2-PyP fully prevented loss of cell viability in response to oxidative stress. Furthermore, Mn-TM-2-PyP resulted in a 2-fold increase in nuclear factor (erythroid-derived 2)-like 2 (Nrf2) protein levels ($P<0.05$), the transcriptional regulator of the antioxidant response element (ARE), and an 8-fold upregulation of mitochondrial SOD2 ($P<0.001$). No change was observed in NADPH oxidase 4 (NOX4) expression. Our data suggest that reactive astrocytosis in ONHAs results in elevated levels of oxidative stress that can be fully prevented by a manganese porphyrin antioxidant. The glioprotective potential of Mn-TM-2-PyP was attributed to its SOD mimetic activity and its ability to induce upregulation of endogenous antioxidant enzymes. Our data support the continued preclinical development of antioxidant approaches for glaucoma.

Title: Astrocyte dynamics at different stages of cuprizone treatment

Authors: *L. G. FRANKLE, J. SHELESTAK, R. CLEMENTS;
Kent State Univ., Kent, OH

Abstract: Cuprizone is a copper chelator that demyelinates neurons and is used to model demyelinating and degenerative diseases. Our previous work using glial fibrillary acidic protein (GFAP) staining confirmed a pattern of activation including increased process number and branching after three, four, and six weeks of cuprizone treatment. The current phase of the project probes whether similar patterns are observed at one or two weeks of cuprizone treatment as well as when such changes begin and what astrocyte subtypes become prevalent at these early stages. Animals were fed 0.2% cuprizone chow ad libitum for one or two weeks, sacrificed, dissected, and their brains halved with one half stained using GFAP and DAPI and imaged using confocal microscopy with astrocytes in the corpus callosum assessed for activation, and one half processed through Western blot. Western blots measured levels of tumor necrosis factor alpha

(TNF-α), interferon gamma (IFN-**γ**), complement component 3 (C3), and epithelial membrane protein 1 (Emp1), in the whole-cell lysate of homogenized samples taken from the corpus callosum or cortex of control and experimental animals. C3 is known to be upregulated in astrocytes that have an A1 reactive phenotype, which releases cytokines that inhibit axonal regrowth and cause death of neurons and oligodendrocytes, as well as by other cell types such as mast cells and macrophages in times of stress. TNF-α along with IL-1α and complement component 1 q (C1q), cause A1 reactivity, as well as contributing to gliosis and demyelination. IFN-**γ** is produced by T cells and natural killer cells of the immune system, but it is also produced by reactive astrocytes, macrophages and microglia. It acts on astrocytes and other glial cells to promote gliosis and inhibit remyelination, both of which are relevant to measuring the progression of cuprizone toxicity. Emp1 is upregulated in another type of activated glial phenotype that is less detrimental - A2. This type is associated with ischemic models and promotes synaptogenesis as well as neuronal and oligodendrocyte survival and outgrowth. Relative levels of A1 and A2 activation are relevant to the progression of the cuprizone toxicity since A1 astrocytes contribute to demyelination and neural disruption and A2 astrocytes preserve neural and oligodendrocyte maintenance. To confirm that presence assessed by Western blot represented astrocyte protein levels of C3 and Emp1, immunofluorescence was employed on fixed tissue slices taken at one and two weeks of cuprizone treatment. Levels of A1 and A2 astrocytes reveal the glial response to cuprizone toxicity and may help elucidate the role of astrocyte pathology in demyelinating states.

Abstract: Extracellular matrix (ECM) in the central nervous system (CNS) forms highly organized lattice like structures called perineuronal nets (PNNs), which encapsulate fast spiking interneurons (FSNs) in the cerebral cortex and CA2 pyramidal neurons in the hippocampus. PNN lattice is composed of chondroitin sulfate proteoglycans (CSPGs), Hyaluronic acid (HA), tenascin R, etc. and lattice holes confine the axosomatic synapses. PNN forming ECM proteins and proteoglycans are secreted by astrocytes, which also perform homeostatic functions including glutamate clearance and extracellular potassium buffering. Previously, we have shown that PNNs modulate biophysical properties of the enclosed interneurons and are prone to degradation by matrix remodeling enzymes such as matrix metalloproteinases (MMPs) released in glioma-associated epilepsy. In the present study, we hypothesized that PNN lattice constitutes a spatial proximity barrier, due to which PNN holes define the placement sites for astroglial processes and axosomatic synaptic contacts, i.e. the tripartite synapse. Consequently, the PNN holes act as units of astroglial homeostatic functions and axosomatic synaptic activity. Our data suggest that astroglial processes are confined to the PNN holes and constitute a non-overlapping spatial interface with PNN CSPGs in both cerebral cortex and hippocampus. PNN expressing neurons possess significantly smaller astroglial coverage area than the PNN lacking neurons suggesting an inhibitory role of PNNs for astroglial spatial proximity to the FSNs. Moreover, in the PNN holes, presence of astroglial processes expressing homeostatic proteins including Kir4.1 and Glt1, in addition to the excitatory and inhibitory presynaptic and postsynaptic terminals, suggest them analogous to the tripartite synapses. We also observed disruption of astrocyte-PNN spatial interface upon experimental PNN degradation in mouse brain *in-vivo* using Chondroitinase ABC enzyme and in a mouse model of glioma-associated epilepsy. Our data suggest that degradation of ECM and PNN assembly under various CNS pathologies characterized by elevated release of matrix remodeling enzymes, may similarly alters the astroglial-PNN spatial interface thereby rendering the units of astroglial homeostatic functions and axosomatic synaptic activity dysfunctional.

Title: Astrocyte influence on GABA catabolism in an iPS cell model system

Authors: *T. E. R. SCHNEIDER[1], S. ROSAS[1], J. V. MCGIVERN[2];
[2]Biochem., [1]Lakeland Univ., Plymouth, WI

Abstract: Succinic semialdehyde dehydrogenase deficiency (SSADHD) is a rare autosomal recessive disorder that presents itself in early childhood through a wide range of severities from patient to patient. The molecular cause of the disorder is due to a mutation in the metabolic enzyme, succinic semialdehyde dehydrogenase (SSADH), which is essential for the proper catabolism of the neurotransmitter γ-aminobutyric acid (GABA). In the cerebrospinal fluid of patients with SSADHD there is a 2-4 fold increase in GABA levels and nearly 30 fold increase in gama-hydroxybutyrate (GHB). Most models have focused on the neuronal aspects of the disease, but our focus using induced pluripotent stem cells has been to examine the glial contribution. We have discovered, using a low cost neurosphere method, that our GFAP+ astrocytes possess the glial transporter GAT3 after a six week differentiation process. This suggests glial cells in our cultures do in fact have the capacity to take up GABA from the media. In order to directly assess the ability for glial tissue to regulate GABA levels in our media conditions we have been exploring both HPLC and ELISA methods to quantify GABA levels. Finally, in order to fully utilize this system to study SSADHD, we are generating an SSADH knockout using CRISPR/Cas9. Establishing glial culture conditions that can be monitored for neurotransmitter catabolism may be a powerful tool for studying the influence of glia not only for SSADHD but for a wide range of neurological diseases.

Title: Investigating the role of glia astrocytes in Parkinson's disease by using a computational model of astrocytes

Authors: *Z. SAJEDINIA[1], S. HELIE[2];
[1]Psychological Sci., [2]Dept. of Psychological Sci., Purdue Univ., West Lafayette, IN

Abstract: Recent findings show that astrocytes are involved in initiation and progression of neurodegenerative diseases. Some studies show that the number of astrocytes increases in Parkinson’s disease (PD), and because astrocytes interfere with neural signaling, we expect to observe abnormal firing patterns in PD-related neural networks. While some studies show an abnormal increase in firing rate (neural bursting) in PD, it has not been shown whether this abnormality relates to the PD excess astrocytes. To investigate this relationship, we need to be able to study astrocytes independently. However, because neurons and astrocytes share many of

the same neurotransmitter receptors, performing physiological experiments on astrocytes is difficult. To overcome this difficulty, computational models could be helpful and an appropriate choice. First, we need a computational model of astrocytes. However, unlike neurons, computational models of glia cells have not yet received much attention. To date, a few computational models of astrocytes have been proposed but none of them is fully functional and widely accepted. In this work, we present a computational model of astrocytes based on the Izhikevich simple model of neurons. First, we include this astrocyte model in one synapse. We show that increasing the number of astrocytes in this synapse results in an increase in neural firing rate (as we see in PD). Second, we extend the model and make a neuron-astrocyte spiking network. Similarly, by increasing the number of astrocytes we show the impairment of the network in categorizing different stimuli. These results suggest the potential involvement of astrocytes in PD, who show a similar deficit in category learning. Because previous computational models of PD have focused only on neurons and did not consider the changes in neural signaling caused by astrocytes, we argue that a more accurate model of PD should include a model of astrocytes in related underlying networks. We hope that this line of research will help understand the underlying mechanisms in PD and suggest new astrocyte targeted treatments for PD.

Title: Fibrinogen chains intrinsic to the brain

Authors: *E. V. GOLANOV[1], M. A. SHARPE[1], A. S. REGNIER-GOLANOV[1], G. J. DEL ZOPPO[2], D. S. BASKIN[1], G. W. BRITZ[1];
[1]Neurosurg., Houston Methodist Hosp., Houston, TX; [2]Hematology, Univ. of Washington, Seattle, WA

Abstract: Fibrin deposition along paravascular spaces can be observed in naive animals and increases following subarachnoid hemorrhage (SAH) involving areas remote from the hemorrhage. Astrocyte (Astro) endfeet form the *glia limitans* (GL) and sheath of intracerebral vessels and express the procoagulant tissue factor (TF). It has been assumed that fibrinogen enters the subarachnoid space through damaged microvessel blood-brain barrier or ruptured vessels. Based on our observation we hypothesize that fibrinogen chains (FC) Aα, Bβ and γ are synthesized by astrocytes. Here we demonstrate *in vivo* and *in vitro* that astroglia are capable of FC expression. SAH in mice was induced by Circle of Willis perforation (control was without perforation). Four days later, mice were anesthetized, perfused, and fixed. Whole brains were processed for immunohistochemical (IHC) analysis of the presence of fibrin or FC on the brain surface. Coronal slices were processed for detection of FC Aα, Bβ, γ and GFAP and IHC was quantitively analyzed. Human brain slices were processed for detection of FC using DAB. For *in vitro* analysis normal human Astro (NHA) were grown to confluence and stimulated with the nitric oxide donor NOC-18 (100 μM), TNF-α (100 nM), and the stable ATP analogue ATP-γ-S (100 μM) for 4 hours. Cultures were fixed, washed/permeabilized, and processed for quantitative immunofluorescence (IF). Four days after SAH FC Aα IF associated with GL increased 3.2 and 2.5 times ($p<0.05$ and $p<0.01$) on the ventral and dorsal brain surfaces, respectively; FC Bβ increased by 3 times ($p<0.01$) on the dorsal surface, and FC γ increased by 3 times ($p<0.01$) on the ventral surface compared to sham animals. FC IF in astrocytes was also observed in the brain parenchyma. NHA constitutively expressed all three FCs. Application of specific siRNA suppressed FC Aα by 76% ($p=0.038$), Bβ by 80% ($p=0.018$) and γ by 78% ($p=0.025$). The FC expression by cultured NHA was differentially affected by biologically significant stimuli. Analysis of human brain tissue samples obtained from different brain sites revealed FC immunoreactivity in astrocytes, suggesting that human brain cells also are capable of expressing FC. We demonstrated for the first time presence that astrocytes are capable of FC expression, which differentially responded to biologically significant stimuli. SAH is followed by increased expression of FCs associated with GL remote from the hemorrhage as well as in brain

parenchyma. There is a possibility that individual FCs can play multiple physiological roles. We conclude that astrocytes are capable of production of FCs, which may be involved in various normal and pathological brain processes.

Title: Telencephalic astrocytes display no regional heterogeneities in stress responses and do not forfeit their neuroprotective roles after surviving intense oxidative stress

Authors: *T. N. BHATIA, D. B. PANT, J. N. WEILNAU, E. A. ECKHOFF, R. N. GONGAWARE, T. DO, D. F. HUTCHISON, A. M. GLEIXNER, R. K. LEAK;
Div. of Pharmaceut. Sci., Duquesne Univ., Pittsburgh, PA

Abstract: Astrocytes have evolved to protect neurons, but it is not known whether they lose some of their neuroprotective abilities under conditions of severe oxidative toxicity. In the present study, we report that primary cortical astrocytes surviving severe paraquat toxicity display stress-reactivity, but continue to tolerate a second toxic paraquat hit of the same intensity, without any additional cell loss. Inhibition of multiple stress-responsive molecules (heat shock protein 70, heme oxygenase-1, glutathione, ERK1/2, Akt, and JNK), either alone or in combination, did not abolish or even attenuate astrocytic stress tolerance. Primary cortical astrocytes surviving these high concentrations of paraquat exhibited Nrf2 activation and higher glutathione content. In primary neuron/astrocyte bilayer cultures, astrocytes surviving intense oxidative toxicity continued to protect neighboring neurons from paraquat exposure, even at high paraquat concentrations that killed 80% of neurons in control monolayer neuron cultures. These findings suggest that stress-reactivity does not inescapably lead to the acquisition of neurotoxic phenotypes in astrocytes. Next, we tested whether astrocytes collected from different subregions of the telencephalon would differ in their capacities to survive intense oxidative and proteotoxic stressors. Unexpectedly, full concentration-response curves revealed that primary astrocytes harvested from the neocortex, entorhinal/piriform allocortex, and hippocampal allocortex were all equally vulnerable to paraquat and proteasome inhibitors (MG132 and lactacystin), and, further, displayed equivalent degrees of stress tolerance against dual hits. All three types of astrocytes also responded similarly to loss of Hsp70 or glutathione synthesis when exposed to

proteotoxic stress. In contrast to astroglia, primary neurons harvested from the same telencephalic subregions clearly displayed selective vulnerabilities to oxidative and proteotoxic stressors. These data support heterogeneity in stress responses in neurons, but not in astrocytes of the telencephalic edifice, and suggest that therapies designed to inhibit these natural stress responses may hasten, rather than lessen neurodegeneration.

Title: Reactive astrocyte heterogeneity after stroke: Identifying region-specific targets for neural repair

Authors: *A. J. GLEICHMAN, R. KAWAGUCHI, M. V. SOFRONIEW, G. COPPOLA, S. CARMICHAEL;
UCLA Sch. Med., Los Angeles, CA

Abstract: Stroke is one of the most common forms of death and disability worldwide, yet few treatment options exist. Tissue repair and recovery after injury is a complex process, involving both scar formation around the site of the injury that likely isolates the damage and prevents spread of immune-related damage molecules as well as remodeling of the neighboring and, in some cases, contralateral tissue. Astrocytes are central to these processes and respond differently in these distinct compartments. While it has long been clear that astrocytes respond to damage in a gradated fashion, the details of these responses are unknown. Here, we use morphologic and phenotypic tools to identify distinct zones of reactive astrocytes after stroke, which we used to inform a transcriptomic analysis to comprehensively map zone-specific astrocytic responses to both white matter and cortical stroke. We are using these transcriptomic maps to identify potential intervention points to promote repair and recovery, with a particular focus on astrocytic control of vascular development after white matter stroke. In order to map the morphologic changes astrocytes undergo after stroke, we developed astrocyte-specific spaghetti monster reporter lentiviruses, injected them sparsely into the cortex or white matter at the time of stroke,

and assessed individual astrocyte morphology at 7 days post-stroke. We also assessed phenotypic changes in post-stroke astrocytes, using markers for proliferation, reactivity, and proteins previously identified as differentially regulated by stroke. Astrocytes undergo stereotyped morphologic and phenotypic changes in both stroke models based on the distance from the infarct border. These differences were used to define zones of reactivity that were then analyzed transcriptomically. To map the transcriptomic changes zone-specific astrocytes undergo after stroke, we used GFAP-Cre/Ribotag mice to selectively isolate astrocyte-enriched mRNA in laser captured reactive astrocyte zones. While some transcriptomic changes are preserved between white matter and cortical stroke, others are not, with potential functional consequences for the recovering tissue. In particular, cortical astrocytes appear to trigger greater angiogenesis and vessel maturation after stroke than do white matter astrocytes. Angiogenesis has been associated with increased recovery after gray matter stroke; using the transcriptomic analyses of gray matter stroke, we are investigating the repair potential of astrocyte-induced angiogenesis in white matter stroke.

Medicine, Natl. Yang-Ming Univ., Taipei, Taiwan; [5]Div. of Nephrology, Dept. of Med. and Immunol. Res. Centre, Taipei Veterans Gen. Hosp., Taipei, Taiwan

Abstract: Chronic kidney disease (CKD) is a progressive loss of renal function that gives rise to accumulation of uremic toxins such as blood urea nitrogen and indoxyl-3-sulfate (I3S) in the blood that causes multiple organ pathology. I3S is a potent physiological agonist of aryl hydrocarbon receptor (AhR), a ligand-activate transcription factor that can be activated by

environmental hormones and endogenous tryptophan metabolites. Notably, I3S toxicity is attributed to its protein-bound property that cannot be removed by hemodialysis, and can penetrate blood brain barrier. Recent studies indicated mental disturbance and cognitive impairment in CKD patients, but the involvement of brain AhR was unknown. In this study, we investigated the molecular mechanism of AhR-mediated glutamate transporter (GLT1) alteration and the subsequent impact on cognitive function in CKD. First, we establish the I3S chronic treatment in cultured astrocytes to mimic the accumulation of I3S *in vivo*. The data showed that I3S can activate AhR and produce reactive oxygen species (ROS). Heme oxygenase-1 (HO-1), an antioxidant protein, was elevated and further increased by AhR antagonist CH223191 treatment in both acute and chronic I3S incubation in cultured astrocytes. Besides, chronic I3S exposure led to GFAP activation and GLT1 reduction, accompanied with the impairment of glutamate uptake activity, and these effects can be reversed by CH-223191. Notably, AhR inhibition could increase surface GLT1 protein expression in cultured astrocytes. We established a 5/6 nephrectomy CKD mouse model that has elevated I3S concentration in both plasma. The data showed that CKD decreased GLT1 and increased reactivated astrocytes in the anterior cortex, with the effect attenuated in the neural lineage-specific nestin-Cre/AhR-floxed (nAhRCKO) mice. Furthermore, nAhRCKO CKD mice showed less anxiety-like behavior and better recognition memory than wild type CKD mice. Thus, chronic I3S accumulation in the brain may cause astrocytic GLT1 hypofunction to disturb glutamate homeostasis in an AhR-dependent manner, which may contribute to the mood disturbance and cognitive declination in CKD.

Title: Sex differentiated connectivity, behavior (memory and anxiety), and pathology associated with astrocyte specific expression of cytoplasmic TDP-43

Authors: *C. M. KHALID-JANNEY[1], D. CARTER[1], C. SULLIVAN[2], T. WHITE[1], K. WILSON[1], I. SERRANO[1], L. GUZMAN[1], M. CAREY[1], S. A. DAVIS[1], M. A. GITCHO[1]; [1]Biol. Sci., Delaware State Univ., Dover, DE; [2]St. Michael's Col., Colchester, VT

Abstract: TAR DNA binding protein 43 (TDP-43) functions as a heterogeneous nuclear ribonucleoprotein that regulates gene expression, RNA stability, RNA transport and localizes to the cytoplasm as a stress response protein. Glial Fibrillary Acidic Protein (GFAP) is an intermediate filament protein found primarily in astrocytes that increases expression when astrocytes are activated. TDP-43 predominantly resides in the nucleus, except under pathological conditions it aggregates in the cytoplasm. To investigate pathological outcomes and non-cell autonomous effects of this pathological condition in astroglial cells, TDP-43 with a defective nuclear localization signal (ΔNLS) under control of the human GFAP promoter (GFAP-tTA) was selectively and conditionally expressed in astrocytes utilizing a doxycycline inducible system. We hypothesize that selective TDP-43ΔNLS expression in astrocytes alters memory and anxiety through a mechanism of non-cell autonomous neuronal degeneration.

Both GFAP-tTA (control) and GFAP-tTA/TDP-43ΔNLS mice were examined across two time points (8 & 16 weeks) under developmental conditional expression (-DOX) and selective expression post weaning (+DOX). A battery of behavioral tests consisting of anxiety tests (Light/Dark Box, Open Field, Hole Board, Elevated Plus Maze), memory tests (8-Armed Radial Maze (ARM), Y-Maze), and a sociability test (Three Chamber Novel Sociability), in differing combinations at each time point. Pathology and biochemistry in the brain were also evaluated at 8- and 16-weeks. Additionally, primary cortical mouse neuron/astrocyte (~90%/~10%) cultures comparing GFAP-tTA and GFAP-tTA/TDP-43ΔNLS were examined for viability, immunofluorescence, Western blot, and proteomics. Primary cortical neuron/astrocyte co-cultures expressing GFAP-tTA/TDP-43ΔNLS showed a significant decrease in neuronal viability compared with littermate controls.

At 8- & 16-weeks of age, GFAP-tTA/TDP-43ΔNLS mice (-DOX) displayed behavioral changes in anxiety and memory, which may be associated with the changes in non-cell autonomous neuronal degeneration. Similarly, TDP-43ΔNLS (+DOX) mice also showed a gene effect of increased anxiety behaviors as early as ~8-weeks of age. Functional Magnetic Resonance Imaging (fMRI) and structural staining (H&E) staining revealed nuclear condensation and neuronal loss in the hippocampus, specifically in the dentate gyrus.

Identifying and exploring this relationship of non-cell autonomous degeneration may expand our knowledge of astrocyte dysfunction associated with neurodegeneration, as well as also providing insight to associated behaviors of interst.

Title: Organochlorines and brain homeostasis: Polychlorinated biphenyls as astrocytic stressors

Authors: *M. S. MCCANN[1], H. R. FERNANDEZ[1], S. FLOWERS[2], K. A. MAGUIRE-ZEISS[3]; [2]Dept. of Neurosci., [3]Neurosci., [1]Georgetown Univ. Med. Ctr., Washington, DC

Abstract: While the etiology of many neurodegenerative diseases remains elusive, evidence suggests that the intersection of environmental stressors and genetic predispositions result in neurodegeneration. The accumulation of polychlorinated biphenyls (PCBs), a class of hazardous organic chlorines once widely used for industrial purposes, is correlated with increased nigral cell death in Parkinson's disease (PD) patients. Here, we studied the impact of Aroclor 1254, a commercially available and once widely-used PCB mixture, on astrocytes. Astrocytes have a critical role in maintaining homeostasis throughout the brain, including at the synapse and at the blood-brain barrier, and serve as the predominant defense against xenobiotic attack in the central nervous system. We hypothesize that PCBs cause astrocytic oxidative stress and related dysfunction including metabolic disturbances, lipid peroxidation, protein modifications that perturb the ability of astrocytes to perform antioxidant capacity. We treated primary murine cortical astrocytes with PCBs and report an increased antioxidant response (*GSTA2, HMOX1, NOX1)* with concomitant lipid peroxidation (via BODIPY 581/591 oxidation) and protein modifications, as well as mitochondrial respiratory impairments. Together, these data suggest that this persistent environmental toxicant disrupts astrocytic redox which in turn may impair neuronal function and cerebral homeostasis.

Title: Investigation of the effect of varying cocaine dosage and RPEC transplantation on astroglial proliferation in cocaine self-administering rats

Authors: *A. KIM, M. P. SUBRAMANIAN, K. VENKITESWARAN, P. S. GRIGSON, T. SUBRAMANIAN;
Pennsylvania State Col. of Med., Hershey, PA

Abstract: It is important to understand the pathogenesis by which cocaine addiction arises, as well as the neurodegenerative effects cocaine has on the central nervous system by way of astrocytosis. Astrocytosis can exacerbate excess inflammatory processes and impair proper axonal regeneration, worsening the neurodegeneration and addiction pathways in the cocaine-affected brain. This cocaine-induced response occurs in the ventral tegmental area (VTA) projecting to the nucleus accumbens (NAc) where amplified astrocytic proliferation may also be seen. This could suggest generalized astrogliosis due to injury or a more specific response leading to a refinement of synaptic connectivity between VTA and NAc neurons. Ultimately, it is important to elucidate the effects cocaine, transplantation and hRPEC introduction into NAc may have on astroglial response in order to better understand the CNS impairment mechanisms of cocaine in the mesolimbic pathway via astroglial influence and how to treat these alterations for victims of cocaine addiction. We assessed the effects of bilateral transplantation of intra-NAc grafts containing growth factor secreting embryonic human retinal pigment epithelial cells (hRPEC) on astroglial proliferation in the VTA of rats trained to self-administer cocaine. Rats were categorized as low or high drug-takers based on the number of cocaine infusion attempts. Separate cohorts were made with rats being treated with either collagen beads (vehicle) or beads attached with hRPECs (20K cells/hemisphere) bilaterally into the medial shell of the NAc. Additionally, rats that self-administered cocaine for 2 days without any surgical intervention were utilized as controls. All rat brain sections were stained for glial fibrillary acidic protein (GFAP), using rabbit polyclonal anti-GFAP antibody. For quantitating astroglial response, stereology using systematic random sampling was used to discern significant differences among groups. Gross histology and preliminary astrocyte counts demonstrate a notable decrease in astrogliosis from the day 2-control rat sections vs. the hRPEC-treated cohort. This comparison

held true between these groups in the high and low-drug takers. There was also a decrease in the astroglial counts from the vehicle-treated rats to that of the hRPEC-treated cohort. Further workup will be done to confirm these results, as more rat brains need to be analyzed to increase sample size, and ANOVA statistical analysis will be applied to assess for statistical significance of these observations. Should our hypothesis hold true, hRPEC would mitigate astrogliosis in the VTA of cocaine-addicted rats and enhance neuronal survival.

Title: Effect of third-trimester of human gestation-equivalent ethanol exposure on hippocampal astrocyte extracellular matrix and DNA methyl transferases gene expression *in vivo*

Authors: *M. GUIZZETTI, J. G. HASHIMOTO, K. R. MCNEALY;
Oregon Hlth. and Sci. Univ. & Portland VA, Portland, OR

Abstract: Prenatal ethanol exposure can cause Fetal Alcohol Spectrum Disorders (FASD), characterized by cognitive and behavioral dysfunctions and increased incidence of psychiatric disorders later in life. We have reported that ethanol exposure in astrocytes changes the levels of several extracellular matrix (ECM) proteins and proteases resulting in altered neuronal development *in vitro*. We have also reported that neonatal (equivalent to the third-trimester of human gestation) ethanol exposure in rats alters hippocampal neuron morphology and the expression of ECM-related genes and proteins *in vivo*. In the present study we have examined the effects of ethanol on gene expression of ECM related proteins and DNA methyltransferases

(*Dnmt*) selectively in hippocampal astrocytes using the translating ribosome affinity purification (TRAP) procedure with transgenic Aldh1l1-EGFP-Rpl10a mice that expresses ribosomal protein Rpl10a tagged with eGFP in cells expressing the astrocytic marker *Aldh1l1*.Litters of Aldh1l1-EGFP-Rpl10a mice were placed in an ethanol vapor chamber or in a control chamber for 4 hours a day from post-natal day 2 (PD2) to PD7. We analyzed mRNA expression in the pull-down fractions, containing astrocyte-specific RNA, and in the input fractions, containing total hippocampal RNA, by qPCR. We also analyzed the same genes in wild-type littermates of the transgenic animals. RNA expression of all laminin isoforms (α subunit-encoding *Lama1-5*; β subunit-encoding *Lamb1-3*, and γ subunit encoding *Lamc1*and 2), *Adamts1, 4, 5*and *9*, *Mmp14*and *15*, *Plat*, *Plau*, *Serpine1*, and *Dnmt1*, *3a*, and *3b*was analyzed. We identified genes that are enriched (*Plat, Plau*,*Mmp14*and *15, Adamts1*and *9, Lama2* and*5, Lamb2*,and*Lamc1*) or de-enriched (*Serpine1, Adamts4, Lama1* and*3, Lamc2,* and*Dnmt1*and *3a*) in astrocytes as well as genes that are expressed in astrocytes and in the whole hippocampus at similar levels (*Adamts5*, *Lama3* and*4*, and *Dnmt*3b). Furthermore, we identified genes that are selectively upregulated by ethanol in astrocytes (*Lama2, Lamc1,* and*Dnmt*3b) and genes that were upregulated only in the whole hippocampus (*Lama4, Lamb1,* and*Dnmt1*). *Plat* and *Adamts9*wereupregulated by ethanol in all the fractions. These results indicate that, during brain development, ethanol alters the expression of some genes in a cell-type specific manner. Notably, *Dnmt3b*, which is expressed in astrocytes and in the whole hippocampus at similar levels, is upregulated by ethanol selectively in astrocytes, indicating that ethanol may alter DNA methylation in this cell type differently than in other hippocampal cells.

Title: Novel A3 adenosine receptor agonist prolongs survival of human traumatized astrocytes

Authors: I.- . WANNER[1], A. KAMALI[1], T. LISTON[2], L. TAJALLI[1], D. HOLSTEIN[3], ***J. D. LECHLEITER**[4];
[1]Semel Inst. for Neurosci. and Human Behavior, Univ. of California Los Angeles, Los Angeles, CA; [2]Astrocyte Pharmaceuticals Inc., Cambridge, MA; [3]Dept. of Cell Systems and Anat., [4]Cell Systems and Anat., UT Hlth. San Antonio, San Antonio, TX

Abstract: Adenosine is central in astrocyte communication and a major danger signal after traumatic brain injury (TBI). Mechanical shear and deformation of brain tissue causes cellular injury and ensuing cell death. Effective therapies for TBI are missing and translation of neuroprotective strategies lack sensitive pharmacodymanic biomarkers. We use an *in vitro*human trauma model to investigate a novel adenosine A3 receptor agonist, AST-004, to improve energy and ion homeostasis of wounded astrocytes (Wanner, IB 2012). Abrupt pressure-pulses injure cultured matured human astrocytes causing mechanoporation and progressive cell death (Halford J et al., 2017). Traumatized astrocytes were treated using a range of AST-004 doses. Integrity-compromise and cell death were identified by live-propidium iodine uptake, followed by cellular and released glial fibrillary acidic protein (GFAP) analyses. Automated microscope stage imaging and immunoblotting provided unbiased pharmacodynamic readout. Cells were counted using binarized images. PI-positive cell numbers increased significantly post-stretching (effect size 3). Stretched cultures treated with AST-004 had significantly reduced cell death versus untreated ones (effect sizes 3.3-3.5). Different cell death stages were assessed by scoring nuclear morphology. One-fifth of permeable cells displayed complete chromatin condensation or nuclear fragmentation, while the majority displayed earlier stages of cellular death. GFAP filament disassembly, breakdown and release correlated with human astrocyte injury and cell death (Halford et al., 2017). Stretching caused a significant increase in disassembled GFAP-bearing astrocytes with pyknotic nuclei (effect size 5.8). This population was significantly reduced by AST-004 (effect sizes 3.8-5). Immunoblotting confirmed GFAP release and breakdown changes. Disassembled GFAP fibers is known to associate with elevated intracellular calcium and subsequent calpain activation. Our data indicated that A3 receptor stimulation prevents compromised human astrocytes from progressing to cell death. Mouse brain injury and knockout studies support an underlying mechanism involving IP3-mediated release of calcium leading to increased mitochondrial energy levels (Parpura V. et al., 2017; Talley Watts L. et al., 2013). We conclude that AST-004 is a potent cytoprotective drug that shifts cell fates of traumatized human astrocytes towards survival and health. Future studies will address drug pharmacodynamics along with astroglial injury defined biomarker monitoring to guide therapeutic dosing for clinical use in TBI patients.

Title: Soluble oligomeric Aβ42 triggers degradation of the cerebrovascular basement membrane and disruption of the astrocyte-vascular interface

Authors: C. D. LIAO[1], A. STUBLEN[2], L. CHAUNSALI[1], H. SONTHEIMER[3], ***I. F. KIMBROUGH**[4];
[1]Fralin Biomed. Res. Inst. at VTC, Roanoke, VA; [2]Virginia Tech. Sch. of Neurosci., Blacksburg, VA; [3]Sch. of Med. and Res. Inst., Virginia Tech. Sch. of Neurosci., Roanoke, VA; [4]Sch. of Neurosci., Virginia Tech., Blacksburg, VA

Abstract: Astrocytes regulate local cerebral blood flow by communicating directly with vascular smooth muscle cells and pericytes. In Alzheimer's disease, a pathologic accumulation of amyloid along the vasculature (vascular amyloidosis) is a well-defined phenomenon. In a recent publication, we demonstrated loss of vascular regulation and astrocytic end-foot displacement in areas of vascular amyloid deposition. However, the pathogenic process through which the astrocyte-vasculature interaction is disrupted and whether end-foot disruption *precedes or follows* overt plaque deposition remains unclear.
Recent evidence suggests a role of *astrocytic* low density lipoprotein receptor-related protein (LRP1) and matrix metalloproteases (MMPs) in mediating the clearance of extracellular amyloid. We hypothesize that soluble, pre-plaque amyloid-beta oligomers (sAβO's) interact with astrocyte surface receptors such as LRP1, resulting in the release of MMPs that degrade the basement membrane, subsequently causing astrocytic end-foot displacement from blood vessels and reduced vascular integrity. After careful optimization and refinement of a protocol for the synthesis of sAβO's, we determined the effect of these oligomers on cultured astrocytes. *In vitro* data suggests that exposure to media containing varying concentrations of synthetic oligomeric Aβ42 causes astrocytes to undergo reactive gliosis, as indicated by increased GFAP staining. Interestingly, 24 hours after application to the culture medium and subsequent washing for analysis, oligomeric Aβ42 remains bound to the cultured astrocytes, suggesting significant binding affinity or intracellular compartmentalization. Additionally, we show that intracerebral injections of oligomeric Aβ42 result in amyloid-beta labeling throughout the hippocampal parenchyma with reduced polarization of astrocytic end-feet, diminished collagen IV and laminin expression around blood vessels in areas of higher Aβ42 density, and elevated LRP1 expression.

Title: *In vivo* spatiotemporal dynamics of astrocytes activity following neural electrode implantation

Authors: *S. P. SAVYA[1], S. WELLMAN[2], J. R. ELES[3], T. D. KOZAI[1];
[1]Bioengineering, [2]Dept. of Bioengineering, [3]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Intracortical microelectrode arrays have become invaluable tools for understanding neuronal function and neurodegenerative diseases due to their ability to communicate neuronal information. However, the use of such microelectrode arrays is limited as they are plagued with chronic instability due to inflammatory reactions, resulting in neuronal loss and glial cell encapsulation. Astrocytes have been well established as a key player during inflammation. With their unique ability to exhibit both pro- and anti-inflammatory mechanisms, they can exert different behaviors in a context-dependent manner - temporally after injury or spatially relative to the lesion. Previous studies have used post-mortem immunohistochemistry to uncover glial responses in relation to chronic electrode implants. Unfortunately, these methods limit cellular dynamics during acute inflammation. Here, we utilize two-photon microscopy to show the spatiotemporal dynamics of fluorescently-labeled astrocytes after insertion of a microelectrode array in the mouse cortex. Early results show astrocytes initiating processes extension 40 min after implantation (0.05um/min). In addition, there are very few astrocytes 6 h post-insertion that initiate soma migration towards the area of tissue damage, with more distant astrocytes (~170um from probe surface) migrating at 72 h. This suggests astrocytes activate subsequently to microglia activation, yet prior to other cells such as oligodendrocyte precursor cells (OPC). Astrocytes also begin to increase in volume 24h after implantation, contributing to vasculature dilation and reorganization. By highlighting and identifying novel patterns of astrocytic activity, the stability and longevity of neural implants may improve due to the development of therapeutic strategies to attenuate the immune response.

Title: Role of HIF-1α-lncRNA BACE1-antisense complex in HIV-1 Tat mediated induction of astrocytic amyloidogenesis

Authors: *S. SIL, G. HU, K. LIAO, S. CALLEN, S. BUCH;
Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Increased life expectancy of HIV^+ patients in the era of combined anti-retroviral therapy (cART) is paradoxically also accompanied by increased prevalence of HIV-associated neurological disorders (HAND) and comorbidities such as Alzheimer's Disease (AD). It is now well recognized that despite effective cART-mediated suppression of viremia in the periphery, lack of penetration of some of the cART regimens across the blood-brain barrier, often results in persistent low-level viral replication in the CNS and accumulation of cytotoxic viral proteins such as transactivator of transcription (Tat). While there are reports on Tat-mediated production of the toxic amyloid protein by neurons, the role of astrocytes as potential contributors of amyloidogenesis remains less explored. The present study was thus undertaken to assess the role of HIV Tat in mediating astrocytic amyloidogenesis, which, in turn, could also have a significant deleterious effect on the neurotoxicity associated with HAND. Our *ex vivo* findings in the autopsied brains sections of that SIV^+ macaques & HIV^+ patients with differential cognitive status, identified brain region specific upregulation of the amyloidogenic components that co-localized with GFAP positive astrocytes. Furthermore, in the cell culture studies Tat-mediated amyloidogenesis correlated with upregulation of Alzhemier's associated markers such as BACE-1, amyloid precursor protein (APP), AβmOC64, p-Tau, as well as increased activity of BACE-1 in human primary astrocytes (HPA) exposed to Tat. Molecular mechanism(s) underlying this process involved upregulation of hypoxia inducible factor (HIF-1α), its translocation to the nucleus & its binding to the long noncoding (lnc) RNA BACE-1AS, resulting in formation of an unique complex that was validated by RNA immunoprecipitation assay and Electrophoretic Mobility Shift Assay. Furthermore, Chromatin Immunoprecipitation Assay identified functional binding of the complex to BACE-1 promoter, leading in turn, to increased expression of BACE-1

that involved transcriptional, post transcriptional & translational mechanisms as well as its increased activity resulting in increased cleavage of APP to its toxic Aβ-42 form. Gene silencing approaches further confirmed the regulatory role of HIF-1α-lncRNA BACE-1AS axis in generation of Aβ. This is the first report demonstrating the mechanism by which the HIV viral protein Tat induces HIV-associated astrocytic amyloidogenesis. Further this complex of HIF-1α-lncRNA BACE-1AS can be targeted to develop adjunctive therapy for HIV^+ subjects on cART therapy.

Title: Neuroimmune consequences of heroin withdrawal on stress enhanced fear learning

Authors: *S. V. PAREKH, J. E. PANICCIA, C. L. LEBONVILLE, D. LYSLE;
Psychology and Neurosci., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Converging evidence suggests opioid abuse leads to increased incidence and severity of post-traumatic stress disorder (PTSD) in clinical populations. For example, heroin use is associated with increased anxiety and severity of PTSD symptoms, while opioid withdrawal produces similar symptoms to those of PTSD. This relationship suggests the possibility of a common underlying neurobiological mechanism of opioid withdrawal and PTSD. Our laboratory has investigated the mechanism of stress enhanced fear learning (SEFL), an animal model of PTSD. We have established that the severe stressor in the SEFL paradigm induces a time-dependent, region-specific increase in dorsal hippocampal (DH) interleukin-1β (IL-1β). Additionally, we have discovered the primary source of this stress-induced DH IL-1β increase is in DH astrocytes. This IL-1 signaling is critical to the establishment of a PTSD-like phenotype, as site-specific antagonism of DH IL-1 signaling abolishes SEFL. To begin to understand more about the relationship between PTSD and heroin withdrawal as well as examine if similar underlying neural mechanisms are involved in heroin withdrawal and SEFL, our laboratory conducted two sets of experiments. The first set of experiments used a chronic escalating heroin dose and withdrawal paradigm to substitute for the severe stressor in the SEFL model to examine whether withdrawal or a history of chronic heroin would be a comparable stressor. The results showed escalating heroin administration followed by withdrawal can substitute for a severe

stressor in the SEFL model in that both severely stressed and heroin withdrawn animals exhibited enhanced freezing levels on Test Day 2 compared to controls. The second set of experiments aimed to explore whether cytokines, specifically IL-1β, were involved in this withdrawal behavior. Protein analysis of IL-1β and glial fibrillary acidic protein (GFAP), a marker of astrocyte reactivity, following a twenty-four-hour withdrawal revealed there were increases in both. Together, these studies provide the first set of evidence that heroin withdrawal may act as a severe stressor in SEFL, produce a PTSD-like phenotype in an animal model, and hippocampal IL-1β signaling may play a critical role in heroin withdrawal and the development of PTSD.

Title: Dexamethasone modifies expression of the five subtypes of dopamine receptors in C6 glioma cells

Authors: *N. LÓPEZ-AMADOR, F. PAZ-BERMUDEZ, A. ÁVALOS-FUENTES, A. NAVARRETE-ALONSO, P. VERGARA-ZUBILLAGA, J. SEGOVIA-VILA, B. FLORÁN-GARDUÑO;
Physiology, Biophysics and Neurosciences, Ctr. for Res. and Advanced Studies of the Natl. Polytechnic Inst., Mexico City, Mexico

Abstract: Background: Previous works have demonstrated that glucocorticoids modify the expression and signaling of certain metabotropic receptors, but sparse evidence is available regarding their effects on dopamine receptors. Recent data on the function of dopaminergic receptors expressed in astrocytes, indicates their important role modulating neuroinflammation and neuroprotection. **Objective**: The main objective of this work is to elucidate the effect of glucocorticoids on the expression of dopamine receptors in glial cells. **Methods**: Cultured C6 glioma cells were treated with dexamethasone in serum-free medium. The glucocorticoid receptor antagonist, mifepristone (RU486), was used as a control to prevent the effect of dexamethasone. Basal expression of the 5 subtypes of dopamine receptors was detected by immunofluorescence. Changes in the expression of dopamine receptors, induced by dexamethasone, were detected by western blotting. Relative densities of luminescence signals were quantified using Image J software. ANOVA with Tukey's post-hoc test was applied to analyze results. **Results**: In C6 glioma cells, the expression levels of dopamine receptors D1

(n=3; p=0.0014), D3 (n=4; p=0.003) and D4 (n=2; p=0.0166) were downregulated by dexamethasone, while dopamine receptors D2 (n=2; p=0.003) and D5 (n=2; p=0.0118) were upregulated, compared with non-treated controls. Remarkably, D2 receptor expression was induced more than 3-fold, compared with controls. **Conclusions**: We demonstrated that the expression of the five subtypes of dopamine receptors can be regulated by glucocorticoids. These results are relevant to obtain a better understanding of the underlying mechanisms in astrocyte response to stress, neuroinflammation and the putative role of glucocorticoids on dopaminergic function. Further investigation could define the effects of glucocorticoid on dopaminergic signaling. This research line may be important to develop novel therapeutic approaches in neurodegenerative disease.

Title: Morphine-mediated release of astrocyte-derived extracellular vesicle miR-23a induces loss of pericyte coverage at the blood-brain barrier: Implications for neuroinflammation

Authors: *K. LIAO, F. NIU, G. HU, S. SIL, S. BUCH;
Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Opioids such as morphine (Mor) are the most potent and efficacious drugs currently available for pain management. Paradoxically, however, opioids have also been implicated in impairing neurocognition likely via breaching the blood-brain barrier (BBB). Pericytes are key players in the maintenance and functioning of BBB. Our previous study has demonstrated that extracellular vesicles (EVs) released from Mor-exposed astrocytes can exert dysfunction of microglial phagocytosis involving activation of TLR7 signaling. The current study was undertaken to examine the effect of miRNAs in the Mor-stimulated astrocyte EV cargo in mediating pericyte loss at the BBB, leading, in turn, to increased influx of peripheral monocytes. Astrocyte-derived-EVs (ADEVs) were purified from control or Mor-exposed astrocytes using the standard differential ultracentrifugation technique followed by characterization using western

blot, transmission electron microscopy, atomic force microscopy and NanoSight analyses. Functional endpoints included assessment of pericyte migration using Boyden chamber, wound healing assays and the endothelial-pericyte 3D co-culture model. Our findings suggested that induction of miR-23a involved signaling via the mu opioid receptor and, furthermore, that the heterogeneous nuclear ribonucleoprotein A2/B1 (hnRNP A2/B1) played a role in the sorting of miR-23a in the EVs. Pharmacological and gene silencing approaches were used to validate these findings. The migration of pericyte involved down-regulation of the miR-23a target- PTEN, which was further validated by overexpressing PTEN or transfecting miR-23a-PTEN target protector in pericytes to attenuate Mor-ADEVs-mediated pericyte migration. Validation of decreased pericyte coverage was also demonstrated *ex vivo*, wherein lesser PDGFβR+ pericytes were found to co-localize with CD31+ brain endothelial cells in microvessels isolated from Mor-administrated mice. In line with these observations and of importance, we also observed increased loss of pericytes and a concomitantly increased influx of monocytes in sections of brains from pericyte-labeled NG2-DsRed mice that were administered Mor for 7 days. In conclusion, our findings indicate that in the brain Mor-mediated dysregulation of miRNA expression in the astrocytes involves cellular crosstalk with the pericytes via the EVs, leading to loss of pericyte coverage at the brain endothelium with increased influx of peripheral monocytes leading to neuroinflammation.

Title: Sex differences in the structural plasticity of nucleus accumbens astrocytes associated with the incubation of cocaine craving

Authors: *R. KIM[1], N. E. BROWN[1], A. TESTEN[2], E. A. WILLIAMS[1], K. J. REISSNER[1,2]; [1]Psychology and Neurosci., Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [2]Neurosci. Curriculum, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Astrocytes play critical roles in many processes in both health and disease. As such, structural and physiological adaptations in astrocytes have been implicated in neuropsychiatric diseases including drug addiction. Previously, we showed that following short-access (ShA, 2-hours/day) cocaine self-administration and extinction training, astrocytes in the nucleus

accumbens (NAc) exhibit a decrease in surface area, volume and synaptic colocalization (Scofield et al., 2016; Testen et al., 2018). However, it is unknown whether similar effects would be observed in other preclinical models of drug addiction, such as the incubation of cocaine craving model. Incubation of drug craving refers to an increase in behavioral measures of drug seeking across abstinence, and is characterized by a number of cellular adaptations in the NAc (Wolf, 2016). Among these, prolonged abstinence is associated with an increased magnitude of suppression of the astrocytic glutamate transporter GLT-1 protein, as well as genetic downregulation of the GLT-1 gene (Fischer-Smith et al., 2012; Kim et al., 2018). Furthermore, the effects of cocaine self-administration on NAc astrocytes have not been investigated in female rats. To address these questions, high resolution confocal imaging of NAc astrocytes was performed using an AAV5-Lck-GFP virus under the control of an astrocyte-specific promoter in both male and female rats, following the parameters often used in the incubation of cocaine craving: long-access (LgA, 6-hours/day) cocaine self-administration followed by 45 days of abstinence. Results indicate that following this protocol, astrocytes in the NAc of male rats show marked decreases in surface area, volume and colocalization with the post-synaptic marker PSD-95. However, these changes in NAc astrocytes were not observed in female rats. These results indicate sex differences in the cocaine-induced changes in astrocytes. In male rats, NAc astrocytes exist in an atrophic state following prolonged abstinence from LgA cocaine self-administration. This retracted phenotype signifies a cellular adaptation that occurs during abstinence and represents a potential mechanism for the incubation of craving. However, in female rats, other mechanisms and cellular adaptations may contribute to the incubation of cocaine craving.

Title: Branching plasticity of nucleus accumbens astrocytes following cocaine self-administration

Authors: *A. TESTEN[1], H. WANG[2], R. KIM[2], M. J. GASTINGER[3], K. J. REISSNER[1,2]; [1]Neurosci. Curriculum, [2]Dept. of Psychology and Neurosci., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [3]Bitplane, Concord, MA

Abstract: Astrocytes are critical players in the maintenance of brain homeostasis via intricate structural interactions with vascular and synaptic elements. These interactions are maintained by fine peripheral astrocytic processes (PAPs) which must dynamically adapt to changes to the local environment, making astrocytes exceptionally plastic. Neurological disorders and substance use disorders are both characterized by imbalances of brain homeostasis, due in part to impaired astrocyte function. However, the impact of these disorders on astrocyte structural plasticity is not well understood. Previously we showed that astrocyte surface area and colocalization with synaptic elements are markedly decreased in the nucleus accumbens from rats after short-access (2h/day) cocaine self-administration and extinction training (Scofield *et al.*, 2016; Testen *et al.*, 2018). These changes are also robustly observed after long-access (6 h/day) self-administration followed by 45 days of forced abstinence (Kim *et al*., unpublished data, linked poster). Abstinence from cocaine thus reproducibly results in a retracted phenotype of accumbal astrocytes, evidenced by decreases in surface area and synaptic colocalization. It is not clear however, if the retracted phenotype is also associated with any quantitative and/or qualitative changes in astrocyte branching pattern, or if this is a consequence of overall shrinkage of PAPs. To this end, branching pattern analysis of previously acquired astrocytes was performed. Astrocytes were reconstructed in 3D and their processes traced in order to construct a high-fidelity wire model using a fast-marching algorithm (Sethian, 1996), powered by Imaris software. Individual wire models were then analyzed by a custom-made MATLAB script, capable of mapping and classifying individual branching nodes as well as performing Scholl analysis. Results show decreased branching complexity of individual astrocytes associated with the short-access/extinction paradigm, which is further deteriorated in the long-access/abstinence paradigm. Scholl analysis on the other hand shows a distinct difference in intersection patterns produced by both self-administration paradigms. Interestingly, the length of individual branch segments (from node to node) remain unaffected by cocaine in either paradigm. In summary, the retracted phenotype of accumbal astrocytes following cocaine self-administration and extinction or abstinence appears not due to simple shrinkage of existing astrocytic processes, but is characterized by remodeling of branching complexity.

Title: Cilostazol restores autophagy flux in bafilomycin A1-treated cultured cortical astrocytes by lysosomal reacidification: Roles of PKA, zinc and metallothionein 3

Authors: *H. KIM[1], B.-R. SEO[1], J. CHOI[1], Y. YOON[2], J.-Y. KOH[3];
[1]Neural Injury Res. Ctr., Asan Inst. For Life Sci., Seoul, Korea, Republic of; [2]Ophthalmology, [3]Neurol., Asan Med. Ctr., Seoul, Korea, Republic of

Abstract: In many neurodegenerative diseases such as Alzheimer disease (AD), lysosomal dysfunction may be a common underlying pathogenic mechanism. While cilostazol, a PDE3 inhibitor/anti-platelet agent, reduces amyloid burden in mouse models of AD, its mechanism has not yet been clarified. In the present study, using cultured cortical astrocytes, we examined the possibility that cilostazol ameliorates lysosomal dysfunction induced by bafilomycin A1 (BA), an inhibitor of lysosomal v-ATPase.To estimate lysosomal pH, cortical astrocytes were loaded with DND189 or acridine orange. Compared to sham wash controls, astrocytes treated with BA for 60 min exhibited reduced lysosomal acidity. In both cases, BA-induced pH changes were reversed by cilostazol, dibutyryl cAMP, or a PKA activator forskolin. Conversely a PKA inhibitor H-89 blocked the effect of cilostazol or cAMP. Then, we examined whether the cilostazol/cAMP/PKA effect was mediated by increases in free zinc levels. FluoZin3 fluorescence showed that all significantly increased intracellular free zinc levels particularly in lysosomes. Addition of TPEN not only blocked the zinc increase, but also abrogated lysosomal acidification in all cases. Indicating that the zinc rises in astrocytes were mainly from MT3, dibutyryl cAMP or forskolin treatment failed to raise free zinc levels in MT3 null astrocytes. Furthermore, addition of dibutyryl cAMP or forskolin failed to reverse BA-mediated lysosomal alkalization in MT3 null astrocytes. Present results present a novel finding that cAMP/PKA can overcome the v-ATPase blocking effect of BA in a zinc- and MT3-dependent manner. The fact that cAMP/PKA can re-acidify lysosomes in the presence of a potent inhibitor of v-ATPase, suggests the possibility of an alternate, zinc-dependent pathway for lysosomal acidification.

Title: Cyclic AMP and PKA overcomes bafilomycin A1-induced lysosomal alkalinization in cortical astrocytes: A possible role of ATP4B, a potassium/hydrogen pump

Authors: *H. LEE[1], Y. YOON[2], J.-Y. KOH[3];
[1]ASAN Med.Center, Seoul, Korea, Republic of; [2]Ophthalmology, Asan Med. Ctr., SEOUL, Korea, Republic of; [3]Univ. Ulsan Col. Med., Seoul-City, Korea, Republic of

Abstract: Vacuolar ATPase (v-ATPase) is the main proton pump to acidify autophagosomes and lysosomes. Its mutations and/or failure of lysosomal localization cause defective lysosomal acidification and autophagy/lysosomal dysfunction, thus contributing to the pathogenesis of lysosomal storage disorders (LSDs) and common neurodegenerative diseases like Alzheimer's disease (AD). Recent studies showed that increases in cAMP levels, directly with db-cAMP or by the action of PDE inhibitors, help acidify lysosomes under certain circumstances and consequently enhance autophagy flux. While upregulation of v-ATPase function may be the key mechanism to lysosomal acidification, we examined the possibility that v-ATPase-independent mechanism is additionally at play, using cultured mouse cortical astrocytes. We first examined effects of cAMP on lysosomal acidification under autophagy-arrested (bafilomycin A1-treated) condition in astrocytes using LysoSensor DND-189, a pH-sensitive fluoroprobe. Compared with lysosomes of sham washed control astrocytes, those of db-cAMP treated astrocytes exhibited more intense fluorescence in accordance with increased acidification even in the presence of bafilomycin A1, a potent yet selective inhibitor of v-ATPase. Furthermore, as a consequence, autophagy flux was increased as evidenced by decreases in the level of LC3-II and p62. To find possible mechanisms of lysosomal acidification that may have bypassed v-ATPase activity, we examined whether another kind of proton pump activity was involved. Since H^+/K^+ ATPase (HK -ATPase) has been found to be associated with lysosomes in certain cases (*Andonian S et al., Mol Reprod Dev. 2001*), we tested omeperazole (OPZ) and lansoparazole (LPZ), inhibitors of HK-ATPase. While neither changed lysosomal pH in control astrocytes indicating minimal role of HK ATPase herein, OPZ or LPZ markedly shifted lysosmal pH to the alkaline direction in bafilomycin A1/db-cAMP-treated astrocytes. Moreover, Western blots showed that db-cAMP treatment substantially increased the level of ATP4B, a subunit of HK -ATPase, and increases its recruitment to lysosomes. Pending further experiments, our results suggest that HK-ATPase may be able to act as a second line proton pump for lysosomes, especially in case of v-ATPase dysfunction. It is intriguing that HK-ATPase induction and lysosomal recruitment appear under the control of cAMP/PKA, which finding may provide new insights into the development of a new class of lysosome-targeted therapeutics.

Title: Synaptic alterations induced by amyloid-beta stimulated astrocytes are tau dependant

Authors: *P. CISTERNAS, X. TAYLOR, A. PERKINS, C. LASAGNA-REEVES;
Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Alzheimer's disease (AD) is a neurological disorder exhibiting loss of cognitive functions, molecularly characterized by the overproduction and accumulation of amyloid-beta (Aβ), followed by intraneuronal aggregation of tau. These events induce astrogliosis and leads to extensive neuronal death. Aβ originates in the neuron and its accumulation precedes tau pathology. On the other hand, tau is necessary for Aβ to exert its neurotoxicity and propagates between neurons at synapses, inducing its aggregation. This evidence situates neurons and synapses as central players in the propagation of tauopathy. However, there are no studies addressing in detail the role of astrocytes in these events, being a key component of synapses. Our goal is to understand the astrocyte-neuron axis from an Aβ-tau perspective and evaluate astrocytes as a new cellular player in neurotoxicity. We used an *in vitro* approach to answer this question. We induced astrogliosis in wt and $tau^{-/-}$ astrocytes adding exogenous recombinant Aβ and measured the amount of tau oligomers secreted in the media. We found an increase in tau oligomers in an Aβ concentration-dependent fashion. To evaluate the neuroprotective effects of tau ablation on astrocytes, we co-cultured neurons with Aβ-stimulated wt and $tau^{-/-}$ astrocytes. In these neurons we assessed synaptic organization by immunofluorescence and western blot, quantifying the number positive ((+)) clusters and the amount of synaptic markers synapsin-1 and PS95 respectively. We evaluated the functioning of the synapse by quantifying the number of CamKII-(+) spines through immunofluorescence. We also evaluated the extent of neuronal death by western blot for apoptosis marker caspase-3. Neurons co-cultured with wt-stimulated astrocytes showed a decrease in both (+) clusters and amount of synaptic markers. They also showed a decrease in the number of (+) CamKII spines, and an increase in caspase-3 amount.

These effects were not present on neurons co-cultured with tau$^{-/-}$-stimulated astrocytes. These results show that astrocytic tau oligomers are necessary for Aβ to exert its neurotoxicity, and that removing astrocytic-tau from astrocytes prevents synaptic degeneration and neurotoxicity. Dissecting the mechanism by which Aβ exerts its neurotoxic effect via tau and identifying new cellular interplays of molecular components in AD will contribute to formulating strategies for managing this disease.

Title: Zinc dyshomeostasis contributes to inflammasome formation induced by LPS or OGD exposure in cortical cell culture

Authors: *H.-S. PARK[1], Y. YOON[2], J.-Y. KOH[3];
[1]Asan Inst. For Life Sci., Seoul, Korea, Republic of; [2]Ophthalmology, Asan Med. Ctr., SEOUL, Korea, Republic of; [3]Univ. Ulsan Col. Med., Seoul-City, Korea, Republic of

Abstract: Following acute brain insults such as ischemia and trauma, neurons and astrocytes form inflammasomes. If excessive, thus formed inflammasomes may contribute to the further propagation of brain injury. Since zinc dyshomeostasis is implicated in brain injury as well as inflammation, in the present study, we examined whether zinc dyshomeostasis contributes to inflammasome formation in cultured cortical cells.In mouse cortical cell cultures, exposure to LPS induced inflammasomes, as indicated by increases in the level of NLRP3, ASC, caspase-1 and IL1β by western blot assay and immunocytochemistry. Concurrently, LPS increased levels of free zinc in neurons and astrocytes. Indicating that rises zinc levels play a role in inflammasome formation, the membrane-permeant zinc chelator TPEN blocked the increase in levels of NLRP3 and caspase-1, as well as the release of inflammatory cytokines into the media. Similar changes were observed in OGD in cortical cultures, a cell model for ischemia. First, OGD induced zinc dyshomeostasis and inflammasome formation. Second, modulation of zinc levels altered the extent of inflammasome formation. Finally, we injected LPS in mice and

examined the brain. Inflammasome formation and microglial activation were induced by LPS. In ZnT3 null mice, which have no synaptic zinc in the brain, LPS induced much reduced inflammasome formation. Combined with the finding that LPS treatment acutely reduced the level of synaptic zinc, this result suggests that release of synaptic zinc may play a role in LPS-induced inflammasome formation.The present study showed that zinc dyshomeostasis, partly caused by synaptic zinc release, plays a role in inflammasome formation in neurons and astrocytes induced by LPS and OGD. In light of evidence that inflammasome formation may contribute to the expansion of brain injury in ischemia, understanding the mechanism of zinc dyshomeostasis and its suppression may help reduce inflammation-related secondary brain injury.

Title: Morphological plasticity of astrocytes in the ventral pallidum after heroin self-administration

Authors: *A. KRUYER, P. W. KALIVAS;
Med. Univ. of South Carolina, Charleston, SC

Abstract: GABAergic projections from the nucleus accumbens core (NAcore) to the dorsolateral ventral pallidum (dlVP) are necessary for reinstated cocaine seeking induced by cocaine-associated cues. While the dlVP receives input from both D1 and D2 receptor expressing neuronal subtypes, D2 projections to the dlVP inhibit motivated behavior and exhibit reduced plasticity after chronic cocaine use. Astrocytes are capable of uptake and release of both GABA and glutamate and are therefore capable of modulating synaptic physiology and astrocytes in the NAcore attenuate drug seeking induced by cues. In order to study the contribution of astrocytes to synaptic plasticity in downstream structures, we labeled astrocytes in the dlVP and examined astroglial proximity to D1 or D2 terminals, as well as surface expression of the GABA transporter GAT-3 using confocal microscopy. Astroglial adaptations after extinction from heroin self-administration and in response to cues that predict heroin delivery are presented here along with a discussion of the contribution these adaptations would be expected to have on synaptic plasticity in the dlVP.

Abstract: Astrocytes, the most abundant population of the glial cells, are essential for neuronal survival and functions. Recently, increasing number of studies show that astrocytes are also involved in various neurodegenerative diseases such as Alzheimer's disease, Parkinson's disease, and amyotrophic lateral sclerosis. Recently, the presence of two reactive astrocyte subpopulations was reported: neuroprotective A2 and neurotoxic A1 astrocytes. Increased number of A1 astrocytes are observed in the brains from patients of human neurodegenerative diseases, and A1 astrocytes are getting attention as a novel target for treatment of these diseases. In this study, we established a method to generate A1 astrocytes in vitro using human iPSC-derived astrocytes. The popular method to generate astrocytes from stem cells uses FBS stimulation. However, it has been reported that serum exposure alters the properties and functions of astrocytes in culture. Therefore, all of our experiments were performed under the condition without serum. At first, we stimulated human astrocytes with the A1-inducing condition reported in rodent primary cells. However, we could not recognize the induction of strong neurotoxicity. Then, we examined several conditions to stimulate human astrocytes and evaluated the neurotoxicity. As a result, we found a condition to induce strong neurotoxic A1 phenotype using human astrocytes. The astrocytes stimulated under the condition showed increased A1 maker expression and hypertrophic morphology. These results suggested that the condition inducing A1 astrocytes has species specificity between mouse and human.
The human A1 astrocytes reported here will provide a beneficial tool to develop the new therapeutic agents for neurodegenerative diseases.

Title: Microglia and their role in the pruning of gustatory nerves afferent terminal fields in the mouse NST

Authors: *C. SUN[1], F. KONG[2], D. L. HILL[1];
[1]Psychology, Univ. Virginia, Charlottesville, VA; [2]Binzhou Med. Col., Yantai, China

Abstract: Age-related decreases in terminal field sizes occur in a variety of sensory systems. We found that this also occurs in the developing gustatory system. The terminal fields of the mouse chorda tympani (CT) and greater superficial petrosal (GSP) nerves in the nucleus of the solitary tract (NST) decrease (i.e., "pruned") approximately 2X from postnatal day 20 (P20) to P30. The terminal field size of the IX does not change with age. By contrast, mice born to mothers fed a Na^+-restricted diet only from embryonic day 3 (E3) to E12 show a failure to prune: the terminal fields in adult Na^+-restricted mice resemble those of young, control mice. We identified the Classical Complement Cascade as a potential pruning mechanism in control mice. This cascade involves reciprocal signaling between terminals/synapses (i.e., taste afferents) and the immune system (i.e., microglia). To directly address the role of microglia in gustatory circuit development, we asked if attenuating microglia function in postnatal control mice leads to a failure to prune terminal fields, or conversely, if augmenting microglia function in postnatal E3-E12 Na^+-restricted mice induces pruning. Through daily injections of minocycline from P15-P40 in control mice or eliminating microglia by feeding control mice PLX5622 from P20-P40, the CT and GSP terminal field volumes were 70%-80% greater than their untreated littermates—they failed to prune. Conversely, through injections of macrophage colony stimulating factor (m-csf) every 3 days from P10-P40, the CT and GSP terminal field volumes in E3-E12 Na^+-restricted mice were 40%-60% less than their untreated littermates—pruning was induced. These findings provide direct evidence of the involvement of microglia in the maturation of central gustatory circuits, and highlight the high degree of plasticity in the circuit that provides direct gustatory input to the brain.

Title: Differential phenotypic effects of hemin on murine and human microglial cell lines

Authors: V. BOINPELLY[1], A. ALEMIFAR[1], J. ZHOU[1], R. SHARMA[1], M. SHARMA[1], ***V. SINGH**[2,1];
[1]Neurobio. and Neurobehavior Res. Lab., Midwest Biomed. Res. Fndn., Kansas City, MO;
[2]Neurol., Kansas City VA Med. Ctr., Kansas City, MO

Abstract: Introduction: Dysregulation of iron homeostasis with consequent iron accumulation in the neuropil has been implicated as a major contributor to brain pathology in ageing and neurodegenerative disorders. Microglia serve diverse roles in multiple processes including inflammation, cellular energetics and synaptic pruning. Many groups have shown toxic effects of hemin on microglia with microglial morphology being considered a strong indicator of the functional state of microglia. However, literature review shows wide variations in hemin doses used for studies on murine and human derived microglial cell lines. **Aims:** To study the effects of various concentrations of hemin on morphology of mouse (BV2) and human (HMC3) microglial cell lines. **Methods:** BV2 and HMC3 (ATCC #CRL3304; embryonic microglia, clone 3; Lot # 70006081) were used. After preliminary experiments, hemin was used at 10 to 500 µM concentrations, in line with those previously reported. Light and fluorescence microscopy to assess cell morphological changes, LDH release assay for cytotoxicity, MTT assay for cell proliferation at various time points and RT-qPCR for gene expression were used. **Results:** Light microscopy showed a robust response of HMC3 cells to hemin (10-50 µM) with change in morphology from arborized (resting) to rounded phenotype with retracted processes which is considered to be an activated microglial phenotype. In contrast, BV2 cell morphology altered only at 250 and 500 µM hemin. Immunofluorescence microscopy showed that hemin (50 µM) upregulated the expression of IBA1 protein. RT-qPCR showed increased gene expression of CD40 at 6h and 24h ($P< 0.0214$) and increased expression of CD68 24h ($P<0.0042$) but not at 6h. Increased levels of IBA1, CD40 and CD68 are considered as markers of microglial activation. MTT assay showed that brief treatment (2h) with 50 µM hemin ($P<0.002$) or longer treatment (24h) with 1 µM hemin ($P<0.0001$) caused significant attenuation of HMC3 proliferation. Hemin at 50 µM was cytotoxic within 2h ($P<0.009$) determined by LDH release. This corresponds to results from other studies showing 60-70% human glial cell death by 3-30 µM hemin. **Conclusion:** The dose of hemin required to induce microglial activation and cell death was much lower in HMC3 cell as compared to BV2 cells. Differential dose response of

murine and human microglial cells to hemin significant implications for future research to study the role of microglia in neurodegeneration associated with iron accumulation.

Title: Multiple morphometric assessment of the microglial cell population in the deafferented spinal trigeminal nucleus

Authors: N. GARCÍA-MAGRO[1], ***P. NEGREDO**[1], Y. MARTIN[2], C. AVENDANO[3]; [1]Univ. Autónoma de Madrid, Madrid, Spain; [2]Francisco de Vitoria Univ. CIF – G80480197, Pozuelo de Alarcon, Spain; [3]Univ. Autonoma de Madrid, Fac. Medicina, Madrid, Spain

Abstract: Microglial cells (MC) in primary sensory territories react promptly to deafferentation by peripheral nerve injury by proliferating, migrating, and changing their structure from a 'resting' to a dynamic 'activated' state. This reaction is primarily associated to the phagocytic role of MC in the removal of cellular debris that ensue denervation. Moreover, when injury brings about a persistent painful condition, the activated MC release signaling molecules and modulates the activity of neighboring neurons, playing a significant role in the development and chronification of neuropathic pain. A variety of parameters has been used to characterize immunolabeled MC, most notably their number, cell soma size, length and complexity of processes, and various topological features. However, unbiased measurements of MC populations have proved hard to obtain. In most cases, selected MC in histological sections are reconstructed with digital tracking software (Imaris, Neurolucida), but completeness of cell labeling and unbiased cell sampling is not always insured. Other studies rely on image analysis (skeletonization and/or segmentation with, e.g., Imaris or Fiji), which is unduly sensitive to multisize, high density, and wide-range luminance profiles. In this work we present an efficient multiple stereological approach to get population data of MC on cell number, soma size and average length of processes in a region with different immunolabeling procedures. This analysis was carried out in the infraorbital nerve (IoN)-innervated region of the caudal spinal trigeminal and upper cervical dorsal horn, in control and IoN-transected C57BL/6 mice. Alternate coronal sections were immunostained with rabbit α-Iba1 (Wako, Osaka) followed by either ABC-DAB

processing, or Alexa 488 immunofluorescence. DAB-reacted sections were used for estimating densities of MC and length of processes using the NewCAST stereological software package (Visiopharm, Hørsholm). The same parameters were assessed on stacks of confocal images (acquired at high resolution in a Leica SP5 confocal microscope). The images were analyzed off-line with the help of Corel Draw software. Results showed a remarkable coincidence of data with the two methods, except for a moderate higher yield of fluorescent images. Analysis of both types of sections by two examiners resulted in a better than 96% coincidence. In addition, we are currently examining whether infiltrating macrophages contribute to the increased reactive cell population in the deafferented Sp5C. We believe that this study will help tackle the challenge of understanding the biology of MG in reliable quantitative terms.

[1]Neural Coding, Allen Inst. For Brain Sci., Seattle, WA; [3]Princeton Neurosci. Inst., [2]Princeton Univ., Princeton, NJ; [4]Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Microglia are known for their complex actions in the brain, including homeostasis, synaptic stripping and phagocytosis. A subset, known as satellite microglia, are closely opposed to their host neurons. To better understand interactions of satellite microglia, their hosts, and other neurons in their territory, we used high throughput serial section EM and 3D reconstruction of a 250x150x100 µm volume of mouse (P 36) visual cortex. We examined microglia contacts in the 3D environment containing 38 microglia and 180 neurons in layer 2/3. We focused on fully

segmented microglia, both AXIS (axon initial segmented associated) (Fig.1) and non-axis type, following branches and fine processes to their termination on neuronal somas.
Individual microglia contacted somas of a subset of neurons, both excitatory and inhibitory within their territory, up to 15-20 per cell at distances of 1 to 50 µm from host. Their ramifications varied from long thin or thick branches, to ruffled protrusions and flat disks. The soma contact sizes ranged from 1 µm to 20 µm. Some processes exhibited complex hand or claw like formations, which appeared to be grabbing fine axons close to the soma. The territories of individual microglia ranged from 80 µm to 120 µm. The contacts with neuronal somas were not strictly nearest neighbor, but a subset of neurons inside the territory.
Within processes of individual microglia, there was evidence of phagocytic activity, supported by existence of small vacuoles (250 nm) and complex phagolysosomes (500 nm).
There were remnants of 50 nm synaptic vesicles inside the phagolysosomes, which appeared encapsulated within the cytoplasmic matrix of the process. Other axons looked partially engulfed within processes, but not encapsulated, reflecting trogocytosis rather than phagocytosis. These interactions may reflect fine scale refinement and homeostasis rather than large scale synaptic stripping and remodeling as occurs during development.

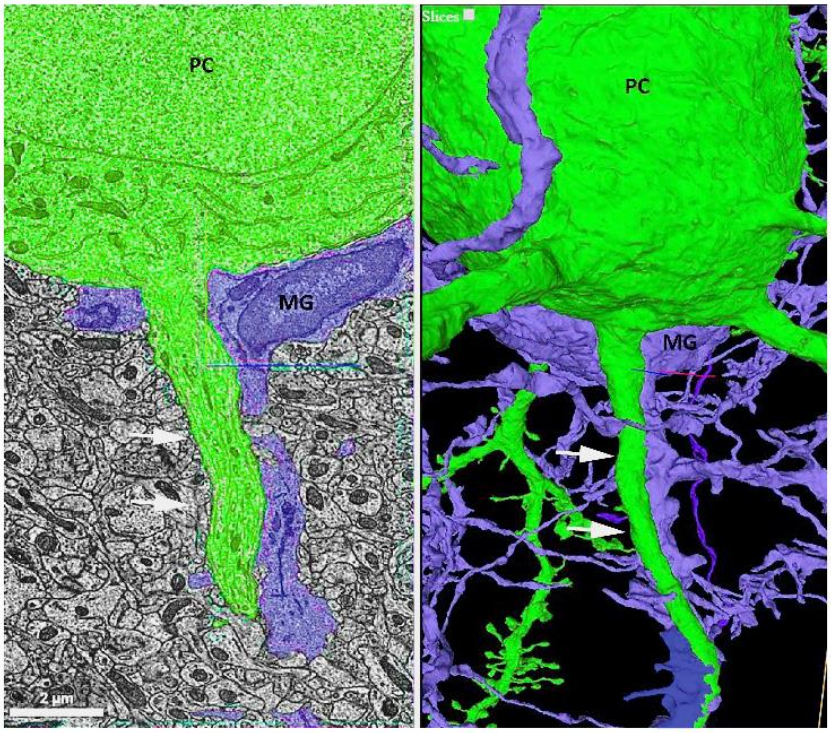

Figure 1. Major processes of satellite microglia (MG) contact axon initial segment (arrows) of host pyramidal cell neuron (PC). Scale bar 2 µm

Title: The atypical cadherin Fat3 is necessary for morphological remodeling in postnatal microglia

Authors: ***T. OKAJIMA**[1], I. KO[2], B. SATO[1], T. CHIBA[1], F. TSURUTA[1];
[1]Grad. Sch. of Life and Envrn. Sci., [2]The Sch. of Life and Envrn. Sci., Univ. of Tsukuba, Tsukuba, Japan

Abstract: Microglia, the resident immune cells in the central nervous systems (CNS), are necessary for the normal development and functions of the healthy brain. It has been shown that the gene expression profile continuously changes from embryonic stages to adulthood, and this variation is closely related to their morphology and functions. Intriguingly, the single cell transcriptome analysis has revealed that microglial heterogeneity peaks during development. Although the morphological changes mediated by gene expression is a key process for the microglial maturation, the mechanisms leading the transition to a mature phenotype are still poorly understood. Here, we reported that one of the atypical cadherin family, Fat3 is a novel candidate that support for the microglial maturation. We found that microglia cell line BV-2 exhibit dynamically extending their protrusions under high nutrient medium condition (HNM). In addition, we observed that the number of BV2 morphological shapes with protrusions are increased compared to normal medium condition. Using DNA microarray analysis, we found that expression of Fat3 is upregulated by culturing BV-2 under HNM condition. Knockdown of Fat3 decreased the microglial protrusions, demonstrating that Fat3 is necessary for inhibiting the retraction of these processes. We also found that Fat3 deficiency perturbed the coordination of microglial maturation through the changes of gene expressions such as CD68 and P2Y12, suggesting that Fat3 is a key factor that controls microglial heterogeneity. Our finding provides evidence that Fat3 expression controls microglial morphogenesis during the developmental stages.

Title: The role of PI3Kg signaling in microglial dynamics and experience-dependent synaptic plasticity

Authors: *B. S. WHITELAW[1], A. K. MAJEWSKA[2];
[1]Univ. of Rochester, Rochester, NY; [2]Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: Microglia are dynamic cells that interact extensively with neurons and glia during development, which allows them to regulate neurogenesis, refine neuronal networks, and influence synaptic plasticity. The same properties that allow microglia to shape the development of the CNS may also lead to neurological disease if not properly regulated. The extracellular signals that mediate microglial dynamics and interactions with neurons are not well understood. Signaling through extracellular nucleotides has emerged as a key mechanism by which microglia sense and interact with their external environment. Specifically, the microglial P2Y12 receptor is crucial for microglial responsiveness to extracellular adenosine tri-phosphate (ATP) and mediates numerous microglial functions, including ATP-dependent chemotaxis, microglia-neuron interactions, and experience-dependent synaptic plasticity. However, little is known about the downstream signaling effectors that mediate these diverse actions of P2Y12. Phosphoinositide-3-kinase gamma (PI3Kg), a lipid kinase activated downstream of Gi-coupled GPCRs such as P2Y12, could translate localized extracellular ATP signals into directed microglial action and serve as a broad effector of P2Y12-dependent functions. Here, we show that PI3Kg mediates the microglial response to laser-induced focal injury in acute slices, which depends on actin polymerization. We are currently investigating other partners in this chemotactic signaling cascade and determining the role of PI3Kg in microglial dynamics and synaptic plasticity *in vivo*.

Title: Newly-born microglial motility and surveillance *in vivo*

Authors: *J. B. ATLAS[1], M. S. MENDES[1], M. MCCALL[2], A. K. MAJEWSKA[1]; [1]Neurosci., Univ. of Rochester Med. Ctr., Rochester, NY; [2]Biostatistics, Univ. of Rochester, Rochester, NY

Abstract: Microglia support the central nervous system (CNS) through their primary role as rapid responders to injury and disease, as well as contributing to neurodevelopment and synaptic plasticity. Microglia maintain these roles and their relative presence in the CNS through a process of self-renewal. Nevertheless, this process of self-renewal and the subsequent maturation of microglia in adulthood remain poorly understood. To investigate these processes, we implemented a pharmacological approach of microglial depletion, enabling us to study the development of these cells as they repopulate the adult mouse brain. Accordingly, PLX5622 was administered in chow to $Cx3Cr1^{GFP/+}$ heterozygous mice starting on postnatal day 60 (P60). PLX5622 inhibits the colony-stimulating factor-1 receptor (CSF-1R), essential for microglial survival and repopulation, effectively eliminating the vast majority of microglia. This approach has been previously shown to yield a robust depletion of microglia in the adult visual cortex, after which microglia rapidly repopulate. In order to study microglial dynamics during maturation, time-lapse 2-photon imaging was conducted in mice via a chronic cranial window during depletion and repopulation. We observed that newly-born microglia rapidly acquire mature characteristics, particularly motility and surveillance, following the cessation of depletion treatment. Further, we observed that maturing microglia exhibit a long-term dysregulation of motility during depletion as they each survey their newly established microenvironment in the brain. These changes in microglial properties are not due to the presence of inflammatory signaling resulting from microglial depletion, as analysis of various cytokine levels as well as astrocytic morphology showed no differences between mice receiving the PLX5622 diet and controls. These findings demonstrate that newly-born microglia quickly resume a dynamic role as they repopulate their environment. Moreover, newly-born microglia may assume a hyper-vigilant state, potentially indicating a distinct level of responsiveness in anticipation of subsequent signs of injury or disease in the brain.

Title: Intra-hippocampal depletion of microglia as a tool to examine the role of microglia in the ontogeny of learning and learning deficits produced by immune challenge

Authors: *M. B. BIELICKI, N. A. HAAS, J. M. SCHWARZ;
Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Early-life immune activation has been linked to male-biased developmental disorders, many of which are associated with learning deficits such as Autism, ADHD, and Schizophrenia. Microglia, the immune cells of the brain, are thought to be involved in the formation of hippocampal circuits important for learning during a critical juvenile period of development. We have found that immune activation with lipopolysaccharide (LPS), on postnatal day (P) 21 in rats, produces hippocampal-dependent learning deficits on P24 in the Context Pre-exposure Facilitation Effect (CPFE) fear-conditioning paradigm. We are currently examining the role of microglia in this learning deficit by selectively depleting microglia in the dorsal hippocampus (dHP) during this unique period of hippocampal development. Clodronate is a drug that, when encapsulated in liposomes, is selectively ingested by and results in the death of phagocytic cells. We infused 3 microliters of liposome-encapsulated clodronate (LEC) into the dHP of male and female rats (Sprague-Dawley) at P16 to determine whether LEC selectively depletes microglia during the critical developmental window during which context learning emerges (P21-24). Immunohistochemical (IHC) staining and RT-PCR were utilized to examine changes in microglia density and gene expression in dHP. We found that LEC decreased the density of microglia and reduced cytokine expression in dHP during this important juvenile period for learning. We then examined how microglial depletion in dHP affected cytokine expression produced by LPS immune activation on P21. Our goal is to determine whether depletion of microglia prevents or potentiates learning deficits in the CPFE paradigm, either alone or following LPS challenge. These experiments will elucidate the role of microglia during a juvenile immune activation and in the development of hippocampal circuits that control learning.

Title: Transcriptional regulation of microglia development and function

Authors: *V. SAHASRABUDDHE, P. KA, H. GHOSH;
NCBS, Bengaluru, India

Abstract: Microglia are the resident macrophages of the central nervous system. They are unique in CNS with regards to their developmental origin and self-renewal capacity. During the course of development, microglia undergo a continual transformation from an immature amoeboid morphology and a phagocytic, proliferative functional state to a mature ramified state with surveillance and synaptic remodeling as their main functions. These functional transformations are also reflected in their distinct, stage-specific transcriptomes. Understanding molecular mechanisms and transcriptional networks that regulate distinct microglial developmental states and enable switching from one functional state to another, is an active area of research.
To this end, we are exploring the role of a basic-helix-loop-helix transcription factor in microglia. Given its known disease relevance and continual expression in mammalian brain, it is important to understand its function in homeostasis. So far, expression and potential roles of this transcription factor remain relatively unexplored, particularly in glial cells. Using inducible CreER-LoxP system for cell- and time- specific deletion of our gene-of-interest in a mouse model, we have identified the role of a novel gene in microglia development. Our preliminary phenotype characterization with microscopy and Fluorescence Activated Cell Sorting (FACS) suggests its functions in maintaining homeostatic microglial frequency and surface profile. We are currently conducting differential gene expression analysis to get mechanistic insights.
Our work could provide new insights about regulation of microglial transcriptional and functional states.

Title: The effects of anti-Alzheimer's drug donepezil on rodent microglial functions

Authors: *Y. MIZOGUCHI, A. MONJI;
Dept. Psychiatry, Fac. Medicine, Saga Univ., Saga, Japan

Abstract: Microglia are resident innate immune cells which release many factors including proinflammatory cytokines or nitric oxide (NO) when they are activated in response to immunological stimuli. Pathophysiology of Alzheimer's disease (AD) is related to the inflammatory responses mediated by microglia. Intracellular Ca^{2+} signaling is important for microglial functions such as release of NO and cytokines. In addition, alteration of intracellular Ca^{2+} signaling underlies the pathophysiology of AD. We had reported that pretreatment with donepezil, an acetylcholinesterase inhibitor, suppressed the TNFα-induced sustained intracellular Ca^{2+} elevation in rodent microglial cells. Using DAF-2 imaging, we also found that pretreatment with donepezil suppressed the production of NO induced by TNFα treatment and the PI3K pathway could be important for the donepezil-induced suppression of NO production in rodent microglial cells. The phagocytosis assay showed that pretreatment with donepezil promoted phagocytic activity of rodent microglial cells through the PI3K pathway. We also tested the effects of donepezil on cellular surface expression of some key proteins such as TREM2 which are important for phagocytosis. These suggest that donepezil could directly modulate the microglial function including phagocytic activity.

Title: Epigenetic modulation of microglia modulates the proinflammatory cytokines expression *in vitro*

Authors: *G. CRUZ[1], L. MONTALVO MARTINEZ[3], L. FUENTES-MERA[4], A. CAMACHO[2];
[1]Univ. Autónoma De Nuevo León, Monterrey, Mexico; [2]Univ. Autónoma De Nuevo León, Nuevo León, Mexico; [3]Biochem. and Mol. Med., Autonomous Univ. of Nuevo León, Ciudad Santa Catarina, Mexico; [4]Univ. Autonoma de Nuevo Leon, Monterrey, Mexico

Abstract: Obesity integrates a low-grade chronic inflammation of peripheral and central organs. It has been shown that toll like receptor - 4 (TLR4) directly modulates inflammation, neurotoxicity and selective behaviors. Microglia in brain efficiently integrates external stimulus contributing to inflammatory responses to disease or injury. Of importance, inflammation might be closely programmed by epigenetic mechanisms during exposure to caloric diets, a pathological mechanism known as "immune priming". Here we tested if pharmacologic epigenetic modulation coordinates pro inflammatory cytokines expression following metabolic stimuli in a microglia *in vitro* model. Microglia cells (SIMA9) were pretreated with inhibitors (5-Azatidine (AZA75nM)) or promoters (S-Adenosylmethionine (SAM 250µM)) of methylation or acetylation promoters (Suberanilohydroxamic acid 500nM) for 24 hours, following by with 100mM palmitic acid or 500ng lipopolysaccharide (LPS) stimulation for 6 hours. Proinflammatory gene expression was analyzed by real time PCR. We found that LPS stimulation promotes IL-6 and IL-1β expression which is positively favored by a methylation or acetylation mechanism induced by SAM or AZA treatment, respectively. By contrast, a decrease in the TNFα expression was found following LPS incubation under methylation or hypomethylation scenarios induced by SAM or AZA, respectively. Of note, microglia hypomethylation induced by the AZA treatment for 6 hours increases the expression of IL-6 following palmitic acid stimulation. Also, palmitic acid increases the IL-1β and IL-1α cytokines following SAHA and AZA, respectively. Finally, TNFα expression decreases during hypo or high methylation induced by SAM or AZA + palmitic acid, whereas acetylation induced by SAHA favoring it at 24 hours. In conclusion, gene expression of IL-6 efficiently responds to changes in methylation, while acetylation positively modulates IL-1β expression, both during LPS and palmitic acid stimulation.

Title: A long non-coding RNA promotes anti-inflammatory microglial polarization and anti-viral defense

Authors: N. W. MATHY[1], P. J. MARTA[2], A. P. KOCHVAR[3], K. M. DRESCHER[1], *A. SHIBATA[3];

Abstract: Upon activation, microglia become polarized towards either the classical M1 pro-inflammatory or M2 anti-inflammatory phenotypes. Increased understanding of the regulatory factors controlling microglial polarization may be critical to modulating inflammation in the CNS. Long non-coding RNAs (lncRNAs) are transcripts that lack protein coding potential and have been shown to regulate gene expression. LncRNAs are likely involved in the regulation of microglial phenotypes and inflammatory processes in the CNS. To identify lncRNAs involved in neuroinflammation, we used microarray analysis. We identified several lncRNAs of interest. LncRNA-25B is significantly upregulated in response to LPS in a microglial cell line compared to IL-4 and unstimulated cells. Validation of the microarray by RT-qPCR showed a 20-fold induction after 6h of LPS stimulation compared to control. Overexpression of lncRNA-25B in microglial cells for 24h significantly reduced levels of M1 markers iNos by 0.5 fold and IL-1β by 0.4 fold and significantly increased M2 markers such as Arginase1 by 4.0 fold as compared to empty vector control (n=3). Knockdown of lncRNA-25B reciprocally decreased levels of Arginase1 by 0.4 fold compared to scrambled siRNA (n=3). To explore the potential *in vivo* significance of lncRNA-25B in neuroinflammation, we utilized a well-established murine model of multiple sclerosis using Theiler's Murine Encephalomyelitis Virus. Analysis of RNA collected from whole brain extracts showed a significant increase in lncRNA-25B (3.1 fold, n=3) in infected animals compared to controls. *In vitro* data demonstrated a significant induction of lncRNA-25B (2.75 fold) after 24h infection of the microglial cell line with 0.1 MOI of TMEV. UV-inactivated virus did not induce lncRNA-25B. Further, overexpression of lncRNA-25B reduced viral burden in microglial cells by 81% compared to the empty vector control, while knockdown of lncRNA-25B significantly increased the viral burden by 2.73 fold compared to a scrambled siRNA. Irf7, a master regulatory of the anti-viral type 1 interferon response, participates in the polarization of microglia. Interestingly, overexpression of lncRNA-25B alone significantly induced expression of Irf7 compared to empty vector control (2.18 fold), while

knockdown of lncRNA-25B significantly decreased Irf7 mRNA levels (0.56 fold). Future experiments will probe the molecular mechanism of Irf7 regulation by lncRNA-25B.

Title: Microglia: Local mRNA translation and synaptic homeostasis

Authors: ***M. VASEK**[1], Y. LIU[1], J. DEAJON-JACKSON[1], J. D. DOUGHERTY[2]; [1]Genet., Washington Univ., Saint Louis, MO; [2]Genet. and Psychiatry, Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: The processes of a single adult microglia make about 300 contacts per hour with neighboring synapses, glia, and vascular endfeet in a healthy brain. During these brief contacts, microglia are receiving signals from neuronal and glial contacts and responding to them through the release of trophic factors and cytokines or by phagocytizing debris, apoptotic cells, and inappropriate synapses. We hypothesize that microglia, like neurons and astrocytes, employ selective mRNA transport and local protein synthesis within their distal processes in order to orchestrate simultaneous and heterogenous responses at each of their many distal loci. Here we show, *in vivo*, that distal murine microglial processes contain mRNAs, ribosomes, and *de novo* protein synthesis through *in situ* hybridization, electron-microscopy, and puromycylation studies, respectively. Additionally, acute blockade of protein synthesis impairs microglial phagocytosis of debris in an *ex vivo* slice model, suggesting that protein synthesis is necessary for this process. We have also identified a list of *in vivo* microglial perisynaptic-enriched mRNAs through translating ribosome affinity purification followed by RNA sequencing on synaptoneurosome fractions of cortical microglia. Microglial mRNA transcripts localized to perisynaptic sites include genes known to modulate synapses, play roles in microglia-neuron signaling, or are known to be dysregulated during CNS inflammation or neurodegenerative disease, including Cathepsin S, Siglec H, classical complement component proteins, and Triggering receptor expressed on myeloid cells 2 (TREM2). Taken together, these data suggest that microglia contain a distinct distal perisynaptic translatome where proteins involved in synaptic remodeling and homeostasis can be locally translated.

Title: The effects of air pollution on microglia cell of the olfactory bulb

Authors: ***N. V. DOS SANTOS**[1], C. R. ARAUJO[1], L. T. JUSTO[1], S. M. O. SHINJO[2], C. D. S. DE ANDRÉ[3], P. H. SALDIVA[1], S. K. N. MARIE[2];
[1]Dept. of Pathology, [2]Dept. of Neurol., Univ. De São Paulo Med. Sch., São Paulo, Brazil; [3]Inst. of Mathematics and Statistics, Univ. De São Paulo, São Paulo, Brazil

Abstract: The complexity of the urban environment makes it very difficult to establish the effects of pollutants on the central nervous system (CNS) of humans. Studies have reported that neurological dysfunctions such dementia may also be associated to air pollution exposure, and have shown that animals, child, and adults living in polluted areas exhibit neuroinflammation and the breakdown of the blood-brain barrier. The airborne fine particulate matter (PM2.5) can enter in the olfactory epithelium, to be transported to the olfactory bulb, and to even reach the olfactory cortex and other brain regions. Recent findings indicate that microglia can detect and respond to inhaled pollutants, indicate that cell may be critical actors responsible for cellular damage caused by pollutants, causing damage, local inflammation and stress responses. While the air pollution effects are not yet understood, suggested causes include microglia activation and neuroinflamation. To investigate this hypothesis fresh samples of olfactory bulb were obtained from 14 individuals from Post Mortem Verification Service of São Paulo city (SVOC) with inclusion criteria: age equal or greater than 18 years, be living in the MASP for at least 3 months, have one close relative to provide reliable and complete information during the interview (previous health conditions, residential address, sociodemographic details, life habits, smoking status, occupation, time of residence in the MASP and time spent commuting) and present no macroscopic alterations of the lungs, brain and in olfactory epithelium. For the anthracosis index it was measured in the pleural surface of the lungs during the autopsy. The pleura surface was photographed and using this images to determine the fraction area of anthracosis. The olfactory bulb were fixed with 4% paraformaldehyde and processed for immunohistochemical assessments. 5 µm-thick paraffin sections were labeled with anti-IBA1 (anti ionized calcium

binding adaptor molecule 1) antibody, as a marker of microglia. Our results show an increased of microglia cell deposition on one side of the olfactory bulb, side that is in contact with the ethmoid bone. We also found a negative correlation ($r = -0.565$, $p = 0.035$) between anthracosis and microglia rate, the trend was maintain in regression models with controlling variables: age, socio-economic index, smoke and gender ($r2=73\%$). This reveals that the microglia role in the neuroinflamation by air pollution is much more complex than previously thought.

Title: Evaluation of GPCR function on glia in the regulation of inflammatory signaling

Authors: *N. L. KOLCH, A. M. SALAZAR, S. M. HERNANDEZ, M. J. KIMMICH, J. W. KINNEY;
Dept. of Brain Hlth., Univ. of Nevada, Las Vegas, Las Vegas, NV

Abstract: Inflammation in the CNS is a necessary response to harmful toxins, brain injury, and other various acute insults. It is not only very critical for the prevention of further damage, but also to promote additional protection to the CNS. Sustained inflammatory signaling (neuroinflammation) in the CNS has been demonstrated to occur in several neurodegenerative disorders, in particular Alzheimer's disease (AD), and promote pathological features of the disease. The activation of microglia serves as initial inflammation response that results in the production of pro-inflammatory cytokines and phagocytosis. However, the chronic activation of microglia imposes negative effects such as enhanced microglial senescence, dysfunctional phagocytosis, and cell death, and further, on several signaling mechanisms in the brain. Given the deleterious effects of neuroinflammation, understanding the mechanisms that relates to the reduction of pro-inflammatory signaling and/or promoting anti-inflammatory signaling is

needed.
Microglia express a number of G-protein coupled receptors (GPCR) that have been implicated in mediating its activation state. In addition, several compounds that bind to these GPCRs have been reported to impact neuroinflammation and other AD-related deficits. However, further description of the underlying mechanisms of these impacts are still needed. In our study, we have investigated the impacts of GPCR ligands on pro- and anti-inflammatory cytokine levels prior to and after the induction of immune response in BV2 cells and glial cultures. We have employed several techniques such as immunoblotting, immunohistochemistry, and Real-Time PCR, to analyze the expression levels of GPCR and cytokines. Our data indicate that activation of specific GPCRs directly impacts expression levels of both pro- and anti-inflammatory signaling cytokines, which can shed light on some important interactions between these signaling molecules.

Abstract: Microglia are the innate immune cells of the brain and display a unique profile of motility and mobility, the study of which can be greatly enhanced by endogenous expression of a fluorescent reporter gene. Iba1 (also called Aif1, Gene ID: 29427) is expressed by all microglia in the brain, some peripheral macrophages and in the testis. The generation of a Sprague-Dawley

rat strain with eGFP expression driven by the Iba1 promoter generated by CRISPR-Cas9 technology was contracted to Applied Stem Cell (Milpitas, CA) by the University of Maryland School of Medicine. Two male and four female homozygous founders were provided and used to generate a colony of transgenics we call the MicGlo Rat. Breeding reveals Mendalian inheritance of the transgene with homozygotes being fully viable but expression of eGFP is variable, the source of which is under investigation. Flow sorting of homogenized brain tissue reliably detects eGFP in Iba1 expressing cells and qPCR of FAC sorted eGFP cells confirmed enrichment of microglia specific genes and a lack of neural and astrocytic genes. Immunohistochemical detection of eGFP and Iba1 in brain tissue sections reveals complete overlap with no extraneous eGFP. Preparation of ex vivo sections indicates eGFP expression is suitable for live-cell imaging in some, but not all, cases. Ongoing characterization of the MicGlo Rat will be reported.

Title: The fractalkine receptor regulates microglia-vascular interactions in the developing brain

Authors: *E. MONDO[1], A. G. KAUTZMAN[1], S. C. BECKER[1], S. L. LIRA[2], D. P. SCHAFER[1];
[1]Neurobio., Univ. of Massachusetts Med. Sch., Worcester, MA; [2]Precision Immunol. Inst., Icahn Sch. of Med., New York, NY

Abstract: Microglia, a resident central nervous system (CNS) macrophage, are born in the yolk sac and take up residence in the CNS embryonically. Once in the brain parenchyma, the precise mechanism regulating the timing of microglial localization to the appropriate brain region remains unknown. Here, we show that microglia are highly associated with vasculature during early postnatal development, a time of active microglial colonization, and these vascular-associated microglia are proliferative and phagocytic. Further, we identify that these microglia-

vascular interactions are dependent on the fractalkine receptor (CX3CR1), but not the canonical CX3CR1 ligand, fractalkine (CX3CL1). Finally, previous work has shown that microglial recruitment to synapses in layer IV of the barrel cortex is critical for the timing of synapse maturation via CX3CR1. We demonstrate that microglia are highly associated with the vasculature during the time in which they are recruited to layer IV synapses of the barrel cortex, and the timing of these microglia-vascular interactions is delayed in CX3CR1 deficient mice. These data provide a new role for CX3CR1 in regulating microglia-vascular interactions in the developing brain, independent of CX3CL1. We further identify an underlying mechanism by which CX3CR1 may regulate the timing of microglial to synapses and subsequent synapse maturation.

Title: Microglial derived innate immune mechanisms governing neural excitability

Authors: *P. A. FEINBERG, S. C. BECKER, D. P. SCHAFER;
Univ. of Massachusetts Med. Sch., WORCESTER, MA

Abstract: During development and continued through adulthood, elaborate mechanisms are used to establish and maintain the appropriate amount and balance of excitation & inhibition (E/I balance). The clinical relevance is exemplified in neuropsychiatric disorders, such as autism spectrum disorders (ASDs), where defects in E/I balance are believed to underlie some of the core clinical features including repetitive behaviors, impaired sociability and increased propensity for seizures. Another emerging feature in ASD are increased inflammatory microglia, a resident macrophage of the central nervous system. Here, we are exploring whether changes in microglial inflammatory state affect E/I balance relevant to neuropsychiatric disease. We show that mice harboring null mutations in interferon regulatory factor 8 ($IRF8^{-/-}$), a transcription factor necessary for modulating inflammatory signaling in microglia, have significantly increased cortical and hippocampal c-Fos, an activity-dependent immediate early gene, in the absence of significant changes in synapse density. In addition, upon administration of

chemoconvulsants there is a profound increase in seizure severity and excitotoxicity. Because IRF8 is highly enriched in microglia in the context of the brain, these data suggest that microglia-derived inflammatory, neuroactive cytokines could be critical to regulate neuronal excitability and E/I balance through synaptic pruning-independent mechanisms. We are now identifying and determining how IRF8-dependent, microglia-derived factors modulate neural excitability, which could have important implications for ASD.

Abstract: Microglia, resident central nervous system macrophages, dynamically survey their neuronal environment and prune away less active synaptic connections. Recent work has

implicated the classical complement cascade in regulating microglia-mediated synapse engulfment and elimination in development and neurodegenerative disease. Here, we identify a complement receptor 3-independent mechanism by which microglia engulf and eliminate synapses in the somatosensory cortex following peripheral sensory deprivation. We find that the microglial chemokine receptor, CX3CR1, is necessary for whisker deprivation-induced microglial engulfment and elimination of structural and functional thalamocortical inputs. Interestingly, microglial recruitment to synapses following whisker removal was relatively unaffected in *Cx3cr1*$^{-/-}$ mice. We then show that the CX3CR1 ligand fractalkine (CX3CL1) is enriched in neurons and phenocopies synapse elimination defects in CX3CR1-deficient mice. To gain more insight into how this signaling is regulated, we performed single-cell RNAseq. These data reveal that, while *Cx3cl1* expression is unchanged, *Adam10*, a gene encoding the metalloprotease known to post-translationally cleave CX3CL1 into a soluble chemokine, is upregulated in the deprived cortex after sensory lesioning. Further, pharmacological inhibition of ADAM10 inhibits microglia-mediated removal of TC-inputs in the deprived cortex. These data support a mechanism by which cleavage of membrane-bound CX3CL1 by ADAM10 is necessary for neuronal signaling to microglia via CX3CR1 to induce synaptic engulfment and elimination following sensory deprivation. Together, we demonstrate that microglia coopt diverse neural-immune signaling mechanisms in different contexts to modify synaptic connectivity and provide new insight into how CX3CR1-CX3CL1 regulates microglial function at synapses in an activity-dependent manner.

Title: Microglia involvement in the development of the human fetal retina

Authors: *K. M. ESCHENBACHER, T. REH, A. SRIDHAR, L. TODD, A. HOSHINO; Biol. Structure, Univ. of Washington, Seattle, WA

Abstract: Studies in model organisms have shown that microglia have important roles in neural development, particularly in formation of synaptic circuitry. We are interested in understanding what aspects of development these cells regulate in the human retina. The timing of microglial migration into the central nervous system (CNS) has been described for several species, but it is currently not known when these cells enter the human retina. One previous study found these cells were present in the retina as early as fetal day (FD) 70. To determine when microglia enter the human retina during development and to better characterize their distribution, we analyzed developing human fetal retina for the presence of microglia from FD45 to FD163 using immunofluorescence and single-cell RNAseq analysis. We found that Iba1-positive microglia are present as early as FD45, and are primarily concentrated in the ganglion cell layer (GCL) and have morphologies typical of microglia in other regions of the CNS. Iba1+ cells are also present in the vitreous and extra-retinal tissues, such as the choroid at this age. Over time, Iba1+ microglia continue to be primarily located in the GCL, with some cells also present in the inner plexiform layer (IPL) and are distributed across the retina. We also used single cell RNAseq to track changes in microglial gene expression across several ages of development and these confirmed their presence prior to FD70. Our results show that microglia are present in the human retina earlier than previously described and may have roles in development at these stages. Finally, we compared the microglia numbers across dissociated cell and 3D fetal retina culture systems, and our results show that microglia numbers are increased in dissociated cultures. Overall, our results highlight the use of the fetal retina *in vitro* system to investigate the roles of microglia in neural development.

Title: Micronuclei released from neurons regulate the microglial activity during brain development

Authors: *S. YANO[1], H. KUBOTANI[2], B. SATO[1], T. CHIBA[1], F. TSURUTA[1];
[1]Grad. Sch. of Life and Envrn. Sci., [2]The Collage of Biol. Sci., Univ. of Tsukuba, Tsukuba, Japan

Abstract: Microglia critically contribute to the conditioning brain environment through phagocytosing cell debris or damaged neurons. In response to the secreting factor from the damaged neurons, microglia transform into active phagocytic forms, migrate, and accumulate around the target cells. When microglia sense exposed eat-me signals, they recognize and eliminate the target cells, contributing to the maintenance of the brain environment. However, the mechanism by which microglia recognize and remove the damaged neurons during development has not been fully understood. Here, we proposed that the micronuclei are secreted from neurons during the developmental stage, followed by regulating microglia activity. Micronuclei are cytosolic chromatin structures that are compartmentalized by a nuclear envelope. We found that micronuclei emerge in migrating neurons and are cleared by the autophagic pathway. Accumulated micronuclei are secreted to the extracellular region when the autophagic pathway is vulnerable in neurons. Besides, released micronuclei from neurons are taken up by the microglia *in vitro*. Using the neuron-specific nuclear membrane labeling mouse, we found that some micronuclei in microglia might originate from the neuronal micronuclei *in vivo*. Moreover, these microglia exhibit amoeboid shape and have thicker primary branches with larger cell bodies. Taken together, these data provide evidence that micronucleus is a novel factor involved in the neuron-microglia communications to maintain the brain environment, and suggest a possibility that they act as a novel microglia-activating factor that underlies the development of the brain.

Title: Vascular and neurogenic rejuvenation in aging mice by modulation of ASM

Authors: *J.-S. BAE[1], S. HAN[1], J. LEE[1], K. PARK[1], I. JUNG[1], H.-J. KIM[3], **H. JIN**[2]; [1]Dept. of Physiology, Sch. of Med., [2]Col. of Vet. Med., Kyungpook Natl. Univ., Daegu, Korea, Republic of; [3]Dept. of Neurology, Col. of Med., Hanyang Univ., Seoul, Korea, Republic of

Abstract: Although many reports have revealed dysfunction of endothelial cells in aging, resulting in blood-brain barrier (BBB) breakdown, the underlying mechanism or mechanisms remain to be explored. Here, we find that acid sphingomyelinase (ASM) is a critical factor for regulating brain endothelial barrier integrity. ASM is increased in brain endothelium and/or plasma of aged humans and aged mice, leading to BBB disruption by increasing caveolae-mediated transcytosis. Genetic inhibition and endothelial-specific knockdown of ASM in mice

ameliorated BBB breakdown and neurocognitive impairment during aging. Using primary mouse brain endothelial cells, we found that ASM regulated the caveolae-cytoskeleton interaction through protein phosphatase 1-mediated ezrin/radixin/moesin (ERM) dephosphorylation and apoptosis. Moreover, mice with conditional ASM overexpression in brain endothelium accelerated significant BBB impairment and neurodegenerative change. Overall, these results reveal a novel role for ASM in the control of neurovascular function in aging, suggesting that ASM may represent a new therapeutic target for anti-aging.

Title: Impaired dynamic of high frequency EEG in insomnia and major depression disorder

Authors: *J. J. JIANG, Sr, H.-C. CHANG, P.-Y. QIU;
Inst. of Neurosci., Shanghai, China

Abstract: Many psychiatric and neurodegenerative diseases including major depression disorder (MDD) are highly comorbid with a range of sleep disorders(1-4). Hyperarousal, which is mainly characterized as the increasing of the beta power density during NREM sleep, is consistent with the subjective feeling of insomnia patients(5-10). Insomnia monkey constructed by knocking out the circadian gene BMAL1(11) displayed Impaired dynamics of high frequency EEG (50-100Hz) which is not payed attention to by traditional sleep analysis. By calculating the relative entropy of the sleep/awake EEG, we found that the beta dynamic of homozygous monkeys is much more sensitive to the change of environment light exposure than that of the heterozygous and wild type ones. The dynamics of beta but not gamma oscillations can be partially rescued by melatonin application. Similar impairment was also found in primary insomnia patients and MDD patients. What's more, the dynamics of beta oscillation is negatively correlated with the HAM-D scores of the MDD patients. And the similar impairment may also exist in schizophrenia and bipolar disorder patients.Thus, we expanded the frequency range of sleep EEG

analysis to high gamma band. And the dynamics of high frequency oscillation of sleep EEG can be used as a stable and reliable marker of sleep quality.

Abstract: Deep convolutional neural networks (CNN) enabled a major leap in image processing tasks including brain imaging analysis. In this work we utilized CNN for age prediction based on T1 MRI. Whereas CNN provides high predictive power, it is often difficult to identify the features that underlie a given prediction, hence these findings are regarded as 'black box' solutions that are difficult to interpret. Discovering which features, or brain structures, contribute most to the prediction of a given model have significant theoretical and translational value. Previous work examined methods to attribute pixel/voxel-wise contribution to the prediction in a single image, resulting in 'explanation maps' (EM) that were found noisy and unreliable. Here, we developed a novel inference framework for combining these maps across subjects, which allow us to achieve a more coherent, reliable measure of the contribution of different anatomical regions to the model's prediction. Our inference scheme was as follows: 1. Compute the derivative of each voxel in a given input volume with respect to the trained model's output. 2. Register different EM to subjects' native anatomical space and then to a common template to enable combining or comparing them 3. Average and threshold these maps to gain a population level EM. We demonstrate this method using CNNs ensemble trained on predicting subjects' age from anatomical T1 brain images of 10,176 healthy subjects, obtained from various open-source datasets. We focus on normal aging considering its widespread effects on brain structure and function. Evaluating the model on an untouched test (n = 588) resulted in MAE of 3.07 years and a correlation between the chronological and predicted age of r=0.98. Using the inference

method, revealed that cavities containing CSF had the highest contribution for age prediction in our model, in line with previous studies reporting a significant age-related volumetric increase. These were followed by subcortical GM, WM, and finally cortical GM. To validate our method, we showed that it substantially increases the replicability of the EM as a function of sample size. Moreover, benchmarking our results against a baseline of VBM studies revealed a significant overlap. Finally, we demonstrate that the model highlights brain regions that had the highest sensitivity to inter-subject volumetric variability. To conclude, we provide a framework for utilizing basic population statistics on a large collection of EM in the context of brain aging. This allows us to highlight specific brain regions exploited by the CNN model and thus provide an insight on the underlying neuroanatomical processes.

Abstract: Brain aging causes gradual synapse loss, slowly influencing cognitive function and explaining why aging is a major risk factor for protein accumulation disorders including Alzheimer's disease (AD). Acceptance is growing for the ideas that exercise and specific foods help avoid poor cognitive aging, noting that a healthy diet is linked to a 40% lower risk for dementia (Sohn, *Nature* 2018 559:S18). Here, plant extracts were tested for their influences on the brain's autophagy-lysosomal pathway and related cathepsin enzymes involved in protein clearance. Particular focus was on cathepsin B (CatB) since it is increased by exercise, and the

CatB enhancement level correlated with improved memory in monkeys and humans (Moon et al. *Cell Metab*. 2016 24:332). Compounds that augment CatB activity were also found to reduce pathogenic proteins and improve synaptic integrity in three AD models (Butler et al. *PLoS ONE* 2011 6:e20501; Farizatto et al. *PLoS ONE* 2017 12:e0182895). Two plant extracts markedly increased the 30-kDa active form of CatB (CatB-30) when applied to hippocampal slice cultures for 3 days. American ginseng (P. quinquefolius) produced a 4-fold increase and the CatB modulation correlated with measures of the synaptic protein GluR1. Bacopa extract (B. monnieri) caused similar CatB-30 enhancement but without correlating with GluR1. Small increases in CatB-30 were produced by Panax ginseng and wild blueberry extracts, and all extracts tested were deemed safe in routine cell viability assays. In a model of age-related protein accumulation stress, American ginseng was the most effective for increasing the autophagy marker LC3-II, reducing protein ubiquitination, and protecting synaptic integrity in brain slices treated with the lysosomal inhibitor chloroquine. Chloroquine is well-known for producing age-related compromise of the autophagy-lysosomal pathway and the typical synaptic decline associated with such stress. These results indicate that select natural products can positively influence a protein clearance pathway in the brain to promote synaptic maintenance. The findings suggest that CatB positive modulation leads to enhanced synaptic health, providing a preventative strategy to preserve proteostasis and reduce the risk of age-related cognitive impairment.

Title: Magnetic resonance diffusion tensor imaging reveals white matter degradation in aging mouse brain

Authors: *M. ZHU[1], C. AKIMANA[2], E. WANG[2], C. K. NG[1];
[1]Dept. of Diagnos. Radiology, [2]Dept. of Biochem. and Mol. Genet., Univ. of Louisville, Louisville, KY

Abstract: Introduction: Magnetic resonance diffusion tensor imaging (DTI) is a widely accepted tool to study microstructural changes of white matter (WM) based on diffusion properties of the WM regions [1]. Previously, several groups have reported age-related WM diffusion changes using various Alzheimer's Disease mouse models [2-4]. However, as of today, there is no DTI

study of WM diffusion in mice during normal aging process, especially those beyond 20 months old. Thus the objective of the current study was to assess progressive diffusion changes during aging in both hippocampal (gray matter) and corpus callosum (white matter) regions.
Methods: Four age groups of C57BL/6 male mice (4, 11, 18, and 27 months, n = 5 for each group) were scanned using a 9.4 T horizontal bore MRI system. A standard spin echo multi-slice (SEMS) imaging sequence was used for DTI acquisition. DTI data were converted and analyzed by DTI quantification software, DTIStudio. Four DTI parameter maps were calculated: fractional anisotropy (FA), mean diffusivity (MD), radial diffusivity, and axial diffusivity. Brain regions examined were restricted to the hippocampus (HC) and corpus callosum (CC).
Results: Significantly decreased fractional anisotropy (FA) was found in CC in mice at 27 months of age compared to 4 months, but not significant in other age groups. Mean diffusivity showed a tendency to decrease over age, however the changes were not shown with statistical significance when comparing various age groups. A decrease in axial diffusivity in CC of as much as 10% was found in the 27 months age group, but not so with in the radial diffusivity determination of the same comparison with any age groups. In contrast, FA measurements was shown to be increased in hippocampal region of mice at 27 months of age, which is not observed by other measurements in all age groups.
Conclusions: Overall, our data suggest that age-dependent changes induce significant axonal damage detected by DTI at extremely old age (27 months), with no detectable myelin damage in white matter as determined by the corpus callosum region in this study. In summary, DTI may be used as an imaging biomarker to monitor age-related degenerative process at extremely old mice, and thus providing the animal model for drug efficacy for intervention of this decline during normal aging as well as added disease related exasperation in the brain.

Title: Aging-induced vascular damage of the mouse thalamus is associated with both motor and memory defects

Authors: *Y. WANG, E. TAYLOR, K. M. KANTAK, B. ZIKOPOULOS, F. SETA, N. HUANG, J. HAMILTON, K. MORGAN;
Boston Univ., Boston, MA

Abstract: Aging is a well-known risk factor underlying cardiovascular disease, but we know little about the effects of aging on the vasculature in the brain. We studied the relationship between aging and vascular damage in the brain of the mouse and correlated vascular changes with behavioral changes in motor and memory-related tasks across age groups. The present study included three age groups: 3 (young), 17-18 (middle-aged) and 24-25 (aged) month old C57B/6J male mice. We used a combination of histology (Prussian Blue staining, n=16) and MRI T2* imaging (n=9) to reveal the relationship between aging and vasculature damage in the brain. We conducted Novel Object Recognition tests (n=16) to test for cognitive defects associated with brain vascular damage. The histological data identified the mouse thalamus especially ventral posteromedial nucleus (VPM) and mediodorsal thalamic nucleus (MD), as the most vulnerable region for aging-induced microbleeds. The functional assay data indicated that vascular defects with aging may lead to motor and memory deficits in the mouse model. The MRI data also indicated the timeline of accumulation of thalamic microbleeds, and significant accumulation was first seen at middle-age, earlier than previously thought. The present study points to vascular disease as a possible factor as early as middle age in causing potentially irreversible brain damage.

Abstract: Aging is a normal process of living beings, characterized by a functional, metabolic and anatomical decline, which is caused by aging and inflicts molecular, cellular and systemic damage and eventually lead to the death of the organism. According to the WHO data, in the next decade, the world population of elderly people will increase from 12% to 22%. One of the factors that reduces the quality of life of this population is cognitive deterioration, which is the most common psychiatric pathology in this stage of life. Therefore, it is critical to have therapeutic tools that reduce cognitive deterioration due to aging. Cerebrolysin (CBL) is a preparation of neuropeptides derived from porcine brains that seems to mimic the action of endogenous neurotrophic factors in terms of brain protection and repair, which is supposed to help the cognitive decline that affects part of the senile population. In the present work, we evaluated the effects of CBL on cognitive performance in aged animals, C57BL6 mice of 18 month of age. Animals were treated with CBL (2 ml/kg i.p.) for 2 months. Then locomotive activity and recognition of novel objects test (NORt) were applied. After the behavioral tests, animals were sacrificed and the number of dendritic spines and types of spines of the pyramidal neurons of the prefrontal cortex, CA1, CA3 and dentate gyrus of the hippocampus and basolateral amygdala were analyzed. In addition, in the same regions, the levels of BDNF, synaptophysin, alpha-synuclein and nNOS were also analyzed. Finally, the number of cells were evaluated by stereology in the same regions. Our results showed that CBL improved the locomotor activity and memory processes in elderly animals. In addition, CBL also increased the BDNF and synaptophysin levels with higher numbers of cells in studied regions. In conclusion, our results suggest that CBL may be a good therapeutic tool in the treatment of cognitive decline of the senile population, because better cognition improves the quality of the life of the senile population (Supported by: CONACyT grants, No. 634581 to LAH and No. 252808 to GF).

Title: A novel model to evaluate *Drosophila* cognitive status

Authors: *C.-C. YU[1], I.-Y. CHEN[2], F.-C. CHANG[2], C.-F. KAO[1,2,3];
[1]Inst. of Mol. Med. and Biochem. Engin., [2]Dept. of Biol. Sci. and Technol., [3]Ctr. For Intelligent Drug Systems and Smart Bio-devices (IDS2B), Natl. Chiao Tung Univ., Hsinchu, Taiwan

Abstract: Earlier studies in *Drosophila* indicate the fruit flies are equipped with sophisticated mechanisms to sense and evaluate the caloric content of various sugars. When presenting the starved fruit flies with two distinct sugar types, the sugar type with higher nutrient value (e.g. the nutritious sucrose vs. non-nutritious arabinose) is the preferred food source. Most importantly, the capability to read the nutrient value of sugars is independent of taste sensation, further suggesting the involvement of post-ingestion nutrient-sensing pathways, including the internal sensors and the computing neuronal circuits, which finalize the feeding decision based on the innate preference to nutritious and palatable food source. The entire computing processes of feeding decision in *Drosophila* can therefore be considered as a resolution of cognitive function. In this project, we exploited a distinct kind of behavior assay that monitors the changes of normal feeding decisions to determine the cognitive status of *Drosophila*. We first re-characterized the capability of *Drosophila* to read the caloric contents between distinct sugar types. Next, as an assessment of cognitive function, we also demonstrated the potential changes of feeding preference in animals with distinct conditions, such as animals with altered life expectancy and animals with neurodegenerative symptoms. Our results suggest the fruit flies lose the ability to discriminate nutritious substances when they pass certain chronological ages, which phenotype may represent the aging-related decline of cognitive functions. Moreover, while the feeding decision toward nutritious sugars is well retained in the genetically manipulated long-lived *Drosophila* at the old age, the disease flies quickly lose their ability to learn and evaluate the nutrient value of sugars along the disease progression. Together, our findings provide functional links between the accurate feeding decision and the cognitive status of *Drosophila*.

Title: The effect of lack of Annexin A1 on hypothalamic pituitary adrenal axis in a model of CORT-induced depressive like behaviour and the potential interaction with hippocampal memory

Authors: *R. CRUPI[1], A. PERITORE[1], E. GUGLIANDOLO[2], R. SIRACUSA[2], D. IMPELLIZZERI[2], R. FUSCO[2], M. CORDARO[2], R. D'AMICO[2], S. CUZZOCREA[2], R. DI

PAOLA[2];
[1]Univ. of Messina, Messina, Italy; [2]Univ. of Messina, MESSINA, Italy

Abstract: The activity of the hypothalamic-pituitary-adrenal axis (HPA) is commonly disregulated in stress-related psychiatric disorders. It was demonstrated that, in a family of sensor receptor of the immune system know as Formyl peptide receptors (FPR) specificly deficient mice for the Formyl peptide receptor 1 (FPR1) and Formyl peptide receptor 2/3 (FPR2/3), show a distinct profile of behaviour characterised by reduced anxiety. Annexin 1 (ANXA1), an endogenous ligand of FPR, is a member of the family of phospholipids and calcium annexes proteins with a well defined role in the delayed early inhibitory feedback of Glucocorticoids (GC) in the pituitary gland. The aim of the present study was first to evaluate the potential role of ANXA1 as a cellular mediator of behavioral disorders in a model of corticosterone (CORT) induced depression and, subsequently, the possible correlation between the depressive state and impairment of hippocampal memory. To induce the depression model, WT,ANXA1 KO and FPR2/3 KO mice, were exposed to CORT for 28 days. Behavioral tests were performed to test anxiety, depression like behaviour, anhedonia and recognition memory. ANXA1 KO mice showed an improvement in depression-like behavior compared to FPR2/3 KO and WT, after CORT administration. Several hippocampal marker for memory and depression, as well as the neurotrophic factors of BDNF and GDNF, pERK elevel and SERT expression, were analised to investigate the role of ANXA1 in the mechanism of action of GCs. In conclusion, we can state that the absence of the ANXA1 protein, even more than the absence of its main receptor (FPR 2/3), is is fundamental to the inhibitory action of GC on HPA axis, but also maintaining hippocampal homeostasis by preventing neuronal damage of chronic condition of depression.

Title: Longitudinal assessment of dynamic brain networks and cognition in healthy women

Authors: *A. P. GEORGOPOULOS[1,2], L. M. JAMES[3,2], S. DOLAN[2];
[1]Neurosci., Univ. Minnesota, Minneapolis, MN; [2]Brain Sci. Ctr., Minneapolis Hlth. Care Syst., Minneapolis, MN; [3]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: We assessed longitudinally cognitive and brain function in 87 healthy women. Participants were enrolled at age 33-96 y, when they had a Montreal Cognitive Assessment (MoCA) score of 25 or greater. Participants were assessed annually (up to 7 years currently) for their cognitive function (MoCA) and for their brain function using magnetoencephalography (MEG). Participants underwent a 1-min resting-state MEG scan using a 248 axial gradiometer system (Magnes 3600WH, 4-D Neuroimaging, San Diego, CA) at a sampling rate of 1017 Hz (i.e. every 0.983 ms). Zero-lag cross-correlations were obtained between all pairs (N = 30628) of prewhitened MEG time series (Synchronous Neural Interactions, SNI [1]). In a recent study [2] we showed that the standard deviation (SD) of the absolute value of SNIs increases with age. In a separate presentation at this meeting [3] we report that SD covaries negatively with MoCA score, such that higher SD values are associated with lower MoCA score. Here we investigated possible SD-MoCA covariation over the period of longitudinal testing at additional 50 lags (~50 ms) of the Cross-Correlation Function (CCF). We found that a negative correlation between SD and MoCA that was stronger and highly statistically significant at CCF lags greater than 8 ms. This indicates that the dynamic brain mechanisms underlying cognitive function operate as a lagged neural network [4], a reasonable suggestion, given that all neural interactions are carried out through fiber tracts with specific, non-trivial conduction velocities. From this perspective, the longer lags above indicate the intimate involvement in cognitive function of relatively slowly-conducting fiber tracts, on the average. Given the diversity of axonal thickness in the cortex (which determines conduction velocity) and its dependence on the origin and the destination of the projection [4], a detailed topographic analysis of the lags of specific interactions (e.g. callosal vs. intrahemispheric) at which significant relations to the MoCA score occur would provide new insights in understanding neural-cognitive processing. Title: Multiphoton imaging reveals that a microglial response to microinjury is elevated in hippocampal white matter and inhibited by glucocorticoid

Authors: J. C. GANT, O. THIBAULT, ***E. M. BLALOCK**;
Univ. Kentucky Coll Med., Lexington, KY

Abstract: Quantifying whether microglial show an 'aggressive', a 'normal', or a 'quiescent' response to brain damage is an area of some debate because microglial responses are highly dependent on their environment. Dynamic responses can be measured *in vitro*, but the *in vitro* preparation itself alters microglial behavior. Post-mortem measures capture the native environment, but lose dynamic responses. Finally, damage magnitude matters. Many experimental models involve large injuries, while many conditions (e.g., microbleeds) induce microscopic changes. Here, we addressed some of these issues by developing a 'microglial response to microinjury' (MRMI) assay. This method images living microglia in an *ex vivo* environment that closely matches microglial native environment, induces a microscopic injury, and quantifies response. CX3cr1-GFP mouse (produce green fluorescent protein in microglia/ macrophages) hippocampal slices are imaged and a small 30x20 um cylindrical avulsion (microinjury) is created. The resulting MRMI is rapid (5-20 min), quantifiable, elevated in white matter, and inhibited by glucocorticoid, consistent with prior reports. Thus, this method appears appropriate for not only assessing the microglial response to microinjury in the context of various disease states, but also in the context of dissecting out the pharmacology of its facilitation or inhibition by different agents.

Title: The effect of cognitive function, subjective cognitive decline, and vascular risk on white matter hyperintensity change in older adults

Authors: *Y. JUNG, R. P. VIVIANO, J. S. DAMOISEAUX;
Wayne State Univ., Detroit, MI

Abstract: White matter hyperintensities (WMH), a manifestation of cerebral small vessel disease often observed in magnetic resonance imaging (MRI) brain scans of older adults, have been associated with cognitive function, subjective cognitive decline (SCD), and vascular risks. Recent studies showed that the WMH in different white matter tracts are uniquely associated with different domains of cognition, but it is still unclear how longitudinal changes of tract-specific WMH are associated with cognitive function, SCD, and vascular risks. A total of 91 healthy late middle-aged to older adults (m: 57, f: 34; age = 67.8±8.3) recruited in two locations (US and Netherlands) participated in this study. Out of the 91 participants, 69 returned for a follow-up session after 18 months. We assessed WMH volume of the anterior thalamic radiation (ATR), forceps minor (Fmin), superior longitudinal fasciculus (SLF), and whole brain on FLAIR MRI images using the lesion prediction algorithm in LST toolbox with manual correction. We measured cognitive function using the Trail Making Test, Digit Symbol-Coding test, and Stroop task, and SCD using the Frequency of forgetting (FoF) scale of the Memory Functioning Questionnaire. As an indicator of vascular risks, we used mean arterial pressure (MAP). To examine the association between WMH volume, cognition, FoF, and MAP we performed linear regression. To examine the association between longitudinal WMH change and cognition, FoF, and MAP we ran linear mixed models. Test site, age, and gender were included as covariates in all models. Lower TMT-A score, a measure of processing speed, was associated with higher WMH volume in the ATR (p = .003), Fmin (p = .003), and whole brain (p = .016). Greater FoF was associated with higher WMH volume in the whole brain (p = 0.004) and ATR (p < 0.001). Higher MAP was related to higher WMH volume in the whole brain (p = .028) and SLF (p = .003). WMH volume of the ATR, Fmin, and whole brain increased over time (all ps < .001). Neither tract-specific nor whole brain WMH volume change was predicted by baseline SCD or cognitive function. However, higher baseline MAP predicted a steeper increase of whole brain WMH (p = .028) over time. Our cross-sectional analyses revealed that cognitive performance, SCD, and MAP were associated with WMH burden, which is consistent with previous findings. However, our longitudinal analyses found that only higher baseline MAP was predictive of WMH increase, and that this effect was whole brain rather than tract-specific.

Title: Age-associated impairments in trace eyeblink conditioning occur earlier in the lifespan than previously suspected

Authors: *R. WEST, P. MAXHAM, L. THOMPSON;
Behavioral and Brain Sci., Univ. of Texas at Dallas, Richardson, TX

Abstract: Eyeblink conditioning (EBC) is a simple and well-established model to assess learning in aging across species. Intact hippocampal function is required for successful acquisition of the trace EBC paradigm. While impairments in trace EBC are well established in advanced age groups (greater than 65 yr of age), the purpose of the current study was to cross-sectionally examine the onset and severity of age-associated learning impairments in acquisition of trace conditioning in individuals aged 19 to 88 yr.
79 healthy individuals, between the ages of 19 and 88 yr (31 male, 48 female) were recruited to perform EBC tasks, and divided by deciles of age (i.e. 30-39, 40-49 yr). All subjects had normal hearing. Sixty trials each were presented using the trace 500 conditioning paradigm. An airpuff (150 ms, 3 psi) applied to the left cornea served as the unconditioned stimulus (US), and a tone (100 ms) served as the conditioned stimulus (CS), separated by a 500 ms interstimulus trace interval. An infra-red detection system was used to blindly score performance on each trial, and inter-trial intervals were pseudorandomly varied. Mean percent adaptive conditioned responses (ADT-CRs; i.e. appropriately timed eyeblinks to shield the cornea from the airpuff) served as a primary measure of task acquisition. Percent of ADT-CRs were compared within and between age groups using one-way ANOVA and Tukey's post-hoc comparisons.
No significant sex-differences were found in average percent of ADT-CRs comparing between males and females across age groups ($p=0.64$). 20- and 30-year-olds exhibited similar high percentages of ADT-CR acquisition ($p=0.8$) and performed significantly better than older cohorts ($p=0.01$). Interestingly, a functionally significant deficit in trace EBC task acquisition was observed in the age decade beginning in the 40s. In further analyses of 40 yr old and older individuals, additional criteria were assessed, including trials-to-40% CRs. After 40 yr of age, impairments in acquisition were observed early in training (before trial 25) in growing subpopulations compared to younger subjects, suggesting a significant timing-dependent effect on overall task acquisition. Potential clinical implications are discussed.

Title: Identification of cell type proportion changes in bulk brain expression profiles

Authors: *O. MANCARCI[1], L. TOKER[2], S. TRIPATHY[3], P. PAVLIDIS[4];
[1]Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada; [2]Universty of Bergen, Bergen, Norway; [3]Psychiatry, Univ. of Toronto, Toronto, ON, Canada; [4]Psychiatry, Univ. British Columbia, Vancouver, BC, Canada

Abstract: Differential expression in whole tissue expression profiles are often used to study neurological disorders. In such studies, differential expression can be a result of a uniform change in gene expression of all cell types, gene expression changes in specific cell types, or changes in cell type proportion. In this study we use our previously published method for detecting cell type proportion changes in bulk tissue brain expression profiles. Our method summarizes gene expression of cell type markers to get an estimate of cell type proportion changes. We use this method to analyze ~800 mouse and human brain bulk tissue datasets from the literature to identify conditions cause changes in cell type proportions. We also expand this method to include robust quality metrics to reliably separate gene regulation from changes in cell type proportions and identify false positive findings. We identify known cell type proportion changes in neurodegeneretive disorders along with novel changes under a wide variety of conditions ranging from neurological disorders in humans to mouse models.

Title: Neuroprotective effects of kinin B2 receptor in organotypic hippocampal cultures of middle aged mice

Authors: *M. TORICELLI[1], S. EVANGELISTA[1], L. OLIVEIRA[1], T. VIEL[2], H. BUCK[1]; [1]Faculdade De Ciências Médicas Da Santa Casa De São, São Paulo, Brazil; [2]Univ. de São Paulo, São Paulo, Brazil

Abstract: Aging is a multifactorial phenomenon that results in several changes at cellular and molecular levels and is considered the main risk factor for some neurodegenerative diseases. Several evidences show the participation of the kallikrein-kinin system in neurodegeneration and this system has been associated with inflammation and immunogenic responses in the central and peripheral systems by the activation of the B1 and B2 receptors. Previous work by our group showed that bradykinin and the B2 receptor played a possible role in neuroprotection. Therefore, the objective of this study was to evaluate the participation of B2 receptors in cell viability, neuroinflammatory response and neuroplasticity in organotypic hippocampal cultures of 6 and 12 month old mice. It was observed that activation of the B2 receptor by bradykinin decreased the inflammatory response and increased plasticity in 12 months old slices. Conversely, there was an increase in the inflammatory response and a decrease in neural plasticity in the six-months old slices. In both ages an increase in cell viability was observed. Our data indicated that the kallikrein kinins system only plays a neuroprotective role in middle-aged animals, that is, in a context in which the aging process and neuroinflammation is already established.

Title: An app a day keeps the doctor informed: Development of smart-device applications as early diagnostic tools to detect hippocampal pathology in adolescent binge drinkers

Authors: A. GALUSHA, A. M. PREUSS, *P. A. BLANKENSHIP; Lewis Univ., Romeoville, IL

Abstract: The ability to effectively navigate through one’s environment is a critical facet in everyday life. Maintaining spatial orientation involves utilizing a variety of spatial cues. In particular, spatial information can be divided into two main types: environmental cues, which include any visual, auditory, or olfactory cues, or self-movement cues, which include

proprioception, vestibular information, and optic flow. The structures that support spatial processing, such as the hippocampus, are especially vulnerable to environmental factors, like alcohol, during the adolescent critical period of development. For example, previous work has shown that a binge drinking pattern of alcohol consumption during adolescence is associated with structural and functional changes in the hippocampus. More recently, self-reports of binge drinking have been associated with impaired performance on hippocampal-dependent spatial tasks. The current study sought to replicate these findings and extend this work by implementing a novel application-based analogue to previously developed spatial tasks. University undergraduates identified as binge drinkers or non-binge drinkers were subsequently tested on an application analogue of the previously developed manipulatory-scale dead reckoning task (DRT). The accuracy of the return trip was examined using a number of measures, including path circuity as well as heading and distance error. While data collection is ongoing, preliminary data suggests an impaired homing accuracy, associated with higher heading and distance errors, in self-reported binge drinkers. These results provide the foundation for developing diagnostic tools for detecting hippocampal pathology.

Title: The effects of fragmentation of the daily sleep-wake rhythm on amyloid-beta levels and neuroinflammation in the 3X Tg-AD mouse model of Alzheimer's disease

Authors: *M. J. DUNCAN[1], E. ASKAROV[1], A. BAKER[1], L. BEECHEM[1], B. D. GILLIS[2], F. SALISBURY[3], L. E. GUERRIERO[3], B. F. O'HARA[3], A. D. BACHSTETTER[1], M. P. MURPHY[2];
[1]Dept. of Neurosci., [2]Dept. of Biochem., Univ. of Kentucky Med. Sch., Lexington, KY; [3]Dept. of Biol., Univ. of Kentucky, Lexington, KY

Abstract: In older humans, fragmentation of the daily sleep-wake rhythm is correlated with the risk of development of Alzheimer’s disease (AD). While sleep deprivation for many consecutive hours increases brain amyloid-beta (Aβ) levels and neuroinflammation, the effects of chronic fragmentation of the daily sleep-wake rhythm are unknown. The present study tested the hypothesis that chronic fragmentation of the daily sleep-wake rhythm stimulates brain amyloid-beta (Aβ) levels and neuroinflammation in the 3XTg-AD mouse model of AD. Female 3XTg-

AD mice (8 months old) were subjected to chronic sleep fragmentation (SF; N=8) or undisturbed sleep (SF; N=8) for 4 weeks. SF consisted of 4 daily sleep disruptions (1 h ea) evenly distributed during the light phase. During SF, mice were kept awake with novel objects and gently simulation with a paintbrush. Mice were individually housed in PiezoSleep cages (Signal Solutions LLC) for sleep recordings during the 1rst and 4th weeks of the study and group-housed in regular cages during the 2nd and 3rd weeks. Compared to US mice, SF mice exhibited lower levels of light phase sleep (17.7% reduction, $P<0.001$) and higher levels of dark phase sleep (14.8% increase, $P<0.05$), with an overall decrease in total 24-h sleep (3.5% reduction, $P<0.001$). After 4 weeks, the mice were euthanized under anesthesia and hippocampal tissue was harvested and stored at -80 C. One hippocampal half was extracted in standard RIPA buffer and Aβ was measured by ELISA (Invitrogen $A\beta_{40}$, KHB3841, or $A\beta_{42}$, KHB3544). Aβ levels were higher after SF vs US (Aβ40: (1.96 ± 0.10 vs 1.63 ± 0.10, $p<0.05$ and Aβ42: 1.48 ± 0.20 vs 0.90 ± 0.10, $p<0.01$). mRNA was isolated from the other hippocampal half and TaqMan low-density gene expression array was conducted for markers of microglial activation (ctsd, cst7, and clec7a) and proinflammatory cytokines (TNFα, IL6, and IL-1β). The composite Z-scores for microglial activation markers and proinflammatory cytokines were significantly higher ($P<0.05$) in the SF than the US hippocampal tissue. These findings demonstrate a protocol for fragmenting the daily sleep-wake rhythm in 3X-Tg AD mice. The results support the hypothesis by revealing that sleep fragmentation for 4 weeks increases hippocampal levels of Aβ40 & Aβ42 and expression of microglial activation markers and proinflammatory cytokines. These studies support the concept that improving sleep consolidation in individuals at risk for AD may be beneficial for slowing the onset or progression of this disease, but more studies are needed to further investigate how sleep fragmentation affects neuropathology in both male and female AD mice.

Title: Effects of chronic sleep restriction on amyloid beta and cognition in C57BL/6 mice

Authors: K. N. BRICE[1], C. W. HAGEN[2], J. L. PETERMAN[1], P. N. BRADEN[1], J. W. FIGG[2], M. J. CHUMLEY[2], G. W. BOEHM[1];
[1]Psychology, [2]Biol., Texas Christian Univ., Fort Worth, TX

Abstract: Alzheimer's Disease (AD) is the 6th leading cause of death in the US. More than 44 million people worldwide, including 5.7 million Americans, are living with this neurodegenerative disease, and those numbers continue to climb. One rarely discussed feature of AD is a disrupted sleep/wake cycle. Sleep is essential for many psychological and biological functions, and a reported 35.3% of adults get less than the minimum 7 hours of sleep per night recommended by the National Sleep Foundation. Moreover, evidence suggests a bidirectional relationship between sleep loss and AD. Previous research indicates that disruptions in sleep often precede symptoms of AD such as cognitive impairments and memory loss. Additionally, sleep loss has been associated with increased amyloid-beta and proinflammatory cytokines in the brain. Prolonged elevations in these proinflammatory cytokines are associated with enhanced amyloid beta production, which accelerates the formation of oligomers and plaques that disrupt synaptic function. The aim of the present study was to elucidate the interaction between chronic sleep restriction, inflammation, and AD pathology in C57BL/6 mice. Our lab has previously demonstrated that mice administered 7 consecutive days of LPS, a bacterial mimetic, exhibit increases in amyloid beta and proinflammatory cytokines in the brain, as well as cognitive deficits. Furthermore, research from our lab has shown that stress can exacerbate the effects of LPS. Adult C57BL/6 mice were subjected to the multiple platform method of sleep disruption for 10 hours per day for 6 weeks. After receiving 7 consecutive days of either LPS or saline injections, animals were subjected to contextual fear conditioning to assess cognitive functioning, after which hippocampal amyloid beta levels were quantified. Although LPS administration failed to increase amyloid beta or cognitive deficits in contextual fear conditioning, chronic sleep restriction itself was associated with deficits in contextual fear acquisition and increased levels of hippocampal amyloid beta compared to control groups. These findings suggest that chronic sleep loss may have a detrimental effect upon cognitive function through increasing amyloid beta levels in the hippocampus, even in wild-type mice. Given the large percentage of adults reporting less than the minimum recommended amount of sleep per night, the alarming climb in rates of AD, and a growing body of work suggesting a link between sleep loss and AD, investigating the detrimental effects of sleep restriction is essential.

Title: Selective activation of the thalamic reticular nucleus restores sleep patterns but does not affect epileptic activity in Alzheimer's disease mice

Authors: *R. JAGIRDAR[1], F. M. SEIBT[2], M. BEIERLEIN[2], J. CHIN[1];
[1]Memory and Brain Res. Center, Dept. of Neurosci., Baylor Col. of Med., Houston, TX; [2]Dept. of Neurobio. and Anat., McGovern Med. Sch. at UTHealth, Houston, TX

Abstract: Alzheimer's disease (AD) is associated with memory impairment, cognitive dysfunction, sleep fragmentation and increased incidences of unprovoked seizures, both nonconvulsive and convulsive. These seemingly disparate symptoms are observed also in transgenic mouse models of AD and have in common the fact that they can be regulated by activity in the corticothalamic network. The thalamic reticular nucleus (TRN) is a major control nucleus in this network and is implicated in spike-wave discharges and seizures in absence seizure models. Since we previously found that activity in TRN is reduced in transgenic mice that express human amyloid precursor protein (APP), a well-characterized mouse model to study AD, we investigated whether restoring activity in the TRN affects the incidence of epileptic spikes or seizures, sleep architecture, or accumulation of Abeta, which has been shown to be modulated by sleep. Selective activation of TRN in APP mice was achieved using viral expression of DREADDs. Activation of the excitatory DREADD hM3Dq using CNO was confirmed both *in vivo* by measuring immunoreactivity of a marker of neuronal activity and *in vitro* using thalamic slices. In APP mice expressing hM3Dq (APP-hM3Dq), acute activation of TRN with a single dose of CNO increased slow wave sleep and reduced sleep fragmentation, with no effect on the frequency or duration of seizures. Chronic treatment of APP-hM3Dq mice with CNO for 30 days reduced sleep fragmentation for the duration of treatment and decreased Aβ plaque accumulation, relative to APP-hM3Dq treated with saline for 30 days. Chronic activation of TRN also had no obvious effects on seizures. These results indicate that selective activation of the TRN is sufficient to restore sleep maintenance and slow wave sleep, with no obvious effects on seizures.

Title: Seizure-induced ΔFosB binds target genes in both disease-dependent and independent manners

Authors: *G. S. STEPHENS[1], Y. ZHENG[1], C.-H. FU[1], J. J. BOTTERILL[2], J. J. LAFRANCOIS[2], H. SCHARFMAN[2,3], Y. LIU[4], J. CHIN[1];

Abstract: The incidence of seizures is increased in Alzheimer's disease (AD), and treatment of AD patients with the antiepileptic levetiracetam improves cognition. We reported that one mechanism by which seizures exert long-lasting effects on cognition is through expression of ΔFosB, a transcription factor with an unusually long half-life. Even infrequent seizures in transgenic mice expressing human amyloid precursor protein (APP) lead to persistent increases in ΔFosB in the hippocampus, similar to what we observed in patients with either AD or temporal lobe epilepsy. ΔFosB epigenetically regulates expression of target genes; however, whether ΔFosB targets the same genes when induced by seizures in different neurological conditions is not clear. We performed ChIP-sequencing to assess the landscape of ΔFosB target genes in APP transgenic mice versus pilocarpine-treated wildtype mice (Pilo mice), a pharmacological model of epilepsy. These mouse models allowed us to compare AD, in which seizures occur in the context of high levels of amyloid beta, and epilepsy, in which recurrent seizures occur in the absence of neurodegenerative conditions. Network profiling of genes bound by ΔFosB in APP mice, Pilo mice, and respective control mice revealed that regulatory programs modulated by ΔFosB in the hippocampus are expanded and diversified in APP and Pilo mice (vs respective controls). Clustering analyses demonstrated that functions related to neuronal development and neurogenesis were consistently represented in ΔFosB target gene networks in all groups of mice (APP mice and nontransgenic controls, Pilo mice and saline controls). However, in both APP mice and Pilo mice, but not their controls, ΔFosB target pathways also included domains of neuronal excitability and plasticity, and glutamatergic signaling. Notably, there were also functional domains that were represented only in APP mice or only in Pilo mice. Our findings indicate that seizure-induced ΔFosB targets some genes regardless of disease

context, but targets others in a disease context-specific manner. Understanding what factors underlie these differences, such as chromatin accessibility or abundance of transcriptional binding partners, could reveal novel insights into the control of gene expression in neurological disorders.

Title: Increased excitability of somatostatin-containing cortical interneurons in presymptomatic AD mice

Authors: H. HU[1], ***A. AGMON**[2];
[1]Dept. of Neurosci., West virginia Univ. Sch. of Med., Morgantown, WV; [2]Dept. of Neurosci., West Virginia Univ. Sch. of Med., Morgantown, WV

Abstract: Alzheimer’s disease (AD) is a devastating, progressive dementia with no known prevention or cure. All efforts to-date to reverse or arrest disease progression have failed, possibly because they were applied too late in the disease process, when irreversible damage to cortical networks has already occurred. Thus, a better understanding of the earliest, presymptomatic stages of the disease is critically needed if we are to develop successful interventions. A consistent finding in human AD patients, postmortem human AD tissue and mouse models of AD, is specific loss of somatostatin-containing (SOM) inhibitory interneurons and synapses in the cerebral cortex. We hypothesized that the normal functioning of SOM interneurons is disrupted very early in the progression of AD, well before the neurons die and before any of the histological or behavioral manifestations of the disease are evident, and that this dysfunction may play a facilitatory role in disease progression. If so, then early interventions which prevent SOM interneuron dysfunction would be highly promising as anti-AD therapies. Using whole-cell recordings in cortical brain slices, we characterized the electrophysiological properties of SOM interneurons in TgCRND8 mice, a transgenic mouse model which expresses a human amyloid precursor protein with familial AD mutations. Brain slices were prepared from 2-4 week old animals, before any pathological or behavioral changes are evident in this mouse model. To identify SOM interneurons, transgenic mice were crossed with mice expressing GFP

in specific populations of SOM interneurons. We compared electrophysiological parameters of SOM interneurons from transgenic animals to those from wildtype littermates, and performed the same comparison for fast-spiking (FS) cells, a separate interneuron subclass. Comparisons were done while blinded to genotype. In SOM, but not in FS interneurons, we found a ~50% decrease in the minimal current level generating an action potential (rheobase). This implies a doubling of the intrinsic excitability of these interneurons, with a possible outcome of increased Ca^{2+} influx, potentially leading to excitotoxic cell death. To our knowledge this is the first report of profound changes in the intrinsic physiology of inhibitory interneurons in pre-symptomatic AD mice.

Lab., Faculdade de Medicina do ABC, São Paulo, Brazil

Abstract: Background: Alzheimer disease (AD) is the most frequent cause of dementia, compromising cognitive and behavioral functions. Its establishment is due to the accumulation of genetic, environmental and metabolic events. It is known that the central nervous system is an important target of thyroid hormones (TH) and evidence shows that thyroid status can modulate the appearance of AD. Aim: to investigate the effect of treatment with T3 and Methimazole in behavior and gene expression of neurotrophins and AD markers in male transgenic mices 3xTg-AD. Materials and Methods: Male 3xTg-AD mices (~30g, N=6, approved by Animal Ethics Committee- CEUA nº 1880171017) were divided into 3 groups, all treated with intraperitoneal injections: (1) treated with T3 (20-30 ng/g of L-T3, physiological dose 5x); (2) treated with

Methimazole (0.05%, 5mg/100g animal body weight); (3) treated with saline solution (control group). At the 15º day of treatment the following tests were applied: Open Field, Elevated Plus Maze, Marble Burying, Tail Suspension and Forced Swimming. One day after the tests, animals were anesthetized with ketamine and xylazine, the brain was harvest and frozen in liquid nitrogen for RT-qPCR analysis. Total RNA of hippocampus was extracted and the gene expression of ADAM10, GSK3, BDNF, NTF3, NGF, GAD65, GAD67, SERT, TPH2, 5HT1A, BMP-7 and SOD2 was carried out by qPCR. Data were analyzed by relative gene expression and were represented as mean ± SEM, and submitted to unpaired Student t-test ($p<0.05$) and was analyzed by Pearson Correlation. Results: Gene expression of GSK3 was significantly reduced in T3 group (0.5930 ±0.1125) compared with saline (1.00 ±0.1083), ADAM10 was significantly reduced in T3 group (0.5119 ±0.1168) compared with saline (1.00 ±0.1215). Expression of BMP-7 was reduced in T3 group (0.5515 ±0.0616) compared with saline (1.00 ±0.08402) and SOD2 was increased in T3 group (2.355 ±0.4314) compared with saline (1.00 ±0.056). In forced swim test the animals treated with T3 decreased the fluctuation time (53.0 ±9.950) compared with saline (124.5 ±9.937) and in tail suspension test the animals treated with T3 decreased the immobilization time (64.60 ±17.19) compared with saline (132.5 ±18.31). In addition, a negative correlation between behavior tests and gene expression of genes related to GABA and serotonin in Pearson Correlation was observed. Conclusion: There was a decrease in depressive behavior and expression of genes related to APP production, β-amyloid peptide production and tau phosphorylation in animals
treated with T3 when compared with control saline group. The data suggest an important role of TH in the modulation of AD and depressive behavior.

Title: Evaluation of the integrity of the blood-brain barrier during the progression of Alzheimer's disease in the 3xTg-AD model

Authors: ***A. ISLAS**[1], M. BERNABE[2], P. GARCIA-DELATORRE[3];
[1]Inst. Mexicano del Seguro Social, Mexico, Mexico; [2]IMSS, Mexico, Mexico; [3]IMSS-UIM Enfermedades Neurológicas, Mexico city, Mexico

Abstract: Alzheimer's disease is the most common cause of dementia worldwide. This is characterized by the accumulation of two proteins mainly: tau in its hyperphosphorylated form, which accumulates forming neurofibrillary tangles and beta amyloid, which accumulates forming plaques. This accumulation starts in brain areas relevant to the formation and maintenance of memory, so, clinically, the main feature of AD is cognitive deficit, however, by the time these symptoms are visible, the disease is already in a relatively advanced stage. It is also known that when the neurofibrillary plaques and tangles become detectable, it is because there was already a previous neurodegenerative process, which is speculated to have to do with a compromise of the integrity of the blood-brain barrier.The triple transgenic murine model (3xTg-AD) that we propose to use in this project develops aggregates of both Aβ and Tau, a characteristic described in the development of AD in humans. This allows us to evaluate if there is an effect of mutations in APP (amyloid precursor protein), Tau and presenilin (PSEN1 and PSEN2) that are affecting the microvasculature in AD. Likewise, we can evaluate the effects of the accumulation of Aβ and tau, pathology that describes from its origins to the EA. Murine models for AD with mutations in APP have already described differences in microvessels such as aggregates of Aβ, hindered microcirculation, etc. In fact, some studies have used the 3xTg-AD model in which they describe a decrease in cerebrovascular volume and an increase in collagen I and IV. In this study we aimed to determine if there are changes in the microvessels at different stages of the progression (3,6, 9 and 13 months) of Alzheimer's disease in a transgenic triple murine model (3xTg-AD) by means of western blot analysis of tight junction proteins. We found that there are differences in the protein composition of the microvessels in the transgenic animals compared to the control animals, as well as that there is a decrease in the amount of protein from the tight junctions during progression.

Abstract: Alzheimer's disease (AD) is the most common type of dementia, affecting approximately 5.8 million Americans. The pathological findings in AD include amyloid plaques containing amyloid beta (Aβ) peptides and neurofibrillary tangles containing hyperphosphorylated tau protein. In addition to neuronal loss, cerebral amyloid angiopathy (CAA) occurs in AD. CAA is characterized by Aβ deposition in the brain microvessels, which leads to increased blood-brain barrier (BBB) permeability and vascular dysfunction, further exacerbating AD pathology. The present study characterized brain vascular function in the Tg-SwDI mouse model of AD which expresses the amyloid precursor protein Swedish K670N/M671L and vasculotropic Dutch/Iowa E693Q/D694N mutations. We isolated brain capillaries from 13-month old Tg-SwDI and wild type (WT) mice and used Western and dot blot analyses to determine the expression of monomeric and aggregated forms of Aβ, P-glycoprotein (P-gp), the receptor for advance glycation end-products (RAGE) and the tight junction (TJs) proteins occludin and claudin-5. In addition, we isolated and cultured brain endothelial cells to analyze barrier function via fluorescein flux. Results indicated that aggregated and oligomeric forms of Aβ are increased in brain capillaries of Tg-SwDI mice compared to WT animals. In addition, the efflux transporter P-gp was decreased in Tg-SwDI mice, while RAGE (which transports Aβ peptides from blood to brain) was increased. Moreover, the TJ protein occludin was decreased in Tg-SwDI mice, while claudin-5 remained unchanged. A decrease in the expression of occludin was related to an increase in BBB permeability in isolated brain endothelial cells in culture, as evidenced by an increase in fluorescein flux through the endothelial monolayer. These findings demonstrated that, in Tg-SwDI mice, impaired Aβ clearance, driven by a decrease in P-gp and an increase in RAGE, leads to the accumulation of aggregated and oligomeric Aβ in the brain capillaries. This accumulation promotes a decrease in the expression of the TJ protein occludin and as consequence, an increase in BBB permeability. Additional studies are underway to analyze the contribution of vascular dysfunction to the progression of AD pathology

Title: Sudden intrabulbar amyloid beta increase simultaneously disrupts olfactory bulb oscillations and odor detection

Authors: *R. H. SOTO, K. ROJAS GARCIA, J. PEÑA ORTEGA;
Dept. de Neurobiología del Desarrollo y Neurofisiología, Univ. Nacional Autónoma de México, Queretaro, Mexico

Abstract: There seems to be a correlation between soluble amyloid beta protein (AB) accumulation in the main olfactory bulb (OB) and smell deterioration both in Alzheimer Disease (AD) patients and animal models. Moreover, this smell-loss seems to be related to alterations in neural network activity in several olfactory-related circuits, including the OB, which is observed both in anesthetized animals and brain slices. It is possible that there is a correlation between these two pathological phenomena but, a direct and simultaneous evaluation of the acute and direct effect of AB on the OB activity while animals are actually smelling has not been performed. Thus, here we tested the effects of acute intrabulbar injection of a low dose of AB (200 pmoles) on the OB local field potential before and during the presence of a hidden piece of smelly food. Our results show that AB decreases the power of OB network activity while impairs the animal´s ability to reach the hidden food. Moreover, we found a strong correlation between the power of the OB oscillations, as well as the correlation between the activities of both OBs, with the performance in the olfactory detection test. These findings provide a direct link between AB-induced OB network dysfunction and smell loss in rodents, which could be extrapolated to AD patients.

Title: Retinal manifestations in mouse model of Alzheimer’s disease

Authors: *J. ZHANG, Y. SHEN;
Univ. of Sci. and Technol. of China, Hefei, China

Abstract: As an important component of the central nervous system, the visual system has driven an increased interest as a new research focus of Alzheimer's disease (AD). Studies in the visual system of AD patients have exhibited that they have worse complex visual functions such as contrast sensitivity, color vision, stereoacuity and visual acuity. The etiology of the visual impairment has been owing to the pathological changes of the visual cortex for a long time. Lately however, supported by modern ocular imaging techniques, it has been demonstrated that dysfunction of the anterior visual system also have an important impact on the development of visual symptoms in AD.
In the present study, we have utilized an array of molecular methods to examine retinal pathology in a well-characterized mouse models of AD(APP23). In our examination of existence of APP and deposits of amyloid plaques, the brains and retinas were collected from transgenic and wild-type mice of 3 to 12 months of age and processed for immunohistochemically analysis. In our results, human APP transgene were detected in several cell subtypes of retina and the APP expression were increased in transgenic mice compared with WT mice. In addition, deposits of Aβ were detected with immunostaining of whole-mount retinas. To our surprise, the deposits of retinal Aβ occurred earlier than that of the brain, indicating retinal pathologies may be among the earliest pathologies of AD. Furthermore, we found retinal neural degeneration in our APP23 mice. The distribution of cells in retinal ganglion cell layer of APP23 mice were sparser than that in WT mice and TUNEL-positive cells were detected in retinal ganglion cell layer in APP23 mice with TUNEL labeling. Moreover, activation of immune cells including microglia and astrocytes were not detected in retinas of APP23 mice, which were different from that in the brain.
The overall results of our research have demonstrated the retinal pathology of APP23 mice and provide a basis for future research of retinal pathology in AD.

Title: The effect of irrelevant visual experience on visual memory

Authors: S. INDULKAR, A. HOLT, S. FOWLER, ***J. SUBRAMANIAN**;
Univ. of Kansas, Lawrence, KS

Abstract: Long term memory storage involves increases in excitatory synaptic strength and connectivity between neurons encoding a novel experience. Such an increase in neuronal excitability would perturb neuronal firing rate homeostasis. Under conditions of neuronal

hyperactivity, such as in Alzheimer's disease, an increase in excitability induced by memory acquisition would further destabilize homeostasis. To identify whether excitability induced by task-irrelevant experience influences memory, we used a visual recognition memory (VRM) paradigm that involves synaptic plasticity in the primary visual cortex. In this paradigm, mice are repeatedly presented with a visual grating of a specific orientation and the recognition memory is assessed as a decrease in the exploration of the same stimulus over time. We tested the VRM in wild type mice and a mouse model of Alzheimer's disease (J20 line with human APP mutations) with or without task-irrelevant visual experience. We found that wild type mice display VRM for grating stimulus when tested one day but not at one month after the training period. In contrast, J20 mice did not exhibit VRM even one day after the training period. In the absence of task-irrelevant visual experience, J20 mice exhibited normal VRM and surprisingly, wild type mice did not. These results suggest that competing visual experiences improve visual memory in wild type mice but disrupt it under conditions of amyloid pathology.

Title: Upregulation of MeCP2 level in red nucleus cause late-life depressive phenotypes

Authors: *Y. CHOI[1], J. RYU[2], H.-S. KIM[1], H.-I. IM[2];
[1]Seoul Natl. Univ. Col. Med., Seoul, Korea, Republic of; [2]Ctr. For Neurosci., Korea Inst. of Sci. & Technol., Seoul, Korea, Republic of

Abstract: Late-life depression affects 8 to 16% of older adults, and often co-occur with other neuropsychiatric disorders that many elderlies suffer from. To develop a protocol that selectively cause depression in old mice, we created a new stress schedule, and named our protocol the Social stress infused Unpredictable Chronic Mild Stress (SUCMS). Our study applied SUCMS to the C57BL/6J (B6) and C57BL/6 x C3H hybrid (B6/C3H) mice in young (2mo) and old age (7mo) to induce depressive-like state. The old B6 and B6/C3H mice, but not young B6 and B6/C3H mice, show increased lethargy when exposed to SUCMS. Interestingly, the old B6 and B6/C3H mice with SUCMS also exhibited cognition deficit. They also showed increased tendency of anxiety. For further study for other neuropsychiatric disorders related to late-life depression, we applied SUCMS in APP/PS1 transgenic mice. SUCMS exposed APP/PS1 transgenic mice showed increased tendency of lethargy, indicating that SUCMS can be also used for investigation of comorbidity study between depression and Alzheimer's disease (AD). Methyl CpG binding protein 2 (MeCP2) is a transcriptional regulator that involves in

maintaining synapses and normal function of cells that reside in the brain. A previous study revealed that elevated MeCP2 in mice causes cognitive deficits and Tau dysregulation. Therefore, we would like to confirm the expression level of MeCP2 in SUCMS exposed brain. They showed increased expression of MeCP2 in the red nucleus (RN), the brain region that is not much studied so far except for having functions of motor integration. Previous studies about RN have shown that activity of RN is related to upper limb tremor, reach-to-grasp movements and the reflex response. Also, a recent human brain imaging study proved significant connectivity between RN and the cerebral cortex. Although it is well known that cerebral cortex plays a key role in memory and perception, how RN affects cognitive function and depressive symptoms is not revealed. Our results indicate that induction of late-life depression results in overexpression of MeCP2 in RN, which eventually cause depressive behaviors, cognition decline and anxiety. We also expect that these pathological alterations in late-life depression affect the major symptoms of AD.

Title: Age-related declines in short-term working memory, but not attention in APPswe/PS1dE9 transgenic mice

Authors: *P. L. SOTO[1], A. V. SAVONENKO[2], B. N. HARRIS[3];
[1]Dept. of Psychology, Louisiana State Univ., Baton Rouge, LA; [2]Pathology, Johns Hopkins Univ., Baltimore, MD; [3]Biol. Sci., Texas Tech. Univ., Lubbock, TX

Abstract: Alzheimer’s disease (AD) is a progressive neurological disease that results in cognitive deterioration, reduces quality of life, and is a significant economic burden on society. Currently available treatments for AD-associated cognitive impairment are minimally effective and can produce undesirable side effects. Thus, in the absence of a cure, there is a need for improved treatments for AD-associated cognitive impairment. The aim of the current study was to evaluate cognitive impairment in a mouse model of AD-associated beta amyloid neuropathology as a first step toward eventual screening of potential treatments. APPswe/PS1dE9 double transgenic male and female mice and non-transgenic littermates were trained on a delayed-matching-to-position (DMTP) or a 3-choice serial reaction time (3CSRT) task. Mice assigned to each task were further subdivided into two groups: (1) a continuous-

testing group, in which mice were exposed to daily experimental sessions five days a week from approximately 3-4 months of ages to 18 months of age and (2) an intermittent-testing group, in which mice were exposed to daily experimental sessions five days a week from approximately 3-4 months of age to 6 months of age, 10-12 months of age, and 16-18 months of age. Both transgenic and non-transgenic mice learned to perform the tasks quickly and with high levels of accuracy. Transient deficits in performance were observed following breaks in testing for both genotypes in both tasks. At 65 weeks of age, transgenic mice in the continuous-testing DMTP group exhibited increased rates of forgetting compared to non-transgenic mice but statistically significant deficits were not apparent in transgenic mice in the intermittent-testing DMTP group. The absence of deficits in transgenic mice in the intermittent-testing DMTP group appears to be due increased forgetting in the non-transgenic mice relative to rates of forgetting in the continuous-testing non-transgenic mice. In comparison, deficits were not apparent in transgenic mice in the 3CSRT task in either the continuous- or intermittent-testing groups. The results demonstrate a selective decline in short-term working memory in APPswe/PS1dE9 mice and indicate that intermittent testing obscures the development of deficits by impairing performance in non-transgenic mice. Future studies evaluating potential experimental treatments (e.g., potential pharmacotherapeutics) in APPswe/PS1dE9 mice can use a continuous-testing DMTP procedure to evaluate the ability of experimental treatments to alleviate or prevent declines in short-term working memory due to Alzheimer's disease-related amyloidosis.

Title: Automated cognitive testing in mouse models relevant to Alzheimer's disease

Authors: *B. KOOPMANS, M. E. SCHOENBERG, M. LOOS;
Sylics, Amsterdam, Netherlands

Abstract: Working memory impairments are observed in a variety of neurological and psychiatric diseases, including Alzheimer's disease (AD) and Schizophrenia. Working memory performance relies on a set of cognitive processes including retrieval of information from short-term hippocampal-based memory storage as well as manipulation of online information by prefrontal executive functions. In order to develop promising interventions to counteract deficits underlying cognitive systems it is key to develop robust preclinical tests in mice that can assess these cognitive functions. However, current working memory tasks for rodents require extensive training, as well as frequent human intervention. Therefore, we aimed to developed an

automated, home-cage (PhenoTyper™) based task to measure working memory deficits in AD and Schizophrenia mouse models using a modified version of the traditional eight-arm radial maze and 24/7 video tracking software. We previously described an automated one-night CognitionWall task that may be used to measure discrimination learning, but that cannot be used to specifically dissect working memory from short-term memory performance. We investigated the effect of a systemic injection of a low-dose, non-competitive NMDAr antagonist (MK-801) on performance in the task, as well as performance of transgenic APP/PS1 mice that showed impairments in the one-night CognitionWall task. The novel working memory tasks allows separate analyses of working memory and reference memory errors. Due to the significant reduction in both training time and human intervention, this PhenoTyper™-based task may prove instrumental in preclinical testing of interventions targeting AD and other cognitive disorders.

Title: Social interest in 5xFAD mice is influenced by genotype of social stimuli

Authors: *F. KOSEL, J. K. GLIKLICH, T. B. FRANKLIN;
Psychology and Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: In addition to cognitive impairments, patients with Alzheimer’s disease (AD) exhibit a number of behavioural and psychological symptoms of dementia (BPSD), with apathy (including social withdrawal) being the most prevalent. We have previously found that the 5xFAD transgenic mouse model of AD can be used to model some of these BPSD, with transgenic females exhibiting an age-related decrease in social investigation from 3 to 12 months of age. The present study examines whether this decrease in social investigation is affected by the genotype of the stimulus conspecific, and whether transgenic 5xFAD males exhibit similar reductions in social investigation. Social approach behaviour in female and male transgenic 5xFAD mice and wild-type controls at 6 months of age was examined using a modified Y-maze apparatus. Preliminary results indicate that transgenic 5xFAD mice exhibit reduced social approach behaviour compared to wild-type controls, and that social approach behaviour is

influenced by the genotype of the conspecific. This research suggests that both female and male transgenic 5xFAD mice model the reduced social interest exhibited by AD patients, and that interactions between individuals carrying AD genotypes can lead to heightened dysfunction in social relationships.

Title: Amyloid β oligomers suppress excitatory transmitter release via presynaptic depletion of phosphatidylinositol-4,5-bisphosphate

Authors: *X. MA, Y. HE, M. WEI, Y. ZHOU, Y. SHEN;
Zhejiang Univ., Hangzhou, China

Abstract: Amyloid β (Aβ) oligomer-induced aberrant neurotransmitter release is proposed to be a crucial early event leading to synapse dysfunction in Alzheimer’s disease (AD). In the present study, we report that the release probability (Pr) at the synapse between the Schaffer collateral (SC) and CA1 pyramidal neurons is significantly reduced at an early stage in mouse models of AD with elevated Aβ production. High nanomolar synthetic oligomeric $A\beta_{42}$ also suppresses Pr at the SC-CA1 synapse in wild-type mice. This Aβ-induced suppression of Pr is mainly due to an mGluR5-mediated depletion of phosphatidylinositol-4,5-bisphosphate(PIP2) in axons. Selectively inhibiting Aβ-induced PIP2 hydrolysis in the CA3 region of the hippocampus strongly prevents oligomeric Aβ-induced suppression of Pr at the SC-CA1 synapse and rescues synaptic and spatial learning and memory deficits in APP/PS1 mice. These results first reveal the presynaptic mGluR5-PIP2 pathway whereby oligomeric Aβ induces early synaptic deficits in AD.

Title: Neuronal calcium homeostasis in dorsal hippocampus in the HNE and 5xFAD mouse models of Alzheimer's disease across age

Authors: *A. O. GHOWERI[1], L. J. OUILLETTE[2], H. N. FRAZIER[1], A. ELHARRAM[5], K. L. ANDERSON[1], R. PARENT[3], J. C. GANT[1], B. BENNETT[6], G. G. MURPHY[4], O. Sci. and Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: With limited treatment options and no known cure, the need to develop novel therapeutics based on underlying cellular mechanisms in aging and Alzheimer’s disease remains imperative. Over the past few decades, a constellation of neuronal phenotypes associated with AD and aging have been extensively studied in animal studies. One potential mechanism highlighted in the calcium hypothesis of brain aging and dementia describes dysregulation of neuronal calcium that impacts cellular physiology and synaptic connectivity. Prior work has described an increase in the Ca2+-dependent afterhyperpolarization (AHP), associated in a few studies, with an increase in intracellular calcium levels. This association has become recognized as a reliable biomarker of normal aging; specifically seen in pyramidal neurons of hippocampal field CA1. Despite this, less is known about the relationship between the AHP and neuronal calcium handling in AD models. In fact, recent work has shown that a reduction in L-type voltage sensitive calcium channels (L-VSCCs) were present in aged APP and PS-1 AD mouse models. This suggests calcium dysregulation in AD models may differ from normal aging; perhaps influencing disease progression.
In this study, we measured the AHP and intracellular calcium across age in the HNE and 5xFAD AD mouse models. The HNE mouse is an oxidative stress-based model of sporadic AD based on gene deletion of aldehyde dehydrogenase 2, resulting in elevated levels of the lipid peroxidation product, 4 hydroxynonenal (HNE). Animals were studied at 1.5, 4, and 10 months of age following along the development of AD pathology (i.e. Abeta). Sharp electrode electrophysiology was used to measure AHPs in neurons of the *stratum pyramidale* in field CA1

of the dorsal hippocampus, and changes in calcium during synaptic activation were quantified using the fluorescent indicator OGB-1. By 4 months, a trend of an attenuated AHP was observed in the 5xFAD animals compared to their wildtype counterparts. However, at this age, 5xFAD mice do not show behavioral deficits in the Morris Water Maze task of spatial reference memory. Interestingly, whereas HNE mice do show memory deficits at 4 months of age, no alterations in the AHP were observed. Preliminary data on the 10-month 5xFAD mice illustrate further reductions of the AHP and intracellular calcium. Thus far, these data corroborate our previous findings of reduced L-VSCCs in AD mouse models and suggest that decreases in somatic calcium may be a precipitating factor in downstream behavior deficits but only in one animal model of AD. These reductions in calcium handling may increase synaptic excitability and stimulate the onset of cognitive decline.

Title: The histological and biochemical effects of A. bisporus (white button mushrooms) on human amyloid precursor protein (hAPP) transgenic mice

Authors: *T. T. DIMOPOULOS, K. M. CRAVEN, R. E. BARKEY, E. N. DOHERTY, C. M. HERNANDEZ, J. M. FLINN;
George Mason Univ., Fairfax, VA

Abstract: Alzheimer’s Disease (AD) affects 5.7 million Americans. White button mushrooms (WBMs) are considered an antioxidant due to their high source of selenium and have been shown to promote nerve growth factors (NGFs), as well as slow cognitive decline in AD. Selenoproteins, particularly Selenoproteins M (SelM) and P (SelP), are an integral part of memory consolidation and preservation in mouse models.
J20/hAPP transgenic mice and wildtype (C57BL/6J) mice from Jackson Laboratories were fed a 10% WBM feed three times per week to yield a 5% total diet of WBMs. Behavioral tests were conducted at 3.5 months and 8 months of age. Interestingly, at 3.5 months J20 mice on the WBM diet had increased latency in Morris Water Maze (MWM) compared to J20 mice on the control diet ($p<0.001$). In contrast, at 8 months, J20 mice on the WBM diet had faster latency ($p<0.005$) in MWM than J20s not on the diet; thus, an ameliorative effect of the WBM diet on spatial memory is evident in these older animals. Preliminary Congo Red staining for Aβ plaques show

increased plaque load at 8 months in J20 mice on the WBM diet, compared to J20 mice not on the WBM diet, in the CA2 and CA3 regions of the hippocampus and corpus callosum. Western Blot and immunohistochemistry (IHC) will determine whether the WBM diet affects SelM, SelP, NGF, and total APP concentration.

Title: The amyloid plaque microenvironment

Authors: *D. C. SOUDER[1], I. A. DREISCHMEIER[2], S. L. WRIGHT[2], K. W. ELICEIRI[3], R. ANDERSON[2];
[1]Dept. of Geriatrics and Gerontology, [3]Lab. for Optical and Computat. Instrumentation, [2]Univ. of Wisconsin-Madison, Madison, WI

Abstract: Background: Amyloid plaque formation is a central event in Alzheimer’s disease (AD) pathology. Our current understanding of plaque formation, clearance, and impact on the surrounding tissue is largely based on mouse models of amyloidosis; however, sporadic AD includes age as a major risk factor and many aspects of AD pathology appear to be specific to humans. Here we utilize APP/PS1 mice, a genetic model of AD, rhesus monkeys that spontaneously develop amyloid plaques with age, and human AD brain tissue to determine if features of the amyloid plaque microenvironment are conserved from mice to humans. **Methods:** Brain tissue was obtained from six-month-old APP/PS1 male mice (n=6), from 28-34 year old male and female rhesus monkeys from the Wisconsin National Primate Research Center longitudinal study on aging (n=7), and from male and female individuals with confirmed AD diagnosis whose brain tissue was banked at the Wisconsin Brain Donor Program (n=14). For each species, tissue sections of the medial temporal cortex were used for histochemistry, immunofluorescence, and 2-photon microscopy. **Results:** Amyloid plaques were associated with astrogliosis, elevated mitochondrial density, and increased cytochrome c oxidase activity. The total area affected by reactive astrocytes was greater in monkeys and humans than in mice; however, mice displayed more robust increase in GFAP expression in the plaque vicinity. We report that plaques induce a unique metabolic signature that is conserved between species.

Furthermore, areas of elevated NAD(P)H fluorescence correlate with high mitochondrial density. These results suggest that functionally distinct mitochondria exist within and around amyloid plaques. **Conclusion:** Our data suggests that mitochondrial dysfunction is a key aspect of AD pathology. Mitochondrial localization, function, and NAD(P)H cofactor status are altered in proximity to amyloid plaques. Importantly, transgenic models of AD fail to capture heterogeneity in the metabolic environment around spontaneously formed plaques, indicating that nonhuman primates may be a better model for understanding the proximal consequence of AD pathology.

Title: Seeding of a fast-acting Abeta peptide accelerates plaque deposition and microgliosis in APP^{NL-G-F} mouse model with no impairment in learning and memory

Authors: *S. G. LACOURSIERE[1], M. H. MOHAJERANI[1], D. A. WESTAWAY[2], R. J. SUTHERLAND[1];
[1]Canadian Ctr. For Behavioural Neurosci., Lethbridge, AB, Canada; [2]Univ. of Alberta, Edmonton, AB, Canada

Abstract: Alzheimer’s disease (AD) is characterized by a stereotypical conformational misfolding of certain brain proteins. Of specific interest is amyloid-β (Aβ) due to its prion-like properties. However, the role of Aβ in AD symptoms remains unclear. It has been hypothesized that the emergence of Aβ plaque impairs cognition and therefore accelerating Aβ pathology should increase the severity of cognitive symptoms. The medial entorhinal cortex of the KI-APP^{NL-G-F}. mouse model, both homozygous positive ($APP^{+/+}$) and negative ($APP^{-/-}$) were seeded with brain homogenates containing fast-acting (FA) or control (C) at 2 months of age. At 3 (n = 14), 4.5 (n = 12), and 6 (n = 8) months of age, learning and memory were tested using the Morris water task (MWT). Groups were randomized with $APP^{+/+}$ and $APP^{-/-}$ with either FA or C injections housed in the same cages; the experimenter was blinded to the experimental manipulation during testing. Immunohistochemical staining showed dramatically increased 82E1 and Iba1 labelling, indicating increased Aβ and microgliosis pathology, respectively, in the

$APP^{+/+}$ FA mice as early as 3 months of age. In the no-platform probe of the Morris Water Task at 6 months, the $APP^{+/+}$ FA mice spent similar time (59.7 ± 8.35%) compared to the non-seeded controls (73.0 ± 2.00; results presented as mean ± SEM); showing no association between Aβ plaque pathology and learning and memory ability. Our results replicate previous reports of the seeding properties of Aβ and its prion-like behaviour (Kane, M.D. et al., 2000). We have also shown that the Aβ seed used spreads rapidly, much faster than we predicted by transneuronal spread; this is either a testament to the seeding ability of specific strains of Aβ or provides evidence against the transneuronal spread of Aβ. Furthermore, our results show that Aβ plaque is not directly the causal agent for memory impairment.

Title: Determining therapeutic amyloid beta reduction necessary for improved cognition in Alzheimer’s mice

Authors: M. C. MAKER[1], J. PRAKASH[2], *C. S. MITCHELL[2];
[1]Columbia Univ., New York, NY; [2]Georgia Inst. of Technol., Atlanta, GA

Abstract: Beta-secretase cleaving enzyme (BACE) is an enzyme encoded by the BACE1 gene that assists in the division of the amyloid-precursor protein (APP). Currently, BACE (beta-secretase cleaving enzyme) inhibitors are being tested for clinical use in familial Alzheimer’s disease (AD) as a possible preventative treatment to prevent or decrease amyloid beta buildup. However, multiple studies have failed to emphasize the extent by which amyloid beta needs to be reduced before improvements to cognition are observed. The goal of this study is to quantify the amyloid beta reductions necessary for significantly improved cognition in transgenic AD mice. A meta-analysis was performed using PubMed keywords “Alzheimer’s disease, amyloid-beta, beta-secretase, and Morris Water Maze”. Ultimately, 23 papers matched inclusion criteria. Escape latency of Morris Water Maze, both the insoluble and soluble 40/42 amyloid beta levels, and the BACE levels were extracted from the papers using WebPlot Digitizer. Descriptive,

exploratory, and predictive analysis are performed on aggregated data. When comparing amyloid beta 42 to escape latency, clustering showed a 25 point decrease in amyloid beta led to a 10 point decrease in escape latency while a 40 point decrease in amyloid beta led to a 20 point decrease in escape latency over the AD model. For reference, Wild-type (WT) mice have an escape latency 25 points lower than the AD model. This exploratory assessment will be further assessed with more explicit analytical methods to predict what treatment effect size is needed from BACE inhibitors for amyloid beta reduction that results in a significant impact on cognition. Results demonstrate amyloid beta needs to be greatly reduced, about 40 points, in order to achieve WT levels of cognition. This same group needed to achieve a BACE decrease of 40 points to achieve these levels of amyloid beta. These findings serve to conclude that BACE inhibitors could have a significant effect on the cognitive decline of patients with either familial or sporadic AD, but require a tremendous amount of amyloid beta and BACE reduction to achieve it.

Title: Disease progression characterization of a new model for Alzheimer's disease

Authors: *X. CHENG[1], L. ZHUANG[1], Z.-Q. XIONG[2];
[1]Inst. of Neuroscience, Chinese Acad. of Sci., Shanghai, China; [2]Inst. Neurosci, Shanghai, China

Abstract: Alzheimer’s disease (AD), with a 10% prevalence in people with age beyond 65, has clinical manifested symptoms mainly including cognitive dysfunctions and neuropsychiatric impairments. Modeling of AD with *C. elegans*, flies and rodents has greatly promoted our understanding of molecular and cellular mechanisms of diseases. However, due to their differential genetics, metabolism, distinctive architecture and circuit connections from humans, these models often could not fully simulate human diseases. Thus, therapeutic trials developed based on them came out with an extremely high failure to work on human patients. Several β amyloid-targeting therapies, including vaccines, antibodies, and inhibitors or modulators of γ- and β-secretase are currently being tested. Although current drug pipeline in clinical trials contains a cohort of potential disease-modifying drugs, a long list of failures of AD clinical trials in recent years has casted a long shadow on the future of AD drug development. It implies that our current theories and mechanistic understanding of AD pathogenesis obtained largely by using rodent models may be incomplete or incorrect. Being phylogenetically and structurally more closer, non-human primates (NHPs) may be a better choice of disease model system to fill the long-lasting gaps at mesoscopic and microscopic level. In the past decades, stereotaxic

injection of the cytotoxin ibotenic acid into the basal forebrain or transection of the fornix of macaque monkeys were used to mimic the loss of cholinergic basal forebrain neurons and associated cognitive deficits. Moreover, intracerebral delivery of ß-amyloid plaques and neurofibrillary tangles has also been used to induce AD-like symptoms in monkeys. However, a lack of genetically-modified AD model has been impeding AD research. We are trying to establish a transgenic macaque model that mimicking both the copy-number duplication/triplication and point-mutation of APP and PSEN1 gene. The disease progression of transgenic monkeys will be characterized by using combined strategies including plasma/CSF biomarker identification, PET imaging and cognitive function behavioral analysis. We hope this would be a valuable model to facilitate AD research.

Abstract: Results from both human and animal studies over the last decade have identified a clear increase in the rate of Alzheimer’s disease (AD) in women. Sex differences in the prevalence or severity of many diseases are well recognized. A common underlying feature of disorders more prevalent in females is an association with stress, such as in anxiety and depression. Stress increases glucocorticoids (GC) in the brain, and the link between GCs and AD has been confirmed by several studies. Differences between males and females in corticotropin releasing factor (CRF) receptors, particularly in the locus coeruleus, have been described extensively by Bangasser and colleagues (2011, 2013, 2018). We previously found that acute stress rapidly increases levels of Aβ in the mouse brain (Kang et al., 2007), and that this effect

was dependent on synaptic activity and CRF. The influence of specific CRF or glucocorticoid signaling pathways on AD pathology has not been defined. Here we manipulate signaling molecules involved in the CRF receptor pathway to determine the mechanisms underlying to sex-related differences in Aβ levels in response to acute stress. Using microdialysis, Aβ levels in the interstitial fluid (ISF) of the hippocampus were measured in male and female APP/PS1 mice (3-4 months old). Samples were collected every hour for a baseline period, 3-hour restraint stress, and 12-hour post stress period. Activators and inhibitors of PKA were administered for 6 hours prior to acute stress to determine the influence of these signaling pathways on acute stress-induced increases in Aβ levels. The increase in Aβ in response to acute stress is a predominantly female response showing a significant difference between male and female mice in the percent increase in ISF Aβ during acute stress, with female mice having a much greater and sustained increase in ISF Aβ compared to males. Inhibiting PKA prior to acute stress completely blocked the stress-induced increase in ISF Aβ levels in female APP mice. Activating PKA in males resulted in a delayed increase in ISF Aβ following acute stress that was not seen in vehicle treated mice. These results suggest that females are more sensitive to stress-induced increases in Aβ, and that acute stress increases Aβ in female mice through stress-induced PKA signaling.

Title: Myelination changes in hippocampal white matter during Alzheimer's pathogenesis and the electrophysiological consequences

Authors: *M. L. RUSSO, T. F. MUSIAL, G. D. AYALA, S. J. AHMAD, L. A. BEAN, D. A. NICHOLSON;
Neurolog. Sci., Rush Univ. Med. Ctr., Chicago, IL

Abstract: Recent work employing diffusion tensor imaging (DTI) has implicated white matter deterioration as a potential predictive biomarker for Alzheimer’s disease (AD). However, few studies have utilized high resolution techniques to understand the tissue-level changes that underlie white matter disruption observed with DTI. Fortunately, *in vitro* experiments and histological examinations of the grey matter have provided some insight into potential

explanations for this phenomenon. Specifically, oligodendrocytes, the myelinating glial cells that are abundant in the white matter, exhibit susceptibility to amyloid beta toxicity in culture. Moreover, light and fluorescence microscopy have consistently shown decreased myelination in and around the cores of amyloid plaques. Such observations suggest that detrimental effects of AD pathology to oligodendrocytes and subsequent changes to myelination may play a role in white matter deterioration. Therefore, we used a combination of morphological and functional experiments to assess how myelin deficits contribute to white matter disruption in AD. First, using conventional electron microscopy we quantified instances of abnormal myelination within the alveus of 5xFAD mice, post-mortem human AD tissue, and corresponding controls. This analysis revealed that aged 5xFAD mice exhibit significantly more instances of abnormal myelination than age-matched controls, as well as all mice classified as young adult or middle aged. Human AD tissue exhibited a similar trend relative to tissue from non-cognitively impaired individuals. Second, whole-cell current clamp was utilized to assess the physiological consequences of myelin disruption in AD mouse models. In the experimental setup, antidromic action potentials (aAP) were initiated by a stimulating electrode placed in the alveus of CA1, and aAP propagation to the soma was monitored by a somatic recording electrode. Statistical analysis revealed a main effect of genotype on successful aAP propagation, such that neurons from 5xFAD mice exhibit lower rates of successful propagation. This data suggests that white matter deterioration observed by DTI in AD patients may be the result of dysmyelination. Further, our findings indicate that myelination changes result in electrophysiological consequences that likely contribute to disrupted neuronal communication during AD.

Title: Distinct gene expression patterns in the dentate gyrus of Alzheimer’s disease mice with differential susceptibility to spontaneous seizures and memory loss

Authors: *C.-H. FU[1], X. ZHANG[2], G. S. STEPHENS[1], Y. LIU[3], J. CHIN[1];
[1]Dept. of Neurosci., Baylor Col. of Med., Houston, TX; [2]Dept. of Pediatrics, Children's Hosp. of Philadelphia, Philadelphia, PA; [3]Dept. of Neurobio. and Anat., Univ. of Texas Med. Sch., Houston, TX

Abstract: Alzheimer's disease (AD) is characterized by amyloid plaques and neurofibrillary tangles, but not all individuals with neuropathology are cognitively impaired. Why some individuals appear resistant to cognitive decline is unclear. Using human amyloid precursor protein (APP) transgenic mice, we found that a proportion of APP mice do not exhibit memory deficits even though they produce similar levels of amyloid-beta (Aβ) as other APP mice that do exhibit memory deficits. Interestingly, memory deficits correlated with spontaneous seizure activity; APP mice with frequent seizures had poor memory, and APP mice that did not have seizures had normal memory. Patients with mild cognitive impairment or AD also have increased incidence of seizures, which predict faster and more severe cognitive decline. To investigate why some APP mice have frequent seizures and cognitive impairment while others do not, we stratified APP mice based on dentate gyrus expression of ΔFosB, a transcription factor whose expression we previously found highly correlates with seizure frequency. We performed RNA-sequencing on dentate gyrus from nontransgenic (NTG) control mice, APP mice with high ΔFosB levels ("APP-high"), and APP mice with control levels of ΔFosB similar to NTG mice ("APP-ctrl"). Of the three groups, APP-high mice differed the most in gene expression patterns compared with NTG mice and APP-ctrl mice. Gene clustering analyses revealed that the expression differences between APP-high mice and NTG or APP-ctrl mice involved many ion channels and excitability-related genes. Surprisingly, despite having similarly high levels of APP/Aβ, APP-ctrl mice had gene expression profiles largely different from that of APP-high mice, but very similar to that of NTG mice. These results suggest that APP-ctrl mice are similar to NTG mice in terms of memory, lack of seizures, and gene expression patterns. Notably, a small set of genes were differentially expressed in APP-ctrl mice compared with either NTG or APP-high mice, suggesting they may play a role in conferring resistance to the effects of Aβ and/or seizures. Understanding how these varying patterns of gene expression arise may provide insight into mechanisms that underlie differential susceptibility to cognitive deficits in AD.

Title: Role of Tip60 in the nuclear and cytoplasmic proteome of amyloid precursor protein-induced neurodegenerative condition

Authors: *B. KARISETTY[1], F. ELEFANT[2];
[1]Dept. of Biol., [2]Biol., Drexel Univ., Philadelphia, PA

Abstract: Alzheimer's disease (AD) has been shown by our group and others to be is associated with epigenetic dysregulation. Histone acetylation, an important epigenetic regulator, is maintained by opposing activities of histone acetyltransferases (HATs) and histone deacetylases (HDACs). Our lab has shown a reduction in the total and neuronal nuclei Tip60 (HAT) levels in human AD hippocampus. We further showed that external stimulation of hippocampal neuronal cells increases Tip60 nuclear import and enhances transcription of target genes. Also, cytoplasmic Tip60 can acetylate microtubules associated with neuronal function. A study suggests that Amyloid Precursor Protein (APP) may participate in Tip60 nucleocytoplasmic shuttling by membrane sequestration, phosphorylation and nuclear import. Notably, shuttling process regulates protein activity and is a common theme in multiple neurodegenerative disorders. Here we used transgenic AD-associated *Drosophila* expressing human APP 695 isoform and double transgenic flies (APP; Tip60) expressing APP with increased Tip60 levels in the brain to explore a role for Tip60 in nucleocytoplasmic shuttling in AD. 1-2-day old adult heads were used for molecular work. mRNA levels of individual (A & B) and total transcript variants (A, B & C) of Tip60 were measured. Interestingly, transcript variant specific regulation (A) was observed in the APP fly line. At the protein level, nuclear and cytoplasmic protein fractions isolated from APP and APP; Tip60 fly heads were used for label-free quantitative proteomics to measure the differential regulated proteins and the nuclear or cytoplasmic enrichment of proteins. We identified many differentially regulated proteins in the APP line with a good number of these respective proteins being restored in the APP; Tip60 line. Proteins involved in pathways like Apo-B biosynthesis and splicing were specifically altered in the nucleus and proteasome and ubiquitin pathways in the cytoplasm. We also observed nuclear enrichment of multiple proteins in APP line and decrease of these respective protein levels in the APP; Tip60 line. These results suggest transcript variant specific regulation of Tip60 and nuclear/cytoplasmic protein enrichment regulation by overexpressed Tip60 in APP-induced neurodegeneration.

Title: Selective TDP-43 expression in an aged APP/PSEN1 background

Authors: *A. ANDERSON, S. DAVIS, K. WILSON, M. GITCHO;
Biol. Sci., Delaware State Univ., Dover, DE

Abstract: TDP-43 functions as a heterogeneous nuclear ribonucleoprotein involved in mRNA transport, mRNA stability, transcription, mitochondrial metabolism, and forms stress granules in the cytosol. TDP-43 is the major pathological protein in frontotemporal dementia and ALS. Previously, TDP-43 pathology has been described in up to 50% of those with Alzheimer's disease. Recent evaluation of this cohort revealed a distinct pathological staging of TDP-43 proteinopathy in an aged population, which overlaps frontotemporal lobar degeneration (FTLD-TDP) and Alzheimer's disease. This overlapping pathological cohort is named limbic-predominant age-related TDP-43 encephalopathy (LATE). Through a model of cortical/hippocampal expression in an APP/PSEN1, we have extended our previously reported characterization of 9-month old mice to determine how age contributes to neurodegeneration. This TDP-43 proteinopathy is present in 20-50% of LATE cases in those 80 and over. The mice characterized for this study are 24 months of age, which may be comparable to approximately 70 years of age in humans. Both human TDP-43 and nuclear localization signal defective (ΔNLS) TDP-43 in an APP/PSEN1 background were evaluated. This model shows severe neuronal loss in the hippocampus, a change in plaque deposition, aggregated tau, and a decrease in survival. This aged model of TDP-43 proteinopathy may be of use in understanding how TDP-43 contributes to neurodegeneration.

Title: Accelerated expression of amyloid-beta biomarkers and behavioral pathologies after moderate alcohol drinking in a humanized triple transgenic mouse model of Alzheimer's disease

Authors: *J. L. HOFFMAN[1], S. P. FACCIDOMO[2], S. M. TAYLOR[1], M. KIM[1], C. W. HODGE[3];
[1]Bowles Ctr. for Alcohol Studies, Univ. of North Carolina - Chapel Hill, Chapel Hill, NC; [2]Bowles Ctr. Alcohol Studies, Univ. North Carolina, Chapel Hill, Chapel Hill, NC; [3]Psychiatry, Univ. North Carolina Chapel Hill, Chapel Hill, NC

Abstract: ***Rationale:*** Alzheimer's disease (AD) is a progressive neurodegenerative disorder, representing the most common cause of dementia in the USA. Elderly populations are consuming more alcohol than prior generations and preclinical research is needed to fully elucidate neurobiological mechanisms that underlie the interaction between AD and alcohol use. We have evaluated the impact of alcohol drinking on the prefrontal cortex and amygdala neuroproteome and bioinformatics revealed a striking association between alcohol drinking and AD pathology. In both regions, the AD-linked proteins tau, amyloid-β (Aβ) precursor protein, and presenilin-1 were identified as the main modulators of alcohol-sensitive protein networks, suggesting that alcohol drinking may alter the course of AD pathology. ***Objective:*** To investigate the effects of chronic alcohol drinking pathologies associated with AD in a triple-transgenic mouse model of AD(3xTg-AD mouse) that expresses human tau, amyloid precursor protein and presenilin-1 genes. ***Methods:*** Male and female 3xTg-AD and control mice (B6129SF2J) were given 24-h access to 25% alcohol/0.1% saccharin+water or 0.1% saccharin+water beginning at 3-mo of age. Mice were tested for behavioral impairments periodically between 40-day bouts of 24-h access alcohol consumption. At approximately 7-mo old and after a final bout of homecage drinking, behavioral impairments were assessed in the open-field, Morris water maze and acoustic startle chamber. Mice were then euthanized and brains were removed for analysis of early-disease biomarkers Aβ40 and Aβ42. ***Results:*** Both genotypes consumed similar amounts of saccharin and alcohol at all time points and behavioral differences emerged at 7-mos. As expected, impaired spatial learning developed in the 3xTg-AD mice; though, alcohol drinking did not exacerbate this deficit. A notable impairment was found in pre-pulse inhibition (PPI) of the startle response for 3xTg-AD alcohol drinking mice as compared to all other groups. These behavioral changes were accompanied by significant increases in Aβ42/Aβ40 ratio in the cortex (CTX) and lateral entorhinal cortex (l-ENT). ***Conclusions:*** Early indicators of learning and memory impairments in the 3xTg-AD mice were not altered by alcohol drinking. However, initial data indicate impaired sensorimotor gating, a common symptom of AD, in the 3xTg-AD alcohol drinking mice. Together with the increased neuropathology the l-ENT and CTX after alcohol drinking, these data support the hypothesis that moderate alcohol drinking may accelerate the onset of AD pathology and may be an important risk factor for the development of AD.

Title: Target validation for Alzheimer's disease using multiplex RNAscope technology

Authors: *K. T. KAYE, N. RUDERISCH, J. PIRO, T. DELLOVADE;
Abbvie, Cambridge, MA

Abstract: Alzheimer’s disease is the most common form of dementia that leads to severe memory loss and cognitive decline, affecting millions of patients and families worldwide. To understand the gene expression changes of aging in the brain, we explore the value of using *in situ* hybridization (ISH) to detect specific target RNA such as APOE. Advanced Cell Diagnostic’s (ACD) Multiplex RNAscope is an automated ISH assay that enables single-molecule detection of multiple RNA targets simultaneously. Using ACD’s Tyramide Signal Amplification probe technology, this assay is designed to significantly boost signal while suppressing background noise. Advantages of this assay include easy-to-use automated technology, strong detection of low expressing genes in any channel, dual ISH and immunohistochemistry (IHC), and compatibility across various tissue samples. High expressing genes such as APOE and TFR were used to validate dual ISH and IHC, which showed exceptional signal across mouse models. Low expressing targets provided challenges in aged tissue due to existing pathology. Despite these challenges, RNAscope technology provides a clear visualization of gene expression changes in aging rodent models, which will help us understand the aging mechanisms in Alzheimer’s patients and select meaningful therapeutic targets.

Title: Probing the role of exosomes derived from peripheral organs and tissues in the onset and progression of Alzheimer's disease

Authors: *W. LAWRENCE[1], D. F. ALZATE-CORREA[3], J. T. MOORE[4], C. L. RINK[5], N. HIGUITA-CASTRO[2], D. GALLEGO-PEREZ[2];
[2]Biomed. Engineering/Surgery, [1]The Ohio State Univ., Columbus, OH; [3]Neuropathology, Ohio State Univ. Dept. of Pathology, Columbus, OH; [4]Biomed. Engin., Ohio State Univ., Columbus, OH; [5]Surgery, The Ohio State Univ. Wexner Med. Ctr., Columbus, OH

Abstract: Alterations in the levels of amyloid beta and phosphorylated tau have been previously documented in non-neural tissues and blood of Alzheimer's disease (AD) patients, however the potential relation of these findings to the onset and progression of AD remains to be elucidated. Furthermore, while neuron-derived exosomes have been implicated in AD, the potential involvement of exosomes derived from peripheral non-neural tissues/organs in the onset and progression of AD is an area that warrants further investigation. We investigated these links through a series of experiments using TG2576 late plaque murine models of AD that overexpress human amyloid precursor protein (hAPP), with aged and sex matched wild type (WT) c57 BL6 mice as controls. Exosomes were isolated directly from peripheral tissues of these mice, including skin, gut, fat and muscle, among others. Exosomes isolated from primary cell cultures derived from these tissues were also studied for comparison purposes. The size and concentration of these exosomes were evaluated through the use of Nanosight. The cargo of these exosomes was characterized with qPCR and Western Blot to detect RNA and proteins related to AD, such as amyloid beta, phosphorylated-tau, and amyloid precursor protein, among others. The results from the qPCR analysis showed the presence of RNA of hAPP in exosomes isolated from peripheral tissues of TG2576 mice, with similar levels of RNA of mouse amyloid precursor protein (mAPP) observed in treatment and control exosomes. The neurotoxic effects of these exosomes was tested by exposing primary murine embryonic hippocampal neurons to various concentrations of treatment and control exosomes. Cultures exposed to AD exosomes exhibited more pronounced signs of early neurotoxicity. Follow-up studies with qPCR and ELISA indicate that exosomes derived from peripheral AD tissues can modulate the expression levels of mAPP *in vitro* compared to exosomes derived from peripheral tissues of healthy mice. Altogether, these findings suggest a potential role for peripheral tissues in the modulation of AD onset and/or progression presumably via exosome-driven endocrine signaling. Ongoing studies are aimed at further probing the role of AD-associated peripheral exosomes using murine models of this condition as well as human tissue specimens.

Cente, Amsterdam, Netherlands; [5]Dept. of Epidemiology, Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA

Abstract: Evidence from postmortem and recent PET studies shows that tau pathology in Alzheimer's disease (AD) starts in the entorhinal cortex and spreads throughout the brain. The increase in tau pathology correlates well with the decline in cognitive function. Currently widely used transgenic tauopathy mouse models overexpress human tau with frontotemporal dementia-linked mutations throughout the nervous system. This results in a global induction of tau pathology and behavioral phenotypes unrelated to AD, such as profound motor function impairments. To test antibody-based treatments that can protect against the spreading of tau pathology and concomitant cognitive decline in humans, a mouse model induced by 'seeding' of tau pathology is required that more closely mimics human tau pathology and cognitive decline. The source of the tau seeds as well as the genetic background in which the seeds are injected are expected to have a large effect on the rate at which tau pathology emerges and thereby the tau load. Here we compared the emergence of pathology in wild-type C57BL/6J mice and in htau mice that express all isoforms of human tau and no murine tau (Andorfer et al. 2003) after seeding with tau seeds isolated from human AD brain (AD-PHF) as well as in vitro amplified AD-PHF seeds in 2N4R recombinant tau. Tau seeds were infused bilaterally into the hippocampus to induce pathology and potential cognitive decline. In htau mice, AT8-positive tau structures were observed in hippocampus as well as other brain regions at 3 and 6 months specifically after seeding with AD-PHF, but not after injection of PBS or control brain isolate. In comparison with htau mice, the number of AT8-positive structures was significantly lower in wild-type C57BL6J mice that were seeded with AD-PHF. No thioflavin-s-positive structures were detected at 3 and 6 months after seeding in either model. When compared with transgenic tauopathy mouse models the amount of AT8-positive tau induced by AD-PHF seeding in htau mice was low. No cognitive deficits were observed at 6 months after seeding in either htau or

wild-type C57BL/6J mice in an extensive cognitive test battery. In conclusion, seeding of AD-PHF by bilateral injection induced tau pathology in htau transgenic mice to a greater extent than in C57BL6J mice, but no cognitive impairment in either htau or C57BL/6J mice 6 months after seeding.

Title: The role of a new truncated tau species in pathological process of Alzheimer’s disease

Authors: *L. BUEE, **S. GUEDJDAL**, M. DERISBOURG, S. EDDARKAOUI, F. VERMON, R. CAILLIEREZ, S. BEGARD, V. GOMEZ-MURCIA, E. FAIVRE, D. BLUM, M. HAMDANE;
Univ. Lille, Inserm, CHU Lille, UMR-S 1172 – Alzheimer & Tauopathies, Lille, France

Abstract: Neurofibrillary degeneration (NFD), which is one of the Alzheimer’s disease (AD) hallmarks, is mainly composed of aggregated Tau proteins. Mechanisms leading to Tau aggregation are not clearly elucidated. Some studies indicated that Tau truncation could have an etiological role in the pathological process of AD. Recently, we have identified new N-

terminally truncated Tau species. Our preliminary data have shown this new Tau species to be a signature feature of AD. In order to establish whether this Tau species has an instrumental role in Tau pathology development, we have performed stereotaxic injections of lentiviral vectors (LV) expressing full-length Tau and truncated Tau species into the hippocampus of wild-type and Tau-transgenic mice. Our immunohistochemistry analyses of brain sections, performed 2 months post injections have showed that Tau proteins are stably expressed in neurons within the whole hippocampus and that the N-terminally truncated Tau species is detected in regions that are relevant to synaptic plasticity and memory. Moreover, this new Tau species is able to potentiate Tau aggregation. Otherwise, we have showed in Thy-Tau transgenic mice that neutralization of this new Tau specie, using a passive immunotherapy approach, has a beneficial effect towards memory and Tau pathology. Overall, our data indicated that this truncated Tau species is involved in Tau pathology development and is a valuable therapeutic target.

Title: Enhanced secretion of cleaved tau from cultured neuronal cells by amyloid-β overproduction

Authors: *T. IKEUCHI[1], **T. ISHIGURO**[1], K. KASUGA[1], Y. HIGUCHI[1], N. MEZAKI[2], T. MIURA[1], T. TOKUTAKE[1], O. ONODERA[1];
[1]Niigata University, Brain Res. Inst., Niigata, Japan; [2]Niigata University, Brain Res. Institiute, Niigata, Japan

Abstract: [Objectives] Aberrant proteins pathologically accumulated in brains of Alzheimer's disease (AD) are amyloid-β (Aβ) and phosphorylated tau. Recent studies have suggested that secretion of tau is an important process in the propagation of tau pathology in AD brains. However, the regulation of tau secretion in neurons has not been elucidated. In this study, we attempted to clarify the mechanism of tau secretion from neuronal cells and the effect of Aβ overproduction to the tau secretion. [Methods] Neuro 2a (N2a) cells which stably express human tau (4R1N) were established. Plasmid DNA encoding human *APP* wild type (*APP*-wt) or *APP* Swedish mutation (*APP*-swe) was transiently transfected into N2a cells. After the transfection, the lysate and culture medium were collected. Secreted and intracellular tau was examined by immunoblot analysis using anti-tau antibodies. γ-Secretase inhibitor (DAPT) was used to inhibit

Aβ production. [Results] Intracellular full-length tau was detected by both N-terminal and C-terminal antibodies against tau in the lysate of N2a cells stably expressing human tau. Secreted tau was detected by N-terminal antibody, but not by C-terminal antibody. Secretion of cleave tau was enhanced by transfection of APP-wt or APP-swe. Treatment with γ-secretase inhibitor (DAPT) attenuated secretion of cleaved tau which was induced by APP-wt transfection. [Conclusion] Cleaved tau is secreted from cultured neuronal cells in physiological condition. Secretion of fragmented tau from cultured neuronal cells was enhanced by Aβ overproduction, which may be relevant to the propagation of tau pathology in AD brain.

Title: The tau_{45-230} fragment induces morphological and functional changes in astrocytes associated with their activation in the context of Alzheimer's disease

Authors: *A. B. FERREIRA, C. PARKER;
Cell and Mol. Biol., Northwestern Univ., Chicago, IL

Abstract: We have shown that tau_{45-230} induces neurodegeneration followed by cell death in the context of Alzheimer's disease (AD) and related disorders. Our previous studies indicated that tau_{45-230} is associated with the cytoskeleton and membrane-bound organelles in hippocampal neurons. This subcellular localization underlies the neurotoxicity of this tau fragment by modifying not only the composition and stability of microtubules and actin filaments, but also the axonal transport of organelles. On the other hand, no data are available regarding the presence and/or the effects of this tau fragment in astrocytes in the AD brain. To get insights into a potential role of tau_{45-230} in glia cells, we first immunostained sections obtained from temporal cortex of AD subjects and age-matched controls using the specific tau_{45-230} antibody recently generated in our laboratory. As expected, no tau_{45-230} immunoreactivity was detected in either neurons or astrocytes in control sections. On the other hand, strong immunoreactivity for this tau fragment was detected in degenerating neurons in AD sections. Tau_{45-230} immunoreactivity was also localized in astrocytes in these AD brain sections. To investigate the effects of tau_{45-230} in astrocytes, glial cultures obtained from embryonic day 18 (E18) pregnant rats were transfected with tau_{45-230}-GFP. Changes in the morphology and gene expression in transfected glial cells

were assessed by means of quantitative Western blot, RT-PCR, and immunocytochemistry analyses. Untransfected cultured astrocytes were used as controls. Our results showed that the expression of tau_{45-230} in astrocytes induced the formation of multiple short astrocytic processes. These morphological changes were associated with the significant up-regulation of GFAP and vimentin, markers of astrocyte activation. Furthermore, the presence of this neurotoxic tau fragment was associated with the expression of pro-inflammatory factors in these glia cells. Together, these results suggest that tau_{45-230} could activate astrocytes contributing to the propagation of the disease process in AD. *This work was supported by NIH grant NS090993 to AF.*

Title: Characterization of synaptic function and behavior of a novel wild-type human tau knock-in mouse model, crossbred with 5xFAD mice

Authors: *D. K. BALSCHUN[1], S. BARENDRECHT[2], A. SCHREURS[1], V. SABANOV[1], S. GEISSLER[2], H.-U. DEMUTH[2], S. SCHILLING[2], H. CYNIS[2];
[1]Brain & Cognition, Katholieke Univ. Leuven, Leuven, Belgium; [2]Fraunhofer Inst. for Cell Therapy and Immunol., Halle, Germany

Abstract: Although preclinical research has resulted in many new therapeutic approaches, their translation mostly failed. One of the reasons is the lack of animal models that sufficiently reproduce the complexity of human AD and the response of human brain circuits to novel treatment approaches. We generated a novel human wild-type tau knock-in model by whole gene replacement and crossed it with the 5xFAD strain to strongly drive Aß-triggered pathology. Mice of both genders at the age of 6 to 8 months were analyzed by histopathological, biochemical, behavioral and electrophysiological methods.
The pathology of 5xFADxhtau-KI at 6-8 months resembled the one found in 5xFAD mice despite human tau expression in cortical and hippocampal neurons. Thus, the model is suitable to study the interaction of human tau and human APP/PS1 in a high-amyloid background. With regard to tau pathology, only a few markers of tau phosphorylation are present in 5xFADxhtau-KI mice. PHF-tau seems to be absent in these mice. At the behavioral level, htau-KI mice

showed normal WT-like cognitive performance. 5xFADxhtau-KI mice, in contrast, displayed cognitive deficits in the Morris water maze. The electrophysiological studies provided clear indications of impaired synaptic plasticity, as significant LTP deficits were found in htau-KI, 5xFADxhtau-KI and 5xFAD mice but basal synaptic transmission was unchanged. In addition to the predominantly postsynaptic deficit in LTP, we found upregulated mIPSC frequencies in all three experimental mouse models and an increased mEPSC frequency in htau-KI mice. These changes are indicative of presynaptic activation of GABAergic and glutamatergic transmission, respectively, in all three mouse lines. Further experiments are required to reconcile these unexpected findings at the mechanistic level. Given the similar degree of synaptic impairment of htau-KI and 5xFADxhtau-KI, our data suggest that amyloid pathology does not aggravate human Tau-induced synaptic dysfunction at this age.

Title: Exacerbation of tauopathy in a mouse model of Alzheimer's disease

Authors: ***B. ULM**[1,2,3], G. XU[1,2,3], S. FROMHOLT[1,2], J. HOWARD[1,2], D. BORCHELT[1,2,3], J. LEWIS[1,2,3];
[1]Dept. of Neurosci., Univ. of Florida, Gainesville, FL; [2]Ctr. for Translational Res. in Neurodegenerative Dis., Gainesville, FL; [3]McKnight Brain Inst., Gainesville, FL

Abstract: *Rationale and Objective:* Alzheimer’s disease (AD) is diagnosed based on the presence of amyloid plaques and neurofibrillary tangles composed of tau. While tau aggregates are primary pathologies in many other neurodegenerative diseases, the presence of extracellular amyloid beta (Aβ) deposits sets AD apart. Studies of familial AD patients has largely demonstrated that amyloid pathology precedes tau pathology, but replicating this temporal relationship of familial AD in mouse models has been challenging.
Methods: In the present study, we generated a mouse model with both hallmark pathologies of

AD, by crossing the APPswe-PS1dE9 model of Aβ amyloidosis with mice that express 0N4R P301L human tau under transcriptional regulation of a doxycycline-suppressible system (rTg4510 mice). From conception onward, doxycycline was administered to suppress transgenic tau expression, while allowing Aβ pathology to progress (14-15 months). Thereafter, doxycycline administration was halted, allowing for induction of human P301L tau expression for the following 6 months of age.
Results: The APPswe-PS1dE9/rTg4510 mice (14-15 months transgenic tau suppression, 6 months transgenic tau expression, n=8) exhibited an exacerbated tau pathology compared to rTg4510 mice expressing only mutant tau with the same treatment (n=9). The exacerbation of tau pathology in this model recapitulates the chronological progression of pathology proposed in the amyloid cascade hypothesis and demonstrates the priming effects of early amyloid pathology on late-life tau pathology. Studies to assess both inflammatory and neurodegenerative changes are ongoing.

Title: Tau induces neurodegeneration in Alzheimer’s disease through the sequestration and inhibition of LSD1 function

Authors: *D. J. KATZ, A. K. ENGSTROM, A. C. WALKER, R. A. MOUDGAL, D. A. MYRICK, S. M. KYLE;
Cell Biol., Emory Univ., Atlanta, GA

Abstract: Alzheimer’s disease (AD) is an irreversible, progressive brain disorder caused by neuronal cell death in the cortex and hippocampus. AD is characterized by the aberrant accumulation of β-amyloid plaques and neurofibrillary tangles of hyperphosphorylated tau (NFTs). However, the molecular mechanism by which NFTs lead to neuronal cell death remains unclear. Surprisingly, we found that the histone demethylase LSD1 is mislocalized to NFTs in AD cases and is completely depleted from the nucleus in the degenerating cortical neurons of PS19 Tauopathy mice. This suggests that NFTs may interfere with LSD1 function by sequestering LSD1 in the cytoplasm. To determine if this interaction is functional, we deleted

LSD1 in adult mice. Loss of LSD1 systemically in adult mice is sufficient to recapitulate many aspects of AD, including widespread neuronal cell death in the hippocampus and cortex, learning and memory defects, and global gene expression changes that match AD cases. If Tau is functioning through the sequestration of LSD1, then reducing LSD1 in PS19 Tauopathy mice should make these mice more sensitive to aggregating Tau. Consistent with this, we find that reducing LSD1 in PS19 mice decreases survival, exacerbates paralysis, and increases neurodegeneration. Reducing LSD1 also exacerbates the genome-wide expression changes induced by the PS19 Tau transgene. Based on these data, we propose the following model: pathological Tau leads to neuronal cell death in AD by sequestering LSD1 in the cytoplasm and interfering with the continuous requirement for LSD1 to epigenetically repress transcription associated with alternative cell fates. If this model is correct, then overexpressing LSD1 should make it more difficult for pathological Tau to deplete LSD1 from the nucleus. This would be expected to delay the ability of Tau to kill neurons. Strikingly, we find that viral overexpression of LSD1 in hippocampal neurons of PS19 mice at 8.5 months, when Tau aggregates have already formed, is sufficient to suppress Tau induced neurodegeneration and block the Tau induced immune response through 11 months. This work establishes LSD1 as a major downstream effector of Tau mediated neurodegeneration and a highly promising target for therapeutic intervention in AD.

Title: Connections between the endoplasmic reticulum stress and tau phosphorylation in Alzheimer’s disease models

Authors: *V. BODART-SANTOS[1,2], M. S. GOMES[1], A. F. BATISTA[1], B. B. NOVO[1], F. G. DE FELICE[1,3];

Abstract: Alzheimer's disease (AD) is caused by several different factors and the pathological endpoint is usually characterized by protein aggregated, like amyloid beta peptide as senile plaques and the intraneuronal accumulation of hyperphosphorylated tau protein as neurofibrillary tangles. A predominant hypothesis in the AD field is that tau hyperphosphorylation, misfolding, and aggregation into tangles impair synaptic plasticity and contribute to neurodegeneration. Our group showed that amyloid beta oligomers (AbOs) increase tau phosphorylation levels in primary hippocampal cultures and in frontal cortex of a non-human primate model of AD, and induce cognitive deficits through a neuronal endoplasmic reticulum stress (ER stress)-related pathway. Other studies showed that ER stress pathways is activate in pretangle hippocampi from AD patients, but the connection between ER stress and tau hyperphosphorylation it is still unclear. In this work, we used primary hippocampal cells to show that the induction of tau phosphorylation by okadaic acid, a PP2A inhibitor, increase the phosphorylation of ER stress related protein PERK, and using the pharmacological ER stress inducer, thapsigargin, the tau phosphorylation levels are increased. We observe that treatment with 4-phenyl butyric acid (4-PBA), an ER stress attenuator, reduce both tau and eukaryotic initiation factor 2 alpha (eIF2a) phosphorylation induced by AbOs *in vitro*, highlighting an important link between the ER stress and tau pathology in AD. To investigate this connection *in vivo*, we used a well-established model in our lab, consisting of a single injection of an AbOs suspension intracerebroventricularly (i.c.v.). Mice injected with AbOs present cognitive impairment observed in different memory tasks that starts soon after the first 24 hours post-injection. Our results indicate that AbOs can trigger the tau phosphorylation in mice hippocampus 7 days after injection and the treatment with 4-PBA (intraperitoneally) prevents AbOs-induced memory loss in the Novel Object Recognition (NOR) task. We found that in a manner similar to AbOs, i.c.v. injection of thapsigargin, promote a memory loss in the NOR task that is accompanied by eIF2a and tau phosphorylation in mice hippocampus, but 4-PBA treatment was able to prevent both *in vivo*. Together our data indicate that tau phosphorylation and ER stress can be activate in parallel by different mechanisms, and the ER stress attenuation presents an alternative to prevents tau hyperphosphorylation in the brain with direct benefits on memory.

Title: Development of a Tau seeding model in the P301S-PS19 transgenic mouse

Authors: *G. DAS DORES, A. HUGOT, M.-H. GANDON, K. LLOPIS, L. ABJEAN, F. IOP, A. FRANÇOIS, R. BILLIRAS, P. MACHADO, N. RIBEIRO PALHA, F. PANAYI, R. JEGGO; Neuropsychiatry Ctr. for Therapeut. Innovation, Inst. De Recherches Servier, Croissy-sur-Seine, France

Abstract: Background: Neuropathogical hallmarks of Alzheimer's disease include intracellular neurofibrillary, tau-containing tangles, extracellular β-amyloid-containing plaques and a likely interrelated impairment of synaptic structure and function. Since many clinical trials aimed at clearing neurotoxic species of β-amyloid have failed to demonstrate efficacy, tau-based treatments have become a point of increasing focus, including the development of tau-aggregation inhibitors. In order to characterize such agents and *in vivo* validate novel tauopathy-targeting hypotheses, well-established rodent models are essential. Accordingly, we developed *in vivo* disease-relevant models of tau aggregation by using tau seeds derived from transgenic mouse tissue. **Methods**: Pathological tau was extracted from 9 months old Tau-P301S mice (PS19 line) and used as seeds to promote aggregation in young Tau-P301S mice. Different experimental conditions have been evaluated (number of injections, different brain areas and time points) to promote tau pathology formation. Tau aggregates were biochemically measured by a homogenous time-resolved fluorescence (HTRF) assay (Cisbio) and using our in-house ultra-sensitive assays with the SIngle MOlecular Array (SIMOA™) technology to quantify total tau aggregation and the pathological tau conformation, MC1. Histologically, specific tau staining was performed by immunochemistry (AT8 and MC1 markers) to evaluate tau pathology. **Results**: Tau seeds derived from P301S-PS19 mice were able to induce progressive tau aggregate formation 3 months post-injection. A significant increase of tau aggregates was observed with the HTRF and SIMOA assays. Moreover, intense MC1 and AT8 staining was also detected 3 months post-injection. **Conclusions**: We have developed an inducible *in vivo* model of tau aggregation using tau seeds derived from TauP301S-PS19 transgenic mice. Complementary studies are currently underway to optimize our experimental conditions in order to reduce potential variability due to different seed preparations or intracerebral injections. Finally, the development of such an induced-tauopathy mouse model may be very useful to assess in vivo efficacy of small molecules inhibitors of tau aggregate formation.

Title: Effect of Pyk2 gene on the spreading of human Alzheimer tau seeds in mouse brain

Authors: *S. NIES[1,2], C. HERBER[1], S. M. STRITTMATTER[1];
[1]CNNR Program, Yale Univ., New Haven, CT; [2]Eberhard Karls Univ. of Tübingen, Tübingen, Germany

Abstract: Alzheimer's disease (AD) is a debilitating neurodegenerative disease that can be distinguished from other dementias through its pathological hallmarks: amyloid-β (Aβ) plaques and neurofibrillary tangles consisting of hyperphosphorylated protein tau. Both proteins are believed to contribute to the molecular causes of AD, with current hypotheses favoring Aβ acting upstream of tau. Nevertheless, the underlying molecular mechanisms – and whether and how the two pathologies are connected – are still under investigation.
Most AD transgenic mouse models have the caveat of overexpressing mutated tau or Aβ. This leads to elevated levels of these proteins from birth, which does not faithfully recapitulate the etiology of human AD. Recently, Virginia Lee's lab has developed a protocol to inject hyperphosphorylated tau extracted from *post mortem* brain tissue of AD patients into mice. This hyperphosphorylated human tau serves as a seed, corrupting endogenous mouse tau into tangles and leading to its spreading even in non-transgenic mice and might thus be able to provide a better model for tau.
We utilized this technique to compare the spreading pattern and density of neurofibrillary tau tangles in mice with various genetic mutations pertaining to proteins implicated in AD. We injected 3-month-old C57BL/6J (WT), Pyk2 null (PTK2B null; Pyk2 KO) and APPswe/PS1ΔE9 (APP/PS1) mice with tau lysates from aged-matched control or AD patient brains (n =10 mice per genotype and lysate, equal male-female ratio) into the hippocampus and cortex (bregma: -2.5 mm, lateral: + 2.0 mm, depth: -2.4 and -1.4 mm). Afterwards, animals were kept for 6 months, perfused with PBS and brains were fixed in 4% PFA. Brains were cut into 40 μm thick sections, then DAB stained with a phospho-tau antibody and immunohistochemically stained for microglial or astroglial activation. We were able to replicate the tau spreading seen in the published data from the Lee lab, though quantitatively at a lower density. We do not see increases in astrogliosis or microglial activation when comparing non-injected, control injected and human AD tau injected mice. When comparing different strains, we observed no difference in tau spreading pattern or overall number of affected neurons in APP/PS1, Pyk2 KO or WT mice injected with human tau. In these studies, neither Aβ plaques nor absence of Pyk2, a part of an Aβ-induced downstream signaling cascade, had a direct impact on tau spreading.

Title: Characterization of Alzheimer brain-derived pathological forms of tau and application to anti-tau antibody discovery

Authors: *H. PATEL, N. VENKAT, J. WU, T. KWON, J. MANOS, K. TITTERTON, C. PREISS, H.-Y. WU, X. LANGLOIS, K. YANAMANDRA;
Abbvie, Cambridge, MA

Abstract: Alzheimer's disease (AD) and other tauopathies are characterized by abnormal phosphorylation and aggregation of tau protein, which is correlated with neurodegeneration and cognitive decline in AD. There is convincing evidence that pathological seed-competent tau can propagate along trans-synaptically connected regions leading to disease progression. These transmitted tau aggregates function as seeding templates to direct misfolding of normal endogenous tau in the healthy recipient cells, leading to the propagation of the pathologic tau forms. However, the specific tau conformations or pathological post-translational modifications that drive the seeding and spreading of pathology are currently not well understood. Therefore, the objective of this study was to identify and characterize the pathological tau forms isolated from human AD brain using different extraction methods and to evaluate the behavior of these tau species in various biochemical and cell based assays. For this purpose, we developed assays using ultra-sensitive digital ELISA platform, Single Molecule Array (SIMOA), targeting N-terminal, mid-domain and C-terminal regions of tau to characterize tau profile in human AD brain material. We also compared our assays to the commercially available Homogeneous Time Resolved Fluorescence (HTRF) assay. Hyperphosphorylated tau was quantified using an ELISA platform against AT8-positive tau forms. Seeding competency was evaluated using FRET-based Biosensor HEK293 cells and hTau primary neurons. Using these different platforms, we characterized the pathological behavior of those tau species isolated from human AD brain. Further, these competent tau seeds were used to generate and develop anti-tau antibodies for therapeutic application and biomarker development.

Title: The effect of progranulin reduction on tau pathology and tau-associated deficits in a mouse model of tauopathy

Authors: *H. TAKAHASHI[1], Z. A. KLEIN[1], S. M. BHAGAT[1], T. IKEZU[2], S. M. STRITTMATTER[1];

Abstract: Progranulin (PGRN) is a secreted glycoprotein expressed by neurons and microglia in the central nervous system and is implicated in Alzheimer's disease (AD) as well as frontotemporal dementia and neuronal ceroid lipofuscinosis. Genetic studies demonstrate an association of the common progranulin gene (*GRN*) rs5848 variant with increased AD risk. We have previously found that the *GRN* AD risk variant has no significant effects on florbetapir positron emission tomographic amyloid imaging as well as cerebrospinal fluid (CSF) amyloid-β (Aβ) 1-42 levels, whereas it is associated with increased CSF total tau levels in the ADNI human subjects. In line with the human evidence, subsequent analyses using the APPswe/PS1ΔE9 mice also showed no exacerbating effects of PGRN deficiency on Aβ pathology, whereas we observed an increase in tau AT8 and AT180 pathologies in PGRN-deficient mice with adeno-associated-virus-mediated human P301L tau expression, independent of Aβ (Takahashi et al. 2017). These human and rodent data suggest that PGRN reduction may increase AD risk by exacerbating tau pathology, rather than by accelerating Aβ accumulation.
In this study, to further investigate effects of PGRN reduction on tau pathology and tau-mediated phenotypes including behavior deficits, gliosis, and neurodegeneration, we used a P301S tauopathy (PS19) mouse model that overexpresses 1N4R human P301S tau and generated PS19 mice with PGRN haploinsufficiency (PS19 *Grn*+/-) or complete loss (PS19 *Grn*-/-). At 7.5 months of age, we observed a significant body weight loss in PS19 *Grn*-/- mice, compared to mice with the other genotypes. In addition, mortality due to tau transgene-mediated hindlimb paralysis was also increased in PS19 *Grn*-/- mice, compared to PS19 *Grn*+/+ mice at 10 months of age. As both *Grn*-/- and PS19 mice are reported to exhibit a disinhibiton phenotype, we tested these animals in an elevated plus maze. We found that PS19 *Grn*-/- mice entered more frequently and spent more time in the open arms, compared to *Grn*-/- or PS19 *Grn*+/+ mice at 10 months of

age, suggesting an exacerbation of the disinhibition phenotype in PS19 *Grn*-/- mice. These animals were then sacrificed and the brains were dissected out and one hemisphere was snap-frozen for biochemical and RNA analyses and the other was fixed with 4% paraformaldehyde for immunohistochemistry. Future experiments will address whether tau pathology and tau-mediated gliosis and neurodegeneration are altered in PS19 *Grn*+/- or PS19 *Grn*-/- mice.

Title: The calcium-containing smooth endoplasmic reticulum is a focus of risk factors for early and late onset Alzheimer's disease

Authors: *D. DATTA[1], Y. M. MOROZOV[4], J. I. ARELLANO[2], M. WANG[6], C. VAN DYCK[3], A. F. ARNSTEN[5];
[2]Neurobio., [3]Psychiatry, [1]Yale Univ., New Haven, CT; [4]Dept Neurobiol, [5]Yale Univ. Sch. Med., New Haven, CT; [6]Yale Univ. Sch. of Med., New Haven, CT

Abstract: TREM2 is a risk factor for late onset Alzheimer's Disease (AD). Current research from mouse models has focused on the role of microglial TREM2 in reducing extracellular Aβ. However, mouse models do not provide the opportunity to explore the newly evolved association cortices that are the most vulnerable to AD neurodegeneration and tau pathology. Our recent data have shown that aging rhesus monkeys exhibit the same qualitative pattern and sequence of tau pathology as humans, with neurofibrillary tangles and autophagic degeneration. Thus, aging monkeys can be uniquely helpful in using high quality immunoelectron microscopy to elucidate the molecular events in association cortex that increase risk for AD pathology. Our new data from aging monkey dorsolateral prefrontal cortex (dlPFC) indicate that TREM2 is found not only in glia, but in neurons, focused on the calcium-storing smooth endoplasmic reticulum (SER). The SER is also the focus of presenilin (PS1, PS2) expression, the genes most commonly linked to early onset, autosomal dominant AD. This nexus of genetic risks suggests that calcium dysregulation is a key factor in AD neurodegeneration, a mechanism that has been recognized but underemphasized in the AD field. Our new data also show that the SER is also a focus of age-related pathology in association cortex, with loss of PDE4D from the SER in spines and

dendrites, and increased PKA phosphorylation of type II ryanodine receptors (RyR2) on the SER at S2808, which causes calcium "leak". We also find evidence of increased PKA phosphorylation of tau at S214, an important step that causes tau to detach from microtubules and aggregate, and primes tau for hyperphosphorylation and neurofibrillary tangle formation. As with pS2808RyR2, pS214Tau aggregates on the SER early in the aging process. Thus, early onset (PS1), late onset (TREM2) and aging, all target the SER in the association cortical synapses most vulnerable to AD pathology. Finally, restabilizing pS2808RyR2 with S107 treatment to reduce calcium "leak", enhances *in vivo* pyramidal delay cell firing and working memory function in rhesus macaques. Therefore, illuminating the cascade of events in the aging cortex may provide an opportunity for therapeutic intervention at early stages of pathology.

Title: Evaluation of the axolotl as a novel model to study physiological response to neurodegenerative diseases

Authors: *L. JAMES[1,2,3], A. WALKER[1,2,3], T. POLVADORE[4], M. MADEN[4], J. LEWIS[1,2,3]; [1]Ctr. for Translational Res. in Neurodegenerative Dis., [2]Dept. of Neurosci., [3]McKnight Brain Inst., [4]Dept. of Biol. and UF Genet. Inst., Univ. of Florida, Gainesville, FL

Abstract: The axolotl, *Ambystoma mexicanum*, has the ability to regenerate entire limbs, tail, and large portions of organs, making it a widely used model for investigating development and regenerative processes. The axolotl brain exhibits both extensive regeneration and continual production of physiologically healthy and functionally diverse neurons, making it a potentially ideal model for investigating physiological response to neurodegeneration. While the full 32 billion base pair genome was primarily sequenced to identify genes responsible for skin and limb regeneration, we identified homologs for genes associated with neurodegenerative diseases such as *GRN* and *MAPT* to illustrate this model's potential. *GRN* codes for progranulin (PGRN), a 593 AA anti-inflammatory, secreted glycoprotein which can be cleaved into 7.5 cysteine-rich, pro-inflammatory granulins, whereas *MAPT* codes for tau, a 441 AA protein involved in microtubule assembly and stabilization. Using the axolotl-omics genome browser and transcriptome assembly, we identified axolotl genes and transcripts homologous to *GRN* and *MAPT*, coined *ax_grn* and *ax_mapt* which code for ax_pgrn and ax_tau, respectively. We then aligned the protein sequences of PGRN and tau with ax_pgrn and ax_tau using the NCBI Protein BLAST

tools and identified corresponding functional domains. The ax_pgrn is 851 AA long and appears to have 10.5 granulin-like motifs that contain the same number of cysteine residues as human granulins. The ax_tau is 528 AA long and has high conservation in the proline-rich, microtubule binding, and C-terminus regions. The ax_tau binding domain is 94% functionally-equivalent to the binding domain of human tau and the proline-rich regions has a similar ratio of prolines. Currently, size is used as the aging marker in axolotl research, however, we show that axolotls develop lipofuscin, a wear-and-tear pigment used as a marker in human aging. We will characterize lipofuscin in young, old, and regenerated tissue to establish a comparative timescale for immunohistochemical staining and protein immunoblotting. Establishing the axolotl as a novel model to study neurodegenerative disease potentially enables researchers to study evolved mechanisms of combatting neural damage.

Title: Declines in behavior and cognition as tau is expressed at different times in the adult *drosophila melanogaster* brain

Authors: *D. B. GONZALEZ[1], D. D. LENT[2];
[1]Biol., California State University, Fresno, Fresno, CA; [2]Biol., CSU Fresno, Fresno, CA

Abstract: The fruit fly, *Drosophila melanogaster*, has proven to be a useful model organism for many human neurodegenerative diseases. Here, we use the fruit fly to demonstrate the progressive decline in behavior and cognition associated with Alzheimer's disease (AD). This disease is characterized by Aβ plaques and Neurofibrillary Tangles (NFTs). Our focus in this study is on the tau protein which forms the tangles and may lead to neurodegeneration and a decline in learning and memory. To investigate tau mediated neurodegeneration, we inserted human tau into two specific areas of the fruit flies' brain, the Mushroom body (MB) and the Ellipsoid Body (EB). These areas have homologous structures in mammals (hippocampus and basal ganglia) that have demonstrated to be necessary for various cognitive behaviors. In addition to spatially constraining the expression of tau, we expressed tau at 3 different life stages (young, middle, and elderly). Investigating the effects of tau through several stages of life allows for a better comparison and possibly a better model for AD. Using the temperature and regional gene expressing (TARGET) system, we are able to express tau only during the adult stage of life. All experiments involved using virgin females to avoid confounds of male-male and male-female

interactions during group behavioral assays. A minimum of ten flies of each age group (5 day old, 15 day old, 25 day old) from each of the fly lines (MB, EB), as well as control groups that shared the same genetic background, but did not express tau, were used for behavioral testing. We assessed behavioral and cognitive declines through a series of learning, memory, and planning assays, along with fluorescent microscopy to analyze tau expression in the fly brain. A progressive decline in learning and memory was found within the transgenic fly lines. Tau expression in the brain also increased as age increased. This exploratory research can support a better *Drosophila melanogaster* model of AD, which can serve to advance treatment at the early stage of the disease and help alleviate symptoms in the future.

Title: Comparison of 11.7T *ex vivo* with 3T *in vivo* MRI signal intensity of the hippocampus of wild-type, Tau, and PSEN1 individual mice: A pilot study

Authors: *A. SOTELO[1], M. DIAMSE[2], N. HUANG[2], K. S. STEED[3], J. HAMILTON[2], J. WISCO[4];
[1]Neurosci., [2]Boston Univ. Sch. of Med., Boston, MA; [3]Biomed. Educ., Brigham Young Univ. and California Hlth. Sci. Univ., Fresno, CA; [4]Boston Univ. Sch. of Med. and Brigham Young Univ., Boston, MA

Abstract: Alzheimer’s disease (AD) causes tremendous damage to the brain over the course of the life of those afflicted. A major focus of AD research pertains to the development of diagnostic tools and methods to examine subtle pathological changes that occur early in the brain. Improving Magnetic Resonance Imaging (MRI) techniques to visualize brain pathology is an important step toward achieving definitive clinical diagnostic imaging. We have been using

3T MRI to assess the pathological effects of PSEN1 and Tau transgenic mice compared with C57BL6 wild-types (WT) in an animal model for AD. Although *in vivo* imaging in a 3T Siemens Trio produced adequate signal to noise for semi-quantitative analysis in our longitudinal study, we wanted to know the extent of signal gain using *ex vivo* imaging in a 11.7T Bruker 500 MHz magnet. Methods: Of the PSEN1, Tau and WT mice bred for this project, we imaged one post-mortem brain hemisphere from amongst subjects in each cohort that were fed a normal diet and were sacrificed at 6 months into the study. We acquired T1 images at 11.7T; and T2, and T2* images at both 3T and 11.7T. In this pilot study we measured and compared the signal intensity differences of the body of the hippocampus from T2 and T2* images. Measurements were acquired from one axial slice at a level where both the anterior and posterior horns of the lateral ventricles were visible using the analysis software Horos (https://horosproject.org/). Results: We show that 11.7T MRI provides superbly clearer signal to noise of all structures of the brain. The average signal between 11.7T and 3T field strengths within a 2 mm ROI of the hippocampus body in the PSEN1 mouse brain T2 image showed an 840 fold increase, and an 85 fold increase in the T2*. In the Tau mouse brain, T2 showed a 746 fold increase in signal; T2* showed a 95 fold increase in signal. In the WT brain, T2 showed a 646 fold increase in signal; T2* showed a 70 fold increase in signal. Conclusion: Although preliminary, results indicate an approximately linear difference in T2 and T2* signal between 11.7T and 3T MR field strengths, and may indicate that post-mortem imaging at high field strength can be added to our protocol to assess pathological changes in the mice brains across transgene cohorts.

Title: Neuronal N27A cell line expressing mutant tau YFP provides a model for Alzheimer’s disease

Authors: *C. R. FREED[1], S. L. HAMMOND[2], W. ZHOU[3];
[1]Clin. Pharmacol., [2]Univ. of Colorado, Aurora, CO; [3]Dept. of Med., Univ. of Colorado Denver, Aurora, CO

Abstract: The incidence of Alzheimer’s disease is rising as the elderly population increases in the United States and around the world. Brain pathology is defined by extracellular β-amyloid (Aβ) plaques and intracellular neurofibrillary tangles of tau protein. Recent studies have suggested that aggregated tau, and not Aβ aggregation, correlates most closely with dementia.

After the failure of many clinical trials targeting Aβ, it is now time to explore treatments that prevent tau pathology. Metabolism of tau can produce hyper-phosphorylation and protein aggregation leading to neuronal toxicity. To model tauopathy *in vitro*, we have used rat neuronal N27A cell lines to stably express either the human P301L mutant tau gene (Mut-tau-YFP) or the wild type tau gene (WT-tau-YFP). These cells can be monitored in live culture by their expression of the YFP gene. We have found that the constitutive expression of the mutant tau gene leads to protein aggregation and formation of large inclusions in every cell, thereby mimicking the neurofibrillary tangles which are present in human Alzheimer's disease. Immunostaining and Western blotting have confirmed that tau is hyperphosphorylated in the Mut-tau-YFP cell line. Interestingly, this sane Mut-tau-YFP cell line can directly secret tau protein into the culture medium. When exposed to oxidative stress, Mut-tau-YFP cells are more vulnerable to cell death than WT-tau-YFP cells. When both cell lines are pre-treated with 150 uM of phenylbutyrate, the drug protects both WT-Tau-YFP and Mut-Tau-YFP cells from hydrogen peroxide-induced cell death. In summary, the N27A rat dopaminergic cell line expressing mutant tau with a YFP reporter can recapitulate the pathological features of tauopathy. This cell line should provide a useful *in vitro* model for studying the molecular mechanisms of tau aggregation and for screening drugs that may have value for treating patients with Alzheimer's disease.

Title: Genetic ablation of the senescence mediator p16 attenuates tau-mediated neurodegeneration

Authors: *C. F. MEYER[1], S. I. GRAVES[2], T. J. BUSSIAN[2], B. L. SWENSON[1], D. J. BAKER[1,2];

Abstract: Cellular senescence is a process characterized by an irreversible cell cycle arrest and a distinct secretory phenotype, which can be induced in response to many intracellular and extracellular factors. Traditionally, these cells have been characterized by exhibiting increased expression of the cell cycle inhibitors $p21^{Cip1}$, $p19^{ARF}$, and/or $p16^{INK4A}$. We, and others, have demonstrated that cells expressing $p16^{INK4a}$ actively drive tissue deterioration with natural aging and in several age-associated diseases, including atherosclerosis, osteoarthritis, and neurodegenerative disease in mice. We have used a transgenic mouse model (termed INK-ATTAC) in combination with a tauopathy-based mouse model of neurodegeneration to demonstrate that removal of $p16^{INK4A}$-positive cells prevents tau-dependent pathology and cognitive impairment, suggesting that senescent initiate disease. Here, we demonstrate that genetic deletion of $p16^{INK4A}$ in the background of $MAPT^{P301S}$ PS19 mice also attenuates tau-dependent pathology. Loss of $p16^{INK4A}$ decreases gliosis, p-tau burden, neurofibrillary tangle development, and importantly, preserves hippocampal and cortical neurons resulting in near baseline cognitive function. This work further highlights the importance of $p16^{INK4A}$-dependent cellular senescence in the initiation and progression of tauopathy-based disease, and narrows the scope for further study implicating senescence in the development of other neurodegenerative diseases.

Title: Lifespan magnetic resonance imaging of novel mouse models of Alzheimer's disease: Phenotyping and comparisons to healthy aging

Authors: *A. JULLIENNE[1], A. OBENAUS[2,4], J. LEE[5], J. I. SZU[3], E. J. BEHRINGER[4], M. AD CONSORTIUM[3,6,7,8,9];

Disorders (UCI MIND), [2]Dept. of Pediatrics, [3]Univ. of California, Irvine, Irvine, CA; [4]Basic Sci., [5]Div. of Physiology, Sch. of Med., Loma Linda Univ., Loma Linda, CA; [6]Indiana Univ., Indianapolis, IN; [7]Jackson Lab., Bar Harbor, ME; [8]Sage Bionetworks, Seattle, WA; [9]Univ. of Pittsburg, Pittsburg, PA

Abstract: The Model Organism Development and Evaluation for Late-Onset Alzheimer's Disease (MODEL-AD) consortium has been established to develop the next generation of Alzheimer's disease (AD) models based on human data. As these models are developed, they are rigorously characterized using genomic, histological, electrophysiological and behavioral measures. Magnetic resonance imaging (MRI) provides multiple contrasts to probe the healthy aging brain of C57BL/6J mice and AD mouse models as they exhibit progressive onset of the disease. Several AD mouse models are being assessed, including 5xFAD (a commonly used model of familial AD) and human amyloid beta (Aß) knock-in mice, wherein the human Aß which forms the characteristic fibrillar plaques of AD is expressed under the murine endogenous promoter. All MODEL-AD mice are compared to age-matched littermates (C57BL/6J) mice at 4, 8, 12 and >18mo (N=8-9/sex/age). Mice underwent high-resolution MRI to assess their phenotype: T2-weighted and susceptibility-weighted imaging (11.7T) were used for brain region volumetric analysis and quantitative analysis of Aß plaque load, and diffusion tensor imaging (DTI, 9.4T) was used to analyze white matter tracts. Emerging data found significant volumetric reductions (~6%) in cerebrum volumes between 8mo-old female C57BL/6J and age-matched 5xFAD mice. Hippocampal volumes were significantly reduced in 4mo-old males but not females when comparing C57BL/6J to 5xFAD mice. DTI metrics that report tissue features, such as fractional anisotropy, radial, axial and mean diffusivity will evaluate the progressive alterations in AD mouse models over their lifespan. Preliminary tractography mapping circuits from hippocampal CA1 to the subiculum found sex-specific differences in the number and density of tracts (streamlines) in healthy 4mo C57BL/6J mice. Such novel sex differences will be analyzed in our novel AD mouse models as well as age-matched healthy control mice. In summary, phenotyping using multimodal MRI can identify altered brain connectivity and regional tissue metrics across the mouse lifespan in healthy aging and in AD models. These MRI approaches can lead to clinically translatable tools for assessment of AD progression in human patients. For more information, see model-ad.org.

Abstract: AD therapy development efforts have consistently failed, despite success in preclinical trials in animal models. This may have many causes, but more predictive animal models would certainly be beneficial. The Model Organism Development and Evaluation for Late-onset AD (MODEL-AD) Center was created to develop, characterize, and distribute more precise preclinical models for late-onset AD (LOAD). Our approach is to engineer mouse models to express combinations of genetic variants identified in human LOAD populations in genome-wide association studies (GWAS). These are being generated into a model that predisposes to AD risk by expressing humanized APOE4 and mutant Trem2. In the future, we will also include humanized APP and MAPT (Tau). GWAS variants are prioritized to impact discrete pathways (e.g. neuroinflammation, lipid metabolism, etc.). Models are prioritized for comprehensive phenotyping based on a newly designed nanoString transcriptomics panel compiled from human post mortem co-expression data from the AMP-AD consortium. This approach enables us to correlate transcript profiles in the mouse models to key human disease processes and pathways. We have edited human AD risk variants into the corresponding mouse genes for *Abca7, Clasp2, CR1, Kif21b, Mthfr, Mtmr4, Plcg2, Shc2, Slc6a17, Snx1* and *Sorl1*. Knockouts of *Abca7, Ceacam1, Il1rap*, Meox2 and *Plcg2* have also been created to model human loss of function variants in the mouse. Analysis at 4, 8, and 12 months shows that some of the AD-associated transcriptomic modules are disrupted in an age-dependent manner, including immune and DNA-repair pathways. The most promising models (as well as existing fAD mouse models) are being phenotyped to 24 months of age using clinically relevant measures including transcriptomics, proteomics, metabolomics, biomarkers in CSF and blood, neuropathology, *in vivo* imaging (for amyloid, tau, blood flow and glucose metabolism) and cognitive assays. This will determine key phenotypes and the therapeutic window for each model in a comprehensive manner. We plan to later combine variants that impact various AD-relevant pathways. Through introducing combinations of human AD risk variants into mice, we expect to create new models that provide more precise and relevant translational models for preclinical development. All models are made available for both academic and for-profit use from The Jackson Laboratory, and all validation data will be shared via the AMP-AD knowledge portal. For more information see www.model-ad.org.

Title: Characterization and deep phenotyping of the 5xfAD mouse model by MODEL-AD

Authors: *S. FORNER[1], M. AD CONSORTIUM[1,2,3,4,5];
[1]Univ. of California Irvine, Irvine, CA; [2]Indiana Univ., Indianapolis, IN; [3]Univ. of Pittsburgh, Pittsburgh, PA; [4]Jackson Lab., Bar Harbor, ME; [5]Sage Bionetworks, Seattle, WA

Abstract: The Model Organism Development and Evaluation for Late-Onset Alzheimer's Disease (MODEL-AD) has been established as a consortium consisting of University of California Irvine, University of Indiana, University of Pittsburgh, Jackson Laboratory and Sage Bionetworks to develop the next generation of Alzheimer's disease (AD) models and institute a standardized and rigorous process for characterization of animal models. One of the goals is to further characterize and deep phenotype well utilized early onset AD models, such as the 5xfAD model. This model is known for recapitulating many AD-related phenotypes and have a relatively early and aggressive presentation. Behavioral assays, Long-term potentiation (LTP) recordings from acute hippocampal slices, RNA-seq, immunofluorescent histology, and biochemical assays were performed in male/female 5xfAD mice and compared to age-matched littermates (C57BL/6J) mice at 4, 8, and 12 months. 5xfAD mice exhibit robust plaque deposition, present throughout the brain by 4 months of age, with plaque numbers and sizes increasing with age, alongside increases in detergent soluble and insoluble Aβ38, Aβ40 and Aβ42 levels in both hippocampus and cortex. Concomitant with plaque deposition are increases in microglia densities, and expression of GFAP by astrocytes. Reductions in $NeuN^+$ neurons are seen from 4 months of age in the cortex. Female mice show increased plaque and Aβ burden, and associated changes in glial cells, compared to male mice, but this may be due to observed increased transgene expression from the Thy1 promoter in female mice. Strong behavioral deficits are seen in the elevated plus maze from 4 months of age, compared to wild-type controls, as well as robust LTP deficits. In summary, 5xfAD mice have a range of cognitive and motor deficits and severe amyloid pathology. All data sets and protocols will be made widely available to the scientific community. For more information, see model-ad.org.

Abstract: Alzheimer’s disease (AD) is the most common cause of dementia in the United States. Approximately 95% of patients have sporadic Late-Onset AD (LOAD) which lacks an inheritance pattern. Therefore, identifying phenotypic patterns are critical for understanding disease progression. Apolipoprotein E4 (APOE4), the strongest genetic risk factor of LOAD, increases AD risk by 3-12 fold depending on copy number. Recent GWAS analysis elucidated the LOAD-associated loci on the triggering receptor expressed on myeloid cell 2 (TREM2). APOE is a known ligand to the TREM2 receptor, and the R47H variant could increase the AD risk by 2-3 fold. Preclinical studies of these risk alleles and their phenotypes are underway by MODEL-AD. Using PET/MRI and a novel analytical scheme, we established the perfusion-metabolism profiles across 27 brain regions in both sexes by using ^{64}Cu-PTSM and ^{18}F-FDG in the APOE4 (*APOE4*$^{E4/E4}$), TREM2 (*TREM2*$^{R47H/R47H}$), and double (*APOE4*$^{E4/E4}$.*TREM2*$^{R47H/R47H}$) knockin (KI) mice. Longitudinal analysis comparing 8mo to 4mo time point revealed that male APOE4 mice and both sexes of TREM2 had hypo- perfusion and metabolism, while female APOE4 mice showed an uncoupled hyper-perfusion and hypo-metabolism phenotype, and was correlated to human AD pathology. In the double KI mice, perfusion and metabolism showed a mixed phenotype which was region dependent. Cross-sectional analysis of KI compared to B6 mice at 8mo showed an overall reduced glucose metabolism. Intriguingly, male APOE4, TREM2, and double mice showed hypo-perfusion and metabolism, while female double mice showed metabolic uncoupling compared to B6. Analysis of blood biochemistry in non-fasted mice revealed no significant difference between genotypes in blood glucose level with age. However, APOE4 decreased the blood cholesterol level, including total cholesterol, LDL, and HDL. By contrast, TREM2 decreases the level of non-essential fatty acid in male mice. To

confirm these findings, RNAseq, nanostring, and immunohgistology was peformed. Consistent with the phyotypes described, key genes involved in the regulation of cerebral perfusion, glucose transportation, and metabolism were altered. Moreover, we observed the vascular disruption by immunostaining of endothelial markers. These data suggest that the new perfusion-metabolism strategy may be able to identify AD-related patterns. Moreover, they replicate clinical manifestations of subjects with the same variants. Finally, additional studies are needed to elucidate the mechanisms and etiology of this uncoupling phenomenon.

Abstract: Current animal models do not fully recapitulate late-onset Alzheimer’s Disease (LOAD), thus are not ideal for therapy development. To address this, the Model Organism Development and Evaluation for Late-onset AD consortium (MODEL-AD) has created a novel LOAD mouse carrying two common risk alleles. Characterization of this model at young and advanced ages will indicate more appropriate disease mechanisms useful in the treatment of LOAD.
Humanized *APOEe4* and the *Trem2*R47H* mutation, two prominent genetic risk factors for LOAD, were inserted into the genome of C57BL/6J mice to create the B6.*APOEe4.Trem2*R47H*

(B6J.*hAT*) model. Cohorts of B6J.*hAT* (with controls) were established at JAX and IU and aged to 2, 6, 12, and 24 months. At JAX, *in vivo* behavior and wellness assays measured activity, frailty, grip strength, coordination, and cognitive ability. At IU, MRI and PET studies using [18F]-FDG and [64Cu]-PTSM were completed. Post-mortem analyses at both sites included blood chemistry, brain immunohistochemistry, transcriptomics, metabolomics, and proteomics. Data from 'omics experiments were systematically compared to analogous data from the Accelerating Medicines Partnership for Alzheimer's Disease (AMP-AD) human disease cohorts. By 12 months, female B6J.*hAT* mice displayed reduced frailty index scores, a measure of aging and vulnerability, suggesting a protective phenotype. B6J.*hAT* and B6.*APOEe4* mice showed decreased levels of total cholesterol, LDL, and HDL at multiple time points - an effect of the *APOEe4* allele that has been reported previously. We also observed a novel splicing event in mice expressing the *Trem2**R47H variant and approximately 50% reduction in TREM2 expression. Global transcriptomics revealed age-related changes in B6J.*hAT* brain samples compared to controls. Differentially expressed genes were enriched in multiple AD-related pathways including immune response, splicesome, and osteoclast differentiation. Proteomic and metabolomics assays further align effects in the mouse models with a subset of changes observed in human post-mortem samples. We observed sex-specific effects from the *APOEe4* allele that generally aligned with LOAD in women.
The MODEL-AD consortium has established a new mouse strain to study the effects of two strong risk factors for LOAD that affect systems-level measures associated with human disease. This model serves a backbone strain for the further addition of LOAD risk alleles to more closely align phenotypes in the mouse to outcomes observed in human AD.

Abstract: Alzheimer's disease (AD) is the leading cause of dementia. The majority of AD cases are late-onset, but a causal mechanism remains unknown. However, there are likely multifactorial contributors like age, environment and genetics that increase the risk for developing the disease. Genetic factors such as rare variants of TREM2 (triggering receptor expressed on myeloid cells-2) strongly increase the risk of developing AD, confirming the role of microglia in AD pathogenesis. Several studies have examined the mechanisms by which TREM2 and its rare variants affect amyloid and tau pathologies and their consequences in both animal models and in human studies. The Model Organism Development and Evaluation Center for Late-Onset Alzheimer's disease (MODEL-AD) has created a mouse models carrying the Trem2*R47H KI allele using CRISP/Cas9 containing a nucleotide G>A point mutation for amino acid sequence change at R47H into the gene. Mice were aged to 2, 8 and 12 months. In addition, the 5xFAD model was crossed with mice carrying the Trem2*R47H variant. Tissue was analyzed using RNA-sequencing, IP Western Blotting and immunohistochemistry. In mice carrying the R47H variant, there is an alternate splicing event, resulting in a 119bp deletion inside exon 2 and decreased mRNA levels. The deleted segment includes the R47H mutation. This alternate splicing event occurs in some non-mutant mice, but is more prominent in Trem2*R47H samples. This finding suggests an alternate splicing effect on *Trem2* due to R47H mutation. Using IP Western Blots, we found the protein level of Trem2 to be reduced by approximately 60% in brain homogenates. This correlates with RNA-sequencing results. PET imaging using 64Cu-PTSM and 19F-FDG shows a reduction in glucose metabolism of mice at older ages. Despite the reduction in messenger RNA, there is significant full-length expression of mutant Trem2 mRNA in mice carrying the Trem2*R47H variant. This is consistent with the reduction in Trem2 protein is observed from brains. Furthermore, this model does not phenocopy a Trem2 knockout since significant expression of Trem2 protein in brain tissue is observed and transcriptome alterations are different and less pronounced. In addition, these mice may show a potential perfusion-metabolism pattern that is different than wild-type mice. Future studies with these models aid in understanding how Trem2 plays a role in the progression of AD.

Abstract: Alzheimer’s disease (AD) is a neurodegenerative pathology characterized by the loss of memory and cognitive impairment. Accumulation of amyloid-βplaques and tangles are key pathological signatures that are associated with the disease. Existing mouse models of AD are based on familial mutations that lead to an early onset of the disease. MODEL-AD is tasked to develop novel models that are more representative of the late onset version of the disease. The consortium is collecting RNA-seq datasets from cortex and hippocampus in a time course of neurodegeneration in both AD model mice and wildtype controls as part of the deep phenotyping of these mice. We are also collecting similar time courses from well-established familial mouse models for comparative purposes. Our RNA-seq datasets include a single-cell RNA-seq pilot for a select set of mice. We are analyzing the data for both differential expressed genes and modules that are either common or specific for the different models. As these modules are refined, we are comparing them to results from AMP-AD to identify which of the same genes are turned on during disease progression in human. All data are released through the Synapse portal. As part of the validation of our RNA-seq analysis pipeline, we have analyzed a time course of gene expression in hippocampus and cortex of 5xFAD mice at 4, 8 and 12 months. We recover, as expected, a strong inflammatory module that is more pronounced in females. While many of the inflammatory module genes peak at 8 months, we see a subset of genes such as members the complement system that continue to increase at 12 months in hippocampus. We are investigating whether the same gene expression profiles are consistent in other mouse models as they are characterized in our phenotypic pipeline as well as compared to human AD modules.

Title: Modulation of corticotropin releasing factor (CRF) in a CRND8 mouse model of Alzheimer disease-like amyloidosis improves spatial navigation in the water maze test

Authors: *C. G. JANUS, G. GIRALDO, H. S. FUTCH, T. E. GOLDE;
Univ. of Florida, Gainesville, FL

Abstract: Chronic psychological stress affects the stress-responsive corticotropin-releasing factor (CRF) and glucocorticoid (GC) signaling systems that are putative targets in neuropsychiatric, cardiovascular, and neurodegenerative diseases. The presence of elevated cortisol levels in Alzheimer disease (AD) patients supports the hypothesis that stress may contribute to the severity of AD. Since stress is also associated with hippocampal damage and impaired memory, we hypothesized that the modulation of CRF activity might mitigate associated comorbidities of anxiety or agitation, ameliorating cognitive function. To this end, we developed a high affinity monoclonal antibody (CTRND05) targeting CRF. In mice, CTRND05 blocks stress-induced increases in corticosterone, and induces phenotypes consistent with suppression of the HPA axis. In this preliminary study, we used the CRND8 mouse model of AD-like amyloidosis. The mice were immunized against CRF for 3 months, starting at 3 months of age with the onset of amyloid deposition in the brain. Two CRND8 transgenic (Tg) groups, immunized against CRF (anti-CRF, n = 11) and immunized with IgG (n = 9), and a group of naïve non-transgenic (nTg) littermates (n = 16) were used. Groups were closely sex balanced. The mice were evaluated at 6 months of age in the SHIRPA screen, followed by the Light/Dark (LD) anxiety test and the spatial reference memory version of the Morris water maze (MWM) test. No differences were found in the physical condition and reflexes between the groups (SHIRPA screen). Although the LD test did not reveal changes in the anxiety of CRND8 mice, the immunization against CRF reduced hyperactivity previously observed in this model. The IgG mice, however, showed characteristic locomotor hyperactivity in the test. The analysis of the search path during learning acquisition in the MWM revealed significant treatment ($p = 0.003$) and treatment by training day ($p = 0.040$) effects. The anti-CRF mice showed comparable search paths to nTg mice ($p = 0.14$), while the paths of IgG mice were longer ($p = 0.02$, Dunnett t, 2-sided test). The improvement in performance of anti-CRF mice was substantiated by the analysis of the latencies to reach the vicinity of the escape platform (annulus of 2 X the platform diameter). Anti-CRF and nTg mice showed short and comparable latencies to the annulus area ($p = 0.78$), that were different from the latencies of IgG mice ($p = 0.004$ and $p < 0.001$, respectively). However, these differences were not reflected in the probe trial test. In conclusion, our results indicate that 3-month long passive immunization against CRF improved the “knowing where” aspect of spatial navigation in CRND8 mice in MWM.

Title: Perinatal choline supplementation normalizes spatial learning and memory deficits in the APP.PS1 Alzheimer's disease model mice

Authors: T. J. MELLOTT, E. M. BRUNS, K. N. CORDEIRO, N. WASIF, A. P. SANKAR, *J. K. BLUSZTAJN;
Pathology and Lab. Med., Boston Univ. Sch. of Med., Boston, MA

Abstract: Prevention of Alzheimer's disease (AD) is a major goal of biomedical sciences. In previous studies we showed that high intake of the essential nutrient, choline, during gestation prevented age-related memory decline in a rat model. We also reported (Mellott et al, PMID:28103298) that the hippocampus of perinatally choline-supplemented AD model APP.PS1 (MGI ID: 3524957) mice exhibited: 1) reduced number and total area of amyloid plaques; 2) preserved levels of choline acetyltransferase and insulin-like growth factor II proteins; and 3) absence of astrogliosis, as compared to APP.PS1 mice reared on control diet. In this study we tested the hypothesis that perinatal choline supplementation ameliorates the cognitive impairment in this model of AD. We placed wild type (WT) females and hemizygous APP.PS1males on the control AIN76A diet (1.1 g/kg of choline chloride) or on a choline-supplemented AIN76A diet (5 g/kg of choline chloride). After 7 days, the animals were mated and the dams continued to consume their prenatal diets through birth and lactation until weaning of the pups on postnatal day 21. Subsequently all offspring consumed the control diet. Learning and memory of the animals of both sexes were assessed in a Barnes maze at 6 and 9 months of age. All animals learned the task. At 6 months of age there were no differences between the experimental groups. At 9 months of age the APP.PS1 mice whose mothers consumed the control diet were impaired requiring 47% longer time to locate the escape pod in the maze at the final trial of training as compared to the WT mice ($p=0.03$). However, the behavior of APP.PS1 mice whose mothers consumed the choline-supplemented diet was ameliorated, resembling that of the WT animals. Perinatal choline supplementation had no effect on the behavior of the WT mice. The results are consistent with a recent report by Velazquez et al (PMID:30622336).

Overall, these data suggest that dietary supplementation with choline during early life may constitute a preventive strategy for AD.

Title: Transcriptomic analysis of chronic levetiracetam treatment in aged 5XFAD mice: Relationship with pharmacokinetics and pharmacodynamics

Authors: *S. J. SUKOFF RIZZO[1], K. D. ONOS[2], K. KEEZER[3], L. HAYNES[3], H. WILLIAMS[3], S. K. QUINNEY[4], A. MASTERS[4], C. BIESDORF DE ALMEIDA[4], A. A. BEDWELL[4], J. A. MEYER[5], C. Abstract: The Preclinical Testing Core (PTC) of the Model Organism Development for Late Onset Alzheimer’s Disease (MODEL-AD) consortium has established a streamlined preclinical drug testing strategy with go/no-go decision points that allow critical and unbiased assessments of potential therapeutic agents. For the present studies, we selected levetiracetam (LEV), a compound currently in clinical trials for the treatment of cognitive impairment associated with AD, for testing in 5XFAD mice. Initial pharmacokinetics (PK) analysis revealed a short half-life of LEV requiring twice daily dosing. Chronic administration of LEV (veh, 10, 30, and 56 mg/kg, p.o., BID). began at 3 mos. of age, prior to the onset of significant amyloid load in 5XFAD mice with all pharmacodynamics (PD) endpoints measured at 6 mos. of age in male and female 5XFAD mice and vehicle-treated age-and sex-matched WT controls (n=11-20 per sex/genotype/treatment) and included: 18-FDG PET/MR, 18F-AV45 PET/MR, autoradiography, immunohistochemistry, spontaneous alternation, open field activity, rotarod, PK analysis, and gene expression profiling using the Nanostring nCounter Mouse AD Panel, which includes a set of 770 genes prioritized for probe design by MODEL-AD that includes coverage of all AD-associated modules from AMP-AD clinical samples with human-mouse homology. In line with

the ARRIVE guidelines, all technicians were blinded to dose and genotype during execution of experiments and throughout data collection and analysis, with all samples and subjects randomized and counterbalanced. Prophylactic treatment with LEV produced dose-related alterations in behaviors related to activity without significant improvements on cognitive performance. LEV also failed to alter amyloid deposition as measured by 18F-AV45 PET or alterations of glucose uptake as measured by 18-FDG PET. Transcriptomic analysis revealed expected gene expression profile changes related to AD in male and female 5XFAD mice relative to age-matched WT controls. LEV treatment resulted in correlations with gene expression modules related to neuron and glial development, and myelination, and anti-correlated with gene expression modules related to synaptic signaling and nervous system development which were mildly dose-related and in some cases sex-dependent. Taken together these data indicate that the 5XFAD mouse model may not be an optimal model for evaluating the PD effects of LEV, however transcriptomic analysis revealed suggestive evidence that LEV ameliorates some of the synaptic damage from the transgene while intensifying the myelination defects related to AD; findings which require further investigation.

Title: Ubiquitin specific protease 13 regulates tau accumulation and clearance in models of Alzheimer’s disease

Authors: *X. LIU, M. HEBRON, S. MULKI, C. WANG, E. LEKAH, D. FERRANTE, W. SHI, B. KURD-MISTO, C. MOUSSA;
Georgetown Univ. Med. Ctr., Washington DC, DC

Abstract: Background: Ubiquitin Specific Protease-13 (USP13) is a de-ubiquinating enzyme that regulates protein ubiquitination and clearance. The role of USP13 is largely unknown in neurodegeneration. In this study we aim to demonstrate whether tau accumulation and/or clearance depends on ubiquitination/de-ubiquitination via USP-13. **Methods:** We used

transgenic animal models of human amyloid precursor protein (APP) or P301L tau mutations and genetically knocked-down USP13 expression via shRNA to determine USP13 effects on tau ubiquitination and levels. **Results:** We found a two-fold increase of USP13 levels in post-mortem Alzheimer's disease (AD) brains. USP13 knockdown significantly increased the activity of the 20S proteasome and reduced the levels of hyper-phosphorylated tau (p-tau) in primary cortical neurons. USP13 knockdown also reduced the levels of amyloid plaques and increased p-tau ubiquitination and clearance in transgenic animal models that over-express murine tau as a result of the expression of familial APP mutations (TgAPP) and the human mutant P301L tau (rTg4510), respectively. Clearance of p-tau appears to be mediated by autophagy in these animal models. **Conclusions:** Taken together, these data suggest that USP13 knockdown reduces p-tau accumulation via regulation of ubiquitination/de-ubiquitination and mediates its clearance via autophagy and/or the proteasome. These results suggest that USP13 inhibition may be a therapeutic strategy to reduce accumulation of plaques and toxic p-tau in AD and human tauopathies. **Keywords:** USP13, Tau, Ubiquitin, Amyloid, Alzheimer's disease

Title: Gene therapy-based cell therapy for neural regeneration and repair

Authors: *G. CHEN, Z. WU, X. HOU, Z. GUO, Y. CHEN, J. YIN, N. MA, L. ZHANG; Biol., Penn State Univ., University Park, PA

Abstract: There are huge unmet medical needs to treat severe neurological disorders such as Alzheimer's disease, Parkinson's disease, Huntington's disease, stroke, spinal cord injury, ALS, and many more. Neuronal loss is the major cause of functional deficits observed in Alzheimer's disease patients, yet adult human brain has largely lost the neuroregeneration capability in most regions. Regenerating millions or even billions of functional new neurons to replenish the lost neurons is critical to restore impaired learning and memory capacity among Alzheimer's disease

patients. We have recently developed an innovative *in vivo* cell conversion technology to directly convert reactive glial cells into functional new neurons inside adult mouse brains through expressing a single neural transcription factor NeuroD1 (Guo et al., Cell Stem Cell). Using AAV-based gene therapy, we demonstrate that our astrocyte-to-neuron conversion technology can regenerate not only a large number of functional new neurons but also can protect a significant number of injured neurons. Therefore, we are developing an innovative gene therapy-based cell therapy to treat neurodegenerative disorders such as Alzheimer's disease. Moreover, after high efficiency NeuroD1-mediated *in vivo* astrocyte-to-neuron conversion, the remaining astrocytes can proliferate and replenish themselves, accompanied with reduced neuroinflammation and increased angiogenesis. The NeuroD1-converted neurons are highly functional, showing repetitive action potentials and robust synaptic activities, and sending out long-range axonal projections to global brain targets. Together, these results demonstrate that in vivo astrocyte-to-neuron conversion technology shows a great potential in the treatment of neurodegenerative disorders through regeneration of new neural tissue consisted of new neurons, new astrocytes, and new blood vessels.

Abstract: A major hallmark of Alzheimer’s disease is dysfunction and loss of synapses due to an excess of amyloid beta (Aβ). Interestingly, individual susceptibility to Aβ synaptotoxicity seems to exist. In particular, mental exercise is thought to delay the onset of Alzheimer’s disease. Our data from the human Alzheimer’s disease brain suggest that the learning-induced

transcription factor Egr1 may play an instrumental role in protecting neurons against Aβ. We found that Egr1, and many synaptic genes that are regulated by Egr1, are increased in the earliest stages of the disease, when Aβ already accumulates but memory is largely intact (Braak 0-II). In later, stages of Alzheimer's disease, there is a significant decline in Egr1 expression and its target genes (Braak III-VI). To directly assess the effects of Egr1 on synaptic function in neurons, we used viral vectors to simultaneously overexpress Egr1 and APP-CT100 (the precursor to Aβ) in cultured hippocampal slices. We measured synaptic transmission using whole-cell patch clamp recordings, and dendritic spine densities using two-photon microscopy. Furthermore, we studied the effects of viral vector-mediated hippocampal Egr1 overexpression on the transcriptome, synaptic proteome and discrimination and reversal learning behavior in an APP/PS1 mouse model. Our data suggest that Egr1 overexpression might render synapses less susceptible to Aβ-induced synaptic weakening and loss of synapses, induce changes in the transcriptome and synaptic proteome, and counteract the effects of the APP/PS1 genotype on discrimination learning, underlining its potential as a tool for gene therapy in early Alzheimer's disease.

Title: Analyzing sex-dependent differences in disease progression in mouse models of CLN3 and CLN8 Batten disease

Authors: ***B. L. MEYERINK**, Z. P. ZENNER, K. A. WHITE, T. B. JOHNSON, S. S. DAVIS, C. SWANSON, C. D. BOOTH, L. A. LANGIN, M. A. PRATT, K. J. TIMM, J. T. CAIN, J. M. WEIMER;
Pediatrics and Rare Dis. Group, Sanford Res., Sioux Falls, SD

Abstract: Batten disease is a group of rare pediatric neurodegenerative disorders characterized pathologically by the accumulation of lysosomal storage material, neuronal death, and glial activation. Clinical features include loss of motor coordination and cognitive function, retinopathies leading to blindness, seizures, and premature death. Clinical data suggests a sex-

linked variation in the onset and progression of these disorders yet traditional use of animal models of these disorders neglect to consider sex as a significant factor in disease characteristics. In this study, we examine sex-based disease differences in *Cln3*$^{\Delta ex7/8}$ and *Cln8*^{mnd} mouse models of Batten disease. To track disease progression, we use the classical histopathological markers of glial activation, astrocytosis, and accumulation of storage material. Additionally, we use a battery of behavioral assays to examine learning and memory, motor function, and mobility. Differences in disease parameters show evidence that sex influences the progression of the disease in certain forms of Batten disease. Pathology analyzed in this study is based on tissue collection that would be impractically invasive in humans and further characterizes the sex-determined differences in these disorders. Our data indicate a need for consideration of sex-based variability in disease presentation when using research models, assessing therapies in clinical trials, and tracking progression of Batten disease in the clinical setting.

Abstract: Mutations in the CLN3 gene cause CLN3-Batten disease (also called juvenile neuronal ceroid liposfuscinosis; JNCL), which is a severe neurodegenerative disorder leading to dementia, epilepsy, motor impairment, and visual degradation. The disease onset varies between 4-7 years of age, but the outcome is fatal in all cases, leading to death between 20-30 years of

age. To date, the function of the CLN3 protein is poorly understood, but mutations disturb the lysosomal storage clearance process. Since CLN3 mutations found in patients predominantly cause reduced abundance or functionality of the protein, strategies to increase levels of functional protein are considered highly promising for therapy. In the current study, we evaluate the therapeutic efficacy of Adeno-Associated virus Serotype 9 mediated delivery of functional CLN3 in a mouse model carrying the most frequent human mutation, *CLN3*$^{\Delta ex7/8}$. We show that a single, intrathecal administration of scAAV9.CLN3 at postnatal day 1 results in robust and widespread expression of CLN3 throughout the brain and spinal cord of *CLN3*$^{\Delta ex7/8}$ mice. scAAV9.CLN3 treatment ameliorates the pathological hallmarks of CLN3-Batten disease such as accumulation of autofluorescent storage material (ASM), as well as ATP synthase subunit C in various regions of the central nervous system in *CLN3*$^{\Delta ex7/8}$ mice. This is also accompanied by a significant reduction in glial activation. More importantly, the therapeutic effects of scAAV9.CLN3 administration persists throughout the lifespan of the treated mice. Along with the histopathological improvement, scAAV9.CLN3 treatment also demonstrates motor and cognitive improvements in *CLN3*$^{\Delta ex7/8}$ mice as assessed by pole climbing assay, rotarod analysis and Morris water maze test. Additionally, intrathecal administration of scAAV9.CLN3 in non-human primates results in widespread expression of CLN3 throughout the central nervous system and is safe and well-tolerated up to 6 months post-injection. Altogether, these data underline that intrathecal administration of scAAV9.CLN3 is a promising therapeutic strategy for CLN3-Batten Disease.

Biosci., San Diego, CA; [4]CHDI Fndn., Saffron Walden, United Kingdom; [5]CHDI Fndn., Los Angeles, CA; [6]CHDI Fndn., Princeton, NJ

Abstract: Despite exciting progress made in clinical trials for treatment of Huntington's disease (HD), the delivery and distribution of large nucleic acid molecules throughout all compartments of the brain remains challenging. Identification of targets that modulate (mutant) HTT levels to which small molecules can be designed can potentially achieve the same result of lowering mHTT levels, but would be superior in terms of distribution and delivery methods. To this end, a total of ~70,000 individual siRNA sequences (four siRNAs per target) were screened in HD human embryonic stem cells (hESC) to identify potential targets for mHTT modulation. Hit selection resulted in 4560 siRNAs which were then counter screened for cytotoxic effects.
For robust determination and elimination of hits that exert their effect on mHTT levels through adverse cellular effects, three different toxicity assays, i.e. RealTime-Glo™, propidium-iodide based high-content image analysis and AKT HTRF were multiplexed together with mHTT HTRF, the primary readout. All QC measures were satisfactory with significant assay windows to select non-toxic candidates. To identify a cut off selection, the results obtained in each assay were ranked, summed and combined with effects on mHTT levels. This resulted in 435 putative non-toxic genes inhibiting mHTT levels, of which 51 genes were targeted by two or more siRNA. Together with one gene that increased mHTT levels when targeted by multiple siRNAs, a total of 52 targets are prioritized in a tier one target validation approach.
With the elimination of targets that upon silencing induced toxicity, a tier one list of candidate genes are being evaluated to determine on-target knockdown efficiency and their corresponding effect on *HTT* mRNA. The downstream cascade to further validate the putative molecular targets, are underway.

Title: Rescue of BDNF/TrkB pathway in Huntington's disease models by a Huntingtin domain: P42

Authors: *S. COULY[1,2], A. CARLES[2], T. MAURICE[2], F. MASCHAT[2];
[1]NIH, NIDA, Baltimore, MD; [2]INSERM UMR-S1198, Montpellier, France

Abstract: Huntington's disease (HD) is a fatal genetic neurodegenerative disorder with no curative treatment yet available. This disorder is due to a mutation in the *HTT* gene which encodes for the Huntingtin protein (Htt). In HD, expression of mutant Htt (mHtt) carrying extended polyQ domain leads to important dysfunction of the BDNF/TrkB signalling pathway. Indeed, in HD there are issues in the production of BDNF, its transport and also on the level of the BDNF receptor: TrkB. P42, a 23aa peptide isolated from Htt, was found to prevent pathological phenotypes induced by mHtt. More specifically, in HD conditions , P42 is able to protect from mhtt aggregation, axonal transport defects and impaired neuronal viability. The aim of our study was to better understand P42 mechanism of action in order to increase its therapeutic potential. In this study we focused on the effect of P42 on BDNF/TrkB pathway. To do so, first we observed the impact of a P42 treatment on BDNF/TrkB associated phenotype in R6/2 mouse model of HD. Mainly, we found that P42 rescues TrkB protein level in the striatum but also restores BDNF transcript level in the cortex. Then we observed that P42 treatment is able to increase BDNF/TrkB associated behaviours such as memory, anxiety and motor coordination affected in R6/2 mice. Using electrophysiological approach we also noticed a significant effect of P42 on neuronal plasticity, which is also BDNF/TrkB dependant. Furthermore, using environmental enrichment through the Hamlet test, we observed that increasing the BDNF expression could have a synergic effect with P42, explained by an effect of P42 at different levels of the BDNF/TrkB pathway. To investigate this question, we analysed the transport of the *Drosophila* BDNF homolog (DNT1) in neurons. We noticed that the expression of P42 is able to decrease pathological phenotype induced on DNT1 transport by the expression of mHtt. All these results suggest that P42 may have an action on BDNF/TrkB pathway through an effect on BDNF transport, additionally to its effect on TrkB protein level.

Title: Mutant Huntingtin does not acutely damage brain mitochondria

Authors: *J. HAMILTON[1], T. BRUSTOVETSKY[1], N. BRUSTOVETSKY[1,2];
[1]Pharmacol. and Toxicology, Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Stark Neurosciences Res. Inst., Indianapolis, IN

Abstract: Huntington's disease (HD) is a hereditary neurodegenerative disorder, characterized by severe motor and cognitive abnormalities, that is linked to a mutation in the ubiquitously expressed huntingtin protein (Htt). Although the mechanisms by which mutant huntingtin (mHtt) induces HD remain incompletely understood, defects in mitochondrial bioenergetics and Ca^{2+} handling have been implicated. The mechanism of deleterious mHtt action could include transcriptional alterations, direct physical interaction with mitochondria, or a combination of these factors. In the present study, we tested the hypothesis that mHtt directly and acutely impairs mitochondria. To test this hypothesis, we treated brain mitochondria from wild-type (WT) mice with mHtt-containing brain cytosolic fraction from YAC128 mice, an HD mouse model, and assessed mitochondrial respiration, membrane potential, ROS production, and Ca^{2+} uptake capacity. The amount of mHtt bound to WT mitochondria following incubation with mHtt-containing cytosolic fraction was greater than the amount of mHtt bound to brain mitochondria isolated from YAC128 mice. However, despite mHtt binding to mitochondria, no abnormalities were detected in any of the tested mitochondrial functions. This is consistent with the results produced in our previous studies, which provided no evidence for defects in isolated, purified brain mitochondria from R6/2 and YAC128 mice (1-4). In addition to experiments with WT mitochondria, we performed experiments in which we augmented the amount of mHtt bound to mitochondria from HD mice by incubating brain mitochondria isolated from YAC128 mice with mHtt-containing cytosolic fraction. Despite enrichment of YAC128 brain mitochondria with mHtt, mitochondrial functions (respiration, membrane potential, ROS production, Ca^{2+} uptake capacity) remained unchanged. Overall, our results suggest that mHtt does not directly and acutely impair mitochondrial functions, arguing against the involvement of this mechanism in HD.

Title: Investigating the role of aging in Huntington disease pathogenesis

Authors: *E. MACHIELA[1], M. SCHMIDT[2], M. R. HAYDEN[3], V. B. MATTIS[4], A. SOUTHWELL[1];
[1]Univ. of Central Florida, Orlando, FL; [2]Neurosci., Univ. of British Columbia, Vancouver, BC, Canada; [3]Univ. of Brithish Columbia, Vancouver, BC, Canada; [4]Board of Governors Regenerative Med. Inst., Cedars-Sinai, West Hollywood, CA

Abstract: Huntington disease (HD) is an autosomal dominant disease caused by a CAG repeat expansion in exon 1 of the huntingtin gene. HD is characterized by loss of voluntary movement, neuropsychiatric abnormalities, and cognitive decline. There are currently no disease-modifying therapies for HD. While age of onset negatively correlates with CAG repeat tract length, this only accounts for some of the variation in onset age observed in HD patients; many other genetic and environmental factors play a role in disease onset. Carriers of the mutation that causes HD can live asymptomatically until mid-life, begging the question of how the aging process may contribute to onset of disease. Accelerated markers of aging and cellular functions that decline during the aging process, such as the stress response and functions of the proteasome and mitochondria undergo rapid decline in HD, further supporting the hypothesis that aging contributes to HD pathology. To investigate the role of aging in HD, we are using induced pluripotent stem cell (iPSC)-derived neurons from HD patients as well as healthy controls. iPSC-derived adult-onset HD neurons exhibit very mild phenotypes and no spontaneous neurodegeneration. To overcome this, we treated HD and control cells with progerin, a truncated protein created by alternative splicing of the LMNA gene. Accumulation of progerin causes Hutchinson-Gilford progeria, a disease of rapid aging. Progerin has also been found in healthy tissues during the aging process and has been linked to cellular senescence. In doing this, we can compare cellular phenotypes in HD neurons that are physiologically “young” and “old” but chronologically identical, to determine the role of physiologic aging in the cellular toxicity of HD. Ultimately, this work will shed light on aging-associated factors that contribute to HD pathogenesis and whether anti-aging treatments may be beneficial for HD patients.

Abstract: Targeting *HTT* mRNA is showing promising results in a Phase 1/2 trial in Huntington's disease (HD) patients, while targeting an RNA splicing mechanism proved to lower HTT protein levels in an HD animal model. This indicates that (mutant) *HTT* mRNA can be considered as an important therapeutic target for HD. Phenotypic screening efforts focusing on *HTT* mRNA as target require a robust and high-throughput assay.
Here we aim to develop a highly sensitive ViewRNA assay able to detect total and allele-specific *HTT* mRNA levels in human embryonic stem cells (hESC) and in hESC-derived neurons. Using a probe set targeting *HTT* exons 42-47, we observed siRNA-mediated depletion of *HTT* mRNA in GEN020 hESCs, which was confirmed on the protein level. PTC compound-mediated knockdown of *HTT* mRNA demonstrated a concentration-dependent response as detected by ViewRNA and confirmed by RT-qPCR. To detect allele-specific *HTT* mRNA we barcoded *HTT* exon 12 *in silico* by introducing silent mutations. Specificity of the probe sets designed for wild-type (wt)*HTT* exon 12 and the barcoded (bc) version was confirmed in GEN020 hESC transiently expressing either wt or bc *HTT* exon 12 mRNA. Moreover, endogenous *HTT* mRNA levels were only detected with the wt exon 12 probe set. Although this probe set targets a significantly smaller region within *HTT* than the exon 42-47 probe set, similar siRNA and compound-mediated *HTT* mRNA depletion was detected for this custom-designed probe set. Taken together, we demonstrated that total and allele-specific *HTT* mRNA expression levels can be robustly detected using ViewRNA technology in hESCs. Our future efforts focus on further optimization of the ViewRNA protocol for high-throughput assays and transferring these assays from hESCs to hESC-derived neurons. Barcoding of exon 12 by gene editing is performed to generate a hESC line to be able to screen for endogenous *HTT* mRNA modulation in an allele-specific manner.

Abstract: Huntington's disease (HD) is a neurological disorder caused by mutations in the huntingtin (HTT) gene, the product of which leads to selective and progressive neuronal cell death in the striatum and cortex. Lowering of the pathogenic mutant huntingtin (mHTT) protein is the most proximal approach to treating this devastating disease. A number of HTT lowering therapies such as AAV-RNA interference (RNAi) and antisense oligonucleotides (ASOs) are in development but invasive delivery methods and relatively poor CNS distribution still remain a challenge. A brain penetrant small molecule that lowers HTT would provide the advantage of oral dosing and systemic distribution. In an attempt to identify novel compounds that reduce mHTT levels, we have developed a phenotypic high-throughput time-resolved fluorescence resonance energy transfer (TR-FRET) assay for quantification of soluble mutant huntingtin in Huntington's Disease patient fibroblast cells. A high throughput screen of over 1 million compounds from the Sanofi compound library was performed. Results from the screen revealed a high hit rate of 1.7% and a confirmation rate of 49% at 10uM. Hit compounds were then tested in concentration response and triaged for toxicity and huntingtin specificity in orthogonal readouts. Hits demonstrating good separation between mHTT lowering and cytotoxicity will be validated in HD-patient iPSC derived neuronal lines for their ability to reduce neuronal huntingtin protein levels.

Abstract: Huntington's Disease (HD) is a rare and devastating inherited neurological disorder characterized by motor disturbances including chorea. Brain HD pathology is most prominent in the striatum, with a selective degeneration of GABAergic medium spiny neurons. The cortex is the main afference to the striatum and indeed, there is a progressive disconnection between cortex and striatum manifested as a reduction in striatal synaptic activity. Thus, we aimed to restore motor symptoms by modulating corticostriatal function in symptomatic R6/1 HD mice. We used *in viv*o MRI, optogenetics and microdialysis and *ex vivo* multielectrode arrays to investigate corticostriatal dysfunction in HD. Then, we applied repeated optogenetic stimulation *in vivo* and evaluate motor learning and coordination in R6/1 mice. Structural and functional MRI showed loss of corticostriatal function in R6/1 HD mice. Also, we measured a reduction of striatal glutamate levels (GluCEST and MRS) and corticostriatal release (optogenetics coupled to microdialysis). The electrophysiological response of striatal neurons to optogenetically-induced corticostratal function was also reduced in HD mice (MEA). Finally, repeated corticostriatal optogenetic stimulation in HD mice (R6/1-ChR2) improved motor learning (accelerating rotarod), coordination (balance beam test), exploratory activity (rearings) and stereotypic behavior (grooming), compared to control R6/1-YFP mice, reaching levels similar to WT mice. This improvement was accompanied by an increase in spine density measured using Golgi-Staining. Thus, we demonstrate *in vivo* an effective optogenetic-induced recovery of HD motor

symptoms. Further investigations will help to understand the mechanisms involved and to design novel therapeutic strategies aiming to restore network dysfunction in HD.

Title: MicroRNA biogenesis deficits in Huntington's disease

Authors: ***S. PETRY**[1], I. ST-AMOUR[1], C. GOUPIL[1], S. S. HEBERT[2];
[1]CHUL, Neuroscience, P0-9800, Laval Univ., Québec, QC, Canada; [2]CHUL, Neuroscience, P0-9800, Laval Univ., Quebec, QC, Canada

Abstract: BACKGROUND: Huntington’s disease (HD) is an autosomal dominant neurodegenerative disorder caused by the expansion of CAG repeats in the exon 1 of the huntingtin gene (HTT). Early transcriptional deregulation is considered to be one of the key events involved in HD pathogenesis. MicroRNA (miRNA) are small non-protein-coding RNAs that regulate gene expression at the post-transcriptional level. Many studies have identified miRNA alterations in HD brain and peripheral system in humans and HD mouse models. Furthermore, miRNA-deficient mice develop HD-related symptoms. Interestingly, we and others have shown that HTT could function in modulating miRNA maturation, strengthening the link between defective miRNA biogenesis and neurodegenerative disorders.
OBJECTIVE: To better understand the role of miRNA biogenesis in HTT-mediated neurodegeneration.
RESULTS: Using Western blot, qRT-PCR and PCR, we analyzed major components of the miRNA biogenesis pathway in a large cohort of human HD brain (cortex and putamen, N=66). This was combined with the analysis of the maturation of selected miRNA species. Consistent with our hypothesis, we observed significant changes in miRNA biogenesis members and miRNA maturation in human AD brain, some of which occurred prior to overt neurodegeneration.
CONCLUSIONS: These data are consistent with a predominant role for miRNA biogenesis alterations as underlying mechanism of miRNA alterations and transcriptional dysregulation

during HD progression. Further investigations are required to delineate the functional relationship between HTT and miRNA biogenesis; more so given the growing interest in gene silencing therapies requiring the endogenous miRNA/RNAi pathway.

Abstract: Huntington's disease is caused by a CAG repeat expansion mutation in the Huntingtin gene and results in chronic expression of the mutant Huntingtin protein (mHTT), leading to cellular dysfunction, including early and reproducible alterations in gene expression. Cell-to-cell pathology has been implicated in HD and other neurodegenerative diseases, therefore we hypothesize that transcriptional dysregulation in HD may involve both cell intrinsic effects as well as modulation by altered miRNA profiles through exosome secretion via the cerebrospinal fluid (CSF), the majority of which is produced by choroid plexus epithelial cells (CPECs). The aim of this study is to determine whether CSF extracellular vesicles (EVs) from HD patients have altered miRNA profiles that distinguish them from unaffected individuals. To model these potential effects, we are using CPECs differentiated from HD patient-derived induced pluripotent stem cells (iPSCs) to investigate disease phenotypes that might contribute to altered miRNA packaging into EVs. EVs were isolated from HD and unaffected patient CSF samples and nanoparticle tracking analysis used to characterize the CSF EV fraction. miRNA was extracted for QIAseq miRNA sequencing. Our miRNA sequencing studies show that it is feasible to detect specific miRNAs in CSF exosome-enriched EV fractions, and that a subset of HD CSF EV miRNAs may differ in abundance compared to healthy controls. Further, EVs isolated from post-mortem HD CSF contain less of a modified species of the RNA binding protein hnRNPA2B1 compared to healthy control samples. Human iPSCs from juvenile and adult onset HD patients,

and unaffected individuals, were differentiated into CPECs and characterized by qPCR and immunofluorescence. Preliminary studies show primary cilia and tight junction alterations in HD CPECs compared to controls. Our results indicate that miRNA packaging into CSF EVs might be dysregulated in HD, and that a subset of this dysregulation may be a result of hnRNPA2B1 mislocalization and an enhanced cellular stress response. We also show that mHTT expression may have an effect on primary cilia and tight junction formation in iPSC-CPECs, which can potentially have an effect on CSF production and content.

Title: The DNAJ proteins DNAJA1 and DNAJB6 modulate polyglutamine aggregation

Authors: *C. HANSEN, C. R. GONZALEZ, S. LIN;
Lund Univ., Lund, Sweden

Abstract: Huntington's disease (HD) is a hereditary neurodegenerative disease caused by CAG repeat expansion in the huntingtin gene, resulting in an expansion of a poly glutamine (polyQ) repeat at the N-terminus of the huntingtin protein. This causes it to abnormally fold and form aggregates resulting in increased neuronal cell death and consequently disease. The DNAJ co-chaperone proteins play a crucial role in transferring misfolded or unfolded proteins to the Hsp70 proteins, which play an essential role for protein folding in the cell. Here, we demonstrate the effect of CRISPR/Cas9-mediated knock out (KO) of individual DNAJ genes on polyQ74 aggregation in HEK293 cells expressing polyQ74 attached to green fluorescent protein (GFP). KO of DNAJB6 resulted in a strong increase in Q74 aggregation whereas KO of DNAJA1 had the opposite effect on polyQ aggregation. KO of DNAJB1 did not change the propensity of polyQ74 to aggregate in cells. These findings where confirmed both by fluorescence microscopy analysis and filter trap assays. DNAJB6KO cells displayed an increased rate of cell death as assessed by tryphan blue exclusion assay, whereas all other KO cell lines did not show more cell death than parental control. These results demonstrates that DNAJ proteins may either act to suppress (DNAJB6) or promote (DNAJA1) polyQ aggregation, and thus that finetuning the cellular levels of DNAJ proteins is critical for suppression of polyQ aggregation and cell survival.

Abstract: Neurodegenerative disorders, including Huntington's disease (HD), involve a complex interplay among neurodegenerative and neuroinflammatory processes, yet these cell type-specific mechanisms remain poorly understood. HD is a fatal neurodegenerative disorder characterized by progressive motor, cognitive, and psychiatric symptoms, and caused by dominant inheritance of an expanded trinucleotide (CAG) repeat in the first exon of the *HTT* gene. Among the earliest and most profound neurodegeneration in HD occurs in striatal medium spiny neurons (MSNs), and death of MSNs is thought to explain many of the characteristic features of the disease. Previous studies demonstrated that transcriptional changes are detectable in the striatum long before the onset of cell death. However, the cell type specificity and the trajectory by which individual cells transit from wellness to disease is not known. Here, we characterized cell type-specific transcriptional changes related to HD by sequencing the transcriptomes of >11,000 single-nuclei from whole striatum in a knock-in mouse model of the HD mutation, $Htt^{Q175/+}$, and from wildtype C57BL/6J littermate controls. Our results demonstrate that hundreds to thousands of genes are differentially expressed in each of the major cell types in the striatum, resolving trajectories of transcriptional dysregulation among individual MSNs, revealing HD mutation-associated transcriptional dysregulation in rare cell types, and illuminating the distribution of neuroinflammatory responses across multiple cell types.

Title: Analysis of non-coding RNA expression in medium spiny neurons of Huntington's disease model mice

Authors: *H. PARK, H. MIYAZAKI, T. YAMANAKA, N. NUKINA;
Lab. of Structural Neuropathology, Doshisha Univ. Grad. Sch. of Brain Sci., Kyoto, Japan

Abstract: Huntington Disease (HD) is an inherited neurodegenerative disorder with symptoms of movement disorders, psychiatric disturbances and dementia. The disease is caused by expanded CAG repeats encoding polyglutamine in the exon1 of huntingtin gene (*HTT*). In the brains of HD patients, the mutant *HTT* product affects the transcriptional profile of neurons by disrupting the activities of transcriptional machinery which alters the expression of many genes including non-coding(nc) RNAs. Until now, the alterations of ncRNA expression in the brains of both HD patients and model mice have not been fully explored, so we focused on the dysregulation of the expression of ncRNAs.
In this study, from candidate ncRNAs suggested by the gene expression profiling data of MSN in 4-week-old R6/2 HD model mice, we identified dysregulated mouse ncRNAs that have homology with human ncRNAs and are assumed to be highly implicated to HD. By performing real-time PCR, we examined the expression levels of these ncRNAs in the striatum and MSN of R6/2 and control mice. Next, we performed *in situ* hybridization (ISH) on the brains of 4-week-old R6/2 and the control mice to observe the expressions and to examine the localizations of the dysregulated ncRNAs. According to the results, however, unlike coding RNAs, most of ncRNAs either could not be detected clearly by conventional ISH or did not show their expression changes. Therefore, ViewRNA ISH, which provides highly specific signals and more precise detection of RNA, was performed to detect those poorly expressed ncRNAs. Using ViewRNA ISH, we observed the alterations of expression levels and the intracellular localizations of ncRNAs such as *Abhd11os* and *Neat1*. Our study revealed that the expression levels of *Abhd11os* and *Neat1* were altered in MSN of presymptomatic R6/2 mice and the disruption of *Neat1* expression might affect paraspeckle formation, which might be implicated to HD pathogenesis. The roles of ncRNA in neurodegenerative disease have not been fully understood due to their low expression levels. Further research is necessary, but it is expected that ViewRNA ISH will help in investigating the expression changes and understanding the functions of ncRNAs, as well as their implications to the human diseases in the future.

Title: Altered vesicles dynamics in a Huntington's disease mouse model studied with 3D tracking of single synaptic vesicle in cortical neurons

Authors: *S. CHEN[1], X. QIN[2], H. PARK[1];
[1]Div. of Life Sci., Hong Kong Univ. of Sci. and Technol., Hong Kong, Hong Kong; [2]Hong Kong Univ. of Sci. and Technol., Department of Physics, Hong Kong

Abstract: Huntington's disease (HD) is an autosomal dominant genetic disease caused by the abnormal expansion of the cytosine-adenine-guanine (CAG) repeat in huntingtin gene. The major symptoms of HD are progressive motor disorder, cognitive deficits and eventual death. Neuronal death was found initially in the striatum and cortex, and later in other brain regions of HD patients. The altered exocytosis was reported in cortical neurons in a Huntington's disease mouse. However, the detailed mechanism of altered exocytosis remains elusive. Here, we investigated single synaptic vesicle dynamics in our HD knock-in mouse model (zQ175). In order to observe the single synaptic vesicles, we used synaptotagmin1-antibody conjugated quantum dot to label single synaptic vesicles in presynaptic terminals of cortical neurons of zQ175. Using dual-focus optics and quenching by trypan blue, we are able to track single synaptic vesicles in three dimensions with a 10Hz imaging frequency up to the moment of exocytosis. We observed altered net displacement of released synaptic vesicles in HD cortical neurons, compared with WT. Consistently, radius of gyration of HD before exocytosis released synaptic vesicles were significantly different from WT cortical neurons. These results indicate that the mobility of synaptic vesicles in HD neurons is altered before they reach their fusion site. We also observed much more abnormal movement of non-releasing synaptic vesicles in HD neurons compared with WT neurons. Moreover, the radius of gyration and instantaneous speed of HD non-releasing synaptic vesicles were significantly different from WT neurons. Thus, we conclude that synaptic vesicles dynamics is altered in cortical neurons at the early stage of HD.

Abstract: Since Huntington's disease (HD) is caused by expression of mutant huntingtin (mHTT) protein, lowering expression of mHTT is a key therapeutic strategy for HD. Reducing the amount of mHTT protein in HD-affected brains is predicted to prevent cellular dysfunction, neurodegeneration and alleviate symptoms of the disease. To date, HTT-lowering approaches include antisense oligonucleotides and RNA interference targeting mRNA, zinc finger transcriptional repressors, and CRISPR-Cas9 methods by targeting DNA. Alternative modalities to enhance protein clearance pathways e.g. the autophagy-lysosome pathway and the ubiquitin-proteasome system (UPS) are under investigation. PROteolysis TArgeting Chimera (PROTAC)-based approaches utilize heterobifunctional molecules to simultaneously bind both the target and an ubiquitin E3 ligase to promote the ubiquitination and degradation of the target molecule. Previously, we have described the development of mHTT aggregate binding molecules for PET imaging in animal models of HD and HD patients. We are now interested in exploring the therapeutic potential of small molecules to reduce accumulation of mHTT aggregates by utilizing them as the target-directed warheads for PROTAC-induced proteasomal degradation. Here, we present tools and assays established to support development of such mHTT-targeting PROTACs. We generated a comprehensive chemistry toolbox of mHTT-PROTACs containing a variety of mHTT "warheads" and E3 ligase recruiters conjugated via different PEG linker lengths. For efficient PROTAC-mediated protein degradation, several complex processes need to occur. Therefore, we have developed *in vitro* assays to investigate target binding, E3-ligase recruitment and HTT lowering. Additional assays to investigate ternary complex formation and target ubiquitination are in development. Finally, we present first proof-of-concept experiments indicating successful reduction of transiently-expressed mHTT protein in HeLa cells. Future work will focus on confirmation of the Mechanism of Action (MoA) via the UPS and testing of HTT PROTACs in neuronal cell lines.

Title: Development of translational imaging biomarkers of disease progression in a mouse model of Huntington's disease

Authors: *L. RIGGALL[1,2,3,4], E. DEMETRIOU[3], B. SIOW[4], G. P. BATES[1], X. GOLAY[3]; [1]HD Centre, Dept. of Neurodegenerative Dis. & UK Dementia Res. Inst., [2]Dept. of Med. Physics & Biomed. Engin., [3]Dept. of Brain Repair & Rehabil., Univ. Col. London, London, United Kingdom; [4]MRI Unit, Francis Crick Inst., London, United Kingdom

Abstract: Huntington’s disease (HD) is a genetic neurodegenerative disorder due to an abnormally expanded CAG triplet repeat region in the *HTT* gene. Magnetic resonance imaging (MRI) has been used to better understand the pathogenesis and progression of HD, but has so far focused on anatomical rather than metabolic changes. However, these may provide earlier and more sensitive biomarkers. Therefore, this project aims to reveal the metabolic processes occurring throughout HD by using *in vivo* MRI approaches in the R6/2 mouse model. R6/2 mice express exon 1 of the *HTT* gene containing ~180 CAGs, and develop HD-like symptoms including cognitive and motor deficits. To begin undertaking a time-course analysis of metabolites, chemical exchange saturation transfer (CEST), was used in R6/2 and wild type (WT) littermate controls at late-stage (12-weeks-old, n = 10 in both groups). CEST is a contrast enhancement technique that enables the indirect detection of metabolites with exchangeable protons. Post-imaging, cellular and molecular techniques were also utilised to validate MRI measures. Two different CEST irradiation amplitudes were used to target protons exchanging at different rates. MTR asymmetry was then used to investigate changes in metabolites important in HD in R6/2 mice, based on the acquisition giving the greatest level of contrast. Preliminary investigations suggest there is a significant reduction in both amide proton hydrolysis and transfer in late-stage R6/2 mice compared to WT controls, indicating changes in mobile proteins and peptides or pH. A significant increase in magnetisation transfer signal was also observed in R6/2 mice, suggesting further alterations in restricted proton species. CEST may, therefore, have

the potential to reveal changes in metabolic processes that contribute to or are altered in HD pathology over time, and provide non-invasive and sensitive biomarkers of pathogenesis. Assessments will now be extended to earlier disease stages, to enable a time-course characterisation of HD for the identification of robust, translational imaging biomarkers by which to track progression and inform therapeutic intervention.

Title: Investigating the role of SRSF6 in incomplete splicing of Htt mRNA in Huntington's disease mice

Authors: *M. A. MASON[1], C. GOMEZ PAREDES[1], A. NEUEDER[2], A. S. PAPADOPOULOU[1], G. P. BATES[1];
[1]UCL Queen Square Inst. of Neurol., London, United Kingdom; [2]Dept. of Neurol., Ulm Univ., 89081 Ulm, Germany

Abstract: Huntington's Disease (HD) is a monogenic neurodegenerative disease caused by an expanded CAG repeat in exon 1 of Huntingtin (*HTT*). The disease is marked by motor, cognitive and psychiatric symptoms than may manifest in childhood or adulthood. Incomplete splicing of *HTT* has recently emerged as a pathogenic mechanism in HD. The *HTT* gene has 67 exons, and with an expanded CAG repeat length *HTT* does not always splice from exon 1 to exon 2, resulting in an transcript that terminates at a cryptic polyadenylation site in intron 1. This mature *HTTexon1* mRNA encodes the N-terminal HTT exon 1 protein that is known to be highly pathogenic in many model systems. Serine/arginine-rich splicing factor 6 (SRSF6) was predicted to bind to CAG repeats and was previously found to reduce levels of incomplete splicing of a mouse *Htt* minigene in cell culture. To investigate whether SRSF6 plays a role in incomplete splicing *in vivo*, we crossed *Srsf6* knock out (KO) mice to zQ175 neo-deleted knock-in (zQ175DN KI) HD mice. We used a QuantiGene expression assay to analyse 2-month old brain and peripheral tissues. As homozygous *Srsf6* KO is embryonic lethal in mice, we were limited to using *Srsf6* heterozygous mice only. However, heterozygosity for *Srsf6* KO did not change levels of incomplete splicing in zQ175DN KI mice. Next, we sought to generate a cell model of incomplete *Htt* splicing in which *Srsf6* could be knocked down further using siRNAs. zQ175DN

KI mouse embryonic fibroblasts (MEFs) were generated due to their high levels of incomplete splicing. Despite ablation of SRSF6 protein in MEFs 3 and 4 days after treatment with *Srsf6*-targeted siRNAs, levels of incomplete splicing remained unchanged compared to vehicle treated MEFs. Therefore, SRSF6 may not play a role in incomplete *Htt* splicing *in vivo* or cell culture. Further work is needed to fully understand the mechanisms of incomplete *HTT* splicing. Using recently published proteomics data, we have identified other possible modifiers of incomplete splicing (e.g. hnRNP C1/C2). Our zQ175DN KI MEFs can be used to investigate whether these proteins play a role in incomplete splicing of *Htt.* Identification of modifiers could inform the design of *HTT* RNA-targeting therapeutics that may reduce levels of the toxic exon 1 HTT protein isoform generated by incomplete splicing.

Title: Investigating the mechanisms of heat shock response impairment in Huntington's disease

Authors: *C. GOMEZ-PAREDES, M. A. MASON, A. S. PAPADOPOULOU, G. P. BATES; Huntington’s Dis. Centre, Dept. of Neurodegenerative Disease, UCL Inst. of Neurolog, Univ. Col. London, London, United Kingdom

Abstract: Huntington’s disease (HD) is a neurodegenerative disorder caused by an abnormal CAG expansion within exon 1 of the huntingtin (*HTT)* gene, which leads to the formation of aberrantly-folded HTT proteins that are highly prone to aggregation. The heat shock response (HSR) is a mechanism responsible for the maintenance of proteome integrity within cells. HSR is induced when cells are exposed to proteotoxic stress such as the presence of HTT aggregates as is observed in HD. The master regulator of the HSR is HSF1, which regulates the transcriptional activation of the heat shock genes. A key step during the attenuation of the HSR is the acetylation of a lysine residue in HSF1. The deacetylation of this residue can be mediated by the histone deacetylase SIRT1. The pharmacological activation of the HSR is a promising therapeutic strategy in HD. Previously, our group reported that pharmacological induction of the HSR led to a reduction in the levels of aggregation in HD mouse models. However, the effects were transient as the ability to induce a HSR became impaired with the disease progression (Labbadia *et al.,* 2011). Our aim is to study the mechanisms involved in the progressive

impairment of the HSR in HD and if this could be ameliorated with *Sirt1* overexpression. We employed NVP-HSP990 (an HSP90 inhibitor that releases HSF1 from its HSP90 inhibitory complex) to induce HSR in HD mice (R6/2) overexpressing *Sirt1* (*n*=6/treatment group) at 9 weeks of age. Brain and muscle tissues were collected at several timepoints after dosing. A QuantiGene multiplex gene expression assay was established to measure the expression of 9 heat shock genes and their regulators. Preliminary data indicated that there was a trend towards improvement in HSR induction for some heat shock genes in R6/2 mice overexpressing *Sirt1* compared to R6/2 after NVP-HSP990 treatment. However, this difference did not reach statistical significance at these timepoints. *Sirt1* overexpression may have an effect on the kinetics of induction of the HSR in HD mice after dosing with NVP-HSP990. This requires further investigation at additional timepoints post dosing.

Title: Huntingtin promotes cadmium neurotoxicity and neurodegeneration in striatal cells via altered metal transport, mitochondrial dysfunction, and protein kinase C delta dependent oxidative stress and apoptosis signaling mechanisms

Authors: *G. KWAKYE[1], M. THOMAS[1], W. CHEN[1], J. JIMENEZ[1], M. SAITO[2], M. MCILVIN[2];
[1]Neurosci., Oberlin Col., Oberlin, OH; [2]Marine Chem. and Geochemistry, Woods Hole Oceanographic Inst., Woods Hole, MA

Abstract: Huntington’s disease (HD) is functionally linked to environmental factors including cigarette use and dyshomeostasis in the levels of metals. Interestingly, one of the most abundant heavy metals in cigarettes is cadmium (Cd), which also accumulates in the striatum and causes neurotoxicity upon exposure. Thus, we hypothesized that heterozygous huntingtin (HTT), responsible for the majority of cases of HD in patients, in combination with Cd exposure would cause neurotoxicity and neurodegeneration via increased intracellular accumulation of Cd and activation of oxidative stress signaling mechanisms in a mouse striatal cell line model of HD. We report that heterozygous HTT striatal cells are significantly more susceptible to Cd-induced cytotoxicity as compared to wild-type HTT cells upon exposure for 48 h. The heterozygous HTT and Cd-induced cytotoxicity led to a NADPH oxidase (NOX) mediated oxidative stress that was attenuated by exogenous antioxidants and a NOX inhibitor, apocynin. Heterozygous HTT

coupled with Cd exposure caused increased expression of protein kinase C δ (PKCδ) and other key oxidative stress proteins levels, enhanced the activation of caspase-9 and caspase-3 mediated apoptosis, and blocked the overexpression of extracellular signal-regulated kinase (ERK). We observed significantly greater intracellular accumulation of Cd and reduced expression of divalent metal transporter 1 (DMT1) protein in the heterozygous HTT striatal cells upon Cd exposure. Treatment with zinc, manganese, and iron as well as exogenous antioxidants significantly attenuated the Cd-induced cytotoxicity. Collectively, these results demonstrate that heterozygous HTT exhibits greater neurotoxic properties when coupled with Cd exposure to cause cell death via caspase mediated apoptosis, altered metal transport, and modulation of ERK and PKCδ dependent oxidative signaling mechanisms.

Abstract: Huntington’s disease (HD) is an autosomal dominant neurodegenerative disorder caused by CAG expansions in the huntingtin gene (*HTT*). Alterations in the neurotrophin tyrosine receptor kinase (TrkB) signaling pathways is thought to contribute to HD pathophysiology. Brain-derived neurotrophic factor (BDNF)-mediated activation of TrkB is a key pathway for neuronal survival, differentiation and synaptic plasticity. A reduction of BDNF in the striatum, cortex and hippocampus from HD post-mortem brain tissue and reduced cortico-striatal BDNF trafficking in HD mouse models has been described, whilst other reports have demonstrated normal levels of BDNF but impaired downstream TrkB receptor signaling. Our current study investigates a potential therapeutic approach to reverse deficits in HD through activation of BDNF - TrkB signaling in HD mouse models using a novel mouse TrkB agonistic monoclonal antibody, 38B8. We injected the antibody intrastriatally and investigated the proximal effects on the proteome and phosphoproteome in wild type and zQ175DN

heterozygous mice at 2 months (presymptomatic) and 9 months of age (symptomatic). While the global protein levels are largely unaffected 4 hours after antibody application, we found close to 300 significantly affected phosphorylation sites, most of which showed increased phosphorylation. Several of these sites are on proteins involved in neutrophin signaling and our analyses provide evidence for an activation of all three major branches of the pathway. Overall, the observed treatment response was similar in both young and aged wild type and zQ175DN heterozygous mice and we did not detect any significant differences between the genotypes. Functional enrichment analyses revealed that proteins with regulated phosphorylation sites are mostly involved in regulation of gene expression, more specifically in mRNA transport, ribosome biogenesis and translation initiation. This outcome matches known consequences of early activated neutrophin signaling and supports data that 38B8 acts as specific TrkB agonist, which can induce equivalent responses in both wild type and mutant genetic background. Our findings demonstrate the functional activity of 38B8 *in vivo*, which supports that direct TrkB receptor activation is a viable approach for the treatment for HD.

Title: Structural neuroimaging and biofluid markers of treatment response in Huntington’s disease: Preclinical evidence with the $p75^{NTR}$ ligand, LM11A-31

Authors: *D. A. SIMMONS[1], B. D. MILLS[2], J. KUAN[1], J. ZHOU[1], T. L. MCHUGH[1], C. AKERS[2], W. SYRIANI[1], M. ZEINEH[2], F. M. LONGO[1];
[1]Neurol. and Neurolog. Sci., [2]Radiology, Stanford Univ., Stanford, CA

Abstract: Huntington’s disease (HD) is caused by an expansion of the CAG repeat in the huntingtin gene and is characterized predominately by striatal neurodegeneration. HD therapeutic development would be facilitated by translatable biomarkers of treatment response.

In HD patient and mouse studies, volumetric magnetic resonance imaging (MRI) and plasma cytokines have been suggested as biomarkers of disease onset/progression but their ability to detect treatment efficacy is understudied. We designed a cross-sectional study of male and female R6/2 mice to assess if structural neuroimaging and meso scale discovery-based biofluid assays can detect treatment effects using the $p75^{NTR}$ ligand LM11A-31 (C31). We previously showed that C31 reduced the HD phenotype in mouse models of the disease. C31 is in a phase 2a clinical trial for Alzheimer's disease, thus translatable biomarkers able to detect its therapeutic effects would expedite its advancement to HD clinical testing. C31 or vehicle (veh) was orally administered (50 mg/kg, once daily 5 days/week) to 4-5 week old R6/2 and wild-type (WT) mice for 7 weeks. At 11-12 weeks of age, MRI, diffusion tensor imaging (DTI) and R2* relaxometry was performed and biofluid samples were collected. T2-weighted MRI revealed significant atrophy in multiple brain regions including striatum of R6/2-veh mice versus wild-types (WTs) which was alleviated with C31 treatment. *In vivo* MRI volumes correlated strongly with those measured *ex vivo* via stereology on Nissl-stained sections. DTI was used to measure mean diffusivity, fractional anisotropy, and neurite orientation dispersion index. The striatum of R6/2-veh mice showed changes in DTI metrics that were consistent with those seen in HD patients and suggest disrupted microstructure, connectivity, and iron levels. C31 partially prevented these changes. C31 also diminished increases in plasma cytokine levels in R6/2 mice including TNFα and IL-6. Finally, we measured urinary levels of the extracellular domain (ecd) of $p75^{NTR}$, a cleavage product released with pro-apoptotic ligand binding that detects progression of other neurodegenerative diseases. Urinary $p75^{NTR}$-ecd was increased in by 44% in R6/2-veh mice and negatively correlated with regional volumes; C31 reduced this increase. These results are the first to show that urinary $p75^{NTR}$-ecd levels are elevated in an HD mouse model and that they can detect therapeutic effects. These findings also suggest that structural MRI and plasma cytokine levels can detect treatment response and that using combinations of these biomarkers would be a viable and powerful option for clinical trials.

Abstract: Over the last years there has been a heave of new therapeutic modalities which are no longer limited to target proteins but also DNA and RNA. These include antisense oligonucleotides (ASO), genome editing such as CRISPR or Zing fingers and small molecules targeting RNA such as splicing modulators or RIBOTACs. With this shift in targets has come the need of developing new techniques or adapting existing ones to formats that would allow for high-throughput screen of therapeutic compounds.
Lowering of the pathogenic mutant huntingtin (mHTT) protein in Huntington's disease (HD) is one of the leading therapeutic approaches to ameliorate the fatal neurodegeneration caused by the poly-CAG expansion in the HTT gene. Recent promising results in Phase 1/2 clinical trials with ASO therapy in HD patients, in addition to animal model data linking a reduction in mutant huntingtin levels to improved symptoms, mHTT mRNA is increasingly being considered an important therapeutic target in HD.
Despite positive ASO clinical trial results, there is still a need to identify small molecules to overcome the challenges of invasive administration, selectivity and poor distributions. Identifying brain-penetrant small molecules with suitable oral dosing would potentially be advantageous over novel biological agents. As such there is a need to develop a robust and high-throughput screening assay that will quantifiably measure levels of HTT mRNA.
CHDI with Charles River Early Discovery are currently using two different techniques, ViewRNA and TaqMan qPCR assays for RNA compound and siRNA screens. In this poster we will present the use of these techniques in evaluating small molecules for the treatment of HD. We will present our initial ViewRNA assay development, compare the technology to the more established TaqMan qPCR assay and evaluate its potential for utilization in a HTS campaign to identify HTT mRNA modulators.

Abstract: Huntington's disease (HD) is a neurodegenerative genetic disorder caused by mutations in the HTT gene containing an abnormally long polyglutamine (CAG) stretch. This leads to excessive production and accumulation of mutant huntingtin protein (mHTT) in the brain. The excessive mHTT protein accumulation causes progressive motor, psychiatric, and cognitive decline and eventually leads to neuronal death. Given that only palliative treatments are available and no effective treatment has been approved, researchers are looking at a variety of potential therapeutics for HD, including the use of GM1 ganglioside. GM1 ganglioside is a sialic acid-containing glycosphingolipid that is found abundantly in the outer leaflet of the neuronal membrane in the brain. GM1 gangliosides play a vital role in cell signaling, calcium homeostasis and cell-cell interactions in the brain. In HD patients, GM1 ganglioside levels are decreased, which contribute to HD symptomology and disease progression. Previous studies found that treatment with GM1 ganglioside obtained from bovine sources improves motor dysfunction in HD rodent models. However, GM1 gangliosides that are obtained from ovine sources are more economical than bovine sources and the goal of our experiment was to test whether the ovine source can produce similar effects in improving motor and cognitive dysfunctions in HD. In our current study, we used intraventricular osmotic pumps to deliver GM1 gangliosides that are obtained from ovine and bovine sources for six weeks in eight to nine months YAC128 mouse model. We used rotarod-, open field-, catwalk-, Barnes maze-, novel-object-recognition- and elevated-plus- maze- tasks to measure motor and non-motor parameters. Our preliminary results indicate that both bovine and ovine sources of GM1 tended to reduce behavioral deficits in YAC128 mice on the rotarod-, open fields-, Barnes maze-, but not on novel-object-recognition-, catwalk-, and elevated-plus-maze- tasks.

Title: Retinoic acid receptor beta protects striatopallidal medium spiny neurons from mitochondrial dysfunction and neurodegeneration

Authors: *W. KREZEL[1], M. CIANCIA[1], M. RATAJ[1], A. NIEWIADOMSKA-CIMICKA[1], V.-A. BALDASSARRO[1], A.-L. CHARLES[2], B. GENY[2];

Abstract: Transcriptional dysregulation observed in Huntington’s disease (HD) may underlay different aspects of HD physiopathology, but the exact mechanisms of the cause and effect of such dysregulation is not clear. Here we show that retinoic acid receptor beta (RARb), a transcription factor strongly downregulated in the striatum of HD patients and mouse models of HD displays neuroprotective activity of striatopallidal medium spiny neurons (MSNs) in mouse. In line with such function, abolished RARb signalling in *Rarβ*$^{-/-}$ mice leads to postnatal loss of a subpopulation of striatopallidal MSNs expressing dopamine D2 receptor (D2R) and behavioural abnormalities including deficits in motor coordination. Our data indicate that this increased sensitivity of D2R^{+} MSNs to cell death may result from abnormal mitochondrial morphology and functions in *Rarβ*$^{-/-}$ striatum. Accordingly, pharmacological increase of calcium concentration using suboptimal doses of thapsigargin, leads to rapid mitochondrial fragmentation and cell death in cultured *Rarβ*$^{-/-}$ MSNs, whereas suboptimal doses of 3-nitropropionic acid, an inhibitor of mitochondrial complex II/ succinate dehydrogenase leads to the loss of D2R^{+} striatopallidal MSNs in *Rarβ*$^{-/-}$, but not in WT mice *in vivo*. Our data point to relevance of compromised RARb signalling in increased sensitivity and loss of D2R^{+} MSNs in HD and point to RARb as a new potential therapeutic target in this disease.

Title: Dental pulp stem cell secretome therapy in a mouse model of amyotrophic lateral sclerosis

Authors: *J. WANG[1], K. ZUZZIO[1], C. WALKER[1,2];
[1]Indiana Univ., Indianapolis, IN; [2]Neuromuscular Res. Group, Richard L. Roudebush Veterans Affairs Med. Ctr., Indianapolis, IN

Abstract: Amyotrophic lateral sclerosis (ALS) is a devastating motor neuron (MN) disease with no cure. Mounting evidence indicates that ALS is a complex disease involving interaction between central glia and the peripheral immune response and neuromuscular interface. Stem cell secretomes contain various trophic factors and cytokines that are beneficial in a variety of conditions. We recently demonstrated that administration of the secretome in adipose-derived stem cell conditioned medium (ASC-CM) during early neuromuscular junction (NMJ) denervation ameliorated NMJ disruption in the mutant superoxide dismutase ($mSOD1^{G93A}$) ALS mouse model. In the present study, we investigated whether dental pulp stem cell conditioned medium (DPSC-CM) therapy at different stages of disease could promote NMJ preservation, prevent MN loss and extend lifespan. We found that DPSC-CM significantly reduced NMJ denervation at postnatal day (PD)47 compared to vehicle-treated $mSOD1^{G93A}$ mice ($P<0.05$). When administered during late pre-symptomatic stages (PD70-P91), DPSC-CM significantly increased MN survival ($P<0.01$) and NMJ preservation ($P<0.05$). For $mSOD1^{G93A}$ mice treated with DPSC-CM beginning at symptom onset through end-stage, days of survival post-onset, as well as overall lifespan, was significantly increased compared to vehicle-treated mice. This study is the first to show the therapeutic benefits of systemic DPSC secretome in an animal model of ALS. Importantly, this is the first report of stem cell secretome effects at multiple stages of ALS disease progression. Our study establishes a foundation for future research related to the treatment effects of DPSC and other stem cell secretome therapies in ALS.

Title: Morpholino oligomers ameliorate pathological phenotype in C9orf72 ALS iPSC-derived lines

Authors: *G. P. COMI[1], **M. TAIANA**[1], M. BERSANI[1], F. BIELLA[1], M. NIZZARDO[1], C. KIZILIRMAK[2], P. RINCHETTI[1], S. BARABINO[2], N. BRESOLIN[1], S. CORTI[1];

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal disorder characterized by progressive degeneration of motor neurons (MNs). GGGGCC repeat expansions in C9ORF72 gene are the most common identified genetic cause, and even if their pathogenic processes are still unknown, many possible mechanisms have been proposed, including loss of function of the C9Orf72 protein and gain of function caused by accumulation of RNA expansion foci that can sequestrate RNA binding proteins (RBPs), and by dipeptide repeats proteins (DPRs) produced by repeat-associated non-ATG (RAN) translation. Patient-specific induced pluripotent stem cells (iPSC)-derived lines and iPSC-derived MNs are promising and reliable methods to better understand C9-ALS pathogenesis. Therapeutic approaches include the use of antisense oligonucleotides (ASOs) designed to bind complementary mRNA and interfere with specific biological processes. We designed two different ASOs with Morpholino (MO) chemistry: against the C9ORF72 expansion and against the C9ORF72 gene promoter. Using these tools, we aimed to characterize the pathological phenotype of the C9-ALS iPSC-derived lines and evaluate the therapeutic effect of MOs administration on specific pathological markers. We reprogrammed iPSCs from C9-ALS patients and controls and differentiated them into MNs. We investigated the phenotype of the C9-ALS lines compared to controls, evaluating cells survival, RAN products expression, RNA foci presence, dysregulation of putative RBPs interacting with RNA foci, R-loops formation, DNA damage, and Stathmin2 expression. Then, we transfected ALS-MNs with MOs and evaluated any modification of the pathological markers previously identified. We observed that MO-based therapy can rescue pathological features in C9-ALS iPSC-derived lines such as accumulation and mislocalization of the protein involved in nuclear trafficking RanGAP, the RNA binding protein Pur-α, TDP-43 as well as R-loops increase, DNA damage and Stathmin2 decrease. Our results suggest that patient specific iPSCs and iPSC-derived MNs are a valuable

tool to deepen the knowledge of C9ORF72 pathogenic mechanisms, and that MO-mediated approaches represent a promising therapeutic strategy that needs to be further validated.

Title: Development of neuronal cell line assays to assess the effects of small molecules on ALS-associated TDP-43 pathologies and toxicity

Authors: *H. J. WOBST[1], M. AIKIO[2], D. G. BROWN[4], N. J. BRANDON[1], S. J. MOSS[3]; [1]Discovery Biology, Neuroscience, R&D BioPharmaceuticals, AstraZeneca, Boston, MA; [2]AstraZeneca-Tufts Lab. for Basic and Translational Neurosci., [3]Dept. of Neurosci., Tufts Univ., Boston, MA; [4]Hit Discovery, Discovery Sciences, R&D BioPharmaceuticals, Astrazeneca, Boston, MA

Abstract: Mutations in the RNA-binding and -processing protein TDP-43 cause rare familial forms of amyotrophic lateral sclerosis (ALS). Moreover, in the majority of ALS cases (~97%) as well as almost half the cases of frontotemporal dementia (FTD) post mortem analysis reveals TDP-43 pathologies in affected tissues. These pathologies include cytoplasmic mislocalization, formation of TDP-43 inclusions and aberrant phosphorylation. Using the neuronal cell lines NSC-34 and SH-SY5Y we can reproduce TDP-43 proteinopathy-associated phenotypes including TDP-43 toxicity, TDP-43 aggregation and hyperphosphorylation at the disease-associated S409/410 site. We identified several series of compounds which were active in a TPD-43 toxicity model in *C. elegans*. We tested representative actives in NSC-34 cells overexpressing TDP-43 to confirm activity in mammalian cells. Furthermore, we investigated whether compounds that rescue toxicity in *C. elegans* and mammalian cells affect TDP-43 aggregation and hyperphosphorylation. Broadly, we identified two classes of compounds: 1.) compounds that rescue TDP-43 toxicity as well as TDP-43 pathologies such as aggregation and/or phosphorylation in mammalian cells; 2.) compounds that rescue TDP-43 toxicity, but not TDP-43 aggregation and/or phosphorylation. Specifically, we found that a series of MAP kinase p38α inhibitors rescue TDP-43 overexpression-induced toxicity in *C. elegans* and mammalian cells. Both genetic and chemical inhibition of p38α reduced S409/410 TDP-43 phosphorylation

and delayed aggregation. In summary, we developed a set of mammalian cell assays to confirm actives from a *C. elegans* screen and investigate whether modulation of ALS-associated TDP-43 pathologies is linked to the rescue of TDP-43 toxicity.

Abstract: Repeat G4C2 expansions in the C9orf72 gene leading to poly-PR proteins has been linked to approximately 11% of known cases of ALS. A yeast strain expressing the C9orf72 dipeptide repeat proteins (PR_{50}) was constructed in a drug-pump deletion background. This strain showed a toxic phenotype which was subsequently used to identify compounds that could rescue this toxicity. The strain was screened against a set of 500K diverse compounds using a high-content flow cytometry assay. Several series of compounds were discovered which rescued the toxic phenotype in yeast and then confirmed in the same strains using an optical density read-out. A target analysis was conducted using the target annotation from the screening library, and then matched against those targets which possessed both yeast and human orthologs. Roughly 50% of the hits were not associated with known targets and work was undertaken to identify these unknown targets in yeast. Multiple photoaffinity probes were synthesized across five chemical series to identify new targets through mass spectrometry-based chemo-proteomics. We will discuss the overall strategies and methods used as well as progress made towards target validation.

Title: ATXN2, a modifier of TDP43 pathology is a new therapeutic target for amyotrophic lateral sclerosis

Authors: *Y. HU[1], Y. WANG[1], U.-M. LIM[4], A. FERNANDIS[4], J. EICHER[2], D. STONE[3], S. PARMENTIER-BATTEUR[1];
[1]Neurosci., Merck, West Point, PA; [2]GpGx, Merck, Boston, MA; [3]GpGx, Merck, West Point, PA; [4]MSD international GmbH, Singapore, Singapore

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease caused by the loss of lower and upper motor neurons leading to progressive muscle weakness and respiratory failure. Although multiple gene mutations can cause ALS, protein and RNA aggregates are major hallmarks of ALS pathology. Ninety-seven percent of ALS patients present TDP43 pathology including aberrant cytoplasmic mislocalization and aggregation with hyper-phosphorylation, C-terminal cleavage and ubiquitination. Phenotypic-based approach has identified Ataxin-2 (ATXN2) as a potent modifier of TDP43-toxicity and this original finding has been confirmed in more relevant *in vivo* models. The goals of our research are 1) to validate the role of ATXN2 in ALS hu-iPSC-neuronal models and 2) to identify the best strategy to modulate ATXN2 activity. Our results showed that knockdown of ATXN2 using lenti-shRNA can significantly attenuate the accelerated neuronal cell death and TDP43-mislocalization in hu-iPSC neurons-derived from ALS patients with C9ORF72 expansion and in AAV8-syn1 mediated TDP43 overexpressing hu-iPSC neurons. Knockdown of ATXN2 also reduced TDP43-containing stress granule formation in hu-iPSC neurons stressed with Sodium-Arsenite. A proteomic study was used to explore the change of ATXN2 interactome in presence of TD43 overexpression in hu-iPSC neurons and identified major pathways including proteins known to be implicated in nuclear/cytoplasmic transport and stress granules formation. Mutation of TDP43 RRM1 and RRM2 domains reduced the interaction of TDP43 with ATXN2, and abolished TDP43 toxicity similarly to ATXN2 knock-down suggesting that inhibition of TDP43/ATXN2 interaction may be a promising strategy for therapeutic intervention. Development and validation of High Throughput Screening enabling assays are established to identify tool compounds toward the validation of this novel strategy against TDP43-induced pathology.

Title: Identification of novel hit compounds using a high-throughput phenotypic screen with SMA patient iPSC-derived motor neurons

Authors: *M. L. HENDRICKSON[1], P. GUYETT[1], J. KOUZNETSOVA[2], W. ZHENG[2], Z.-W. DU[1];
[1]BrainXell, Inc., Madison, WI; [2]NIH/NCATS, Rockville, MD

Abstract: Spinal muscular atrophy (SMA) is an inheritable cause of infant mortality that is characterized by the loss of lower motor neurons and skeletal muscle atrophy. The degeneration of motor neurons is caused by insufficient levels of survival motor neuron (SMN) protein, which is encoded by two nearly identical genes SMN1 and SMN2. Most cases of SMA harbor homozygous deletions of the SMN1 gene and retain at least one copy of SMN2. Hence, a promising treatment strategy is to upregulate levels of the full-length SMN protein originating from the SMN2 gene. Drug discovery screening platforms typically use SMA fibroblasts or lymphocytes, yet the identified molecules often had limited efficacy in SMA mouse models, especially rescuing motor neuron (MN) degeneration. Therefore, MNs from SMA patients should be used early in drug discovery to increase the likelihood of identifying effective small molecule therapeutics. At BrainXell, we established new technologies to rapidly differentiate SMA patient induced pluripotent stem cells (iPSCs) into large quantities of neurons. We also used genome editing to endogenously fuse SMN2 with a nanoluciferase (NLuc) reporter, which enables high-throughput screening (HTS) that monitors the expression levels of SMN after 48 h exposure to each compound. The assay was adapted to meet HTS requirements, including: large batch sizes, 1536-well format, minimal well-to-well variation, short-term culture, plating by automated dispenser, and low reagent volumes. Applying a quantitative HTS approach, we screened the LOPAC, NPC, and MIPE libraries (>6,000 compounds) in a dose dependent manner. After demonstrating feasibility, we expanded the screen to the larger Genesis library (95,000 compounds) in order to identify novel hit molecules. Compounds that increased SMN2 expression by >20% were considered hits. Analysis of the combined 100,000 compound qHTS identified 81 hit candidates, which were rescreened in triplicate. Ten compounds increased SMN2 expression by 20% with EC50 < 10 μM. We then used an ELISA to validate the increased SMN2 expression after 48 h treatment in a non-engineered SMA-patient cell line. This screening paradigm identified and validated 3 new hit compounds that have promising efficacy and potency.

Abstract: Myotonic dystrophy type I (DM1) is a neurodegenerative and hereditary disease. It is due to a genetic mutation on chromosome 19, which is linked to the repetition of the chain of cytosine, thymine and guanine (CTG); the number of these repetitions is less than 50 for healthy subjects. The DM1 symptoms are dependent of the age onset and could vary from patient to patient. DM1 main symptoms are distal muscle weakness and myotonia. This disorder is difficult to diagnose. The objective of this project is to evaluate the integrity of the white matter by Diffusion Tensor Imaging (DTI) and the volume of gray matter by Voxel Based Morphometry (VBM) in patients with DM1. This will help us to find biomarkers useful to characterize the evolution of this disorder resulting in a better diagnosis and prognosis. In the present work 37 DM1 patients and 35 healthy controls volunteer participants were matched by age, sex and level education. They underwent an MRI session in a 3T MR Scanner with a 32 channel Head-Sense Coil. Diffusion tensor images have the following parameters: 33 diffusion directions, b=800s/mm^2, isometric spatial resolution (2mmx2mmx2mm), 70 slices and T1 weighted high resolution images were acquired with a FOV=240x240, 180 sagittal slices and spatial resolution of 1 mm^3 For statistical data analysis un-paired sample t-test was applied for both kind of analysis using FSL 5.0.8 software. DTI images were corrected by movement and eddy currents

and TBSS script was applied. Cluster with statistical significance P<0.01 were found in orbitofrontal white matter regions, anterior cingulate cortex and corpus callosum. Atrophy in white matter paths is significant in frontal brain areas, which imply that different control processes are altered. T1 weighted images were corrected by movement and VBM script was applied clusters with P<0.01 were found in cerebellar and occipital gray matter showing grey matter atrophy in the group of patients. Lobules VI and Crus I cerebellar regions have projections to prefrontal area 46 which is associated with working memory and attention processes.

Title: Amyotrophic lateral sclerosis drug discovery via high-throughput phenotypic screening using induced pluripotent stem cell-derived human motor neurons

Authors: *P. GUYETT[1], M. L. HENDRICKSON[1], J. KOUZNETSOVA[2], Z.-W. DU[1];
[1]BrainXell, Inc., Madison, WI; [2]NCATS, Rockville, MD

Abstract: Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease primarily affecting motor neurons. Unfortunately, there are only two drugs approved to treat the condition, neither of which increases patient survival by more than a few months. This sobering reality highlights the urgent need for new ALS therapeutic development, which has been plagued by high failure rate during clinical trials. This high failure rate suggests that pre-clinical screening strategies need to be re-evaluated. One of the markers of disease in ALS patients is the aberrantly low expression of neurofilament light chain (NFL) in motor neurons. Further, recovery of NFL to normal levels prevents hallmark phenotypic changes in ALS neurons. Therefore, we wanted to establish a clinically relevant screening platform to identify compounds that return expression of NFL to normal levels in ALS patient derived motor neurons. At BrainXell, we established new technologies to rapidly differentiate ALS patient induced pluripotent stem cells (iPSCs) into large quantities of neurons. We then used genome editing techniques to endogenously fuse NFL with a nanoluciferase (NLuc) reporter, thus enabling a high-throughput screening (HTS) system that monitors the expression levels of NFL after 72 h exposure to each compound. The assay was adapted to meet HTS requirements, including: large batch sizes, 1536-well format, minimal well-to-well variation, short-term culture, plating by automated dispenser, and low reagent volumes. Applying a quantitative HTS approach, we screened the LOPAC, NPC, and MIPE libraries (>6,000 compounds) in a dose dependent manner. Compounds that increase NFL expression by 50% (to approximately normal levels) were considered hits. From these screens we identified 50 hit compounds that are currently going through secondary validation. Preliminary data looks promising. For example, one of these hits restores normal expression of NFL with no observed neurotoxicity. From this work, we established a high-throughput phenotypic screening strategy that is more clinically relevant in order to increase the likelihood of clinical success for any therapeutic candidate that comes out of our drug discovery funnel.

Title: Effect of RAGE pharmacological inhibition in the progression of the disease in hSOD1^{G93A} ALS mouse model

Authors: L. LIU, S. GRAUZAM, K. M. KILLOY, M. R. VARGAS, *M. PEHAR;
Cell and Mol. Pharmacol. and Exptl. Therapeut., Med. Univ. of South Carolina, Charleston, SC

Abstract: Amyotrophic lateral sclerosis (ALS) is characterized by the progressive degeneration of both upper and lower motor neurons. Several lines of evidence indicate that astrocytes play a key role in the progression of the disease. Accordingly, astrocytes isolated from mutant human superoxide dismutase 1 (hSOD1)-overexpressing rodents induce the death of co-cultured motor neurons. We recently identified RAGE, the receptor for advanced glycation end products (AGEs), as a potential effector of astrocyte-mediated neurotoxicity. Motor neuron death induced by hSOD1^{G93A}-overexpressing astrocytes was prevented by RAGE blocking antibodies or two different RAGE pharmacological inhibitors, FPS-ZM1 and RAP. Moreover, motor neurons isolated from RAGE knockout mice were not sensitive to the neurotoxic signal derived from ALS-astrocytes. We previously reported the presence of increased RAGE expression in the spinal cord of early symptomatic hSOD1^{G93A} mice. We now present evidence of increased RAGE expression in the spinal cord of two other ALS mouse models (TDP-43^{Q331K} and TDP-43^{A315T}), suggesting the potential involvement of RAGE signaling beyond mutant SOD1-linked ALS. To evaluate the relevance of RAGE signaling in ALS pathology we tested the effect of FPS-ZM1, a previously described RAGE pharmacological inhibitor with the ability to cross the blood-brain barrier, on the onset and progression of the disease in hSOD1^{G93A} mice. Male and female hSOD1^{G93A} mice were randomly assigned into vehicle and FPS-ZM1 (1 mg/kg) treatment cohorts. Treatment started at the age of 60 days by daily i.p. injections. We observed no significant effect of the drug in the disease onset or survival of hSOD1^{G93A} mice when both genders were combined in the analysis. However, when compared with vehicle-treated mice, mice treated with FPS-ZM1 showed improved grip-strength for several weeks after disease onset. We also observed a significant delay in the age at which female hSOD1^{G93A} mice on FPS-ZM1 treatment exhibited 5% or 10% weight loss. These results suggest that RAGE inhibition could potentially have a beneficial effect only at early stages of the disease.

Title: A gene therapy approach to directly reprogram reactive astrocytes into functional motor neurons in SOD1^{G93A} ALS mouse model

Authors: *M. PAN, Y. LIU, A. REDILLA, C. KERSTETTER, G. CHEN;
Huck Inst. of Life Sci., University Park, PA

Abstract: Amyotrophic lateral sclerosis (ALS) is an adult-onset, irreversible neurodegenerative disease, characterized by loss of motor neurons in the spinal cord, brain stem, and motor cortex, resulting in progressive muscle weakness, paralysis, and death within 3-5 years after diagnosis. There is no effective therapy available to halt the disease progression or provide a cure. Therefore, exploration of a new therapy is urgently needed. Our lab has pioneered an *in vivo* neuroregeneration technology to directly convert endogenous reactive glial cells into functional neurons after injury or diseases. Here, we develop a novel strategy to directly convert reactive astrocytes into functional motoneurons in the spinal ventral horn of SOD1^{G93A} ALS mouse model through adeno-associated virus (AAV)-based gene therapy. AAV-treated SOD1^{G93A} mice showed increased number of motoneurons in the spinal cord and significant improvement of motor functions in multiple behavioral tests. This gene therapy approach also extended the lifespan and delayed hindlimb paralysis in the SOD1^{G93A} mice. Our findings suggest that regenerating motoneurons from internal glial cells might lead to an innovative therapeutic treatment for ALS through replenishing the lost motoneurons and restoring the lost motor functions.

Title: Effect of inhibition of sodium/proton exchanger 5 (NHE5) on the alternative splicing of survival motor neuron 2 (SMN2)

Authors: S. KANDA[1], E. MOULTON[2], ***M. E. R. BUTCHBACH**[2,1,3];

Abstract: Spinal muscular atrophy (SMA) is an autosomal recessive pediatric-onset neurodegenerative disease caused by the loss of spinal motor neurons which leads to generalized muscle atrophy. SMA is caused by mutations or the loss of *survival motor neuron 1* (SMN1). The human genome contains a duplicate copy of *SMN1* known as *SMN2*. The major difference between these genes is a cytosine to thymine (C-to-T) transition located in an exonic splicing enhancer (ESE) element within exon 7. The majority of the *SMN2* mRNA transcripts lack exon 7 (SMNΔ7) forming a truncated and unstable SMN protein. Since *SMN2* copy number is inversely related to disease severity, it is a well-established target for SMA therapeutics development. 5-(N-ethyl-N-isopropyl)-amiloride (EIPA), an inhibitor of sodium/proton exchangers (NHEs), has previously been shown to increase exon 7 inclusion and SMN protein levels in SMA cells. In this study several NHE inhibitors were evaluated for their ability to modulate *SMN2* expression. EIPA as well as 5-(N, N-hexamethylene)-amiloride (HMA) increase exon 7 inclusion in *SMN2* splicing reporter lines as well as in SMA fibroblasts. EIPA and HMA are more selective at inhibiting the NHE5 isoform than other NHE inhibitors. NHE5 is expressed in fibroblasts as well as in neuronal cells. Knockdown of *NHE5* also increases *SMN2* exon 7 inclusion in SMA cells. These results show that NHE5 inhibition increases *SMN2* expression and may be a novel target for therapeutics development.

Title: Scalable cGMP compliant expansion of human fetal and iPSC derived neural progenitor cells

Authors: A. FULTON, A. LAPERLE, *G. LAWLESS, K. ROXAS, P. AVALOS, C. SVENDSEN;
Cedars Sinai Med. Ctr., Los Angeles, CA

Abstract: Transplanted human fetal-derived neural progenitor cells have been used to treat multiple neurodegenerative diseases with mixed success. Early attempts engrafted primary fetal tissue in the striatum of Parkinson's disease patients to restore dopamine production. More recently, fetal-derived neural progenitors were engineered to produce glial cell line-derived neurotrophic factor (GDNF). These cells and were used in a completed Phase 1/2a trial delivering the cells to the spinal cord of ALS patients as a first ever cell and gene therapy.

Traditionally, such neural progenitor cells are expanded as either a monolayer or in suspension as aggregate cultures. Single cell passaging of either culture modality is not ideal as this passage method can lead to early cell senesce, which limits expansion potential, or can induce the cells to differentiate. Mechanical chopping has been successfully used to expand both fetal and iPSC-derived neural progenitor cells to scales suitable for early phase clinical trials. However, this method is time-consuming, labor-intensive, and challenging to implement at larger scales. We have developed a novel in-line passaging technique that maintains the expansion rate and cellular identity of mechanical chopping but that is faster, scalable, and can be implemented in a fully sealed system. Fetal and iPSC-derived neural progenitor cells produced with this new method maintain similar growth rates to cells expanded under traditional mechanical chopping methods. These cells also transplant efficiently in the spinal cord of nude rats, where they are safe for up to 3 months. This novel in-line mechanical passaging method will permit expansion of fetal and iPSC-derived aggregate cultures to scales necessary for later stage clinical trials and full therapeutic production.

Title: iPSC derived neural progenitor cells genetically engineered to express GDNF can engraft and provide neuroprotection in the SOD1 ALS rat spinal cord

Authors: *A. H. LAPERLE, **G. LAWLESS**, A. FULTON, K. ROXAS, P. AAVLOS, V. J. GARCIA, C. N. SVENDSEN;
Cedars-Sinai Regenerative Med. Inst., Los Angeles, CA

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a debilitating neurodegenerative disease affecting approximately 30,000 individuals in the US at any given time. Currently there are only two FDA approved drugs used to treat the disease, Edaravone and Riluzole, both of which slow progression only slightly. Promising preclinical treatments have included transplantation of supportive glial cells and delivery of glial cell line-derived neurotrophic factor (GDNF). Our group has generated and extensively characterized human fetal-derived neural progenitor cells that can differentiate into astrocytes and that can be transfected with lentivirus to stably produce GDNF. These GDNF-producing cells engraft efficiently in the spinal cord and slow the loss of

ChAT+ motor neurons in the SOD1 ALS rat. These cells have been banked under cGMP and we just completed a Phase 1/2a trial delivering the cells to the spinal cord of ALS patients as a first cell and gene therapy. While promising, the scalable use of fetal-derived neural progenitor cells is limited by the availability of starting material and a limited expansion potential. Further, the lentiviral transduction used to induce GDNF expression in these cells results in a heterogeneous population with varying copy number and GDNF production levels. To address these challenges, we have developed scalable, cGMP-applicable neural progenitor cell lines derived from human induced pluripotent stem cells (iPSCs). These iPSC-derived cells engraft efficiently in the ALS rat spinal cord and provide neuroprotection to diseased motor neurons, similar to the fetal-derived cells used in our clinical trial. Taking advantage of the clonal expansion capabilities of iPSCs, we generated clonal lines with a single copy GDNF construct inserted in the AAVS1 safe landing site. These lines uniformly express and produce GDNF. We also used this approach to generate iPSC-derived neural progenitor cell lines with more sophisticated constructs including a tetracycline-inducible promotor for regulated GDNF expression. These inducible expression systems could permit tailoring of GDNF dose to individual patients and present the added safety feature of turning off GDNF expression if required. These new iPSC-based lines are scalable to clinically relevant production volumes, uniformly produce GDNF, are safe for up to three months *in vivo,* and represent a promising new combination therapy for ALS.

Title: Human neural progenitor cells secreting glial cell line-derived neurotrophic factor (CNS10-NPC-GDNF) for the treatment of amyotrophic lateral sclerosis (ALS) - Clinical trial update

Authors: *P. AVALOS[1], K. ROXAS[1], P. ALLRED[2], H. BABU[2], C. PATIL[2], J. P. JOHNSON[2], R. H. BALOH[2], C. N. SVENDSEN[1];
[1]Regenerative Med. Inst., [2]Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal, progressive neurodegenerative disease characterized by rapid loss of muscle control and eventual paralysis. Symptoms result primarily from the death of spinal and cortical motor neurons. The annual incidence for ALS in developed

countries ranges from 0.4 to 2.4 per 100,000 individuals. ALS is typically lethal within 3-5 years of onset. Treatment is largely symptomatic and focused on improving quality of life. Currently, the only two FDA-approved treatments, riluzole and edaravone, have a limited effect on this devastating disease. Therefore, ALS is an ideal candidate for novel gene and cell therapy approaches. There is strong evidence that following an initial trigger within the motor neurons, further decline in their health is modulated by diseased astrocytes. Critically, the presence of healthy astrocytes can support dying motor neurons. Additionally, the growth factor, glial cell line-derived neurotrophic factor (GDNF), is able to protect dying motor neurons. The challenge is that targeted delivery of new astrocytes or beneficial growth factors to the central nervous system is difficult, as they do not penetrate the blood brain/spinal cord barrier. Human neural progenitor cells genetically modified to stably secrete GDNF (CNS10-NPC-GDNF) can be transplanted into the lumbar spinal cord, where they migrate into areas of motor neuron degeneration, mature into new supportive astrocytes and release GDNF leading to motor neuron protection. Therefore, a CIRM funded, 18 subject Phase 1/2a, single-center, blinded (as to side of injection), safety study of two escalating doses of CNS10-NPC-GDNF delivered unilaterally to the lumbar region of ambulatory ALS patients with moderate leg involvement is being performed under an active IND (Clinicaltrials.gov NCT02943850). The trial has a unique design in that CNS10-NPC-GDNF were injected unilaterally into the lumbar spinal cord, allowing the contralateral side to serve as an internal control. Although the primary objective is to assess the safety and tolerability of two doses of CNS10-NPC-GDNF, secondary outcome measures, including muscle strength, nerve conductivity tests and MRI, are being performed during the study period for preliminary signs of efficacy. At this time all subjects have been enrolled into the trial and received CNS10-NPC-GDNF treatment. This presentation will give an update of this ongoing clinical trial.

Abstract: Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disorder characterized by a gradual loss of motor neurons that leads to paralysis and death. Studies indicate that neuromuscular junction (NMJ) denervation occurs in the early stages of the disease while neuronal cell bodies in the spinal cord remain intact. It is important to elucidate the molecular mechanisms that lead to NMJ denervation in ALS and identify interventions to improve neuromuscular function in ALS patients. We found that the synapse organizer laminin β2 decreases in NMJs of ALS model $SOD1^{G93A}$ mice, and transgenic expression of laminin β2 in skeletal muscles of $SOD1^{G93A}$ mice ameliorates NMJ denervation. In this study, we evaluated a stem cell-based therapy in $SOD1^{G93A}$ mice by using stem cells as vectors to express and secrete proteins that promote NMJ maintenance and are neurotrophic. The objectives of this study are (1) to determine whether human umbilical cord-Wharton's jelly derived mesenchymal stem cells (hMSCs) from multiple donors secrete synapse organizer laminin β2 and neurotrophic factors at similar levels, and (2) to evaluate hMSCs derived from different donors in vivo in $SOD1^{G93A}$ mice for NMJ maintenance and life-span extension. We discovered that hMSCs derived from multiple donors can increase the secretion of laminin β2 and neurotrophic factors by stimulation in media supplemented with growth factors. Furthermore, we confirmed that unilateral injection of hMSCs increased NMJ innervation rates and average myofiber cross sectional area in MSC-injected muscles compared to non-injected contralateral muscles. Then, the hMSCs obtained from two donors were transplanted separately into $SOD1^{G93A}$ mice by combined intrathecal and bilateral intramuscular injections. We analyzed hMSCs' survival length in the muscle after injection using immunohistochemistry. Importantly, injection of hMSCs obtained from the two donors improved neuromuscular function of injected $SOD1^{G93A}$ mice, and prolonged the lifespan of $SOD1^{G93A}$ mice compared to the vehicle injected $SOD1^{G93A}$ mice. Thus, injection of hMSCs obtained from donors could be an efficient treatment method to reduce NMJ denervation and improve the quality of life of ALS patients.

Abstract: Presynaptic active zones play an essential role as synaptic vesicle release sites for synaptic transmission. In our previous studies, we identified the mechanism for active zone organization at mammalian NMJs that involves the interaction of muscle-derived synapse organizer laminin β2 with presynaptic voltage-gated calcium channels (VGCC). In this study, stimulated emission depletion (STED) super resolution microscopy analysis supports our molecular mechanism suggesting that laminin β2 anchors PQ-type VGCCs in front of postsynaptic junctional folds. PQ-type VGCC can then function as a scaffolding protein for active zone–specific proteins. Based on the knowledge obtained from wild-type NMJs, we evaluated the active zone proteins in NMJs of amyotrophic lateral sclerosis (ALS) mouse models. ALS is a neurodegenerative disorder in which NMJ denervation occurs before the death of motor neuron cell bodies in the spinal cord, suggesting a “dying-back” neuropathy. The mechanisms underlying NMJ denervation in ALS remain unknown. The pathogenesis of ALS may involve changes in protein levels, which are important for the maintenance of NMJ active zones and regulation of neurotransmission. For this purpose, we analyzed active zone proteins in NMJs of $SOD1^{G93A}$ mice, a rodent ALS model, at an early, pre-symptomatic stage (P85) and a symptomatic stage (P140). Interestingly, we found that the quantity of active zone proteins Bassoon, Piccolo, and PQ-type VGCC decreased in innervated NMJs of ALS mice compared to age- and sex-matched wild-type mice. We also found that laminin β2 level decreased in $SOD1^{G93A}$ mice and transgenic expression of laminin β2 in $SOD1^{G93A}$ mice ameliorated NMJ denervation. These results suggest that the level of laminin β2 protein is critical for the

maintenance of NMJs in ALS patients. As a therapeutic source of laminin β2, we evaluated stem cells as vectors to express and secrete proteins that promote NMJ maintenance and are neuroprotective. We identified that stimulating human mesenchymal stem cells (hMSCs) in media supplemented with growth factors can increase laminin β2 and neurotrophic factor secretion. Transplanting the stimulated hMSCs in $SOD1^{G93A}$ mice maintained NMJ innervation and prolonged $SOD1^{G93A}$ mice survival. This could prove to be an efficient and a long-term delivery system for laminin β2 to reduce NMJ denervation and increase the quality of life of ALS patients.

Title: Peptide-directed selective knockdown of misfolded SOD1 as a therapy for amyotrophic lateral sclerosis

Authors: *T. ZHOU[1], T. GUAN[1], Y. WANG[2], H. MARZBAN[1], J. KONG[1];
[1]Univ. of Manitoba, Winnipeg, MB, Canada; [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease, in which misfolded SOD1 (superoxide dismutase 1) plays a central role of pathogenesis. Targeting misfolded SOD1 is therefore a rational approach towards a cure for ALS. Here we present a new approach to selectively knockdown misfolded SOD1 by insertion of the CT-4 epitope of Derlin-1 into the chaperone-mediated autophagy system. In this study, we report efficiency and specificity of CT-4 peptide in knocking down misfolded SOD1 *in vitro* and *in vivo*. Our results revealed that CT-4 treatment resulted in a selective degradation of misfolded SOD1 in a dose-, time- and lysosomal activity-dependent manner *in vitro*. The *in vivo* studies revealed that CT-4 treatment resulted in knockdown of misfolded SOD1 in the tissues from G93A transgenic mouse model of ALS. In addition, our daily injection of CT-4 peptide significantly delays disease onset and extends lifespan of G93A transgenic mice of ALS. Furthermore, we explored the potential mechanism underlying which CT-4 peptide delays disease onset. Our data indicated that knockdown of misfolded SOD1 could directly affect MCT1 protein expression in SC, suggesting that CT-4 peptide treatment results in preservation of MCT1 expression, maintenance of axon

myelin and protection of neurons in ALS animal model. Therefore, the peptide may be developed into a cure for ALS.

Title: Investigating Cx43 HC and GJ localization and function in amyotrophic lateral sclerosis

Authors: *J. A. JOSEPH[1], M. L. GALLARDO[2], A. A. ALMAD[3], A. POKHAREL[1], S. GROSS[1], A. TAGA[1], J. CONTRERAS[2], N. MARAGAKIS[1];
[1]Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Dept. of Pharmacology, Physiol. & Neurosci., Rutgers Univ., Newark, NJ; [3]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Connexin 43 (Cx43) is the most ubiquitous connexin in the central nervous system and forms hemichannels (HC) and gap junctions (GJ) in astrocytes. Increases in Cx43 expression and activity are observed in neurodegenerative diseases including Alzheimer's and Parkinson's. Our lab recently reported that Cx43 upregulation in astrocytes contributes to motor neuron (MN) toxicity in Amyotrophic Lateral Sclerosis (ALS). We demonstrated that astrocyte expression of Cx43 is increased in frontal cortex and spinal cords of ALS patients and in the $SOD1^{G93A}$ ALS mouse model, and that $SOD1^{G93A}$ astrocyte mediated MN toxicity was in part due to Cx43 HCs. Given $SOD1^{G93A}$ astrocytes incite disease progression but not onset, this suggests astrocytes, and potentially Cx43, play a key role in disease propagation. In the majority of patients disease propagation occurs in contiguous anatomic regions over time, but out lack of understanding fundamentally limits the design of disease modifying therapies after diagnosis. We aim to understand the role of Cx43 in ALS disease spread using a novel triple transgenic $SOD1^{G93A}$;GFAP-Cre;$Cx43^{fl/fl}$ mouse and human ALS induced pluripotent stem cell (hiPSC) models to examine Cx43 HC localization and function.
In order to determine the ratio of Cx43 HC to total Cx43, we employed a published method to pulldown HCs in vitro. This technique utilizes biotin binding on lysine residues of Cx43 HC extracellular domains, then biotin-streptavidin binding to pulldown proteins and blot for Cx43. We then determine the percentage of Cx43 HCs to total Cx43 using total protein linear modeling described by Retamal et al. We performed this in ALS hiPSC astrocyte cultures using six patient lines, including controls, sporadic, and familial lines. We also used qPCR to test toxicity profiles

of WT, disease, and the triple transgenic mouse astrocytes.
Our data suggest total Cx43 is dramatically increased in $SOD1^{G93A}$ astrocytes, including Cx43 HC levels. Interestingly, the ratio of Cx43 HC to total Cx43 expression in this model is increased and suggests a greater percentage of Cx43 HC exists on the membrane. Initial studies using ALS hiPSC-derived astrocytes show similar increases in Cx43 expression and HC localization. qPCR data show the $SOD1^{G93A}$ astrocyte-mediated toxicity is not related to the A1 toxicity phenotype. Disease astrocytes and Cx43 KO disease astrocytes have similar profiles despite the lack of Cx43 expression.
Cx43 is a novel protein associated with ALS disease progression and the mechanism of HC toxicity has yet to be explored. Using novel models, our findings shed light on a potential role for Cx43 HC in ALS and as a potential therapeutic target.

Title: Nicotinamide riboside modestly extends survival in ALS-linked mutant $hSOD1^{G93A}$ mice

Authors: B. A. HARLAN, K. M. KILLOY, M. PEHAR, *M. R. VARGAS;
Cell and Mol. Pharmacol., Med. Univ. of South Carolina, Charleston, SC

Abstract: Amyotrophic lateral sclerosis (ALS) is the most common adult-onset motor neuron disease, caused by the progressive degeneration of motor neurons in the spinal cord, brain stem, and motor cortex. Approximately 10-20% of familial ALS is caused by a toxic gain-of-function induced by mutations of the Cu/Zn-superoxide dismutase (SOD1). Nicotinamide adenine dinucleotide (NAD^+) is an essential redox molecule and a key player in several signaling pathways that govern fundamental biological processes. Activation of NAD^+-dependent signaling pathways has a major effect in the capacity of the cell to modulate mitochondrial function and counteracts the deleterious effects of increased oxidative stress. We have previously shown that increasing NAD^+ availability improves antioxidant defenses and abrogates the neurotoxicity of ALS-astrocytes towards co-cultured motor neurons. Nicotinamide riboside (NR) can serve as an NAD^+ precursor and effectively increases total NAD^+ content in different cell types and tissues. Here we explore the role of an NR supplemented diet in the ALS-like pathology displayed by mice expressing the ALS-linked mutant $hSOD1^{G93A}$. We found that NR

modestly extends the survival of hSOD1^{G93A} mice, decreases reactive gliosis in the spinal cord and appears to confer increased metabolic flexibility in the skeletal muscle. Our results suggest that modulating NAD^+ availability could be a potential therapeutic strategy in ALS.

Hlth., Loma Linda, CA

Abstract: The mislocalization of proteins has been recognized as a hallmark of many neurodegenerative diseases. Our prior work on host-catalyzed viral assembly led to the discovery of multi-protein complex (MPC) “assembly machines” playing previously unappreciated roles in protein homeostasis. Assembly machines cannot easily be detected by conventional proteomics, in part due to their transience/lability. However, these targets are druggable if you can figure out how to detect them, which is what we have done. Remarkably, some of the small-molecule chemotypes have robust activity against both TDP-43 mislocalization as well as on stress-induced TDP-43 aggregation, and in both sporadic and familial ALS cellular models. TDP-43 and Ran GTPase proteins that are implicated in ALS pathophysiology was detected as part of the assembly machine. The most advanced compounds demonstrate *in vivo* protection against motor neuron degeneration by a variety of metrics in transgenic *C. elegans* (TDP-43 A315T), *D. melanogaster* (C9orf72 repeat expansion), and mouse (SODG93A) ALS models. Evidence for distinctive aberrant assembly machine target engagement is observed in both SOD G93A transgenic mouse brain and in sporadic ALS patient-derived fibroblasts by use of drug resin affinity chromatography (DRAC) to identify the proteins comprising ALS-involved normal and aberrant assembly machines. These tools also correlate findings in cells to activity of the drugs, and, using peripheral blood mononuclear cells (PBMCs), identify specific patient subsets of the

ALS phenotype which respond best to a given assembly modulator. Taken together, our findings support the hypothesis that in many cases ALS is a disease of assembly machine dysfunction correctable by small molecule allosteric site-targeted assembly modulators. This suggests a new conceptual lens - catalyzed assembly modulation - through which to view ALS pathophysiology. We have established tools that have practical application to better understand the molecular basis for ALS and at the same time be used in clinical trial patient selection, and objective assessment of therapeutic efficacy. Compounds to these distinctive novel targets correct molecular defects in ALS and are being advanced in a manner that may allow individualization of therapy for patient subsets defined by peripheral DRAC signatures. These signatures are predicted to appear very early in disease pathogenesis, perhaps even prior to onset of clinical symptoms and aid in the reversal of ALS disease course.

Title: Raltegravir effectively reverses ERVK integrase-mediated pathology

Authors: *D. L. DI CURZIO[1], M.-J. NADEAU[1], B. MEEK[1], M. GURM[2], R. DOUVILLE[1,2]; [1]Biol., Richardson Col. for the Envrn. & Sci. Complex, Univ. of Winnipeg, Winnipeg, MB, Canada; [2]Immunol., Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: Endogenous retroviruses embody over 8% of the human genome, with endogenous retrovirus-K (ERVK) being the most intact and biologically active ERV. ERVK has been shown to have biological roles in health and disease, including various cancers, Human

Immunodeficiency Virus (HIV) infection, and Amyotrophic Lateral Sclerosis (ALS). ERVK encodes an integrase (IN) enzyme, a class of retroviral enzymes known to cause DNA damage during integration of viral DNA into host genomes. Since genomic instability and immune impairment are hallmark pathological findings in ALS, we hypothesized that the ERVK IN enzyme contributes to neuropathology in ALS. Our aim was to determine if the IN inhibitor Raltegravir reverses ERVK IN pathology. We examined levels of DNA damage, expression of innate antiviral protein interferon regulatory factor 3 (IRF3), and cell death in human astrocytes (SVGA cells) overexpressing ERVK IN and *ex vivo* human motor cortex and spinal cord tissue using immunohistochemical techniques. Western blot was also used to examine these pathological changes in ERVK IN-transfected SVGAs. Raltegravir treatment was performed on the transfected astrocytes to examine the therapeutic effects of ERVK IN inhibition. In comparison to neuronormal (NN) controls, patients with ALS exhibit enhanced ERVK IN expression in the motor cortex and spinal cord, along with increased levels of the modified histone and DNA damage marker, γH2AX, and necroptosis cell death marker, MLKL. Cytoplasmic IRF3 aggregates and impaired IRF3 nuclear translocation were also found in $ERVK^+$ cells in ALS motor cortex compared to NN controls. ERVK IN-transfected SVGAs showed perinuclear and nuclear aggregates of ERVK IN along with nuclear accumulation of DNA damage marker γH2AX, which occurred in conjunction with aberrant perinuclear deposition of DNA repair protein BRCA1. SVGA cells co-transfected with ERVK IN and constitutively active IRF3 showed cytoplasmic IRF3 sequestration, which prevented nuclear translocation of IRF3. Raltegravir treatment of ERVK IN expressing SVGAs reduced γH2AX foci, overall levels of ERVK IN, and IRF3 translocation to the nucleus was restored. The ERVK IN enzyme drives DNA damage, impairs DNA repair, and suppresses innate antiviral immunity. Together, these molecular mechanisms may contribute to neuropathology in ALS. ERVK IN-driven pathology is reversed by HIV IN inhibitor drug Raltegravir. FDA-approved integrase inhibitors, such as Raltegravir, may confer therapeutic benefit in ALS.

Title: Beneficial effects of mesenchymal stem cell-derived exosomes and of exosome-shuttled microRNAs on the activated phenotype of mouse and human-derived astrocyte cell cultures in amyotrophic lateral sclerosis

Authors: *G. B. BONANNO[1,3,4], F. PROVENZANO[1], M. BALBI[1], S. NYBERG[5], L. FERRAIUOLO[5], C. MARINI[2], B. PARODI[2], D. GIUNTI[2], T. BONIFACINO[1], N. KERLERO DE ROSBO[2], C. USAI[6], M. MILANESE[1,3], A. UCCELLI[2,3,4], P. J. SHAW[5];

Res. Council (CNR), Genoa, Italy

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease affecting motor neuron (MN) viability Degeneration of MNs has been linked to neuroinflammation, supported mostly by activated microglia and astrocytes. We have shown that intravenous administration of mesenchymal stem cells (MSCs) to the $SOD1^{G93A}$ mouse model of ALS prolonged survival, ameliorated motor skills and reduced inflammation in the spinal cord (Mol Med 18: 794, 2012). These beneficial effects were not associated with MSC differentiation and we postulated that they were due to paracrine mechanisms. As possible paracrine mechanisms supporting the MSC effects, we studied here the activity of IFNγ-primed MSC-derived exosomes and exosome-shuttled miRNAs on spinal cord astrocyte cultures from 120 day-old symptomatic $SOD1^{G93A}$ mice or on human iNPC-derived astrocytes from sporadic and familial ALS patients,. Twenty four hours exposure of symptomatic $SOD1^{G93A}$ mouse-derived astrocytes to MSCs-produced exosomes significantly reduced the overexpression of the astrogliosis markers GFAP and vimentin and of the neuroinflammatory marker NLRP3. $SOD1^{G93A}$ astrocytes were characterized by increased expression and release of the pro-inflammatory cytokines IL1β, TNFα e IL6. These alterations were strongly reduced after exosome exposure. To verify the impact of astrocyte treatment with exosomes on MN viability, spinal MNs from $SOD1^{G93A}$ embryos were co-cultured with exosome-treated or control astrocytes. Viability of MNs was increased when co-cultured with exosome-treated astrocytes. We also tested the effects of transfecting $SOD1^{G93A}$ astrocytes with mimics of 9 miRNAs, which have been found up-regulated in MSCs and present in exosomes. Seven out of 9 miRNA mimics affected the reactive phenotype of astrocytes by significantly decreasing the overexpression of GFAP, IL1β and TNFα. Finally, we verified the effects of human MSC(hMSC)-derived exosomes on iNPC-derived astrocytes (iAstrocytes) from SOD1 or C9orf72-mutants and sporadic ALS patients. hMSCs-derived exosomes activated the p62-Nrf2-NQO1 antioxidant pathway in iAstrocytes. The amelioration of iAstrocyte phenotype by hMSCs-derived exosomes translated into a direct rescue of iAstrocyte-mediated neuron toxicity. Thus, exosomes derived from primed-MSCs, and their miRNAs cargo, are able to modulate the neuroinflammatory and antioxidant pathways in reactive ALS-astrocytes. These effects have a direct positive impact on spinal MN viability and pave the way to translational preclinical in-vivo studies.

Title: Long-term voluntary physical exercise exerts neuroprotective effects and alleviates subsequent akinesia and gait disturbance in a rat model of Parkinson's disease

Authors: *W.-L. TSAI[1], C.-W. KUO[2], Y.-H. CHEN[3], Y.-Z. HUANG[4], Y.-T. HUANG[5], C.-W. HSU[5], S.-C. HSUEH[1], J.-H. LAI[1], Y.-H. CHIANG[1], C.-F. CHANG[6], T.-J. KAO[1], T.-H. Hospital/Chang Gung Univ., Taoyuan, Taiwan; [5]Chang Gung Univ., Taoyuan, Taiwan; [6]Taipei City Hospital, Zhongxiao Br., Taipei, Taiwan

Abstract: Background: Parkinson's disease (PD) is the second most prevalent neurodegenerative disorders affecting 7-10 million individuals. The pathologic hallmark of PD is a loss of nigrostriatal dopaminergic neurons, leading to several motor and non-motor disturbances, e.g. akinesia, gait disturbance, depression, and anxiety. Recent animal studies demonstrate that physical exercise improves the behavioral and neuropathological deficits in PD. However, the underlying mechanism is still unclear. In this study, we investigated whether long-term effects exercise have the neuroprotective effects in dopaminergic nigrostriatal neurons and further alleviate the impairment of gait pattern, locomotor activity, akinesia and anxiety in PD rats.
Methods: A hemiparkinsonian rat model, generated by unilateral injection of 6-hydroxydopamine (6-OHDA) into the medial forebrain bundle (MFB), was applied to evaluate the neuroprotective effects and motor behaviors. The comprehensive spatiotemporal gait analysis, open field locomotor activity, akinesia, apomorphine-induced rotational analysis as well as dopaminergic neurons degeneration level were assessed every week and up to 8 weeks after daily voluntary running wheel exercise.
Results: When compared with the sham-treated group, we found that 8 weeks of voluntary exercise significantly reduced the 6-OHDA induced motor deficits in gait pattern, locomotor activity, akinesia, rotational behavior, and anxiety. Immunohistochemically, tyrosine hydroxylase (TH)-positive neuron in the substantia nigra was significantly preserved in the exercise group.

Conclusions: Our results demonstrate that long-term exercise training is effective for neuroprotection and further attenuates motor declines induced by 6-OHDA in an experimental model of PD. Our data further highlight the potential therapeutic effects of long-term physical exercise that might be relevant to the clinical effect for the further potential application of human PD subjects.

Title: Decelerating photoreceptor degeneration by the flavonoid luteolin in a mouse model of retinitis pigmentosa

Authors: *A. LI[1], X. LIU[1], F. LIU[1], J. HUANG[2], Y. XU[1];
[1]GHM Inst. of CNS Regeneration, Jinan Univ., Guangzhou, China; [2]American Intl. Sch. of Guangzhou, Guangzhou, China

Abstract: Retinitis pigmentosa (RP) is a hereditary retinal disease with progressively sequential losses of rods and cones that ultimately lead to blindness. The prevalence of RP is approximately 1/3500, whereas no effective treatment has been available so far. Luteolin as an important flavonoid derived from several herbs is known to exert antioxidant and anti-inflammatory effects, and yet its influence on RP is little explored. Here we examine whether luteolin mitigates the impairments of retinal morphology and function in rd10 mice, a slow photoreceptor-degeneration model of RP, and attempt to unmask the underlying mechanism. Luteolin or vehicle phosphate-buffered solution was intraperitoneally injected into rd10 mice daily from P14 to P25 when photoreceptor degeneration reaches peak. Immunohistochemistry, visual behaviors and electroretinogram were applied to assess the structure and function of retinas after the designated treatments. Intracellular levels of calcium ions and reactive oxygen species (ROS)

were measured fluorometrically. Quantitative polymerase chain reaction and protein array screening followed by western-blotting confirmation were used to identify the potential signaling pathways involved in this process. Compared to the sham control, luteolin significantly retained the normal retinal structure and increased the survival of photoreceptors in rd10 mice, accompanied with the improved visual behavioral performance and light responses at P25. Meanwhile, cytosolic calcium overload, ROS level elevation and photoreceptor apoptosis in rd10 mice were largely attenuated. Additionally, expression of pro-inflammatory cytokines after luteolin treatment was down-regulated, concurrent with the reduced immunoreactivity of glial fibrillary acidic protein in Müller cells, an indicator for the overall retinal inflammation. The above-mentioned beneficial effects of luteolin was likely mediated via the Jun N-terminal kinase (JNK) pathway given that inhibiting the phosphorylation of JNK diminished these biological alterations. Collectively, administration of luteolin helps to delay photoreceptor degeneration and subsequently maintains visual function in RP possibly through JNK pathway-mediated neuroprotection.

Abstract: Background: Neonatal hypoxic-ischemic (HI) insult is a leading cause of disability and death in newborns, with therapeutic hypothermia being the only currently available clinical intervention. Thus there is a great need for adjunct and novel treatments for enhanced or alternative post-HI neuroprotection. Extracellular vesicles (EVs) derived from mesenchymal stromal/stem cells (MSCs) have recently been shown to exhibit regenerative effects in various injury models. Here we present findings showing neuroprotective effects of MSC-derived EVs in the Rice-Vannucci model of severe HI-induced neonatal brain insult.**Methods:** Mesenchymal stromal/stem cell-derived EVs were applied intranasally immediately post HI-insult and

behavioral outcomes were observed 48 h following MSC-EV treatment, as assessed by negative geotaxis. Brains were thereafter excised and assessed for changes in glial responses, cell death, and neuronal loss as markers of damage at 48 h post HI-insult.**Results:** Brains of the MSC-EV treated group showed a significant decrease in microglial activation, cell death, and percentage tissue volume loss in multiple brain regions, compared to the control-treated groups. Furthermore, negative geotaxis test showed improved behavioral outcomes at 48 h following MSC-EV treatment.**Conclusion:** Our findings highlight the clinical potential of using MSC-derived EVs following neonatal hypoxia-ischaemia.

Title: Curcumin: Novel treatment in neonatal hypoxic-ischaemic brain injury

Authors: *E. ROCHA FERREIRA[1], **C. SISA**[2], S. BRIGHT[1], T. FAUTZ[1], M. HARRIS[1], I. CONTRERAS RIQUELME[1], C. AGWU[1], T. KURULDAY[1], D. HILL[1], S. LANGE[3], M. HRISTOVA[1];
[2]Maternal and Fetal Med., [1]Univ. Col. London, London, United Kingdom; [3]Univ. of Westminster, London, United Kingdom

Abstract: Hypoxic-ischaemic encephalopathy (HIE) is a major cause of mortality and morbidity in neonates, with a global incidence of 3/1000 live births. HIE brain damage is associated with an inflammatory response and oxidative stress, resulting in the activation of cell death pathways. There is an unmet clinical need for the development of novel therapeutic interventions for the treatment of HIE. Curcumin is an antioxidant reactive oxygen species scavenger, with anti-tumour and anti-inflammatory activity. Curcumin has been shown to attenuate mitochondrial dysfunction, stabilise the cell membrane, stimulate proliferation, and reduce injury severity in adult models of spinal cord injury, cancer, and cardiovascular disease. The role of curcumin in neonatal HIE has not been widely studied due to its low bioavailability and limited aqueous solubility. This study aimed to investigate the effect of curcumin treatment in neonatal HIE, including time of administration and dose-dependent effects. Our results indicate that curcumin administration prior to HIE in neonatal mice elevated cell and tissue loss, as well as glial

activation compared to HI alone. However, immediate post-treatment with curcumin was significantly neuroprotective, reducing grey and white matter tissue loss, TUNEL+ cell death, microglia activation, reactive astrogliosis and iNOS oxidative stress when compared to vehicle-treated littermate controls. This effect was dose-dependent, with 200μg/g BW as the optimal dose-regimen and was maintained when curcumin treatment was delayed by 60min or 120min post-HI. Cell proliferation measurements showed no changes between curcumin and HI alone, suggesting that the protective effects of curcumin on the neonatal brain following HI are most likely due to curcumin's anti-inflammatory and antioxidant properties, as seen in the reduced glial and iNOS activity, and decrease of phosphorylated STAT3 Y705 and S727 protein levels. Also, curcumin-treated animals showed an increase in ipsilateral PHB, supporting its neuroprotective role as a mitoprotective and neuroprotective agent. In conclusion, this study suggests curcumin as a potent neuroprotective agent with potential for the treatment of HIE. The delayed application of curcumin further increases its clinical relevance.

Title: Properdin a novel target for neuroprotection in neonatal hypoxic ischaemic brain injury

Authors: *M. H. HRISTOVA[1], C. SISA[2], Q. AGHA-SHAH[1], B. SANGHERA[1], A. CARNO[1], C. STOVER[3];
[2]Maternal and Fetal Med., [1]Univ. Col. London, London, United Kingdom; [3]Univ. of Leicester, Leicester, United Kingdom

Abstract: Hypoxic-ischaemic (HI) encephalopathy is a major cause of neonatal mortality and morbidity, with global incidence of 3 per 1000 live births. Intrauterine or perinatal complications, including maternal infection constitute a major risk for the development of neonatal HI brain damage. The mechanisms underlying the trigger of brain damage under the conditions of HI alone and infection-sensitised HI overlap, but also differ. During HI brain damage inflammatory response and oxidative stress occur, causing subsequent cell death. The presence of an infection however sensitises the neonatal brain making it more vulnerable to the HI damage. Currently, therapeutic hypothermia is the only clinically approved treatment

available for HI encephalopathy, however it is only partially effective in HI alone and ineffective in infection-sensitised HI. Therefore there is an unmet clinical need for the development of novel therapeutic interventions for the treatment of HI. Such an alternative is targeting the complement system. Absence of the classical pathway in the neonatal HI brain is neuroprotective, however there is paucity of data on the participation of the alternative pathway and in particular the role of properdin in HI brain damage. Our study aimed to validate the effect of global properdin deletion in two models: HI alone and LPS-sensitised HI thus addressing two different clinical scenarios. Our results indicate that global properdin deletion in a Rice-Vannucci model of neonatal HI and LPS-sensitised HI brain damage, in the short term, clearly reduced forebrain cell death and microglial activation, as well as tissue loss. In HI alone, deletion of properdin reduced TUNEL+ cell death and microglial post-HI response at 48h post insult. Under the conditions of LPS-sensitised HI, properdin deletion diminished TUNEL+ cell death, tissue loss and microglial activation at 48h post-HI. Overall, our data suggests a critical role for properdin, and possibly also a contribution in neonatal HI alone and in infection-sensitised HI brain damage. Thus, properdin can be considered a novel target for treatment of neonatal HI brain damage.

Title: Soy isoflavone daidzein but not genistein protects Neuro2a cells from oxidative stress via AMPK and mitochondrial enhancement

Authors: S. ITO[1], *K. NAGAI[2];
[1]Koshien Univ., Hyogo, Japan; [2]Dept. of Food and Nutr., Senri Kinran Univ., Osaka, Japan

Abstract: Oxidative stress is involved in most of the neurodegenerative diseases, such as Parkinson's disease and Alzheimer's disease. Although the antioxidative property of soy isoflavones was reported in different experimental models, it has been believed that the protection was achieved as antioxidants against reactive oxygen species rather than their effects in the cells. While typical soy isoflavones daidzein and genistein were reported to activate mitochondrial biogenesis regulator Peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC1α) via Sirt1 activation. Thus, we hypothesized that daidzein or

genistein attenuates oxidative stress induced cell damage via sirtuin activation followed by mitochondrial biogenesis. In this study, we studied whether daidzein and genistein can protect the neuronal cell line Neuro2a cells from oxidative stress via mitochondrial enhancement. We treated cells with sodium nitroprusside (SNP) as an oxidative stress model. At first, we analyzed if isoflavones actually show cell protective function against oxidative stress and increases intracellular mitochondria. Pretreatment with daidzein or genistein reduced SNP-induced cell death, and increased intracellular mitochondria evaluated by cytometric analysis stained with JC-1 even under oxidative stress condition. Then, we studied mechanisms of cell protection and mitochondrial biogenesis. Although in the previous report, isoflavones induced mitochondrial biogenesis via Sirt1 activation, sirtuin inhibition did not affects cell protection and mitochondrial biogenesis. Next, we focused on AMP-activated protein kinase (AMPK) which was reported to regulate PGC1α activity. In the presence of AMPK inhibitor dorsomorphin, effects of daidzein on cell protection and mitochondrial biogenesis were attenuated. However, effects of genistein were not affected by drosomorphine. Our data suggested that protective effects of daidzein but not genistein achieved via AMPK activation followed by PGC1α. Our data suggests that consumption of soy isoflavones reduces the risk of neurodegenerative diseases via affecting intracellular signaling and mitochondrial biogenesis.

Title: Gastrointestinal hormone-related neuroprotection induced by molecular hydrogen in Parkinson's disease model mice

Authors: *M. NODA, Y. UEMURA, T. NIIYAMA;
Pathophysiology, Grad. Sch. Pharm. Sci. Kyushu Univ., Fukuoka, Japan

Abstract: We have been investigating the protective and preventive effects of molecular hydrogen (H_2), as a new medical gas, in a model of Parkinson's disease (PD) [1]. The mechanisms of how H_2 works are still in debate but indirect effects of H_2 are suggested in case of chronic drinking H_2-containint water. It takes time and persists for at least a couple of days in a mouse model of PD [2]. The evidence that drinking H_2 water was the most effective way rather than inhaling H_2 in PD model animal led to the finding that H_2 induces ghrelin production and

release from the stomach by activating β1 adrenergic receptors. [3]. However, ghrelin may not the only factor mediating the beneficial effects of H_2. We still observed protective effects of H_2 in PD model mice using ghrelin-knock out (KO) mice [4], though we have not yet analyzed which factors are upregulated in ghrelin-KO mice, which are supposed to compensate the lack of ghrelin. To confirm the upregulation of ghrelin by H_2, we used stomach ghrelinoma (SG-1) cells. We treated SG-1 cells with H_2-containing medium, changing medium every day. We observed that ghrelin mRNA was significantly increased after 7 days, but not 1 or 3 days. The upregulation of ghrelin mRNA was not observed by treatment of noradrenalin (NA). On the other hand, the release of ghrelin from SG-1 cells was significantly stimulated by NA, but not by incubation with H_2 for 7 days.

Though the molecular mechanism of H_2-induced upregulation of ghrelin is still under investigation, the distinct mechanism due to the brain-stomach connection may help to understand the broad spectrum of H_2 function.

Title: Inhibition of miRNA let7i enhance the progesterone-induced neuroprotection

Authors: *S. KIM[1], T. NGUYEN[2], M. SINGH[1];
[1]Cell and Mol. Physiol., Loyola Univ. Chicago Stritch Sch. of Med., Maywood, IL; [2]Pharmacol. and Neurosci., Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Our laboratory reported that the miRNA, let7i, increases as a function of ischemic injury (e.g., stroke), and that overexpression of let7i negatively regulates Pgrmc1 expression, disrupts progesterone (PROG)-induced BDNF release and reduces PROG's cytoprotective

effects. We also discovered that oxidative stress caused by H_2O_2 resulted in an increase in let7i expression in both C6 astrocyte glial and SH-SY5Y neuronal cell lines. These data provided insight into the possibility that inhibition of let7i expression may be a strategy to facilitate PROG's protective efficacy, especially against insults/ diseases in which oxidative stress plays a role (e.g., stroke, traumatic brain injury, and such neurodegenerative diseases such as Alzheimer's disease). Based on this, we hypothesized that let7i represses PROG's neuroprotective effects by down-regulating the expression of Pgrmc1, and therefore that inhibiting let7i could facilitate PROG-induced neuroprotection against oxidative insults. Our data revealed that overexpression of let7i in C6 astrocytes and differentiated SH-SY5Y cells decreased the expression of Pgrmc1 and also abolished the protective effect of PROG against H_2O_2-induced oxidative stress. Previously, using the middle cerebral artery occlusion (MCAo) model of stroke, applied to ovariectomized mice, we demonstrated that let7i inhibitor, delivered via intracerebroventricular (ICV) injection, enhanced the neuroprotective effects of PROG. Similarly, let7i inhibitor reversed the negative effect of miRNA let7i on PROG-induced protection against oxidative insults in both C6 astrocytes and SH-SY5Y neuronal cell lines. Collectively, these data support the potential role of let7i as a therapeutic target, whereby its inhibition can enhance PROG-induced cytoprotection. By extension, our data suggest that when considering the role of progesterone in protecting the brain against trauma and neurodegenerative diseases, simultaneous inhibition of let7i may be an important adjuvant therapy.

Title: Germinated brown rice reduced glutamate-induced apoptotic cell death in mouse hippocampal HT22 cell line

Authors: *E. M. OO[1], F. PADUNGRAKSART[4], C. TURBPAIBOON[1], L. KHOWAWISETSUT[2], P. UAWITHYA[3], V. CHAISUKSUNT[5], P. SOBHON[6], S. CHOMPOOPONG[1];

Abstract: Glutamate has been reported to lead to neurodegenerative diseases, including Parkinson's and Alzheimer's diseases. While apoptosis plays a role in glutamate-mediated

toxicity, the related mechanism is through reactive oxygen species accumulation and excessive oxidative stress with a resultant of increased neuronal cell death. It is well known that germinated brown rice (GBR) contains high content of gamma aminobutyric acid (GABA), which exerts various pharmacological effects. However, the mechanism of neuroprotective effects of GABA in GBR is still undefined. In this study, it was aimed to investigate whether GBR prevents glutamate-induced toxicity in HT22 hippocampal neuronal cells. Pure GABA compound was used as standard control and its equivalent concentrations were calculated according to the involvement of 11.9 μg of GABA in 100 mg of GBR in previous reports. The exposure of glutamate at 4mM caused 55.4 ± 0.6 % of cell viability (MTT assay) and 50.6±1.9% of apoptotic cell death (PI and Annexin V flow cytometry). Using Western blot analysis, it was mediated through an alteration in the expression of c-Jun and its active form phosphorylated c-Jun (p-c-Jun), which are downstream products of the c-Jun N-terminal kinase (JNK) mediated apoptotic pathway. In HT22 cell line, the pre and co-treatment of 100 μg/ml of GBR or 0.125 μM of its equivalent GABA concentration significantly decreased both c-Jun and p-c-Jun expression at *p value* < 0.05. Furthermore, GBR amended glutamate-induced toxicity and reduced the number of apoptotic cells through the phosphorylation of c-Jun at amino acid residual serine 73. These ameliorated actions were also blocked significantly by bicuculline, a $GABA_A$ antagonist. In conclusion, GBR shows the protective effect against glutamate-induced toxicity in HT22 hippocampal neuronal cells. Therefore, these data imply that GABA in GBR may be a potent nutraceutical to prevent neurodegenerative diseases caused by oxidative stress and apoptosis.

Title: Inhibition of interleukin 6 signaling prevents paclitaxel-induced neuropathy in mice

Authors: *W. BOEHMERLE[1], P. HUEHNCHEN[1], M. ENDRES[2];
[1]Charite Universitaetsmedizin Berlin, Berlin, Germany; [2]Charité-Universitätsmedizin, Berlin, Germany

Abstract: Neurotoxic phenomena are among the most common side effects of cytotoxic chemotherapy and affect a large number of patients. With a prevalence of 0.5% of the general population, chemotherapy-induced peripheral neuropathy (CIN) is an immense yet unmet medical need. The microtubule-stabilizing drug paclitaxel frequently leads to CIN, which further increases the burden of disease and often necessitates treatment limitations. The pathophysiology of CIN remains poorly understood: It was previously shown that paclitaxel binds to the neuronal calcium sensor-1 (NCS-1) protein, which modulates the Inositol-1,4,5-trisphosphate receptor ($InsP_3R$) inducing calcium (Ca^{2+}) release from the endoplasmatic reticulum in dorsal root ganglia neurons (DRGN). The subsequent activation of the Ca^{2+}-dependent protease calpain contributes to cell death of DRGN *in vitro*. However, other studies point to an inflammatory reaction after paclitaxel treatment with cytokine release and macrophage infiltration of DRGN. In this study, we aimed to investigate the role of the pro-inflammatory cytokine interleukin-6 (IL-6) in the development of paclitaxel-induced neuropathy and elucidate possible upstream and downstream molecular targets of IL-6 signaling. We demonstrate that adult male IL-6 knockout mice are protected from developing functional and histological signs of paclitaxel-induced neuropathy. Our *in vitro* data shows that DRGN produce IL-6 after paclitaxel exposure, which could be prevented by co-treatment with the calpain inhibitor MDL28170. Inhibition of the NCS-1 - $InsP_3R$ interaction by co-incubation with therapeutic levels of lithium blocked IL-6 release from DRGN after paclitaxel treatment. Furthermore, a preemptive application of an IL-6-neutralizing antibody (MAB406) resulted in the prevention of paclitaxel-induced neuropathy in adult C57Bl/6 mice. Histological analysis confirmed the protective effect of MAB406 treatment prior to paclitaxel application.
In conclusion, we demonstrate that the cytokine IL-6 is essential for the development of paclitaxel-induced neuropathy in mice. Pharmacological interference of IL-6 signaling with an IL-6-neutralizing antibody prevents paclitaxel induced neuropathy. This is of clinical interest as it was previously shown that patients receiving IL-6 neutralizing antibodies reported less symptoms of CIN. Additionally, IL-6 contributes to tumor
progression in certain cancers. Thus, preventive treatment with IL-6-neutralizing antibodies might yield synergistic effects regarding an enhanced antiproliferative treatment and prevention of dose-limiting neurotoxic side effects of chemotherapy.

Title: Small molecule inhibitors of SARM1 prevent axonal degeneration *in vitro* and *in vivo*

Authors: *R. KRAUSS, T. BOSANAC, T. M. ENGBER, R. DEVRAJ, R. HUGHES;
Disarm Therapeutics , Cambridge, MA

Abstract: Axonal degeneration is an early and ongoing event that causes disability and disease progression in many neurodegenerative disorders of the central, peripheral, and ocular nervous systems, including multiple sclerosis, ALS, peripheral neuropathies, and glaucoma. SARM1 is the central driver of an evolutionarily conserved program of axonal degeneration downstream of inflammatory, mechanical, metabolic, or chemical insults to the axon. SARM1 contains an intrinsic NADase enzymatic activity essential for its pro-degenerative functions, making it a compelling therapeutic target to treat neurodegeneration characterized by axonopathy.
We have screened a small molecule library to identify inhibitors of SARM1 enzymatic activity using a biochemical assay. With these screening hits as a starting point, we developed potent SARM1 inhibitors that protect rodent and human axons *in vitro* from mechanical, chemical and metabolic damage. In sciatic nerve axotomy (SNA) and a paclitaxel model of chemically-induced peripheral neuropathy (CIPN), we observed that SARM1 inhibitors prevented increases in nerve cADPR, a proximal biomarker of SARM1 activity, and plasma NF-L, a clinically accessible downstream biomarker of axonal degeneration proposed for diagnostic and prognostic use in several neurodegenerative disorders.
This is the first demonstration that pharmacological inhibition of SARM1 can reproduce the axonal protective phenotype observed in SARM1 knockout mice. The availability of SARM1-dependent biomarkers of axonal degeneration enables rapid translation of SARM1 inhibitor therapeutics from discovery to the clinic. SARM1 inhibitors have the potential to prevent axonal degeneration in peripheral and central axonopathies and provide a transformational disease-modifying treatment for these disorders.

Title: A GLP1 receptor agonist ameliorates disease progression in mouse models of monogenic infantile neurodegenerative diseases

Authors: *L. POUPON BEJUIT, M. P. HUGUES, S. WHALER, A. A. RAHIM;
UCL Sch. of Pharm., London, United Kingdom

Abstract: Rare infantile neurological disorders are particularly challenging to treat given the lack of sufficient knowledge of the pathology and the rapid progression of disease. These genetic disorders are usually terminal as there are currently no effective disease-modifying therapies available to treat them.
GLP1-R agonists that are approved for the treatment of type 2 diabetes mellitus have been shown to be neuroprotective in several animal models of adult neurodegeneration and could be a good therapeutic option to attempt to treat rare infantile neurological disorders. Semaglutide is a modification of existing GLP1-R agonist and this newer version have been recently develop with a longer half-life of 7 days. For the first time, we investigated the neuroprotective effects of the once-weekly GLP1-R agonist semaglutide in two unrelated mouse models of infantile genetic neurodegenerative disease; Niemann-Pick disease type C and Infantile Neuroaxonal Dystrophy, which are respectively knock-out for the gene *NPC1* and *Pla2G6*.
In this study, we demonstrate that a systemic administration of semaglutide improved locomotor function and had significant neuroprotective effects on both diseases. The molecule is also able to reduce neuroinflammation, apoptosis and microglia activation. These results are supportive of semaglutide having a potential therapeutic application as a treatment for these two unrelated NPC1 and INAD diseases but also others for which there is no treatment available.

Title: High choline diet prevents cyclophosphamide- and doxorubicin-induced reductions in high affinity choline uptake in the striatum and hippocampus of C57Bl/6J and MMTV-PyVT mice and attenuates tumor growth

Authors: B. JOHNS, L. WECKER, ***R. M. PHILPOT**;
Psychiatry and Behavioral Neurosci., Univ. South Florida, Morsani Col. of Med., Tampa, FL

Abstract: Women constitute the majority of patients who report chemotherapy-related cognitive deficits, deficits of learning, memory, attention and processing speed that can impair day-to-day functioning. Many chemotherapeutic agents suppress ovarian function, decreasing circulating estrogen levels. Because estrogen regulates high affinity choline uptake (HACU) and HACU is the rate-limiting step for acetylcholine synthesis, chemotherapeutic agents may indirectly impair cholinergic systems that mediate cognitive functions. The present study determined whether cyclophosphamide (CYP) and doxorubicin (DOX) could reduce circulating estradiol (E^2) and impair HACU in the frontal cortex (CTX), striatum (STR) and hippocampus (HCC) of nontumor-bearing (C57Bl/6J) and tumor-bearing (MMTV-PyVT) female mice. Because high choline diets can maintain cholinergic function under conditions of high neuronal demand, the present study also determined whether a 2% choline diet could prevent the effects of CYP+DOX on HACU.

3 days following administration of CYP+DOX or equivalent volumes of saline: 1) circulating E^2 was 20-30% lower in nontumor- and tumor-bearing mice administered CYP+DOX (37 ±7 and 37 ±5 pg/ml, respectively) than in nontumor- and tumor-bearing control mice (54 ±11 and 46 ±17 pg/ml, respectively); 2) HACU was 8-18% lower in the STR of nontumor- and tumor-bearing mice administered CYP+DOX (167 ±11 and 155 ±8 pmol/mg/5min, respectively) than in nontumor- and tumor-bearing control mice (181 ±6 and 189 ±11 pmol/mg/5min, respectively); and 3) HACU was 11-16% lower in the HCC of nontumor- and tumor-bearing mice administered CYP+DOX (46 ±4 and 46 ±3 pmol/mg/5min, respectively) than in nontumor- and tumor-bearing control mice (55 ±4 and 52 ±2 pmol/mg/5min, respectively). HACU in the CTX was unaffected by CYP+DOX.

When nontumor- and tumor-bearing mice were placed on 2% choline two weeks prior to chemotherapy, circulating E^2 and HACU were unaffected by CYP+DOX administration. Importantly, after 1 week, the total tumor volume of mice on standard diet increased by 85%

(1513 ±180mm^3) while those on 2% choline increased by only 54% (1200 ±162mm^3). Further, after 2 weeks, mice placed on 2% choline receiving CYP+DOX exhibited total tumor volumes (1068 ±196mm^3) that were 23-35% smaller than that of mice on standard diet receiving CYP+DOX (1392 ±296mm^3) or saline (1645 ±230mm^3) and 17% smaller than mice on 2% choline receiving saline (1283 ±247mm^3). Therefore, a 2% choline diet protects against CYP+DOX-induced impairments of circulating E^2 and HACU, attenuates tumor growth and may enhance the anti-tumor effects of CYP+DOX.

Title: Erythropoietin induces neurogenesis gene expression and JAK/STAT signaling components 2h after application and reverts damage in hippocampal Ca1 cells

Authors: *S. F. CORNELIO-MARTINEZ;
Biologia Celular y Mol., Ctr. Universitario De Ciencias Biológicas Y Agro, Guadalajara, Mexico

Abstract: Background: Glutamate is the major excitatory neurotransmitter in the brain involved in physiological events. However at high extracellular concentrations it triggers excitotoxicity. Previously, we reported neuroprotection mediated by Erythropoietin (EPO) against excitotoxicity in the hippocampus of neonate rats through the induction of its own expression and EPO receptor (EPOR) (Rivera-Cervantes *et al.* 2019). This work is focused on the induction of JAK/STAT pathway and neurogenesis genes mediated by monosodium glutamate (MSG) and EPO in the hippocampus of neonate rats. Methods: Neonate rats were administered with MSG at 1, 3, 5, and 7 postnatal days (PD), and recombinant-human EPO (rhEPO) at 8 PD. Animals were killed 24h after last application of MSG and 2, 6, 12 and 24h after rhEPO treatment. Total mRNA was isolated from the hippocampus and used to synthetize cDNA. We utilized RT2 Profiler Microarrays for JAK/STAT and Neurogenesis to determined gene expression changes by Real-Time PCR. Results: GMS administration did not cause an effect on JAK/STAT pathway and related genes, while it induces an up-regulation of 9 neurogenesis genes (S100a6, Bmp8a, Cxcl1, Hes1, Dcx, Ntf3, Ascl1, Dvl3 and Ep300). Contrastingly, there was an up-regulation of genes JAK1, JAK2, STAT1 and STAT3 of the JAK/STAT pathway and up-regulation of 83 neurogenesis genes, because rhEPO treatment. Furthermore, 32 of the 83 neurogenesis genes belong to Notch, Wnt and BMP signaling pathways, which plays key roles in the in the regulation of neurogenesis. Conclusions: We observed a coordinated response of neurogenic gene expression matched by an upregulation of the JAK/STAT pathway upon rhEPO treatment.

This correlated with a major reversion of MSG-induced damage. In addition, we consider there is evidence to support that abnormal neural morphology caused by MSG excitotoxicity is owed to the expression of a number of neurogenesis genes.

Title: NYX-2925, a novel NMDA receptor modulator, improves chronic pain and its affective state in rats with paclitaxel-induced neuropathy

Authors: *N. GHOREISHI-HAACK, J. S. BURGDORF, J. M. PRIEBE, J. D. AGUADO, A. M. LYNCH, M. BOWERS, C. N. CEARLEY, J. R. MOSKAL;
Aptinyx Inc., Evanston, IL

Abstract: NYX-2925 is a novel, oral, small molecule NMDA receptor modulator currently in clinical development for the treatment of chronic pain including painful diabetic peripheral neuropathy (DPN) and fibromyalgia. Results from previous studies demonstrated the analgesic effects of NYX-2925 in rat models of nerve injury-induced neuropathic pain, DPN, and formalin-induced persistent pain. In the studies presented here, the effects of NYX-2925 were evaluated in a rat model of chemotherapy-induced peripheral neuropathy (CIPN) using measures of both evoked and non-evoked pain. To induce CIPN, rats were given 4 injections of paclitaxel (2 mg/kg, i.p.) every other day. The onset of neuropathy was evaluated weekly, and only rats with baseline allodynia were included in the studies. To measure mechanical hypersensitivity, a single dose of NYX-2925 (1-100 mg/kg, p.o.) was administered to CIPN rats 3 weeks after the first paclitaxel injection. Tactile allodynia was evaluated at 1 hour, 24 hours, and 1 week after NYX-2925 administration. NYX-2925 at 10 mg/kg (at the 1h and 24h timepoints) and 30 mg/kg (at the 24h time point) alleviated tactile allodynia. For thermal hypersensitivity measures, NYX-2925 was administered orally and cold allodynia evaluated via the acetone test 1 hour after drug administration. A single dose of NYX-2925 (10 mg/kg, p.o.) resulted in significant thermal analgesia when compared to vehicle-treated rats. To evaluate negative affective components linked with chronic pain, NYX-2925 (10 mg/kg, p.o.) was administered to CIPN rats, and spontaneous ultrasonic vocalizations (USVs) measured in the homecage recording for 24 hours. CIPN rats showed higher rates of spontaneous aversive calls (20 kHz USVs), and decreased rates of spontaneous hedonic calls (50 kHz USVs). NYX-2925 decreased the number of aversive calls

and increased the number of hedonic calls emitted by CIPN rats. Non-evoked pain was also measured by the frequency and type of USVs emitted during the non-tactile stimulation periods of a heterospecific rough-and-tumble play assay 1 hour after NYX-2925 (10 mg/kg, p.o.) administration. In the heterospecific rough-and-tumble play assay, NYX-2925 administration increased the number of hedonic calls during the non-stimulation periods that were suppressed by CIPN in vehicle-treated rats. Together, these data suggest that NYX-2925 alleviates evoked pain, both mechanical and thermal hypersensitivity, induced by paclitaxel treatment. Furthermore, these data suggest that NYX-2925 improves negative affect induced by CIPN in the rat.

Abstract: Defects in protein quality control systems lead to accumulation and aggregation of misfolded proteins, hallmarks of many neurodegenerative diseases. Further perturbations activate series of parallel adaptive responses to reestablish protein homeostasis. Pharmacological modulation of the integrated stress response (ISR), mediated by eukaryotic translation initiation factor 2α (eIF2α) phosphorylation-dephosphorylation and downstream signaling shows great promise in cytoprotection in many neurodegenerative diseases. Guanabenz (GBZ), an α-adrenergic receptor agonist, crosses the blood-brain barrier to restore protein homeostasis and attenuates neurotoxicity in several cellular and animal models of neurodegenerative disease. This current study pursued an analogueing strategy to identify novel compounds with improved ability to modulate ISR and to reduce the cellular burden of misfolded proteins with the ultimate

goal of providing greater cytoprotection than Guanabenz. We analyzed 432 structurally distinct GBZ analogues for activation of ISR signaling and identified PromISR-6, a potent GBZ analogue that selectively activated PERK (Protein Kinase R-like ER kinase)-eIF2α signaling pathway. The sustained eIF2α phosphorylation, translational repression and autophagy induction effects make PromISR-6, the most efficacious GBZ analogue in reducing Huntingtin aggregation and promoting survival in a PC12 model (Inducibly expressing mutant Huntingtin, GFP-mHtt-74Q) of Huntington's disease. Subsequently, we explored the effects of PromISR-6 on Parkinson's disease (PD) using a *Drosophila* model that express mutant α-Synuclein A30P protein. The α-Synuclein A30P expression-mediated behavioral and neuropathological deficits such as locomotor dysfunction, loss of dopaminergic neurons and reduced life-span were investigated in flies treated with PromISR-6 from day one post-occlusion up to 40 days. Our data describe a novel GBZ analogue and its spectrum of biological activities that lays the foundation for future development of efficacious GBZ-based therapeutics to treat neurodegenerative diseases.

Dept. of Psychology, Boston, MA; [6]Dept Psychology, Northeastern University, Ctr. for Translational NeuroImaging, Boston, MA

Abstract: Maraviroc (MVC) is an antiretroviral agent and C-C chemokine (CCR5)-receptor agonist that is currently used for the treatment HIV. The interaction between chemokine and opioid receptor signaling, suggests that MVC could be a possible mode of treatment therapy for opioid addiction. Opioids like oxycodone (OXY), are used as analgesics to alleviate pain, and repeated exposure can lead to the development of tolerance and addiction. The present study consisted of two experimental groups of rats, one exposed to daily IP injections of MVC (10 mg/kg, n = 8) and the other to saline vehicle (n = 9) one hr before placing them into a testing

chamber consisting of two adjoining rooms previously identified as preferable or non-preferable. On this first day of testing all rats were given an IP injection of OXY (3.0 mg/kg) and placed into their non-preferred room and filmed for 15 min before removal. On day 2 all rats are injected with saline immediately before being placed into their preferred room. This treatment and placement procedure were done for 8 consecutive days so that each rat was exposed to OXY four times in their non-preferred room and saline in their preferred room. On day 9 they were exposed to the open chamber and scored for the time spent in either room. MVC significantly decreased place preference as compared to vehicle suggesting it interfered with the development of drug seeking behavior following repeated exposure to OXY. In contrast, acute treatment with MVC (10 mg/kg, IP) had no significant effect on established OXY self-administration (0.1 mg/kg/infusion; IV) under a fixed-ratio or progressive-ratio schedule of reinforcement. The apparent diffusion coefficient derived from diffusion weighted imaging, a measure of parenchymal edema, was significantly altered in hippocampus and anterior cerebellum in vehicle treated rats but not with MVC treatment. Similarly, resting state BOLD MRI showed enhanced functional coupling with the accumbens/ventral pallidum with vehicle but not MVC. These data suggest the OXY-induced changes in gray matter microarchitecture and functional connectivity were blocked by the pretreatment with MVC.

Title: Development of a human high throughput screening platform for simultaneous assessment of compound efficacy and safety for glioblastoma treatment

Authors: R. PADILLA, A. FANTON, C. ANDERSEN, O. GUICHERIT, C. CARROMEU, ***F. ZANELLA**;
StemoniX, San Diego, CA

Abstract: Glioblastoma Multiforme (GBM) are aggressive brain tumors with poor prognosis. Therapeutic management for GBM is currently limited; with Temozolomide currently being the standard of treatment for GBM. However, even when combined with radiotherapy only up to 20 percent of patients show favorable response to Temozolomide. Importantly, due to their requirements for potency and efficacy, oncology drugs can be quite toxic. In this study, the U87 GBM cell line was tagged with mCherry to serve as a traceable model for GBM. To study their growth behavior in a physiologically relevant system amenable to drug discovery, U87-mCherry

cells were co-cultured with human induced pluripotent stem cell-derived cortical neurospheroids in a high throughput based screening platform. The neurospheroids are composed of a balanced co-culture of cortical neurons and astrocytes with mature functional neuronal circuitry evidenced by spontaneous calcium oscillations. Previously, the model has been successfully utilized in independent neurotoxicity and drug discovery studies. Thus, by combining U87-mCherry and the high throughput neurospheroids, the proliferation and infiltration patterns of the GBM cells as well as the preservation of cortical functionality can be analyzed within the same high throughput platform. Proof-of-principle studies focused on Temozolomide, Carmustin, Paclitaxel and Cisplatin to identify and profile compound efficacy versus it's toxicity with the ultimate goal of providing a platform that can separate safe and effective compounds from those that have minimal efficacy and deleterious toxicity. In summary, the work described herein suggests a novel framework approach for combining human induced pluripotent stem cell-derived cortical neurospheres with GBM, enabling more streamlined drug discovery of compounds against aggressive brain cancers.

Title: Gintonin, a ginseng-derived exogenous lysophosphatidic acid receptor ligand, attenuates mutant Huntingtin toxicity

Authors: *B. CHEON[1], M. JANG[1], Y. CHANG[1], S. LEE[2], J. CHOI[1], I.-H. CHO[1];
[1]Kyung Hee Univ., Seoul, Korea, Republic of; [2]Korea Inst. of Sci. and Technol. (KIST), Seoul, Korea, Republic of

Abstract: Gintonin is a ginseng-derived exogenous G protein-coupled lysophosphatidic acid (LPA) receptor ligand. Although previous *in vitro* and *in vivo* studies demonstrated the therapeutic role of gintonin against Alzheimer's and Parkinson's diseases, the neuroprotective effects of gintonin in Huntington's disease (HD) are still unknown. In this study, we investigated whether gintonin could ameliorate the mutant huntingtin toxicity in cellular or animal model of HD. Gintonin reduced cell death and mutant huntingtin (*HTT*) aggregates in ST*Hdh* cells. It also mitigated neurological impairment in mice with adeno-associated viral (AAV) vector serotype

DJ-mediated overexpression of N171-82Q-mutant *HTT* in the striatum. Taken together, our findings firstly suggested that gintonin exerts neuroprotective effects in ST*Hdh* cells and AAV vector-infected model of HD. Thus gintonin might be a therapeutic candidate to treat HD.

Title: At the forefront of mitochondrial dysregulation: Deoxygedunin imparts neuroprotection via mitophagy in retinal cells

Authors: *A. MANGANI[1], C. JOSEPH[1], M. MIRZAEI[1], V. GUPTA[2], S. GRAHAM[2]; [2]FMHS, Clin. Med., [1]Macquarie Univ., Sydney, Australia

Abstract: Mitophagy is a quality control mechanism to mitigate dysfunctional and fissioned mitochondria through a catabolic degradation process akin to autophagy. There are only a few studies that link anomalous mitochondrial autophagy or mitophagy to ocular dysfunction. A natural compound, which is also a TrkB agonist deoxygedunin has shown potent neurotrophic activity. Herein, we examine the effect of deoxygedunin on mouse photoreceptor cells and mice retinas and evaluate if mitophagy acts as an underlying process in administering neuroprotection. Mouse photoreceptor cell line 661W ($3x10^5$) were subjected to pharmacological inhibitors, Cyclotraxin-B (CTX-B,1uM): TrkB inhibitor, TAT PEP-5 (TAT, 1uM):p75NTR inhibitor and Deoxygedunin(1uM). To accurately, assess alterations in mitochondrial regulation, we incubated 661W cells and fresh ex-vivo mice retinas with Rotenone (400nM) in culture media. Mitophagy markers were assessed by western blotting of sample lysates and immunocytochemistry using specific antibodies (n=3).

In our studies, deoxygedunin treatment alone resulted in increased phosphorylation of Ulk1 S757. Inhibition of TrkB receptor via CTX-B, displayed, significant downregulation of pUlk1 S757 compared to p75NTR receptor inhibition via TAT. Further treatment of deoxygedunin, rescued the phosphorylation of Ulk1 S757 in 661W cells and mice retinas treated with inhibitors. Deoxygedunin also upregulated mitophagy markers downstream to Ulk1, such as BNIP3, BNIP3L/Nix but did not induce apoptosis. Downregulation of PINK1 was markedly seen in CTX-B than TAT treated cells and retinal tissues, deoxygedunin treatment resulted in the

elevation of these proteins leading to phosphorylation of Ubiquitin at S65 thereby activating Parkin. Distinct cargo receptors such as SQSTM1/p62, Optineurin, and NDP52 were also activated upon ubiquitination (pUb S65) upon deoxygedunin treatment. Finally, LC3B which aids in recruiting the autophagosome to lysosome, were highly expressed in deoxygedunin treated retinal cells and tissues, resulting in targeting of dysfunctional mitochondria to lysosomes resulting in mitophagy. Similar results were obtained with rotenone-treated cells but albeit to a lesser extent in ex-vivo retina.
Overall these results suggest that deoxygedunin treatment rescues retinal cells and tissues undergoing apoptosis upon mitochondrial dysregulation by activating the mitophagy cascade. This study also highlights the potential of deoxygedunin as a pharmacological drug in mitigating retinal diseases and opens up possible avenues in treating other neurodegenerative diseases.

Title: Systemic administration of a novel allosteric modulator, SRI-32743, alleviates HIV-1 Tat protein-potentiated cocaine rewarding effects in HIV-1 Tat transgenic mice

Authors: *J. ZHU[1], P. M. QUIZON[2], Y. Y. WANG[2], H. M. STACY[3], S. O. CIRINO[3], J. P. MCLAUGHLIN[4], S. ANANTHAN[5];

Sci., Univ. of South Carolina, Columbia, SC; [3]Pharmacodynamics, Univ. of Florida, Gainesville, FL; [4]Pharmacodynamics, Univ. of Florida, Gainesville,, FL; [5]Chem., Southern Res. Inst., Birmingham, AL

Abstract: Cocaine abuse has been shown to increase the incidence of HIV-1 associated neurocognitive disorders (HAND). We have demonstrated that HIV-1 Tat protein allosterically modulates dopamine (DA) reuptake via human DA transporter (hDAT). This study determined whether a novel allosteric modulator, SRI-32743, pharmacologically blocks Tat binding to hDAT and alleviates Tat-potentiated cocaine rewarding effects in inducible HIV-1 Tat transgenic (iTat-tg) mice. The iTat-tg mouse model recapitulates many aspects of neurocognitive impairments observed in HIV infected individuals. SRI-32743 inhibited [^{3}H]DA uptake (IC_{50},

9.9 µM) with a 17-fold greater inhibition than the potency of [^{3}H]WIN35,428 binding (IC_{50}, 168 µM) with 68.4% and 71.4% of its E_{max}, respectively. Tat (140 nM) induced 30% and 20% reductions in [^{3}H]DA uptake and [^{3}H]WIN35,428 binding, respectively, which were attenuated by SRI-32743, while SRI-32743 alone did not alter DAT function and binding. SRI-32743 and indatraline, a competitive DAT inhibitor, increased the cocaine IC_{50} values of [^{3}H]DA uptake by 164% and 280%, respectively. The cocaine (1 µM)-induced dissociation rate (0.238 ± 0.030) of [^{3}H]WIN35,428 binding was similar to that induced by 50 nM SRI-32743 (0.187 ± 0.027); however, SRI-32743 slowed the cocaine-induced dissociation rate to 0.032 ± 0.005. Pharmacokinetics study shows that SRI-32743 is BBB-permeable with a 2.52 and 2.08 ratio of brain to plasma concentration (ng/ml) at 15 and 60 min, respectively. Following a 14 day-doxycycline treatment to induce Tat protein, the iTat-tg mice exhibit a 2-fold potentiation of cocaine-CPP which was dose-dependently ameliorated by pretreatment of SRI-32743 (1 or 10 mg/kg/d, i.p.) prior to CPP, while SRI-32743 alone did not alter basal cocaine-CPP relative to saline controls. These preliminary data raise the exciting possibility of potential therapeutic interventions for neurocognitive dysfunction in HAND, particularly effective for those with concurrent cocaine abuse.

Abstract: Phospholipids in brain cell membranes are enriched in docosahexaenoic acid (DHA). Besides its role in modulating membrane fluidity, this (n-3) polyunsaturated fatty acid (PUFA) is known to offer diverse functions, in particular, synthesis of oxylipins that are pro-resolving. DHA is important in the developing brain. In recent years, (n-3)PUFAs, in the form of fish oil, have been widely used and are one of the most consumed supplements in human populations. Besides DHA, brain phospholipids also show high levels of arachidonic acid (ARA), an (n-6)PUFA which is linked to inflammatory responses. The apparent Yin-Yang mechanism for DHA and ARA is due mainly to different phospholipases A2 (PLA2) for their release from membrane phospholipids. Both PUFAs are susceptible to lipid peroxidation by free oxygen radicals, leading to production of 4-hydoxyhexenal (4-HHE) and 4-hydroxynonenal (4-HNE), respectively. These lipid-derived aldehydes are present in all brain regions as well as in body organs. Considering the involvement of cytosolic PLA2 and that the release of ARA is associated with neuro-inflammation, neurotrauma and neurodegenerative diseases, it is reasonable to extend efforts to understand factors that modulate the (n-3)/(n-6) PUFA ratio and their peroxidation products. In our recent study, weanling pups from dams given control and DHA (1%) diets showed changes in the (n-3)/(n-6) PUFA ratio in all brain regions. However, increases in 4-HHE (but not 4-HNE) were observed only in the cerebral cortex and hippocampus. In the present study, we measured the concentration of 4-HHE and 4-HNE in a group of adult mice fed a DHA (1%) diet for three weeks. Results demonstrated minimal changes in the brain but substantial increases in 4-HHE levels (but not 4-HNE) in the heart. Feeding DHA to adult mice for three weeks also increased 4-HHE levels in liver but not in kidney. Although the physiological significance of changes in fatty acids and peroxidation products upon DHA supplementation needs to be examined further, these studies provide evidence of different extents of lipid peroxidation in different organs and with respect to different ages in mice.

Title: Mitigating postoperative neuroinflammation with presurgical choline-supplemented diet in male mice

Authors: *S. V. MAURER[1], C. KONG[2], N. TERRANDO[2], C. L. WILLIAMS[1];
[1]Dept. of Psychology and Neurosci., [2]Anesthesiol., Duke Univ., Durham, NC

Abstract: Perioperative neurocognitive disorders (PND) occur when peripheral surgery leads to cognitive deficits, partly due to neuroinflammation (Subramaniyan & Terrando, 2019). Previous research has shown that increased neuroinflammation and corresponding cognitive deficits in a contextual fear response task due to peripheral surgery is prevented by cholinergic receptor agonists (Terrando et al., 2011). Hence, we sought to assess the impact of dietary choline in preventing the neuroinflammation after peripheral surgery. Nine-week old male C57/BL6J mice were given either a synthetic control diet (1.1 g/kg choline) or a choline-supplemented diet (4.95 g/kg choline) *ad libitum* for 3 weeks. Mice were then either given tibial fracture surgery, or a sham surgery. Mice were sacrificed and brains were fixed in 4% paraformaldehyde. Brains were sliced and stained using immunohistochemistry (IHC) for ionized calcium-binding adapter molecule 1, a marker for microglia. Microglia in the dentate gyrus of the hippocampus were counted and classified based on activation state. The numbers of activated microglia were increased in the Surgery+Control Diet group, but this effect was blunted in the Surgery+Choline Diet group. No increase or decrease was seen in the sham surgery groups. Based on these results, we next examined the effects of choline diet and peripheral surgery on cell division in the hippocampus. Mice of the same age and sex were given the same dietary groups for 3 weeks. They were then given either tibial fracture surgery or no surgery. 5-bromo-2'-deoxyuridine (BrdU) injections were administered to analyze cell division 1 hour and 10 hours post-surgery. Mice were sacrificed either 24 hours or 2 weeks after surgery. Brains were extracted, fixed, sliced and stained using IHC to stain for BrdU, doublecortin (DCX), and glial fibrillary acidic protein (GFAP) for dividing cells, young neurons, and astrocytes, respectively. Surgery increased the numbers of BrdU+ cells at both timepoints. Though no differences in DCX expression were seen after 24 hours, an upregulation of DCX+ cells was seen in the dentate gyrus 2 weeks after peripheral surgery. Surgery also led to increased numbers of ectopic granule cells: DCX+ cells in the hilus, rather than in the granule cell layer of the dentate gyrus. Additionally, there was an increase in astrocytic density due to surgery, which was blunted by dietary choline supplementation prior to surgery. Overall, our data indicate that presurgical dietary choline can resolve surgery-induced neuroinflammation and may serve as a novel treatment for perioperative neurocognitive disorders.

Title: Naked mole-rats, neuroprotection, and the endocannabinoid system: Upregulation of cannabinoid receptor 1 in naked mole-rats leads to increased control of neuroprotective characteristics during hypoxic and anoxic insult

Authors: *B. M. BROWE[1], T. J. PARK[2], J. R. LARSON[3];
[1]Depart of Biol. Sci., [2]Dept of Biol. Sci., Univ. of Illinois at Chicago, Chicago, IL; [3]Dept Psychiatry, Univ. of Illinois at Chicago Dept. of Psychiatry, Chicago, IL

Abstract: Naked mole-rats (NMRs) are strictly subterranean rodents that live in large communal colonies in sealed and chronically oxygen-depleted burrows. NMRs exhibit unusual tolerance to hypoxia, compared to other mammals; this tolerance involves down-regulating oxygen demand in response to low oxygen conditions. Mammalian brains typically suffer irreversible damage after brief periods of oxygen deprivation such as occur during stroke or cardiac arrest; this damage is thought to result from glutamate excitotoxicity, neuroinflammation, and oxidative stress. Brain slices from NMRs maintain synaptic transmission under anoxia and longer latency to anoxic depolarization compared to other rodents. Additionally, adult NMR brains retain the NMDA receptor subunit (GluN2D) associated with neonatal hypoxia tolerance and show a blunted intracellular calcium response to hypoxia. Retrograde synaptic signaling by endogenous cannabinoids is a form of neuromodulation in various brain regions, including the hippocampus. The endocannabinoid system has been described as an endogenous neuroprotective system that, once activated, can prevent glutamate excitotoxicity and intracellular calcium accumulation. Currently the mechanisms of cannabinoid-modulated neuroprotection during hypoxia are not well understood; however, cannabinoid agonists appear to enable robust protection from oxygen deprivation and ischemia. Also, NMDA-elicited increases in intracellular calcium are enhanced by CB1 receptor (CB1r) antagonists and inhibited by CB1r agonists. In the present study, we used hippocampal brain slices to measure electrophysiological responses to hypoxia in CA1 pyramidal neurons. Interestingly, pretreatment of NMRs with either a CB1r antagonist (AM251) or a CB1 agonist (WIN 55,212-2) maintained synaptic transmission and increased latency to anoxic depolarization after oxygen deprivation *in vitro*. We also demonstrated that CB1r appears to be highly expressed at both GABAergic and glutamatergic synapses in the hippocampus. Furthermore, analysis of multiple brain regions suggest that the NMR endocannabinoid system responds to hypoxic insult differently than other rodents as demonstrated by differential

expression levels of the endocannabinoid 2-AG after 5-hour hypoxia exposure *in vivo*. Our results indicate that the neuroprotective characteristics of the endocannabinoid system may be utilized in the hypoxia-tolerant NMR in a more direct manner than previously seen in other mammals.

Title: Epigenetic regulation of microglial function during neurodegeneration

Authors: *J. SULLIVAN[1], P. AYATA[1], S. VEUGELEN[1], S. AGRAWAL[1], A. BADIMON[2], A. SCHAEFER[1];
[1]Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Neurosci., Mount Sinai, New York, NY

Abstract: As postmitotic cells, neurons are incapable of replacing themselves and, while adult neurogenesis may occur, this limited capacity cannot compensate for large-scale neuronal loss during neurodegeneration. Therefore in order to preserve brain function, it is of the utmost importance to understand the mechanisms that cause neuronal death and dysfunction. Recent work has identified a potential causal role for microglia, the brain's immune cells, in neurodegenerative diseases such as Alzheimer's disease. During homeostasis, microglia exist in diverse functional states that reflect their microenvironment and our previous work identified that the region-specific activation states of microglia is controlled by an epigenetic mechanism. However, microglia can also completely shift their morphology, transcriptome and function to enter a pro-inflammatory state after brain injury or infection. This inflammatory activity which may initially be beneficial for host defense can have extremely deleterious effects on tissue health if left unchecked. Therefore we sought to understand how transcriptional regulation impacts the inflammatory activation of microglia and if modulation of microglial functional states can impact disease progression. By targeting various epigenetic processes, we reveal different activation states of microglia to either repress inflammation or increase phagocytosis. Here we will show our most recent data highlighting the dependence of microglial function on epigenetic regulation of transcription and its potential implications for the treatment of neurodegenerative diseases.

Title: Identification of mitochondrial enhancer as therapeutic option for Huntington's disease

Authors: *D. HU[1], M. THOMPSON[2], D. ADAMS[3], X. QI[1];
[1]Physiol. & Biophysics, [3]Genet., [2]Case Western Reserve Univ., Cleveland, OH

Abstract: The molecular mechanisms by which expanded huntingtin protein (Htt) leads to neuropathology in Huntington's disease (HD) have been intensively studied for decades. However, there is no treatment available for HD. We previously reported that treatment of the rationally designed peptide inhibitors sufficiently reduced the neuropathology and motor deficits in HD animal models. These findings suggest that enhancing mitochondrial function is a potential therapeutic strategy for HD. Given the challenges of clinical translation of peptide therapeutics, we tend to identify small molecule that can rescue mitochondrial function and reduce neuronal loss in HD. Screened from a pool of 3,000 bioactive molecules, CHIR99021 was the top small molecule that improved mitochondrial membrane potential, mitochondrial respiratory capacity and cell viability in HD cells. The protective effects of CHIR99201 on mitochondrial function and cell viability was validated in neurons differentiated from iPSC of HD patients. Administration of CHIR99021 efficiently prevented the loss of medium spiny neurons and the accumulation of mutant Htt aggregation, and reduced the motor deficits in both R6/2 and YAC128 HD mouse models. Treatment of CHIR99021 restrained Drp1-dependent mitochondrial fragmentation. In combination of unbiased proteomics and biochemical analyses, we further showed that treatment with CHIR99021 influenced calpastatin-calpain pathway in vitro and in vivo. Thus, our study presents a distinguished approach for drug development by targeting mitochondrial integrity, and it suggests CHIR99201 and its analogs as a potential disease-modifying treatment for HD.

Abstract: Selective neuronal vulnerability is an increasingly appreciated feature of neurodegenerative disorders. A striking example is the type-dependent degeneration of retinal ganglion cells (RGCs) following optic nerve crush (ONC): >80% of all mouse RGCs die within two weeks, but types vary dramatically in their vulnerability (X. Duan et al., Neuron, 2015). To investigate mechanisms of selective RGC resilience, we used single-cell RNA-sequencing (scRNA-seq) to track the survival and gene expression of RGC types. As a foundation, we first derived a comprehensive scRNA-seq atlas comprising 45 retinal ganglion cell (RGC) types in adult mouse and used immunohistochemistry to match molecular signatures with morphological types. We then performed scRNA-seq at six time points spanning the first two weeks after injury. We developed a novel computational framework that enabled the accurate tracking of individual RGC types after ONC, allowing us to determine the relative resilience and the kinetics of cell death for each type. Next, we utilized these rankings to examine the morphological, physiological and molecular changes in types with different resilience to ONC. We found that most vulnerable RGCs maintained dendritic morphology, firing rate, and feature selectivity for 2-5 days before declining sharply and dying, whereas resilient RGCs were robust throughout the time course. Differential expression analysis among types revealed factors correlating with resilience and susceptibility. To determine if these factors could mediate RGC survival, we used AAV-based overexpression or knockdown *in vivo* and identified several genes that improved survival. Our study presents a comprehensive and systematic framework to study selective

neuron resilience at the single cell level and identifies novel molecular targets for neuroprotection. A companion poster (A. Jacobi, N. Tran et al.) demonstrates that some of these genes also regulate axonal regeneration following injury. (Supported by NIH and Wings for Life.)

Title: Single-cell transcriptomics identify intrinsic resilience of neuronal subtypes and distinguishes specific mediators for axon regeneration after injury

Authors: *A. JACOBI[1,2], N. M. TRAN[2], W. YAN[2], K. SHEKHAR[3], C. WANG[1], I. E. WHITNEY[2], M. E. ARNOLD[1], A. REGEV[3], Z. HE[1], J. R. SANES[2];
[1]Kirby Ctr. of Neurol., Boston Children's Hospital, Harvard Med. Sch., Boston, MA; [2]Mol. and Cell. Biol., Harvard Univ., Cambridge, MA; [3]Broad Inst. of MIT and Harvard, Cambridge, MA

Abstract: After optic nerve crush (ONC), only ~20% of retinal ganglion cells (RGCs) survive for longer than 2 weeks and hardly any of the survivor's regenerate axons. Some axons can be induced to regenerate, however, by manipulations such as mTOR activation, but no treatments to date are sufficient to restore useful vision, and regeneration, like survival, varies dramatically among RGC types (Duan et al., Neuron, 2015). In a companion poster (Tran NM, Jacobi A et al.), we report on the use of high throughput single cell RNAseq to generate a cell atlas comprising 45 RGC types and to characterize the relative resilience to ONC across all RGC types. To identify mediators of axon regeneration, we examined gene expression differences between resilient and susceptible types at 6 times after ONC and tested the effects of differentially expressed genes on survival by AAV-based overexpression or knockdown. Here, we extended this work to seek factors that promoted axon regeneration and found some that did. They include genes that also affected survival and others that promoted regeneration but not survival. In parallel, we used similar methods to investigate the enhanced recovery observed with manipulations known to promote regeneration such as deletion of PTEN or PTEN plus SOCS3

(Sun et al., Nature 2011). These transcriptomic comparisons allowed us to identify RGC types whose survival and regeneration is improved by these treatments, as well as gene expression patterns that correlate with improved survival and regeneration. Finally, to distinguish RGCs that regenerate from those that survive but do not regenerate, we established a new retrograde labeling technique that allowed us to isolate and transcriptomically profile only regenerating RGCs. Ongoing work is aimed at determining which RGC types, among all survivors, regenerate, and identifying genes that promote regeneration.

Authors: K. KODAMA, K. YOSHIKAWA, M. TAKEMURA, Y. NAKAMURA, K. NAKASHIMA, *N. MORIOKA;
Pharmacol., Dept. Pharmacol., Grad. Sch. of Biomed & Health. Sci., Hiroshima Univ., Hiroshima, Japan

Abstract: Microglia are one of glial cells that reside in the central neuron system (CNS) and known to maintain CNS homeostasis as an immune cell. They also play a crucial role in eliciting an inflammatory response in the CNS through the production of inflammatory cytokines and are involved in the pathogenesis of various neurological diseases associated with chronic inflammation. The nuclear REV-ERB is known to exert as a transcriptional regulatory factor and involved in the regulation of circadian rhythm, inflammation, and lipid metabolism. However, the role of REV-ERB in microglial inflammatory responses is unknown. The current study investigated the effect of REV-ERB agonist SR9009 on the inflammatory response in cultured rat primary microglia. Treatment of cultured microglia with lipopolysaccharide (LPS) evoked up-regulation of inflammatory cytokines mRNA (interleukin-1β, interleukin-6, tumor necrosis factor-α). Pre-treatment with SR9009 suppressed LPS-induced inflammatory cytokines mRNA expression. Mitogen-activated protein kinase (MAPK) p38 and nuclear factor kappa B (NF-κB) are crucial in the LPS-induced pro-inflammatory cytokine expression. Stimulation of cultured microglia with LPS induced phosphorylation of both p38 and NF-κB subunit p65. These effects were significantly prevented by pretreatment with SR9009. In conclusion, these results indicate that REV-ERB is involved in the inhibition of inflammatory responses through the regulation of

pro-inflammatory cytokine expression, and the inhibitory effects of REV-ERB are mediated by blockade of MAPK p38 and NF-κB subunit p65.

Abstract: Multiple sclerosis (MS), an autoimmune disease of the central nervous system, is characterized by inflammation, demyelination, and varying degrees of neurodegeneration. In some patients this neurodegeneration can be chronic and intractable, leaving patients with profound disability. Here, we investigate a relatively understudied aspect of neurodegenerative MS pathology: alterations in synaptic connectivity. Using the retinogeniculate system, a circuit that is frequently affected by optic neuritis and therefore highly relevant to MS patients, we show in postmortem human MS tissue, a nonhuman primate MS model, and two rodent models of demyelination that synapses are significantly reduced and microglia engulf large amounts of presynaptic material. Using animal models, we then show that these events can occur independent of local demyelination and axonal degeneration, but coincide with gliosis and the deposition of complement factor C3, but not C1q, at synapses. Finally, using a novel AAV strategy to specifically inhibit activated complement at the synapse we show that we can protect synapses from elimination and preserve visual function. Ultimately, this approach could be used

to prevent synapse loss by microglia with very high spatial and temporal precision in human patients, and may be broadly applicable to other neurodegenerative diseases, including Alzheimer's disease, where microglia and complement have been implicated.

Title: Receptor protein tyrosine phosphatase beta/zeta regulates microglial activation: Evidence for a neuroprotective response of microglia through upregulation of pleiotrophin, not midkine

Authors: *G. HERRADON, M. GABRIEL, R. FERNÁNDEZ-CALLE, A. RAMIREZ, J. M. ZAPICO, A. RAMOS, B. DE PASCUAL-TERESA, E. GRAMAGE;
Facultad de Farmacia. Univ. San Pablo CEU, Madrid, Spain

Abstract: Pleiotrophin (PTN) and Midkine (MK) are neurotrophic factors that exert neuroprotective effects and limit glial responses in animal models of Parkinson's disease (PD). PTN and MK signal through different receptors including Receptor Protein Tyrosine Phosphatase (RPTP) β/ζ, which is abundantly expressed in the CNS. They bind to RPTPβ/ζ and inhibit its phosphatase activity, causing increases in tyrosine phosphorylation of RPTPβ/ζ substrates that are involved in neuroprotection. To test the possible role of RPTPβ/ζ in microglial activation, we treated BV2 cells (mouse microglia) with Lipopolysaccharide (LPS) and the recently developed RPTPβ/ζ inhibitors MY10 and MY33-3. Both inhibitors reduced LPS-induced microglial release of nitric oxide (NO) and LPS-induced increases of iNOS mRNA levels. In contrast, inhibition of RPTPβ/ζ potentiated LPS-induced increase of TNF-α mRNA levels whereas it did not cause significant changes in COX-2 levels. The results demonstrate an important role of RPTPβ/ζ in microglial activation. Since PTN/MK, the RPTPβ/ζ endogenous inhibitors, play important roles in PD and neuroinflammation, we aimed to assess the possible

role of RPTPβ/ζ in an *in vitro* model of neuronal injury. Neuroblastoma SH-SY5Y cells were treated with the parkinsonian toxin MPP+ and MY10. MPP+ induced a significant decrease of SH-SY5Y cell viability whereas co-treatment with MY10 did not cause relevant effects. When BV2 cells were incubated with the conditioned media from SH-SY5Y cells treated with MPP+ and/or MY10, we observed a significant decrease in the viability of BV2 cells incubated with the media from SH-SY5Y cells treated with MPP+, but no apparent influence of co-treatment with MY10 was detected. Interestingly, in BV2 cells incubated with the media from SH-SY5Y cells treated with MPP+, we detected a highly significant increase of *Ptn* mRNA levels, which was attenuated in BV2 cells incubated with the media from SH-SY5Y cells treated with MPP+ and the RPTPβ/ζ inhibitor MY10. In contrast *Mk* levels in BV2 cells were not affected by any treatment. The data indicate that the media from SH-SY5Y cells treated with MPP+ decreases microglia viability but may elicit a neuroprotective response of microglia by inducing a significant increase of microglial *Ptn* levels.

Title: Chronic high fat diet feeding suppresses microglia activation and anxiety induced by intermittent exposures to lipopolysaccharides

Authors: *H.-T. HUANG[1], Y.-M. KUO[2], P.-S. CHEN[3], *S.-F. TZENG[4];
[1]Life Sci., [2]Inst. of Basic Med. Sciences, Dept. of Cell Biol. and Anatomy, Col. of Med., [3]Dept. of Psychiatry, Col. of Med., [4]Dept. of Life Sci., Natl. Cheng Kung Univ., Tainan, Taiwan

Abstract: Gliosis, a reactive change of astrocytes and microglia, is observed in the hypothalamus (HT) of obese rodents and humans. In the recent study, using high-fat diet (HFD)-fed animal model, we have observed that HFD feeding caused prolonged microgliosis in arcuate nucleus (ARC) of HT. To investigate if environmental stress stimuli can augment HFD-fed mice to develop emotional disorder, intermittent peripheral inflammagen (lipopolysaccharide; LPS) challenge (iLPS) were conducted during the onset period of HFD feeding. Male mice received 1 mg/kg of LPS (or saline) by i.p. route at week 1, week 2, and week 8 after Chow (iLPS+Chow) or HFD (iLPS+HFD) feeding. Through QPCR analysis, we found that hypothalamic IL1-β and

TNF-α mRNA levels were upregulated at 24 hour after the initial injection of LPS (1 week). Although no difference in the expression of these cytokines was detected at 24 hour after the second-time LPS injection, the upregulation of IL-1β and TNF-α was detected at 24 hour after third-time LPS injection (8 week). These findings suggest that intermittent LPS injection can elevate the expression of proinflammatory cytokines in HT. Subsequently, the animals (saline+Chow, saline+HFD, iLPS+Chow, iLPS+HFD) were continuously fed by either Chow or HFD up to 5 month. Immunofluorescence for examination of microglia in emotion related brain regions including nucleus accumbens (NAc), anterior cingulate cortex (ACC), insula, and basolateral amygdala (BLA) showed that activated microglia were found in BLA, insula, and ACC of the iLPS+Chow group when compared to saline+Chow. Moreover, an increased cell body size of microglia was detected in NAc, ACC, and insula of the saline+HFD group when compared to those of the Chow+saline group. Interestingly, the combination of iLPS with HFD attenuated microglia activation induced by iLPS+Chow or saline+HFD in the indicated brain regions. Through animal behavioral tests, we found that the iLPS+Chow group developed abnormal anxious behavior, whereas chronic HFD feeding can lessen iLPS-induced anxiety. Thus, our findings demonstrate that chronic HFD feeding can reduce iLPS-induced microglia activation in emotion-related brain regions, possibly leading to diminishing iLPS-triggered anxiety development in mice.

Title: Microglial responses to citrullinated self and non-self proteins

Authors: *M. M. STANDIFORD[1], E. M. GRUND[1], C. L. HOWE[2];
[1]Mayo Clin. Grad. Sch. for Biomed. Sci., Rochester, MN; [2]Neurol., Mayo Clin., Rochester, MN

Abstract: Citrullination, also known as deimination, is a post-translational modification whereby arginine residues are irreversibly converted into citrulline. Citrullination has been implicated in several autoimmune conditions, including multiple sclerosis (MS). While citrullinated proteins, particularly citrullinated myelin basic protein (MBP), have been shown to be upregulated in MS, the consequences of this modification with regard to MS are unknown. Citrullination may alter-self peptide immunogenicity by changing how these peptides bind to MHC molecules or T cell receptors. Additionally, it is unknown if citrullinated peptides can activate microglia, the resident phagocytes and innate immune cells of the brain. We show that citrullinated myelin debris drives a microglial phenotype characterized by activation of pro-inflammatory signaling pathways that

ultimately results in the release of pro-inflammatory cytokines and chemokines. We demonstrate that this microglial response is not only specific to citrullinated MBP but is partially mimicked by citrullinated viral proteins. These findings suggest a common mechanism whereby a citrullinated peptide sequence derived from either virus or myelin may contribute to innate immune activation and neuroinflammation in MS.

Title: Comparative study among the anti-inflammatory supplementation on microglial cells

Authors: *M. SAKAI[1], H. TOMITA[2,4], Z. YU[4,3];
[1]Dept. of Disaster Psychiatry, [2]Dept. of Psychiatry, [3]Dept. of Disaster Psychatry, Grad. Sch. of Medicine, Tohoku Univ., Sendai, Japan; [4]Dept. of Disaster Psychiatry, Intl. Res. Inst. of Disaster Sci. (IRIDeS), Tohoku Univ., Sendai, Japan

Abstract: Activated microglia are polarized two phenotypes M1 and M2, which are known to release inflammatory factors, anti-inflammatory cytokine and neurotrophic factors to maintain homeostasis of brain. Microglia producing TNF-α plays an important role in the sustained fear memory. Previous investigations have demonstrated that minocycline inhibits M1 type microglial activation. We reported that pretreated minocycline inhibited fear memory retention induced TNF-α production and enhances fear memory extinction, indicates that drugs that inhibit TNF-a production may be beneficial for the treating patients with post-traumatic stress disorder (PTSD). Despite women appear to be more susceptible than men to PTSD, administration of minocycline causes severe side effects in women, which is urgently needed to find safety and efficacy of supplementation in PTSD treatment. This study due to compare the effects of anti-inflammatory supplementations which could inhibit M1 microglia activation. Four kinds of supplementations: vitamin E (VE), α Lipoic-acid (α-LA), N-acetyl carnitine (NAC) and Acetyl-L- carnitine (ALCAR), with small molecular weight that can pass through blood-brain barrier, which anti-inflammatory activation have been reported. Four supplementations were administered to the microglial cell line MG-6 to examine the inhibitory effects on increased microglial inflammatory activation by LPS stimulation. Our results showed that NAC inhibited LPS induced Tnf and Il1 at both transcription and protein levels, whereas increased IL10, IL4 transcription levels. ACLAR and alpha-LA, inhibited Tnf and Il1transtription levels but did not reach significance. Recent studies indicated that inhibited apoptosis associated gene BCL2 by IL-10. In particular, NAC significantly reduced microglial TNF-α by induced Il10 transcription.

Our finding indicated that NAC as a potent supplement which may use for anti-inflammatory supplement in CNS, which could be useful for PTSD treatment.

Title: Investigating the functional significance of TSPO-NOX2 interaction in primary microglia

Authors: D. J. AZZAM[1], V. NUNES DE PAIVA[1], S. GUARIGLIA[2], *T. R. GUILARTE[1]; [1]Envrn. Hlth. Sci., Florida Intl. Univ., Miami, FL; [2]New York State Inst. for Basic Res., Staten Island, NY

Abstract: Translocator protein 18 kDa (TSPO) is a biomarker of brain injury and inflammation that has been extensively used in preclinical and clinical studies. TSPO is expressed in microglia and astrocytes, and TSPO levels increase rapidly following diverse CNS pathologies. NADPH Oxidase (NOX2) is a multi-subunit enzyme that is highly expressed in microglia and is a major source of ROS production in the CNS. We have previously shown a direct protein-protein interaction between TSPO and NOX2 subunits in primary microglia (Loth et al., SfN Annual Meeting, 2017). The functional significance of this novel interaction is not known but may involve modulation of reactive oxygen species (ROS) production in microglia with important implications to neuroinflammation and neurodegeneration. To determine if deletion of TSPO would modify the expression of NOX2 subunit genes, we generated primary microglia from TSPO-wildtype (WT), -heterozygous (HET), and -knockout (KO) mice. Levels of mRNA expression for *Tspo* and the *Nox2* subunits *gp91phox*, *p22phox*, *p40phox*, *p47phox*, *p67phox*, and *Rac1* were measured using qRT-PCR. We also measured *Vdac* mRNA expression as a mitochondrial marker since TSPO is highly expressed in mitochondria. We found a TSPO gene dosage effect on *Tspo* mRNA expression in primary microglia that was confirmed at the protein level. Importantly, mRNA expression of the *Nox2* subunits *gp91phox*, *p22phox*, and *p67phox* were significantly decreased in microglia from TSPO-KO mice with no effect on *p40phox*, *p47phox*, and *Rac1*. No significant effect of TSPO gene deletion was found on *Vdac* gene expression levels. These findings suggest transcriptional regulation of specific NOX2 subunit genes by TSPO gene deletion. Ongoing studies are determining the effect of TSPO deletion on NOX2 subunit protein expression and enzymatic activity. Based on our previous identification of a novel TSPO-NOX2 interaction and a putative increase in TSPO surface expression in activated

microglia, we determined if modulating ROS production would alter the subcellular distribution of TSPO in primary microglia. We found that exposure of primary microglia to the ROS inducer tert-butylhydroperoxide (TBHP) increased the cell surface expression of TSPO from approximately 13% under basal conditions to over 30% in the presence of TBHP. This effect of TBHP was abrogated by the ROS scavenger N-acetyl cysteine (NAC). Our findings suggest for the first time that TSPO, known as a mitochondrial protein, can increase its surface expression in microglia under conditions of increased ROS production. This effect may be associated with a functional TSPO-NOX2 interaction.

Title: Inhibition of fatty acid amide hydrolase suppresses inflammation in LPS-activated BV2 microglial cells

Authors: *K. YAGYU[1,2], M. TANAKA[1], S. SACKETT[1], Y. HIRATA[2], Y. ZHANG[1];
[1]Dept. of Anatomy, Physiol. and Genet., Uniformed Services Univ., Bethesda, MD; [2]United Grad. Sch. of Drug Discov. & Med. Inform. Sci., Gifu Univ., Gifu, Japan

Abstract: Fatty acid amide hydrolase (FAAH) is an integral membrane enzyme and belongs to a large serine hydrolase family. Numerous studies have suggested that FAAH represents a potential therapeutic target for several neurological diseases, since its inhibition can exert neuroprotective and anti-inflammatory effects by boosting the endogenous levels of N-acylethanolamines (NAEs) including endocannabinoid anandamide (AEA). However, the role of FAAH in the inflammatory response and the mechanisms by which pharmacological inhibition suppresses inflammation have not been well-elucidated in reactive microglia. In this study, we analyzed the effects of two commonly used FAAH inhibitors PF-3845 and URB597, together with siRNA knockdown to characterize FAAH inhibition on lipopolysaccharide (LPS)-induced inflammation in BV2 microglia cells. Treatment with PF-3845 suppressed LPS-induced

prostaglandin E_2 (PGE_2) production along with downregulation of cyclooxygenase-2 (COX-2) and microsomal PGE synthase. PF-3845 reduced the expression of pro-inflammatory cytokines such as IL-6 and IL-1β, but had no effects on the expression of anti-inflammatory cytokines. The anti-inflammatory effect of URB597 was not as potent as that of PF-3845. FAAH knockdown also suppressed PGE_2 production and pro-inflammatory gene expression. Surprisingly, the knockdown of FAAH enhanced anti-inflammatory gene expression such as IL-4 and IL-10 in the absence or presence of LPS treatment. Furthermore, Cannabinoid receptor antagonists did not affect the above-mentioned phenomena, suggesting that the effects of the FAAH are independent of cannabinoid receptors. Together, these results indicate that the dynamic change of M1 to M2 microglia polarization might underlie the therapeutic effect of targeting FAAH in several neurological and neuropsychiatric diseases.

Title: Palmitate increases microglia-derived TNF-alpha levels and impairs hippocampal insulin signaling

Authors: *H. M. MELO[1], G. SEIXAS DA SILVA[2], B. C. DE MELO[1], J. T. S. FORTUNA[1], S. T. FERREIRA[1], F. G. DE FELICE[1];

Abstract: Unhealthy diets and poor lifestyle habits are related to an increasing burden of metabolic disorders worldwide, including type 2 diabetes (T2D) and obesity-related insulin resistance. T2D and obese patients exhibit cognitive impairment and increased risk of developing dementia. However, the fundamental mechanisms underlying these clinical observations remain largely unknown. Elevated levels of free fatty acids in the circulation is linked to metabolic dyshomeostasis and peripheral insulin resistance, especially saturated fatty acids (SFA), such as

palmitate. Interestingly, brain palmitate uptake is increased in obese patients, with a positive correlation with aging. Thus, to understand how excessive levels of SFAs could impact brain function, we investigate the impact of palmitate, the most abundant circulating SFA, on the hippocampus, an important brain region for learning and memory. Interestingly, infusion of palmitate into the lateral cerebral ventricle of mice led to microglial activation and increased tumor necrosis factor alpha (TNF-alpha) levels in the hippocampus. In addition, palmitate reduced insulin expression and induced neuronal insulin receptor substrate 1 (IRS-1) phosphorylation at multiple inhibitory serine residues in primary hippocampal cultures. Importantly, palmitate failed to cause insulin signaling impairment in the presence of minocycline or infliximab, which inhibits microglial activation and neutralizes TNF-alpha, respectively. Altogether, our results delineate a pro-inflammatory mechanism underlying the deleterious effects of palmitate on neuronal insulin signaling, a pathway centrally involved in the learning and memory process in the brain. In addition, our findings contribute to the understanding of how unhealthy diets and metabolic disorders render the brain susceptible to memory defects and to dementia.

Title: 7,8-dihydroxyflavone prevents 3-nitropropionic acid induces striatal toxicity by modulating the TrkB receptor and microglial activation pathway

Authors: *S. A. AHMED, M. KWATRA, B. GAWALI, S. PANDA, V. NAIDU;
Pharmacol. and Toxicology, NIPER-Guwahati, Kamrup, India

Abstract: Huntington’s disease (HD) is an autosomal governing neurodegenerative disorder caused by production of mutant huntingtin(Htt) protein followed by death of the GABAergic neurons in the striatum. These neurons depend on an afferent supply of brain derived neurotrophic factor-(BDNF) which binds to its tropomyosin receptor kinase B (TrkB) receptor for maintaining plasticity, differentiation and survival. Impaired BDNF-TrkB signaling is assumed to be the mechanism underlying degeneration of neurons in HD. Therefore, we aimed to investigate an active molecule which mimics similar to BDNF in activating the TrkB receptor and its downstream pathway. 7,8-Dihydroxyflavone (7,8-DHF), has a better BBB penetrating ability and our results stated the treatment with 7,8-DHF causes a dose dependent manner activity in ameliorating the various behavior alterations caused by 3-nitropropionic acid (3-NP).

Histopathological and electron microscopy evidences from striatal region of 3-NP mice brain treated with 7,8-DHF showed more healthier neurons with intact mitochondrial morphology and very less autophagic vacuoles. These protections by 7,8-DHF may be due to an increase level of ATP which in turn down regulates cytochrome c releases from the mitochondrial matrix and inactivates Bad protein activation. It also enhanced the BDNF levels by promoting cAMP response element-binding protein (CREB) activation. Moreover, it showed an anti-inflammatory as well as anti-apoptotic potential with reduction in Iba-1, Cox-2 and Bcl-2 expression levels. 7,8-DHF also enhances phosphorylation of TrkB (Ty706) and Akt (Ser473/Thr308) and promotes its downstream signaling cascades in 3-NP induced striatal toxicity in experimental mice which might be the mechanism for its striatal neurons protection.

Title: The NF-kB transcriptional factor modulates microglia activation

Authors: *H. CHOI[1], G. AHN[1], M. BAEK[2], K. JUNG[4], Y. CHAI[3];
[1]Dept. of Bionanotechnology, [2]Inst. of Natural Sci. and Technol., [3]Dept. of Bionanotechnology/Department of Mol. & Life Sci., Hanyang Univ., Ansan, Korea, Republic of; [4]Korea Convergence Technol. Campus of Korea Polytechnic Ⅱ, Incheon, Korea, Republic of

Abstract: The transcription factor (TF) nuclear factor-kB (NF-kB) plays a critical role in regulating the neuroinflammation in microglia. NF-kB family is composed of NF-kB1 (p50), NF-kB2 (p52), RelA (p65), RelB and cRel, which mediates production and secretion of various pro-inflammatory genes, cytokines, and chemokines. To address the role of transcriptional responses in microglia cells, we established p65 knock-out (KO) microglia BV2 cell line and studied the immune-modulatory effects using RNA-seq analysis. The gene expression profile was performed with BV2 control, lipopolysaccharide (LPS)-treated BV2 control, p65 KO BV2 and LPS-treated p65 KO BV2. Using differentially expressed genes (DEGs), we identified downregulated patterns of interferon-stimulated genes, cytokines, and chemokines. Moreover, we further analyzed DEGs to identify transcriptional motifs (-950 bp to +50 bp of the 5' upstream promoters) and epigenetic modification. TF motif analysis revealed that the DNA sequences for Stat1/2, Irf1, Irf7, Irf9 were significantly enriched in downregulated genes in LPS-treated p65 KO BV2 cells. Also, those genes were reduced H3K27ac level in their promoter. Taken together, these results provide the p65 orchestrates the LPS-stimulated immunomodulatory response of BV2 involved in Stat1, Irf1, Irf7, Irf9, and histone modification (H3K27ac).

Title: Exploring the mechanisms that govern microglia dynamics during photoreceptor cell death and regenerative neurogenesis in zebrafish

Authors: *M. NAGASHIMA[1], P. F. HITCHCOCK[2];
[1]Univ. of Michigan, Ann Arbor, MI; [2]Dept Ophthalmol, Univ. of Michigan Dept. of Ophthalmology and Visual Sci., Ann Arbor, MI

Abstract: Understanding the mechanisms that govern regenerative neurogenesis will advance the field of stem cell-based therapies. Increasing evidence shows that acute inflammation is

necessary and sufficient for the neurogenic response of neural stem cells. Chronic inflammation, however, is detrimental. Microglia are endogenous immune cells of the macrophage lineage within the central nervous system that secrete cytokines and chemokines, which function to govern inflammation. In the zebrafish retina, Müller glia serve as intrinsic stem cells that, in response to neuronal death, dedifferentiate and undergo a single asymmetric division to produce retinal progenitors, which rapidly proliferate, migrate and differentiate to replace the ablated neurons. In this study, we used the mutant zebrafish, *midkine-a*^{mi5001}, which has a loss-of-function mutation in *midkine-a*, which encodes a growth factor/cytokine that has multiple functions in neural development, inflammation, and disease. We investigated the molecular mechanisms by which microglia mediate inflammation during the selective death and regeneration of photoreceptors. In wildtype retinas following a photolytic lesion, photoreceptors become TUNEL-positive by 1 day post lesion (dpl). Nearby microglia respond to the cell death rapidly and by 3 dpl phagocytose the dying photoreceptors. In the mutant retina, the time course of photoreceptor cell death and microglial activation is unaltered, however, activated microglia fail to phagocytose dying photoreceptors, resulting in dysregulation in the expression of inflammatory cytokines. These data suggest that Midkine-a orchestrates inflammatory status of the damaged retina by mediating communication between dying photoreceptors and microglia.

Title: Quantitative proteomics reveals docosahexaenoic acid-mediated neuroprotective effects in lipopolysaccharide-stimulated microglial cells

Authors: *C. M. GREENLIEF[1], B. YANG[3], R. LI[4], X. GENG[7], B. MOONEY[5], K. L. FRITSCHE[6], D. Q. BEVERSDORF[2], J. C. LEE[8], G. Y. SUN[9];

Missouri, Columbia, MO

Abstract: The high level of docosahexaenoic acid (DHA) in phospholipids in the brain has spurred significant interest in its role in brain health and diseases. Recent studies provided evidence for DHA to play a role in inhibiting inflammatory responses in microglial cells,

although the mechanism(s) remains elusive. In this study, a global proteomic approach was used to examine effects of DHA on microglial cells stimulated with lipopolysaccharides (LPS). Deep proteome coverage was achieved using the parallel accumulation serial fragmentation (PASEF) method in a hybrid trapped ion mobility spectrometry (TIMS) - quadrupole time-of-flight mass spectrometer (TIMS-ToF). Using label-free quantitative proteomics, a total of 2858 protein groups (with more than one unique peptide) were confidently identified and quantified in BV-2 microglial cells. Treating the cells with LPS and/or DHA altered cell morphology and expression of 43 proteins with a differential abundance (greater than 2.0-fold change). Bioinformatic analyses further indicated that these differentially abundant proteins were involved in the nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) pathway, fatty acid metabolism, mitochondrial activity, response to bacterium, cytoskeleton, DNA binding, and ribosome biogenesis. Quantitative analyses of cell viability, tumor necrosis factor alpha, phospho-NF-κB p65, inducible nitric oxide synthase and prostaglandin E2 expression levels were consistent with the biological outcomes of the altered protein concentrations. Together, these data indicate for the first time multiple mechanisms of DHA-mediated protective effects in LPS-stimulated BV-2 microglial cell at the global proteome level. This information may shed light on a new basis for therapeutic strategies of DHA against inflammation.

Title: Decoding the role of P2X7 in neuroinflammation

Authors: *R. C. GRUBER[1], L. WOODWORTH[1], J. GANS[2], J.-M. CHAMBARD[3], K. SINGH[4], D. BANGARI[4], T. SAMAD[1], D. OFENGEIM[1];
[1]MS and Neuroinflam. Res., [2]Translational Sci. Genomics, Sanofi, Framingham, MA; [3]IDD In Vitro Biol. Pharmacol., Sanofi, Vitry, France; [4]Translational In Vivo Models, Sanofi, Framingham, MA

Abstract: Background: Neuroinflammation has been implicated in many disorders of the central nervous system, in particular Multiple Sclerosis (MS). Active MS lesions exhibit demyelination and oligodendrocyte loss, as well as infiltration with CD68+ macrophages, microglia and lymphocytes. Within active lesions, axons are largely devoid of myelin, and are vulnerable to injury. P2X7 is a purinergic receptor activated by high levels of ATP and is

expressed by macrophages and several cell types of the CNS, including microglia and oligodendrocyte precursor cells (OPCs). While extracellular ATP levels are typically low, cytosolic concentrations of ATP range between 5 and 10mM. Therefore, CNS insults such as inflammation, trauma, stroke, and neurodegeneration can cause a marked release of intracellular ATP into the extracellular space, making ATP an important danger signal. While it is clear that P2X7 activation contributes to the release of IL-1β and other inflammatory cytokines, P2X7 downstream signaling and the consequences therein remain unclear. **Objective:** To characterize the downstream signaling of P2X7 in microglia and assess whether inhibition of P2X7 activation in the CNS reduces central inflammation, and attenuates disease pathology. **Results:** We studied a microglial P2X7 activation signature by using BzATP as the activation stimulus in the presence or absence of a P2X7 antagonist. We have compared this signature to previously published microglial signatures and have identified genes that are partially and fully inhibited by a P2X7 allosteric inhibitor. We further validated select P2X7 signature genes in human primary macrophages. Finally, we observe therapeutic efficacy of a P2X7 antagonist in an experimental autoimmune encephalomyelitis (EAE) mouse model of MS, with a corresponding reduction in demyelinating lesions and plasma neurofilament heavy (NFH), as a potential biomarker of axonal injury. **Conclusion:** We have established a P2X7 microglial signature and demonstrated *in vivo* activity using a P2X7 allosteric inhibitor. In summary, the microglial signature along with *in vivo* activity demonstrate the validity of P2X7 as a target for central inflammation and shed light on the inflammatory signaling downstream of P2X7.

Title: Functionally engineered extracellular vesicles derived from mesenchymal stem-cells provide neuroprotection by attenuating microglia activation in retinal ischemia

Authors: *R. PATEL[1], B. MATHEW[1], S. RAVINDRAN[2], C.-C. HUANG[2], M. CHENNAKESAVALU[1], L. GAMBOA ACHA[1], S. ROTH[1];
[1]Anesthesiol., [2]Oral Biology, Col. of Dent., Univ. of Illinois at Chicago, Chicago, IL

Abstract: Many retinal diseases involve loss or dysfunction of multiple types of retinal neurons, endothelial cells, and pericytes leading to oxidative stress, inflammation, and retinal ischemia. Retinal inflammation with activated retinal microglia (RMG) is major event in diabetic retinopathy. Our previous studies using a rat model of retinal ischemia have demonstrated robust neuroprotective effects of MSCs derived extracellular vesicles (EVs) when injected in the vitreous. MSCs produce extracellular vesicles (EVs) which are specifically involved in intercellular communication and are capable of transferring protein and nucleic acids between cells. The neuroprotective effects of MSCs appear to be largely mediated by EVs in retinal ischemia and are related to anti-apoptosis and anti-inflammatory actions, as shown in recently published studies. Preliminary data suggests that this neuroprotection is in part due to the RMG uptake of MSC-EVs. MSC-EVs appear to suppress the activation of RMG. RMG are the resident macrophages of the neuronal tissue capable of inducing cell proliferation through their activation upon injury; however, RMG exacerbate the situation by releasing toxic and pro-inflammatory compounds, particularly cytokines. RNA Seq analysis indicated miR-424 as one of the primary anti-inflammatory miRNAs in MSC-EVs. Anti-inflammatory effects of MSC-EVs can be enhanced by generating Functionally Engineered EVs (FEEs) containing increased levels of miR-424. In this study we have developed engineered EVs containing increased levels of miR-424. EVs were isolated from MSC conditioned media and characterized by Western Blot (WB), Nanoparticle Tracking Analysis, and Transmission Electron Microscopy. *In vitro*, the cultured RMGs were pre-incubated for 24h with EVs or FEE miR-424 and subjected to Oxygen Glucose Deprivation (OGD) with experimental groups: OGD, OGD+MSC-EVs/FEE miR-424, and OGD+CM minus EVs/FEE miR-424 as the control. The outcomes were measured by evaluating cell death (LDH), inflammatory cytokines, nitric oxide levels (NO) and ROS measurements. MSC enhanced FEE-miR424 confer significant neuroprotective effects *in vitro*. This study demonstrates that FEEs miR-424 suppresses RMG activation.

Title: A focused transcriptome of aging-associated, immune-driven cognitive failure reveals distinct patterns hippocampal gene expression in aged vs. young rats following an acute immune challenge

Authors: *L. DEFLITCH, C. R. FITZGERALD, B. METENKO, N. TANAKA, S. L. PATTERSON, H. E. ANNI;
Biol., Temple Univ., Philadelphia, PA

Abstract: Aging increases the risk of an abrupt cognitive decline, termed delirium, following an injury or illness. An episode of delirium is associated with a greater risk of developing Alzheimer's disease and other forms of dementia, yet very little is known about the underlying mechanisms. Data from rodent models suggests that aging primes cells of the innate immune system in the brain to produce a dysregulated response to immune challenges. Aged (24-month-old) Fischer Brown Norway (F344xBN) rats are generally healthy with no major physical or cognitive deficits. However, following a single i.p. injection of *E. coli*, these aged rats mount an exaggerated CNS inflammatory response (e.g. greater production of proinflammatory cytokines, like IL-1β) relative to young (3-month-old) rats, leading to deficits in hippocampus-dependent long-term memory and related synaptic plasticity.
To further investigate how age and an immune challenge can compromise the capacity for memory-related synaptic plasticity, we are now using NanoString multiplex gene expression analysis of whole hippocampal extracts and hippocampal synaptoneurosomes. Screening samples against a curated gene expression panel of over 700 genes makes it possible to more closely examine differences in how the brains of young and aged animals respond to an acute immune challenge, and how these differences may contribute to immune-driven cognitive failures like delirium. The genes of the panel were selected for involvement in immune responses, neuron-glia interactions, synaptic plasticity and related memory functions. Our preliminary data show changes in expression of a number of microglial activation- and cytokine-related genes, genes related to autophagy, glial- and neurogenesis, and genes related to neurotransmitter synthesis and storage.
We are using a time-course to study whether aged animals display different inflammatory mechanisms from young animals or if their mechanisms are similar but follow a delayed time course. Animals are sacrificed and their mRNA extracted at two time points after the *E. coli*

injection: either one day, while animals are still physically ill, or four days, when animals are physically recovered, (i.e. no fever, normal eating) post-infection. Studying the gene expression patterns throughout this time-course of inflammatory response should increase our understanding of how an acute immune challenge can compromise cognitive function in aged brains.

Title: Suppression of microglia mediated neuroinflammation by small molecule NFκB inhibitors

Authors: B. ASTRY, R. GRANT, *K. BRADLEY, K. BRUMBAUGH, J. RIVARD, M. CARLSON-HABEGGER, M. LARSON, **J. KIRK**, A. HUDACEK, G. WEGNER;
R&D Systems, Bio-techne, Minneapolis, MN

Abstract: It has been shown that long-term production of proinflammatory cytokines by activated microglia plays a role in neurodegenerative disorders like Parkinson's disease and multiple sclerosis. Here we investigated if inhibition of the NFκB signaling pathway, an important factor in the inflammatory response, could alter the chemokine and cytokine profile of the BV-2 mouse microglia cell line. Using the Toll-like Receptor 4 (TLR4) agonist lipopolysaccharide (LPS), we stimulated BV-2 cells and subsequently treated them with two different small molecule inhibitors, MLN4924 (a NEDD8 E1 Activating Enzyme inhibitor) and Celastrol (a NFκB inhibitor). Cell supernatants and lysates were measured for 48 mouse cytokines/chemokines/growth factors using the R&D Systems® Mouse Magnetic Luminex® Assay. LPS stimulation increased multiple proinflammatory cytokines, including IL-1α/IL-1F1, IL-1β/IL-1F2, IL-6, IL-27, and TNF-α, and the chemokines CCL4/MIP-1β, CCL5/RANTES, CXCL1/KC and CXCL10/IP-10/CRG-2. Treatment with either MLN4924 or Celastrol resulted in significant decreases in the levels of the proinflammatory cytokines and chemokines. We then investigated if MLN4924 and Celastrol act by inhibiting the canonical and/or non-canonical NFκB signaling pathway. We showed that MLN4924 and Celastrol inhibited IκB-α degradation and MLN4924 inhibited p100 degradation. This indicates that these small molecules act by inhibiting NFkB signaling. In addition, MLN4924 also preserved RelA/NFκB p65 phosphorylation and reduced ubiquitination of TNF R1/TNFRSF1A. These results suggest the small molecule inhibitors MLN4924 and Celastrol can be used to suppress microglia-mediated neuroinflammation.

Title: Lipopolysaccharide or Il-1β microglial inflammasome activation bi-directionally alters morphine reward in a time-dependent manner sensitive to anti-inflammatory interventions

Authors: ***A. R. ALLEYNE**[1], T. J. CIRINO[1], S. O. EANS[1], H. M. STACY[1], P. ZHANG[1], S. STEVENS[2], B. LIU[1], J. P. MCLAUGHLIN[1];
[1]Pharmacodynamics, Univ. of Florida, Gainesville, FL; [2]Pharm. and Hlth. Sci., Albany Col., Colchester, VT

Abstract: Neuroinflammation has been shown to both suppress and potentiate the rewarding effects of abused substances like morphine, but the underlying mechanisms are poorly understood. We hypothesize that microglia inflammasome activation upregulates inflammatory cytokines in the CNS that mediate bidirectional changes in reward circuitry. To test this, C57BL/6J (C57) mice and secreted phosphoprotein 1 gene-disrupted (SPP1 KO) mice, a C57 strain possessing impaired microglial activity, were used in a model of brain-exclusive inflammation produced by i.c.v. administration of lipopolysaccharide (LPS, 100 ng) prior to morphine treatment in a morphine-conditioned placed preference (CPP) assay. C57 mice showed time-dependent alterations in morphine CPP. A 45 min. LPS pretreatment decreased morphine CPP 88%, whereas a 90 min. LPS treatment resulted in a 3 fold increase in morphine place preference. SPP1 KO mice and C57 mice pre-treated with the anti-inflammatory agent, indomethacin (10mg/kg, i.p.) prior to LPS, showed no change in morphine preference at either time point. Using a two-bottle choice (TBC) assay, voluntary consumption of morphine in C57 mice treated with LPS (0.3 mg/kg/d, i.p.) was reduced up to 80% as compared to vehicle-treated mice, but returned to normal in two days. Further demonstrating the involvement of inflammatory cytokines, a 90 min pre-treatment of C57 mice with interleukin-1β (IL-1β;

2µg/kg/d i.p.) prior to daily morphine-place conditioning resulted in a two-fold increase in morphine CPP that was blocked by indomethacin. Histological studies utilizing immunohistochemistry (IHC) and Western Blot techniques evaluated morphological and established marker expression (Iba1, TMEM119 and GFAP) of gliosis within the reward pathway (nucleus accumbens (NAc), ventral tegmental area (VTA), and pre-frontal cortex (PFC). Additional studies evaluated inflammasome activation in brain microglia. Preliminary data suggests a time- and dose-dependent alteration in microglia count and morphology in a brain region-specific manner which is differentially sensitive to SPP1 gene disruption. Overall, these results enhance our understanding of the bi-directional influence of neuroinflammation on morphine reward, and may identify novel therapeutic treatments for opioid addiction.

Title: Role of microglia in immune mediated retinal ganglion cell protection and axon regeneration

Authors: *R. PASSINO, C. YOON, L. HUFFMAN, O. NELSON, B. SEGAL, R. GIGER; Univ. of Michigan, Ann Arbor, MI

Abstract: In adult mammals, retro-orbital optic nerve crush injury (ONC) results in retinal ganglion cell (RGC) death and failure of severed axons to regenerate beyond the lesion site. Under certain circumstances, however, activation of the innate immune system leads to robust RGC protection and axon regeneration. For example, intraocular injection (i.o.) of zymosan or mechanical damage to the ocular lens triggers an immune response that protects injured RGCs and promotes lengthy growth of GAP43+ RGC axons. By contrast, i.o. lipopolysaccharide (LPS) injection causes an inflammatory response that is neurotoxic and does not support axon regeneration. The pro-regenerative effects of the immune system extend beyond the visual system; conditioning injury induced regeneration of ascending sensory axons in the spinal cord depends on a well-orchestrated inflammatory response.
We previously showed that β-glucan is the main active ingredient of zymosan and signals in a

dectin-1 and toll-like receptor 2 (TLR2) dependent manner to promote RGC axon regeneration. Dectin-1 is broadly expressed by innate immune cells, including microglia. Dectin-1 is absent from retinal neurons and astrocytes. To explore the contribution of microglia to zymosan mediated RGC protection and axon regeneration, we used pharmacological inhibition of Colony-Stimulating-Factor 1 receptor (CSF1R). Flow cytometry revealed a greater than 90% depletion of microglia in the retina, brain, and spinal cord in mice treated with inhibitor. Pharmacological inhibition of CSF1R does not alter ocular infiltration of blood-derived immune cells following i.o. zymosan injection. However, zymosan-mediated protection and regeneration of RGCs is partially, yet significantly reduced, indicating that microglia are important for the full-blown regenerative response to zymosan. Injury to the sciatic nerve, prior to transection of the dorsal columns (DC) in the spinal cord, results in enhanced (DC) axon regeneration. Pharmacological inhibition of CSF1R attenuates conditioning injury induced DC axon regeneration. Together, our studies reveal pro-regenerative effects of microglia in immune-mediated neuro-repair.

Title: Defective microglia-neuronal communication in mice expressing the human polymorphic variant CX3CR1$^{I249\text{-}M280}$ leads to the dysregulation of genes governing neurogenesis, myelination and microglial activation

Authors: *K. A. CHURCH[1], A. MENDIOLA[2], S. CARDONA[1], D. VANEGAS[1], S. LIRA[3], C.-H. LIN[1], A. E. CARDONA[4];
[1]Biol., Univ. of Texas at San Antonio, San Antonio, TX; [2]Glastone Inst., Univ. of California San Francisco, San Francisco, CA; [3]Immunol. Inst., Ichan Sch. of Med. at Mount Sinai, New York, NY; [4]Dept. of Biol., The Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Multiple sclerosis (MS), a disease affecting 2.3 million people worldwide is characterized by the demyelination of axonal nerve fibers in the central nervous system (CNS) leading to disability and cognitive deficits. In the CNS, the CX3CR1 receptor is found on microglia and signals through the neuronal derived Fractalkine (FKN). This binding is known to inhibit microglia mediated neurotoxicity. Elucidating how human CX3CR1 polymorphisms

regulate microglia-neuronal function is relevant to understand mechanisms that lead to disease progression and to develop targeted neuroprotective approaches. To test the hypothesis that mice expressing the human CX3CR1$^{I249/M280}$ (hCX3CR1$^{I249/M280}$) polymorphic variant confer susceptibility to demyelination via microglial toxicity we utilized the cuprizone model of demyelination/remyelination. Our findings show severe demyelination, neuronal damage, and delayed remyelination, accompanied by microglia clustering in demyelinated regions of the corpus callosum (CC) in hCX3CR1$^{I249/M280}$mice. These findings were also confirmed in mice lacking the mouse receptor or the ligand FKN. Observing the loss of CC1^{+} mature oligodendrocytes in hCX3CR1$^{I249/M280}$ mice prompted the comparison of glial and neural progenitors indicating that CX3CR1-FKN may regulate neurogenesis thus interfering with neuron-OPC communication for oligodendrogenesis. NanoString analysis on tissues isolated from the SGZ neurogenic niche revealed an upregulation of genes involved in oxidative stress to neurons, notch signaling by microglia, and carbohydrate catalysis in hCX3CR1$^{I249/M280}$ expressing mice. The analysis also revealed a downregulation in genes involved in stem cell proliferation and differentiation in hCX3CR1$^{I249/M280}$ expressing mice. Overall our study indicates that FKN promotes neuroprotection by triggering anti-inflammatory microglial responses that support neurogenesis that are regulated by CX3CR1 polymorphic variants. This research has the potential to provide gene target therapies for the advancement of the MS field by providing evidence of a neuroprotective role of CX3CR1 that can be manipulated to enhance remyelination and repair.

Title: Microglial specific depletion of TAK1 contributes to neuroprotection after murine cerebral ischemia

Authors: *P. HABIB, T. ZEYEN, A. REICH, J. B. SCHULZ;
Dept. of Neurol., Univ. Hosp. Aachen, RWTH Aachen Univ., Aachen, Germany

Abstract: Background: Neuroinflammation and apoptosis play a crucial role in the expansion of the infarct core and the adjacent penumbra after cerebral ischemia. The key regulator of gene transcription NF-kB and the MAP kinases JNK, p38/MAPK and ERK share a common upstream

activator, the transforming growth factor-beta-activated kinase 1 (TAK1). TAK1 is upregulated after stroke and seems to have cell specific response pattern. Microglia are a main source of TAK1. However, little is known about the function and regulation of microglial-specific TAK1 after cerebral ischemia. **Purpose:**To gain further information about the biological function and regulation of TAK1 in microglial cells after cerebral ischemia.**Methods:**Tamoxifen-dependent conditional depletion of TAK1 in microglial cells was induced in CX3CR1-Cre^{ER}-TAK$^{fl/fl}$mice. The Cre negative CX3CR1-TAK$^{fl/fl}$mice served as a control group. We performed 30 minutes of middle cerebral artery occlusion (MCAo) followed by 72h of reperfusion.Laser Doppler flowmetry during surgery confirmed sufficient MCA occlusion.Weight, general status and focal neurologic dysfunction were evaluated at various time-points before and after MCAo or sham surgery. Lesion sizes weredetermined via computer-assisted infarct volumetry.Examining cell specific interactions primary microglia and mixed cell cultures were subjected tooxygen-glucose deprivation (OGD) followed by viability assays (LDH, CTB), gene expression analysis and protein measurement. TAK1-deficiency was induced by using tamoxifen and/or the general TAK1-inhibtor 5-7-Oxozeanol. **Results**: Infarctvolumes were reduced in TAK-1 deficient mice compared to the control group. In addition, TAK1-depletion significantly reduced neurological deficits and weight loss after MCAo. Ischemic tolerance of TAK1-depleted microglia as well as TAK-1 inhibited mixed cell cultures was significantly increased compared to the control group. Furthermore, TAK1-depletion and -inhibition decreased the mRNA- and protein-levels of pro-inflammatory cytokines, such as TNF-a, IL-1b and IL-6.**Conclusion:**Microglial-specific depletion/inhibition of TAK1offers a promising strategy in stroke therapy.

Title: Increased phagocytic activity of monocyte derived microglia-like cells in adrenoleukodystrophy associated with neuronal damage

Authors: *Y. GONG[1], V. KREOUZIS[2], F. EICHLER[3];
[1]Massachusetts Gen. Hosp., Boston, MA; [2]MGH, Boston, MA; [3]Massachusetts Gen. Hosp. | Harvard Med. Sch., Boston, MA

Abstract: Adrenoleukodystrophy (ALD) and adrenal myeloneuropathy (AMN) are metabolic diseases associated with a deficiency in the ABCD1 peroxisomal transporter, leading to

ineffective metabolism of very-long chain fatty acids (VLCFA). Both have been associated with progressive myelin loss at their respective critical periods, but the presence and potential for neuronal damage has not been extensively studied. It has been previously shown that microglia activation is related to disease progression and symptomatology, while in addition peripheral blood monocytes infiltrate the brain through the blood brain barrier, thus being able to promote neuronal damage. We hypothesized that neuronal damage is thus in part associated with the microglia and peripheral blood monocyte infiltration of brain tissue in ALD and AMN, which would be associated with neuronal damage markers in patient sera. There was a around 50% increase in neurofilament light chain detected in serum of attempts with ALD and AMN (male: 176pg/ml±35, female: 176pg/ml±29) compared to controls (male: 90pg/ml±22, female: 126pg/ml±42), suggesting neuronal cell death in the central nervous system. To investigate the role of the immune driver in the brain of affected individuals we sought to derive microglia-like cells from patient peripheral blood monocytes. Preliminary data suggested a correlation between C1q and TNF-a with the phagocytic activity of the derived microglia-like cells towards synaptosomes in a small ALD and AMN cohort. The current work will further investigate the role of pro-inflammatory, anti-inflammatory, and phagocytic markers during a phagocytic event in the patient derived microglia-like cells. For conclusion: our finding of elevated neurofilament light chain suggests that axonal degeneration can be detected through a serum biomarker. The concurrent detection of activated monocytes suggests that increased phagocytosis may be contributing to axonal degeneration in humans affected by AMN. Importantly our findings in combined biomarkers of monocyte and axonal dysfunction allow for more effective temporal diagnosis of pathology associated with ABCD1 peroxisomal deficiency.

Title: The utility of vibrotactile cues as supplemental movement feedback varies across application site and individuals after stroke: A pilot study

Authors: *A. THOMAS[1], V. A. SHAH[1], G. BALLARDINI[2], T. STOECKMANN[3], M. CASADIO[2], J. R. MCGUIRE[4], R. A. SCHEIDT[1,5,6], L. A. MROTEK[1];

Col. of Wisconsin, Milwaukee, WI; [5]Feinberg Sch. of Medicine, Northwestern Univ., Chicago, IL; [6]Div. of Civil, Mechanical and Manufacturing Innovations, Natl. Sci. Fndn., Alexandria, VA

Abstract: Vibrotactile feedback (VTF) can provide a form of supplemental movement feedback that improves upper extremity movement accuracy in the absence of visual feedback in healthy individuals. A recent pilot study suggests that VTF can also improve motor control in the more involved arm in some survivors of stroke by providing cues about that limb's motion. We sought to advance development of a new VTF-based assistive technology by determining if there is a single best site on the body to apply VTF, one that is common across individuals. Four stroke survivors used VTF to guide 1D (left/right) reaching movements. VTF was provided using two 10 mm eccentric rotating mass vibration motors taped to specific locations on the body. The motors have an operating range of 50-250 Hz and a peak vibration of 2.8 G; vibration was described as mild to moderate. Participants sat comfortably with their more-affected hand fixed to the handle of a passive 2D horizontal planar robot and were asked to make reaches with that hand. They saw a 5x5 grid of points (the *workspace*) on a vertically oriented screen with the five points of the middle row used as targets. A single point was highlighted when it was the current target. VTF encoded the position of the reaching hand; no vibration was applied when the hand was at the center of the workspace and vibration intensity increased as the hand moved away from the center of the workspace. Trials consisted of 16 reaches between the 5 points in the middle row of the grid. Subjects verbally indicated when each target was acquired. Subjects experienced eight feedback conditions: visual cursor feedback of hand motion; no vision & no VTF. VTF was applied to each forearm (motors on C6/C8 dermatomes on the wrist extensor muscles); near each knee (motors on L3/L4 dermatomes on the knee extensor muscles); and torso (motors on C6 dermatome on the trapezius muscle). We computed the target capture error at the end of each reach. Performance excelled with visual feedback in all subjects. Ability to interpret and use VTF varied widely across application sites in a way that varied person by person. Two of the participants capitalized on the VTF to improve reach accuracy in the absence of visual feedback relative to the no vision & no VTF condition. One of these individuals performed best when the VTF was applied to the less-affected knee, whereas the other successfully used VTF when it was applied to the less-affected arm. For the other two participants, performance degraded in the presence of VTF. These data, collected in a small heterogenous cohort, suggest that an individualized approach may be needed when developing VTF-based assistive technologies to augment upper extremity kinematic performance.

Title: Theta power is a longitudinal EEG spatial and spectral biomarker of spontaneous motor recovery after stroke

Authors: *L. M. OSTROWSKI[1,2], A. N. DUSANG[4,5,1], A. CLOUTIER[2], F. GIATSIDIS[2], S. S. CASH[3,6], L. R. HOCHBERG[1,4,2,6,5], D. J. LIN[2,1];

Hosp., Boston, MA; [4]Sch. of Engin., [5]Carney Inst. for Brain Sci., Brown Univ., Providence, RI; [6]Dept. of Neurol., Harvard Med. Sch., Boston, MA

Abstract: INTRODUCTION: Current neurorestorative therapy options to enhance upper extremity motor recovery after stroke are limited. Neurological biomarkers that reflect underlying biological processes and correlate with motor recovery could provide important surrogate clinical endpoints for stroke recovery trials. Slow-wave oscillations on EEG have been linked to cerebral dysfunction after stroke, but robust EEG biomarkers that track with upper extremity motor recovery have yet to be defined. Here, our aim is to define spatial and spectral properties of EEG that provide optimal biomarkers for upper extremity motor recovery in the first three months after stroke.
METHODS: We recorded natural-state, high-density 128-channel EEG data in 15 patients within one week and subsequently at six weeks and three months after ischemic stroke. We used a

customized semi-automated pipeline for offline EEG data pre-processing (eye-blink and artifact rejection). Spectral power was calculated in leads overlying the contra- and ipsilesional motor cortex, contra- and ipsilesional hemispheres, and over the whole scalp, in predefined bands: delta (1-4 Hz), theta (5-7 Hz), alpha (8-12 Hz) and beta (13-30 Hz). We used the Upper Extremity Fugl-Meyer Assessment (UE-FMA) to quantify upper limb motor impairment at each time point.
RESULTS: Absolute theta power was the only spectral feature which correlated with UE-FMA at all timepoints (at enrollment $R^2 = 0.23$, $p = 0.067$; at six weeks $R^2 = 0.35$, $p = 0.026$; at three months $R^2 = 0.25$, $p = 0.067$, Pearson's r). The largest number of spectral correlates were found at six weeks, where relative theta power in the lesioned hemisphere had the strongest relationship of all spectral bands in all spatial regions ($R^2 = 0.63$, $p < 0.001$). Favorable change in UE-FMA linearly correlated with decrease in absolute theta power in the lesioned hemisphere between six weeks and three months ($R^2 = 0.34$, $p = 0.028$), but not between enrollment and six weeks. Finally, theta power in the lesioned hemisphere at six weeks, but not at enrollment, was predictive of UE-FMA outcome at three months (absolute power $R^2 = 0.25$, $p = 0.066$; relative power $R^2 = 0.54$, $p = 0.003$).
CONCLUSION: EEG spatial and spectral features contain useful information indicative of spontaneous upper extremity motor recovery. Theta power in the lesioned hemisphere may be an optimal cross-sectional and longitudinal spectral biomarker and may be particularly informative for motor recovery at six weeks post-stroke as opposed to the immediately acute setting.

Abstract: The objective of this work was to evaluate cell therapy in type two diabetic rats with stroke using the triple model image of stem cell labeled with multimodal nanoparticle. After the isolation, immunophenotypic characterization and lentiviral transduction of human bone marrow stem cells (hBM-MSC), these cells were labeled with multimodal nanoparticles (MNP) with magnetic and fluorescent properties (visible and infrared wavelength) that were previously characterized. Cell viability was analyzed by MTT assay and BLI, and quantify the MNP load internalized into the cells by MRI, NIRF, and ICP-MS. Male Wistar rats (200-230g) were divided into four groups: non-diabetic and diabetic, followed stroke induction or sham surgery. The type 2 diabetes animals fed high-fat diet for one week, followed by a one-time injection of 30 mg/kg streptozotocin. The stroke induction was performed using photothrombosis in the motor cortex, confirming the ischemic lesion by local blood perfusion analysis and TTC staining. 24h after surgery, half of the animals of each group received hBM-MSC labeled with MNP. The triple modal image (MRI, NIRF and BLI) was performed before surgery and 4, 24h and 7 days after cells implantation. Also, cell therapy was evaluated using behavioral tests and immunohistochemical staining. Immunophenotypic characterization and differentiation induction of hBM-MSC showed to be adequate for cell therapy. Physicochemical characteristics of the MNP was an average diameter of 40.1 nm and zeta potential of 32.0 mV in pH of 7.4. The optical characterizations showed the dual fluorescence (visible and infrared). The signal of MNP load internalization in hBM-MSC had a close correlation (r=0.99) with the corresponding MNP-labeled by MRI, ICP-MS and NIRF, in which the maximum value of MNP load found was 0.65 *p*g of MNP/cell with a cellular viability reduction of less than 8%. After 7 days of hBM-MSC implantation, the behavior analysis showed high improvement in T2MD+Stroke in comparison to sham and stroke groups ($p<0.001$), as well as T2MD group($p=0.05$), as well as the BLI signal of the T2MD+Stroke group (3E9 photons/s) showed high value in comparison to stroke group (5E8 photons/s), without signal detection in T2MD and sham groups, while the NIRF and MRI analysis showed low signal in all groups. The Fluoro-Jade B identified neuronal degeneration secondary to ischemia and NeuN showed the density neuronal after cells implantation, in according to behavioral pattern of recover. This study showed functional and structural improvement after cell therapy in stroke lesion of diabetic rats using nanobiotechnological resources.

Title: Chemogenetics-mediated acute inhibition of excitatory neuronal activity improves stroke outcome

Authors: Y.-C. WANG[1], F. GALEFFI[2], W. WANG[1], X. LI[1], H. SHENG[1], U. HOFFMANN[1], D. A. TURNER[2], ***W. YANG**[1];

Abstract: Introduction. Ischemic stroke is a devastating disease caused by a sudden interruption of blood flow to an area of the brain and subsequent brain infarction. Immediately after ischemic stroke and during infarct maturation, a cascade of deleterious events takes place, including metabolic supply-demand mismatch, dysfunction in ion channels, and excessive release of neurotransmitters. Accordingly, homeostasis in neuronal networks is impaired, which leads to excitotoxicity and peri-infarct depolarizations, both crucially contributing to infarct expansion. In the current study, we hypothesized that inhibition of excitability and depolarization of excitatory neurons in the brain reduces the occurrence of cortical spreading depolarizations and improves stroke outcome. To test this hypothesis, we used a chemogenetic approach that is based on Designer Receptors Exclusively Activated by Designer Drugs (DREADDs).
Methods. We generated hM4Di-TG transgenic mice expressing the inhibitory hM4Di, an DREADD receptor, in forebrain excitatory neurons. Clozapine-N-oxide (CNO) was used to activate hM4Di DREADD. Electrophysiological analysis of excitatory neuronal suppression in the hM4Di-TG mouse brain was conducted both in hippocampal slices by synaptic responses and in vivo with induction of potassium-evoked cortical spreading depression occurrence. Ischemic stroke was induced by transient occlusion of the middle cerebral artery. Neurologic function and infarct volumes were evaluated.
Results. Activation of the inhibitory hM4Di DREADD by CNO led to a significant reduction in evoked synaptic responses in hippocampal slices. Likewise, potassium-induced cortical spreading depression episodes were diffusely inhibited, including frequency, latency to onset, and DC shift duration. With respect to physiology and motor function, hM4Di expression showed no overt effect in the absence of CNO, and CNO treatment alone did not induce any notable changes in control or hM4Di-TG mice. Finally, hM4Di-TG mice treated with CNO at either before ischemia or after reperfusion exhibited significantly improved neurologic function and smaller infarct volumes compared to CNO-treated control mice.
Conclusions. Our data indicate that acute inhibition of a subset of excitatory neurons after ischemic stroke can prevent brain injury and improve functional outcome. This study, together with the previous work in optogenetic neuronal modulation during the chronic phase of stroke, supports the notion that targeting neuronal activity is a promising strategy in stroke therapy.

Title: Gait endurance improves after vagus nerve stimulation combined with upper limb rehabilitation in ischemic chronic stroke, a case series

Authors: *A. VAN DE WINCKEL[1], S. GONZALES[2], D. K. KLINE[3], C. N. PRUDENTE[4], T. BISSON[2], K. L. FROST[5], D. PIERCE[4], B. TARVER[4], N. D. ENGINEER[4], T. J. KIMBERLEY[3]; [1]Dept. of Rehab Medicine, Div. of Physical Therapy, Div. of Rehabil. Sci., [2]Dept. of Rehabil. Medicine, Div. of Physical Therapy, Univ. of Minnesota Twin Cities, Minneapolis, MN; [3]Sch. of Hlth. and Rehabil. Sci., Massachusetts Gen. Hosp. Inst. for Hlth. Professions, Boston, MA; [4]MicroTransponder, Inc., Austin, TX; [5]Boston Scientific, St Paul, MN

Abstract: Introduction Recent studies demonstrated improved upper limb motor function by pairing vagus nerve stimulation (VNS) with upper limb motor rehabilitation in patients with chronic stroke. The goal of this case series study was to determine whether VNS/upper limb rehabilitation generalized to improved walking ability without specific gait training. **Methods** Six participants (3 female) with unilateral ischemic chronic stroke were randomized in a double-blinded, sham-controlled pilot that was a subset of a larger study. The average age was 63.33 ± 8.00 years (53-73 years), 5 left and 1 right hemiplegia; 18.00 ± 6.07 months post-stroke. All participants had left VNS implantation. The experimental group received 0.8 mA VNS stimulation with upper limb rehabilitation, 3x/week for 6 weeks (18 visits) involving more than 400 movement trials. The control group received the same rehabilitation but with sham-VNS (0.0mA). Participants, assessors and therapists were blinded to group allocation during the real-VNS versus sham-VNS treatment period. After 3 months, group allocation was revealed and the control group crossed-over to receive 6 weeks of 0.8mA VNS paired with rehabilitation. All patients received VNS combined with home-based upper limb rehabilitation in the follow-up period. Outcomes included 6 Minute Walk Test (6MWT), self-paced and fast-paced 10m walk test at baseline, post-test (6 weeks) and follow up assessments. **Results** For the 6MWT, the experimental group improved by 32.97 ± 20.63m at post-test, 39.72 ± 22.59m at 3 months and 31.92 ± 22.01m at 2 years follow-up compared to baseline. Two of three participants in the experimental group exceeded minimal clinical important difference (36.6m) in walking distance. While initial improvement of 8.89 ± 13.67m was seen post-training in the sham-VNS group, the group decreased -44.86 ± 24.67m walking distance at 3 months from baseline. They improved 44.1 ± 15.61m after 0.8mA VNS/rehabilitation and 48.86 ± 17.52m at 3 months, but declined -

16.48 ± 25.19m walking distance at 2 years follow-up, all compared to the original baseline. However, the control group practiced less at home (270.67 ± 50.62 sessions) compared to the experimental group (982.00 ± 307.44 sessions). Self-paced and fast-paced walking speed did not change appreciably during treatment in either group. **Conclusions** Gait endurance improved after VNS/upper limb training compared to sham-VNS/upper limb rehabilitation, even though there was no statistical significance given the small sample sizes. Gait speed does not appear to be impacted by VNS. This preliminary evidence suggests secondary gains following VNS may generalize beyond the trained activities.

Title: Effect of EMG triggered electrical stimulation with blood flow restriction technique on hand function in stroke survivors - A randomized controlled study

Authors: *N. CHOUDHARY;
Physiotherapy and Rehabil., Government Physiotherapy Col. (Dr. S.N. Med. College), Jodhpur, India

Abstract: Background and Aims: Post stroke upper limb impairment strongly influences disability and patient's quality of life. Blood flow restricted (BFR) exercise has been identified as a possible rehabilitation intervention. The objective of this study was to determine the effectiveness of electromyogram (EMG) triggered neuromuscular electrical stimulation (NMES) combined with BFR to improve arm strength and function in stroke survivors. **Methods:** 6 chronic stroke survivors were screened and randomized into experimental and control groups with n=3 each. Control group received standard upper limb rehabilitation intervention along with EMG triggered NMES to wrist extensors for 15 minutes once daily, 4 days a week for 10 weeks. Along with the standard interventions, subjects in the experimental group were given EMG triggered NMES to wrist extensors combined with BFR for 10 minutes (fig.1). Vascular occlusion was achieved using elastic wraps proximally on the arm just below the shoulder joint. The Fugl-Meyer (FM) motor assessment for upper extremity was the primary outcome measure. Motricity Index (MI), Box and Block test (BBT) and Barthel Index (BI) were secondary outcome measures. Clinical assessment was taken at baseline, after 5th week and at the end of 10th week. **Results:** Statistical analysis was conducted using SPSS 22. Scores of four outcome measure (FM, MI, BBT and BI) were compared using ANOVA and it was observed that there was a highly significant difference ($p > 0.01$) between these outcome measures. Further analysis in the scores of FM ($F= 12.067$), BBT ($F= 10.035$) and BI ($F= 7.538$) showed significant difference ($p > 0.01$) between control and experimental group whereas difference in MI scores were non-significant. **Conclusions:** EMG triggered neuromuscular electrical stimulation combined with BFR is a safe and feasible strategy for stroke rehabilitation to strengthen upper limb without using external weights.

Abstract: Lack of blood flow to the brain, i.e., ischemic stroke, results in loss of nerve cells and therefore loss of function in the affected brain regions. There is no effective treatment to improve

lost function except restoring blood flow within the first several hours. The purpose of this work was to examine the use of electrical stimulation on the impaired upper extremity to improve functional recovery after stroke. We developed an animal model using implanted electrodes onto the nerve of the paretic limb and applied daily electrical stimulation. The skilled forelimb reaching test and ladder rung bar walk test were used to evaluate functional outcome after stroke and electrical stimulation. We also used anterograde tracing from the layer V pyramidal neurons to evaluate possible formation of new neuronal connections from the contralesional cortex to the deafferented subcortical structures, such as the red nucleus, pons, and spinal cord. Our preliminary results indicate that our model of peripheral nerve electrical stimulation promotes recovery after stroke. The mechanisms underlying this recovery are presently under investigation.

Title: Serum BDNF levels by BDNF genotype in stroke patients

Authors: *W. CHANG, K. KIM, A. LEE, H. KIM, Y.-H. KIM;
Physical and Rehabil. Med., Samsung Med. Center, Sungkyunkwan Univ. Sch. of Med., Seoul, Korea, Republic of

Abstract: Introduction: Brain-derived neurotrophic factor (BDNF) is involved in neuronal survival, synaptic plasticity, learning and memory, and neuroplasticity in both the intact and the damaged brain. A single nucleotide polymorphism in the human BDNF gene at codon 66 (val66met) is present in one or both alleles. The replacement of val66 by met66 disrupts cellular processing, trafficking, and activity-dependent secretion of BDNF. However, there was a lack of study with serum BDNF according to BDNF genotype in stroke patients. In this study, we aimed to investigate the difference of serum BDNF level according to BDNF genotype in subacute stroke patients. **Methods:** Ninety-two stroke patients (mean age 63.1 yrs) were recruited in this study. All participants took the standard rehabilitation program included daily 2-hours of

physical therapy and 1-hour of occupational therapy, 5 days a week, for 2 weeks during subacute stroke phase (from 2 weeks after onset). We measured the serum BDNF, proBDNF and MMP-9 at T0 (before the standard rehabilitation program), and T1 (2 weeks after the standard rehabilitation program). In addition, all participants were assessed with NIH Stroke Scale (NIHSS) for stroke severity, Fugl-Meyer assessment (FMA) for motor function and for Korean Mini-Mental State Examination (K-MMSE) for cognitive function at T0 and T1. Data were analyzed by the BDNF polymorphism (Val/Val group vs. Met allele group). **Results:** 46.4% and 53.6% participants were classified into Val/Val and Met allele groups. Each stroke severity, motor and cognitive function showed significantly improvement after the standard rehabilitation program for 2 weeks in each group ($p<0.05$). There was no significant difference in serum BDNF at T0 between the two groups; however, proBDNF showed significant higher in Met allele group than Val/Val group ($p<0.05$). In Val/Val group, there was no significant difference in serum BDNF between T0 and T1. However, serum BDNF and proBDNF showed the increases from T0 to T1 in Met allele group, respectively ($p<0.05$). **Conclusion:** These results demonstrated that the polymorphism of BDNF may influence on the serum BDNF and proBDNF levels by the comprehensive rehabilitation in subacute stroke patients. Further study will be needed to clarify the role of serum BDNF in subacute stroke patients.

Title: Augmented-reality-based paretic arm training improves reaching performance by altering functional brain networks in chronic stroke

Authors: *P.-C. SHIH[1], A. VILLRINGER[1,2], B. SEHM[1,2];
[1]Neurol., Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany; [2]Day Clin. for Cognitive Neurol., Univ. Hosp. Leipzig, Leipzig, Germany

Abstract: Stroke-induced persistent arm paresis, and its detrimental consequences on life quality is a major challenge for neurorehabilitation research. Here we assessed behavioral and neuronal effects of an augmented-reality (AR)-based paretic arm training that aims to enhance task-specific function while preventing compensatory movements. Nineteen chronic stroke patients (age: 60.4±13.7 years, onset time 6.4±4.7 years ago) underwent an object-hit training in the AR environment using the exoskeleton system KINARM (BKIN Technologies Ltd, Ontario,

Canada). This device creates a well-controlled environment for movement training and assessment while restricting trunk compensation. The whole experiment lasted 8 weeks, with a four-week control period (only regular therapy), a four-week training period (AR-paretic arm training and regular therapy), and three measurement points (baseline, pre-training, and post-training). The training comprised twelve sessions (40 minutes/day, three days/week). At each measurement points, patients performed: (1) behavioral assessments, including daily activity tasks (Jebsen-Taylor Hand Function Test; JTHF) and basic reaching kinematic assessment (Visually-Guided Reaching test; VGR inside the KINARM); (2) MRI, including resting-state fMRI, elbow movement task-fMRI and structural scans. While no changes were found for the control period (pre-training vs. baseline), our training induced significant changes (post-training vs. pre-training) on behavior and functional MRI. Behaviorally, we found that patients did not only complete daily activity tasks more efficiently (completion time: from 355.44±67.36 sec to 340.30±66.32 sec, $p<0.001$), but also improved the trajectory accuracy during the basic reaching task (trajectory deviation: from 1.38±0.10 cm to 1.23±0.03 cm, $p<0.01$). Task-fMRI during paretic elbow movements revealed a reduction in BOLD signal in the anterior cingulate cortex (cluster corrected $p<0.05$) after training, a region related to error monitoring. Our findings demonstrate that a short-term augmented-reality-based paretic arm training induces brain plastic changes and further improve daily living activity in chronic stroke.

Title: Role of astrocyte-derived GDNF in neuronal protection and brain recovery after ischemic stroke

Authors: *Z. ZHANG[1], N. ZHANG[2], S. DING[1];
[1]Univ. of Missouri-Columbia, Columbia, MO; [2]Dalton Cardiovasc. Res. Ctr., Columbia, MO

Abstract: Astrocytes play a non-cell autonomous role in neuroprotection after ischemic stroke. Glial cell-derived neurotrophic factor (GDNF) was originally isolated from a rat glioma cell-line supernatant and is a potent survival neurotrophic factor. Focal ischemic stroke (FIS) is a leading cause of human death. Reactive gliosis and glial scar formation is a hallmark of FIS. Reactive

astrocytes experience dramatic spatial and temporal changes of morphology and gene expression in peri-infarct region (PIR). Here, we investigated whether and how reactive astrocytes-derived GDNF affects neuronal death and brain damage after FIS. Using *CreER^{T2}-LoxP* recombination technology, we generated inducible and astrocyte-specific Gdnf conditional knockout (cKO), i.e., *Glast-Gdnf$^{-/-}$* cKO mice to investigate the effect of endogenous astrocytic GDNF on neuronal death, brain damage, and recovery after photothrombosis (PT)-induced FIS. Under non-ischemic conditions, we found that *Glast-Gdnf$^{-/-}$* cKO mice exhibited significant lower number of Brdu+ and Ki67 cells as well as DCX+ cells in the dentate gyrus (DG) in hippocampus in adult mice, indicating astrocytic GDNF can promote adult neurogenesis. Under ischemic conditions, *Glast-Gdnf$^{-/-}$* cKO mice had a significant reduction in infarct volume after 2, 4 and 14 days after PT as compared with WT litter mates after PT. *Glast-Gdnf$^{-/-}$* cKO mice also exhibited a significant reduction in FJB+ degenerating neurons in PIR. Moreover, *Glast-Gdnf$^{-/-}$* cKO mice had lower densities of Brdu+ and Ki67+ cell in the PIR than WT mice, indicating that astrocytic GDNF can promote cell proliferation in the PIR. Furthermore, behavioral tests showed that deletion of GDNF caused more motor deficits after stroke and low recovery. In summary, our study suggests that reactive astrocytes-derived GDNF plays important roles in reducing neuronal death and brain damage through neural regeneration in PIR after PT, and promoting endogenous neurotrophic factor release from reactive astrocytes might be a potential therapeutic approach in stroke therapy.
Key words: Focal ischemic stroke; penumbra; neuronal death; brain infarct; astrocytes; Glast; PT; cKO mice

Title: Optimizing conditions for labeling bone marrow stem cell with multifunctional near-infrared dye-magnetic nanoparticles for cells homing and tracking analysis in global cerebral ischemic model

Authors: *M. P. NUCCI[1,2], I. S. FILGUEIRAS[2,3], J. V. M. FERREIRA[2], P. C. MACHADO[2], J. B. MAMANI[2], F. A. DE OLIVEIRA[2], G. N. A. REGO[2], P. ESPINHA[2], L. E. B. DE SOUZA[4], D. M. C. FANTACINI[4], A. T. KONDO[2], D. T. COVAS[4], L. F. GAMARRA[2];

Abstract: Optimizing conditions for the labeling process in bone marrow stem cells (BMSC) was performed with different concentrations of multifunctional near-infrared dye-magnetic nanoparticles (MFNP): 10, 30 and 50 µgFe/mL, 10^6 cells/well were plated into 24 wells plate with 2mL of RPMI medium (10% SFB), in order to determine the best concentration in the internalization process. The process was performed in three magnetic conditions: without magnet, with static magnet (placed below the culture wells) and with dynamic magnet (oscillating in the frequency of 0.25Hz), with and without filtration (0.45µm filter), as also in different incubation times: 3, 6, 10, 18 and 24 hours. In each condition analyzed was evaluated the cellular viability by MTT and BLI assays. The quantification of MFNP internalized was analyzed by ICP-MS, near-infrared fluorescence (FLI) and MRI. After determining the best condition of the internalization of MFNP into BMSC, these cells were administered via tail in rats (N=20) with global cerebral ischemia (Pulsinelli et al., 1979), that is the permanent occlusion of bilateral vertebral arteries and temporary occlusion of bilateral common carotids arteries. The homing and tracking of MSC labeled with MFNP after implanted in the rats were evaluated by BLI, FLI, and MRI at 1, 3, 7 and 14 days. The best condition of the internalization of MFNP into BMSC was with the dynamic magnet (32,7ng/10^6cells) as showed by Prussian blue, ICP-MS and FLI, had a higher concentration in comparison with the static magnet with 10,3ng/10^6cells and without magnet 6,4ng/10^6cells. The best incubation time was with 10 hours, following this time was observed a plateau until 18 hours, finalized with an internalization decay, this fact can be explained considering the exocytosis process of the MFNP by BMSC. The cellular viability for all concentrations and incubation times was low than 9%. Using the best condition of MFNP labeling, after one day of cells implantation was possible to detect in the global cerebral ischemia model the BMSC homing and tracking by FLI (3,21x10^8 photons/s) and BLI (8,21x10^8 photons/s) and with lower sensitivity by MRI. After 7 days of cells implantation, the FLI signal was lower 3,4x10^7 photons/s, but the BLI signal increase to 3,4x10^9 photons/s. In the control animals were not possible to localize in the brain the BMSC labeled with MFNP. The ICP-MS quantification of *ex vivo* brain showed a MFNP load proportionate to found by FLI (1d: 8ng, 3d: 7.3, 7d: 3.2ng e 14d: 0.5ng). Therefore, the optimization of internalization parameters of the MFNP into stem cells is essential to analyze the cells homing and tracking for a long time during the cellular therapy process.

Title: No evidence of functional peri-infarct circuit remapping in mouse somatosensory cortex after ischemic stroke

Authors: *W. ZEIGER[1], M. MAROSI[2], S. SAGGI[1], C. HE[1], C. PORTERA-CAILLIAU[1]; [1]Neurol., Univ. of California Los Angeles, Los Angeles, CA; [2]Femtonics, Budapest, Hungary

Abstract: Stroke is the fifth leading cause of death and the leading cause of adult disability in the United States. While advancements have been made in prevention and acute treatment of stroke, there is currently a paucity of treatments aimed at improving recovery. Many patients exhibit partial spontaneous recovery, suggesting that the brain has endogenous mechanisms to restore lost functions. The process by which one area of the brain subsumes the function previously performed by an area damaged by stroke is termed remapping. Strong evidence supports a role for peri-infarct cortex in remapping of function following stroke; this area undergoes structural, physiologic, and transcriptomic changes during recovery, but the downstream effects on cortical circuits are largely unknown. Here, we targeted photothrombotic (PT) strokes to individual barrels in the barrel field of mouse primary somatosensory cortex, sparing neighboring barrels. We hypothesized that spared barrels in the peri-infarct homotopic cortex would take over the 'lost' functionality by responding to the whisker. Initially, we used longitudinal intrinsic signal imaging (ISI) through chronically implanted cranial windows before and after a PT stroke to the C1 barrel but found no evidence of remapping (i.e., regions that responded to C1 whisker stimulation) anywhere in the peri-infarct region even up to one month after stroke. However, it is possible that the remapping process involved small numbers of neurons that would not evoke a sufficient signal to be detected by ISI. Therefore, we turned to *in vivo* two-photon (2P) calcium imaging in *Thy1*-GCaMP6s transgenic mice before and after a PT stroke to the C1 barrel to monitor whisker-evoked responses of individual layer 2 /3 neurons in the adjacent D3 barrel. At baseline (before stroke), ~25% of active neurons in the D3 barrel respond to stimulation of the D3 whisker, but only ~8% of neurons respond to the C1 whisker. Although we predicted that the percentage of C1 whisker-responsive neurons in the intact D3 barrel would increase after stroke, we found that only ~2% of neurons in the D3 barrel responded to C1 whisker stimulation, even at one month after stroke. These results suggest that the spared, peri-infarct homotopic barrel cortex is not involved in functional remapping after stroke, despite evidence of structural plasticity. We are presently testing whether additional factors that drive plasticity are required to recruit neurons in peri-infarct cortex in remapping lost functionalities. Our data implicates other mechanisms (e.g., subcortical) in functional recovery after stroke.

Title: Effects of environmental enrichment on the expression of presynaptic active zone proteins in the brain of hypoxic-ischemic encephalopathy

Authors: *S.-Y. SONG[1,3,4], S. PYO[1,3,5], H.-S. OH[1], J. YU[1,3], Y.-K. SHIN[1,3], A. BAEK[2], J. SEO[1,3], S. WI[1,3], B.-G. NAM[1,3,4], E. CHO[1,3,5], S. JO[1,3,5], H. JEONGHYUN[1,3,4], J. CHOI[6], S.-R. CHO[1,3,4];

Sci., Yonsei Univ., Seoul, Korea, Republic of; [6]Chungnam Univ. Col. of Med., Daejeon, Korea, Republic of

Abstract: Hypoxic ischemic encephalopathy (HIE) is a disease of the brain caused by the lack of perfusion to the brain. The need for an effective treatment of ischemic brain disease is all the more increasing, but the current treatment fails to achieve full recovery and the mechanism of its recovery is not well understood.The brain is an organ that is capable of modify itself as a response to environmental stimuli. Environmental enrichment (EE), which consists of complex combinations of physical, cognitive, and social stimuli, is a therapeutic approach that employs this trait of plasticity.
However, not many are known about the changes in the expression protein molecules that EE can bring. Through this study, we focus on how EE can enhance synaptic plasticity in the protein level, and lean toward the specific mechanisms of how rehabilitation can affect synaptic plasticity.
At six weeks of age, the mice were randomly assigned to either EE or standard cages (SC) for two months.Rotarod, and ladder walking tests were performed to evaluate neurobehavioral function. In order to identify synaptic plasticity-regulating genes regulated by EE, a qPCR and western blotting were used to measure the expression in cortex, basal ganglia and hippocampus. Among the synaptic plasticity-regulating genes, the expression of Active zone and Ca^{2+} channel proteins was also confirmed.The level of synaptic plasticity-regulating genes was significantly higher in the cortex, basal ganglia and hippocampus of EE mice at 8 weeks.
By exposing HIE models to EE, we seek to induce changes in the synaptic plasticity, and the

consequent changes in the expression of neurons, presynaptic active zone protein such as RIM, and behavior. RIM activate priming by disrupting Munc 13 homodimerization vesicle fusion, and Ca^{2+} ion channel would occur and induce synaptic plasticity. The dynamics of synaptic plasticity comes from the changes of these molecules. As a result, mice exposed to EE showed significant improvements in rotarod and ladder walking performances compared to SC mice. To summarize, we confirm that EE induces recovery of the motor function by studying animal models' behavior, and we attribute the recovery to the significant increase in presynaptic proteins such as RIM in the brain. By studying the functions of these presynaptic proteins, we hope to shed light on the understanding of damage recovery in various brain/neural disease.

Abstract: A major obstacle to achieving recovery of motor function following stroke lies in the debilitating effects of muscle spasticity, e.g. the inability to inhibit activity in flexor muscles when attempting to perform an extension at the wrist. According to Aguiar et Baker (2018), in healthy subjects when one activates wrist extensor muscles 30ms or 70 ms prior to perform an H-reflex test on wrist flexors, one can observe a facilitation of flexor H-wave responses for the former and an inhibition for the latter. According to these studies, the facilitation depends on Ib afference from wrist extensor and on Ia afference from wrist flexors. They have also shown that corticospinal tract is involved in this facilitation and inhibition. In stroke patients, however, they have shown that the inhibition of the flexor H-reflex response due to wrist-extensor stimulation disappears and is replaced by facilitation. This observation means that when stroke patients try to activate the wrist extensor there is an augmentation of the reflex activity in wrist flexors, leading to a disruption of the inhibition needed to successfully perform an extension of the wrist. Based on these mechanisms, the cessation of wrist-flexor inhibition (i.e. spasticity) in stroke patients could have at least two origins: 1) loss of supraspinal inhibition for wrist flexors and/or 2) loss of spinal inhibition due to insufficient activation of extensors.
When applying a recently proposed system for post-stroke rehabilitation that relies on a brain-machine interface (BMI) coupled to a robot to move the paretic arm, overcoming spasticity has proven to be a major hurdle. In the last decades, however, fundamental and clinical research has shown positive effects of mirror therapy for the recovery of arm and hand function. Based on the studies described above, we hypothesized that by using movements 1) encourages central inhibition of tonic flexor activity and 2) increases motor unit recruitment of wrist extensors, we could use mirror therapy to reduce the spasticity of the limb. We therefore asked a chronic stroke patient to perform mirror therapy with 1) ballistic movements that require inhibition of tonic activity by premotor cortex and 2) movements against resistance to increase the required extensor activation and further suppress flexor activity via the inhibitory action of 1b reafference. Here we will show decreases in wrist and finger flexor activity and increases of wrist and finger extensor activity during mirror therapy that has been targeted to reduce spasticity at the wrist and fingers, as described above. This was observed following 20 months of BMI training coupled with mirror therapy and active movements.

Title: BCI-controlled functional electrical stimulation and robotic glove assistance for upper limb motor rehabilitation in severely impaired chronic stroke patients within a longitudinal personalized trial: The avancer clinical trial approach

Authors: C. BIGONI[1], E. BEANATO[1], **A. ESPINOSA**[2], A. CREMA[3], M. COSCIA[2], M. J. WESSEL[1], G. SPIGONI[2], S. MICERA[1], *T. L. LAABS[2], N. BIRBAUMER[2], F. C. HUMMEL[1]; [1]Ecole Polytechnic Federale de Lausanne, Lausanne, Switzerland; [2]Wyss Ctr. for Bio and Neuroengineering, Geneva, Switzerland; [3]Univ. of Geneva Med. Sch., Geneva, Switzerland

Abstract: Upper limb motor deficits in severe stroke survivors often remain unsolved. Novel neurotechnologies may support upper limb motor recovery in this subgroup if suitably combined and administered. We propose a personalized, neurotechnology-based upper limb rehabilitation strategy using a two-to-one individual based cumulative longitudinal intervention combining different neurotechnologies. Two interventional steps are provided sequentially. In the first one, a hybrid BCI able to non-invasively detect motor intention triggers a robotic glove that assists-as-needed paretic hand movements, and supramotor threshold FES to activate 6 muscles of the affected upper limb to induce movements of different complexity. Motor intention is detected from up to 16 EEG channels and from the EMG activity of up to 8 muscles in the paretic arm. The motor rehabilitation exercises include upper limb mobilization and functional tasks. In the second step, 20 minutes of tDCs of the motor cortex is administered on top of the previous intervention. Switch from the first to the second intervention and from the second to the end of therapy is individualized on the ongoing functional improvement, continuously monitored with the wrist and hand sections of the Fugl-Meyer scale, when this reaches an individual functional plateau. Clinical and quantitative assessments are longitudinally performed, including structural and functional MRI, TMS and EEG-/EMG-based evaluations. Up to 40 severe hemiparetic chronic stroke patients will be enrolled in 2 groups. One group will start immediately the therapy upon recruitment; the other will start the therapy three months after to assess spontaneous motor recovery (control condition). The individual patient study design allows each patient to train as long as necessary to achieve a maximal treatment magnitude and functional improvement. The study design allows to compare the impact of each therapy step within and between individuals, contributing to extend the knowledge on the dynamics and mechanisms of neurorehabilitation processes. Compared to ‘one suits all’ treatment strategies, such a personalized interventional strategy offers an ideal scenario to maximize treatment effects in severe chronic patients in whom no further spontaneous remission is expected.

Title: A novel gene therapy approach to treat hemorrhagic stroke in mouse striatum through direct astrocyte-to-neuron conversion technology

Authors: *F. YANG[1], Y. CHEN[2], X. HE[2], Z. LIU[2], G. CHEN[3];
[1]The Dept. of Biol., [3]Biol., [2]The Pennsylvania State Univ., University Park, PA

Abstract: Intracerebral hemorrhage (ICH) is induced by rupture of arteries in the brain as a result of hypertension, aneurysm or other blood vessel abnormalities. Low oxygen environment induced by ICH causes reactive astrogliosis, neuronal death and corresponding functional deficits. Currently, none of the treatment methods provide an effective way to rescue the loss of neurons. Our lab previously demonstrated that reactive astrocytes in the ischemic injured cortex can be directly converted into functional neurons through overexpression of a single transcriptional factor NeuroD1 (Chen et al., BioRxiv, 2018). In this work, we use collagenase to induce ICH in mouse striatum, and then use adeno-associated virus (AAV) to overexpress transcription factors in the reactive astrocytes induced by ICH. After 3 weeks, we found a substantial number of the AAV-infected astrocytes showed neuronal morphologies, and were immunopositive for neuronal marker NeuN. Many of these astrocyte-converted neurons were also immunopositive for GABA and DARPP32, which are typical markers for the medium spiny neurons in the striatum. We also found that the infarct volume caused by ICH decreased after astrocyte-to-neuron conversion according to the MRI imaging analysis. We are currently conducting behavioral tests to investigate whether our novel gene therapy approach can promote functional recovery after *in vivo* astrocyte-to-neuron conversion in the ICH mouse model. Our research suggests that direct astrocyte-to-neuron conversion technology may provide a novel therapeutic treatment for ICH through high efficiency of neuroregeneration to replenish the lost neurons.

Title: The intensity of vagus nerve stimulation determines efficacy in improving recovery or motor function after stroke

Authors: *T. DANAPHONGSE, D. PRUITT, M. LUTCHMAN, N. PATEL, P. REDDY, V. WANG, A. PARASHAR, M. KILGARD, S. HAYS;
The Univ. of Texas at Dallas, Richardson, TX

Abstract: Vagus nerve stimulation (VNS) paired with rehabilitative training enhances recovery of function in multiple animal models of stroke and brain injury and is currently under investigation for use chronic stroke patients. Identification of the most effective methods for delivering VNS is of crucial importance to maximizing therapeutic benefit. Previous studies suggest that VNS-dependent recovery of motor function is supported by plasticity within central networks, and the extent of invoked cortical plasticity is determined by varying parameters such as stimulation intensity. In this study, we sought to determine the optimal stimulation intensity to maximize recovery of motor function after stroke. Rats trained on the supination assessment task were given ischemic lesion in motor cortex and separated into groups receiving varying stimulation intensities (0.4 mA, 0.8 mA, and 1.6 mA) paired with post-lesion motor training. Our data indicates that 0.8 mA stimulation intensity results in maximal motor function recovery when compared to other stimulation intensities. Functional recovery also generalized to an untrained task that assessed forelimb use asymmetry. We then injected a retrograde tracer virus into the trained forelimb to investigate whether corticospinal connectivity was associated with motor function recovery. Rats receiving 0.8 mA VNS demonstrated significantly greater corticospinal connectivity than rats in other groups. The results of this study suggest stimulation intensity determines efficacy of VNS therapy when paired with motor training, and that 0.8 mA proves more effective than other intensities that were tested.

Abstract: Stroke survivors are often left with chronic disability due to hemiparesis of the upper limb, even after medical and rehabilitation care. Adjunctive therapies that can enhance neuroplasticity during effective motor rehabilitation (RT) is a current focus in the field. One such promising therapy is remote limb ischemic conditioning (RLIC) which is a safe and non-invasive procedure that consists of causing shorts bouts of ischemia to a limb. RLIC has been shown to enhance the learning of motor tasks in healthy adults (Cherry-Allen et al., 2015; 2017; Sutter et al.,2018). However, recent findings suggest that RLIC does not improve motor recovery compared to RT alone in the subacute phase, at least not in middle-aged rats (Barksdale et al., 2018, SfN abstract). The aim of these studies was to determine the effect of RLIC on motor recovery when added to RT during the chronic phase in middle-aged rats and in the subacute phase in young adult rats. Male Long-Evans rats were trained on the single pellet reaching (SPR) task until proficiency was reached and then a surgery was performed to model a cortical stroke by applying endothelin-1 to the caudal forelimb area of the motor cortex. Rats were aged 8 mos in the chronic study and 4-5 mos in the subacute study. RT was started 7 days in the subacute study or 6 weeks post-op in the chronic study and consisted of SPR for 60 trials every day for 14 days. RLIC was administered every 48 hours during RT. RLIC consisted of a blood pressure cuff being applied to the hindlimb and inflated above 200 mmHg for 3 cycles of 5 minutes on and 5 minutes off under isoflurane anesthesia. A control group did not have the blood pressure cuff inflated but was kept under isoflurane for the same amount of time. Ischemia was confirmed by skin temperature drop and/or color change of the hindlimb paw. Performance on the SPR, Schallert Cylinder, and Foot Fault tasks was assessed pre-op, post-op, and post-RT. Current results suggest that RLIC does not enhance motor recovery in the chronic phase of stroke in middle-aged rats. Preliminary data will be presented on the effects in the subacute phase in young adult rats.

Title: Direct reprogramming of reactive astrocytes to mature neurons reduces Glia scare formation and enhances neuronal repair after ischemic stroke

Authors: *M. Q. JIANG[1], S. YU[1], L. WEI[2];
[2]Dept. of Anesthesiol., [1]Emory Univ., Atlanta, GA

Abstract: Regenerative therapies including cell transplantation have been extensively investigated in recent years for the treatment of CNS injuries such as stroke. In the present investigation, we explored an innovative stroke treatment of reprogramming endogenous astrocytes into induced neurons (iNeurons) for neuronal repair after focal ischemic stroke. A mCherry tagged NeuroD1 lentivirus was generated under a mouse GFAP promoter for *in vitro* and *in vivo* infections. Cultured astrocytes expressing mCherry/NeuroD1 adopted neuronal morphology and expressed neuronal markers Tuj-1, NeuN, and synaptic proteins 2-4 weeks after infection. Proliferation was drastically reduced compared to control cultures. Converted cells developed significantly longer processes (>20-100 mM) inspected at 6 weeks after infection. A focal ischemic stroke of the right sensorimotor cortex was induced in adult GFAP-Cre x Rosa-YFP mice. Astrocytes from this mouse remain YFP positive regardless of cell phenotype. The lentivirus containing mCherry-NeuroD1 and the GFAP promoter was injected into the peri-infection region 3 days after stroke, which transduced ~10% of reactive astrocytes accumulated in the peri-infarct region. Six weeks later, converted cells were identified by the co-labeling of YFP (the astrocyte origin marker), mCherry (the marker for NeuroD1 transduction), and NeuN (mature neuron marker). Around ~60% of converted cells expressed NeuN and showed neuronal morphology. Western blot assay of the peri-infarcted region detected significant higher levels of BNDF and FGF10 in NeuroD1-transfected mice compared to animals received empty vector. Meanwhile, the area of gliosis noticeably decreased. Stroke mice received NeuroD1 transfection performed significantly better in the rotarod test and corner test and showed a preventive effect

on chronically developed depressive behavior 4 months after stroke. Thus, astrocyte to neuron reprogram enforces parenchymal neurogenesis and helps to improve functional recovery after stroke.

Title: A novel approach for training eye hand coordination using tracking sensors with emerging user interface in chronic stroke survivors - A randomized controlled study

Authors: *M. CHOUDHARY[1], N. CHOUDHARY[2];
[1]Shree IG Hosp. and Active Hlth. Ctr., Jodhur, India; [2]Physiotherapy and Rehabil., Government Physiotherapy Col. (dr. S.N. Med., Jodhpur, India

Abstract: Background and Aims
Eye-hand coordination is essential for humans, as many activities in daily life require precise eye and hand functions. The stroke survivors have poorer eye-hand coordination when using their hemiparetic hand. A significant correlation exists between eye-hand coordination performance and hand function test scores. The aim of this study was to develop a low cost system for testing and training eye and hand coordination using gamification as a tool for improving hand function in chronic stroke patients.
Methods
6 subjects (mean age 63.2± 4.3 years) with chronic stroke were screened and randomized into experimental and control groups with n=3 each. Both groups received 1 hour of standard upper limb physical therapy, 6 days a week for total 4 weeks. Experimental group also played a customized eye hand coordination game called "HandEye" using Tobii Eye X® and Leap Motion® for 3 sessions of 2 minutes each. Primary outcome measure was BBT (Box and Block Test).
Statistical Analysis
Statistical analysis was done using SPSS version 22. The change in outcome measure from pre to post intervention was evaluated separately in each group and compared using ANOVA. A p-value of less than 0.05 was considered as significant. The correlation between eye hand coordination testing and primary outcome measure was done in the experimental group using Pearson’s correlation coefficient.
Results
A significant improvement in scores of BBT was found in both experimental (F=234.244,

p<0.001) and control (F=85.099, p<0.001) group from pre to post intervention but the change in BBT scores were higher in experimental group. The difference between change in BBT scores from pre to post intervention were significant (F= 52.071, *p*<0.001). Pearson's correlation analysis revealed a highly positive relationship (r^2 = 0.604; p <0.01) between scores of HandEye and BBT of the hemiparetic extremity in the experimental group.

Conclusion

Natural user interface technology and gamification techniques can be useful for hand rehabilitation in stroke survivors.

Title: Differences in functional recovery and kinematic reach analysis after task specific and task non-specific rehabilitation in a mouse model of stroke

Authors: R. TOMAZIN[1], A. GOURLEY[1], E. STANKUTE[1], L. EBERT[1], *A. L. KERR[2]; [2]Psychology, Neurosci., [1]Illinois Wesleyan Univ., Bloomington, IL

Abstract: Stroke results from a blockage in blood supply (ischemic) or a bleed (hemorrhagic) in one hemisphere of the brain. Worldwide, approximately 10 million people are left with moderate to severe disability due to stroke, with the most common deficit being upper extremity impairment. Current stroke rehabilitation strategies utilize task specific training of a skill, meaning one practices the specific skill they want to regain. However, it is possible that there are more transferrable types of rehabilitation that target skilled use can generalize to similar tasks and may be as effective in rehabilitating debilitated skills. The current study utilized several skilled reaching tasks (e.g., the Pasta Matrix Reaching Task and the Single Pellet Reaching Task) in a photothrombotic mouse model that show parallels to human dexterous movements in order to observe the functional effects of task specific versus task non-specific upper extremity rehabilitation post-stroke. We also used kinematic analysis of the SPRT to understand the quality and differences of skilled reach behaviors between groups after stroke and rehabilitation. All mice were pre-operatively trained on the SPRT to establish the skill. Following photothrombotic stroke, mice were separated into three groups for a total of 10 days of rehabilitative training: SPRT (task specific), PMRT (task non-specific), and control. Following 10 days of rehabilitative training, all mice were again assessed on the SPRT. Though we did not detect differences in functional outcome between animals receiving SPRT or PMRT rehabilitative training, we did observe significant differences in degree of abnormality of the skilled reach post rehabilitative training between task-specific, task non-specific, and control rehabilitative training groups. This may indicate that task specific rehabilitative strategies may promote more true recovery due to the lesser degree of abnormalities in movement post-training as compared to task non-specific therapy and control groups. Task non-specific training, while beneficial for functional outcome, may result in more compensatory movements.

Title: Intermittent rehabilitative training is protective, but not functionally beneficial, following stroke in C57BL/6 mice

Authors: *V. NEMCHEK[1], E. M. HAAN[1], V. PAVLIK[1], A. L. KERR[2];
[2]Psychology, Neurosci., [1]Illinois Wesleyan Univ., Bloomington, IL

Abstract: Stroke is a leading cause of disability worldwide. Focused training of the impaired limb has been shown to improve its functional outcome in animal models. However, most human stroke survivors exhibit persistent motor deficits. While there are many possibilities to explain these discrepancies, one likely contributing factor is the difference in rehabilitation intensity between experimental (animal) and clinical (human) settings. The current study investigated the effect of training intensity on behavioral outcome in a mouse model of stroke. After learning a skilled reaching task, mice received a unilateral photothrombotic stroke to the forelimb representation area of sensorimotor cortex, affecting the preferred reaching limb. Post-operatively, animals received either daily rehabilitative training, intermittent rehabilitative training (every other day), or no rehabilitative training. Each training group completed 14 total rehabilitation sessions; the daily group completed them in 14 days and the intermittent group competed them in 28 days. Assessment of the impaired limb after rehabilitation illustrated that daily training resulted in significantly better performance than no training. The intermittent group fell between the other two groups, being statistically significantly different than both daily training and no training conditions. Interestingly, intermittent training appeared to protect against functional decline observed in control mice, which did not train, without improving reach ability beyond the initial stroke deficit. Our results indicate that intensity of rehabilitation is important for optimal recovery, with intermittent training being enough to protect against functional decline but not enough to provide significant behavioral gains.

Title: Serum levels of BDNF in subacute and chronic stage after stroke

Authors: *K. KIM[1], H. KIM[2], A. LEE[2], Y.-H. KIM[2], W. CHANG[3];
[1]Samsung Med. Center, Sungkyunkwan Univ. Sc, Seoul, Korea, Republic of; [2]Samsung Med. Center, Sungkyunkwan Univ. Sch. of Med., Seoul, Korea, Republic of; [3]Physical and Rehabil. Med., Samsung Med. Ctr., Seoul, Korea, Republic of

Abstract: Introduction: Brain-derived neurotrophic factor (BDNF) is involved in neuroplasticity in both the intact and the damaged brain. Although serum BDNF is used as a biomarker in major depressive disorder and bipolar disorder, there was a lack of reports with serum BDNF about neuroplasticity in stroke patients. In this study, we aimed to investigate the potential of BDNF as biomarker in neuroplasticity by serial analyzing the serum BDNF from subacute to chronic stage in stroke patients. **Methods:** Ninety-two stroke patients (mean age 63.1 yrs) were recruited in this study. We measured the serum BDNF, proBDNF and MMP-9 at T0 (2 weeks after onset), T1 (4 weeks after onset) and T2 (3 months after stroke onset) in each participant. In addition, all participants were assessed with NIH Stroke Scale (NIHSS) for stroke severity, Fugl-Meyer assessment (FMA) for motor function and for Korean Mini-Mental State Examination (K-MMSE) for cognitive function at three time points. Repeated measures ANOVA with Bonferroni correction were performed to determine the serial change from T1 to T3. **Results:** Each stroke severity, motor and cognitive function showed significantly improvement from T0 to T2 ($p<0.05$). There was no significant difference between serum BDNF at T0 and T1. Serum BDNF at T0 and T1 tended to higher than that at T2 without statistical significance. ProBDNF and MMP-9 significantly decreased serially from T0 to T2. In addition, proBDNF and MMP-9 showed significantly higher at T0 and T1 than T2, respectively ($p<0.05$). **Conclusion:** It is well known that the neuroplastic potentials decrease from subacute to chronic stage in stroke patients. Therefore, the results in this study may suggest that serum proBDNF and MMP-9 could be used as biomarker for neuroplasticity in stroke patients. However, further study should be needed to clarify these results considering functional improvement in stroke patients. Title: Effects of closed head injury on short term memory in rats

Authors: *O. MARTÍNEZ GUZMAN[1], M. CACERES-CHACON[1], M. RIVERA-LÓPEZ[1], R. Y. RAMOS-SÁNCHEZ[2], D. M. OJEDA[2], D. SIERRA-MERCADO[1];

Abstract: Approximately 4 million cases of traumatic brain injury occur yearly in the United States. The most common form of brain injury, concussion, is frequently seen in sports and combat. The brain movement within the skull caused by concussion leads to diffuse axonal injury through tearing of neuronal axons, which may lead to motor and cognitive dysfunction. However, the susceptibility of specific behaviors such as short-term recognition memory to concussion remains unclear. We hypothesize that concussion will impair short-term memory. Concussion can be modeled in rodents with a closed head injury (CHI). Here, a guide tube was placed above the head of anesthetized male rats, and a 260g weight was dropped from a height of 42cm, impacting the animal's head. At impact, free rotation of the head downward occurred due to displacement of the underlying surface. To assess the effects of CHI on memory, a novel object recognition test (NOR) was performed (Sham: n=4, CHI: n=4,). In the NOR, a rat is placed in an open field with a familiar and novel objects and time spent with each object is recorded. CHI caused a decreased ratio of time spent with the novel object (Sham: 0.41, CHI: 0.65; p=0.0461) indicating a deficit in a short-term recognition memory. To test for motor deficits, distance traveled, and speed were recorded in an open field. Notably, no motor deficits were detected. Thus, cognitive deficits may occur independent of effects on motor function. Next, we will assess activity in brain regions involved in recognition memory.

Abstract: Glutamate is known to be released into the extracellular space immediately after concussion in a rat fluid percussion model. Another important transmitter in the brain is adenosine triphosphate, although the trend of adenosine triphosphate after concussion is not known. We used a close head injury model to create concussion and measured the value of glutamate and adenosine triphosphate by a biosensor before and after injury. Glutamate value increased immediately following injury as reported previously. The adenosine triphosphate value in the extracellular space raised immediately after insertion of biosensor in a non-injured rat cortex due to stab wound injury. But the adenosine triphosphate value of the injured rat showed higher value compare to non-injured rat. Western blot analysis did not show increase of activated microglia at least after single concussion injury.Both glutamate and adenosine triphosphate are released immediately after concussion injury in rat.

Title: Astrocyte injury defined biomarker associate with neuro-vascular unit compromise acutely after rat controlled cortical impact

Authors: *I. B. WANNER[1], H. ABDIRAHMAN[1], I. BONACORSI[1], V. PARRILLI[1], M. WALKER[2], N. HARRIS[2];
[1]Semel Inst., [2]Dept. of Neurosurg., UCLA, Los Angeles, CA

Abstract: Key for translating preclinical neurotrauma studies into clinic are the use of same noninvasive biomarkers. Traumatic brain injury (TBI) compromises neurovascular unit integrity with risk to neurological function. The pericontused cortex is an urgent clinical priority as tissue

surrounding the impact site has potential for recovery. This project established reproducible cytometric and noninvasive biomarkers acutely after controlled cortical impact (CCI) in adult male and female rats. Novel astrocyte injury defined (AID) biomarkers were used to define acute TBI phenotypes and to link biofluid and cellular injury metrics. AID biomarkers were aldolase C (ALDOC), glial fibrillary acidic protein breakdown products (GFAP-BDPs), glutamine synthetase (GS) and astrocytic phosphoprotein 15 (PEA15, Halford et al., 2017). Rat immunoglobulin (IgG) levels marked blood-brain barrier breach and blood extravasation on coronal vibratome sections. Glial and vascular injuries were compared to neuronal damage measured by pan-neurofilament (NF) and NeuN. Images were systematically analyzed using thresholding and structural feature segregation in Fiji. Cerebrospinal fluid (CSF) was drawn via cisterna magna puncture. Serum from tail vein blood was depleted using albumin-binding magnetic beads. Biofluids and recombinant protein calibrants were measured by immunoblotting with rat IgG-preadsorbed antibodies. Pericontused gray matter was defined by engorged veins, via MRI and histology, by interstitial bleeding and by NeuN reduction. Pericontused neuropil had reduced NF levels and a unique profile of fiber fragmentation. Automated skeleton analyses of GS signals documented fewer processes in pericontused versus sham astrocytes. Intact gray matter astrocytes had high levels of somatic ALDOC whereas pericontused swollen astrocytes were ALDOC depleted. Disperse interstitial and capillary ALDOC signals were measured and validated by recombinant ALDOC competition. ALDOC, GS and PEA15 levels were elevated in CSF and serum acutely (30 min - 5 hrs) and 24 hrs after CCI versus sham. GFAP-BDPs were elevated at 24 hrs postinjury in CSF and serum. Hemorrhagic injury cores had damaged astrocytes displaying a pathological GFAP pattern. In conclusion, AID markers defined astroglial injury types that coexist with neuronal and vascular injuries. They manifest acutely compromised neuro-vascular units in the pericontused cortex that were distinct from the impact core. Thus, AID biomarkers act as noninvasive surrogates of these injury types. Biomarkers of brain tissue compromise and loss can facilitate diagnosis, classification and treatment monitoring of TBI patients.

Abstract: A traumatic brain injury (TBI) experienced early in life affects developmental and functional outcomes, especially when left untreated. Clinical and experimental TBI disrupt cognitive performance, for which a critical need arises to develop rehabilitation strategies that mitigate cognitive and motor deficits. We hypothesized that rehabilitation targeting spatial and contextual memory circuits would prevent the onset of injury-induced cognitive impairments in juvenile rats. Rehabilitation occurred in a box with a peg board floor (24”x24”) that allowed 3” plastic pegs to be inserted at 1” intervals in designated layouts (Peg Forest Rehabilitation; PFR). Male and female juvenile rats (post-natal day 35; n=24) were subjected to sham or midline fluid percussion injury. Beginning one week post-injury, rats were exposed to either PFR or cage control exploration (15 min/day). PFR allowed free navigation through random configurations of the peg-filled arena for 10 days over 2 weeks. Control rats remained in their home cage in the center of the arena with the peg-board removed for 15min/day/10days. One week post-rehabilitation (1 month post-injury), cognitive performance was assessed for short-term (novel object recognition; NOR), long-term (novel location recognition; NLR), and working (temporal order recognition; TOR) memory performance calculated as a discrimination index between novel and familiar objects. An overall effect on NOR discrimination index existed in females ($F(3,8)=4.050$, $p=0.050$), with TBI-PFR rats having the highest discrimination index. Overall effects existed on percent time spent between objects in NOR (males: $F(3,8)=59.67$, $p<0.001$; females: $F(3,8)=14.67$, $p=0.0013$), NLR (females: $F(3,8)=5.667$, $p=0.0222$), and TOR (males: $F(3,8)=12.67$, $p=0.0021$) tasks. Thus, the self-guided, intermittent PFR that involves dynamic, novel spatial navigation can prevent TBI-induced cognitive impairment in juvenile rats. PFR serves as a therapeutic intervention to investigate cellular and molecular mechanisms of effective rehabilitation. Spatial navigation training may have clinical relevance.

Title: Effects of chronic repetitive mild traumatic brain injury on intra-op and post-op weight gain in adult male Sprague Dawley rats

Authors: *M. A. GRAHAM[1,2], P. T. JUZANG[1,2], T. E. WHITE[1,2];
[1]Atlanta VA Hlth. Care Syst., Atlanta, GA; [2]Neurosci. Inst., Morehouse Sch. of Med., Atlanta, GA

Abstract: Traumatic brain injury (TBI) is a major health concern, with mild TBI (mTBI) being the most common type of injury. This is especially true for the military population, in that there were 4300 reported cases of TBI among active-duty military service members in 2018, where more than 84% were classified as mTBI. Anthropometric measures such as weight gain/loss are key standards of health and wellness assessment, and are often used to indicate recovery milestones following injury. While they have been reported, there is a remarkable lack in the evaluation and implications of these measures in TBI research, particularly in preclinical models. In this study, we aimed to determine if a model of chronic repetitive mTBI (rmTBI) affects weight gain adult male rats. Twenty-four adult male Sprague Dawley rats (226-250 g at time of arrival) were randomly assigned to one of two groups: SHAM (n=12) and TBI (n=12). A craniotomy was performed on all animals with a trephan drill bit (6 mm diameter) with the center 4 mm posterior and 3-4 mm lateral to bregma. Chronic rmTBI was performed on TBI animals using a unilateral mild controlled cortical impact injury administered in 5-day intervals over the course of 15 days (4 injuries total - one every 5 days). Three weeks of behavioral testing was conducted 14 weeks post-injury. Animals were weighed immediately prior to each surgical procedure during the intra-op period (four measurements total), once weekly for 17 weeks during the post-op period, and on the day of sacrifice. Three data points were recorded for each weight measurement: overall weight, weight gained per time point, and total weight gained. TBI animals weighed a mean 18.75 ± 11.62 g less overall ($p=0.036$) g at intra-op day 15, gained a mean 6.25 ± 2.89 g less weight between intra-op days 10 and 15 ($p=0.041$), and gained a mean 11.98 ± 7.93 g less total weight through intra-op day 15 ($p=0.043$) than SHAM animals. No significant differences were detected prior to intra-op day 15 or at any time point during the post-op period, though some notable trends were observed. Chronic rmTBI seems to have a gradually increasing negative effect on weight gain in male rats during the intra-op period. This effect may be attributed to the stress and pain of the surgical procedures and repeated injuries. The lack of

differences observed during the post-op period likely resulted from the level of variability within each group, which may have been caused by differing injury recovery patterns between groups and stress from behavioral testing. The results of this study suggest that anthropometric measures, including weight gain, should be monitored closely immediately following TBI to facilitate healthy recovery from injury.

Abstract: Problem Statement: Mild Traumatic Brain Injury (TBI) is a closed head injury caused by explosions, traffic accidents, falls and impact sports. Approximately, 80% of hospital-reported TBIs are classified as mild. An important manifestation is axonal injury identified with Diffusion Tensor Imaging (DTI) by reduced fractional anisotropy. Mild TBI is a risk factor for several degenerative and traumatic diseases including Post-Traumatic Epilepsy (PTE). Mild TBI has been related to Chronic Traumatic Encephalopathy (CTE) generated by hyperphosphorylated tau protein proposed as mild TBI biomarker. However, this correlation does not seem to hold in all traumatic situations related to mild TBI.
Objective: In a first experiment, we investigated if conditioned fear generated by delay or trace fear conditioning could serve as a biomarker for mild TBI identified by reduced fractional anisotropy. In a second experiment, we applied this biomarker concept to the sodium channel

blocker 5,5-diphenylhydantoin (phenytoin), an antiepileptic drug.
Methods: In the first experiment, male C57BL/6N mice, single-housed, anesthetized with isoflurane, body-protected with nylon coats and foam ear plugs, were exposed to a 1.4 msec supersonic helium wave from a 6 feet long and 2 inches wide aluminum tube on Day 1. The reflective pressure was 56.9 psi at the mouse head. On Day 3, all mice were subjected to training for auditory trace or delay fear conditioning, models of declarative and non-declarative memory, respectively. On Day 4, all mice were tested for conditioned fear, and on Day 5, the animals were cardioperfused, and their brains were analyzed in a 14.1 TESLA MR imager. In the second experiment, blast and fear conditioning were run as before except for phenytoin being i.p. injected (10 mg/kg) into the anesthetized animal during preparation for the blast.
All three major behavioral expression modes of fear conditioning: contextual freezing (to the training context), preCue and Cue freezing were analyzed.
Results: The main significant inverse correlation was found between contextual freezing and fractional anisotropy in the lateral corpus callosum (r=-0.603, Z=-3.56, p=0.0004) and to a slightly lesser extent in the medial corpus callosum (r=-0.464, Z=-2.562, p=0.0104). Thus, conditioned contextual freezing was qualified as biomarker of blast-induced mild TBI. Phenytoin enhanced contextual freezing and thus axonal injury after blast with all pathological consequences related to mild TBI to be considered. It is important to realize that this action requires a preceding traumatic event. This may be a mechanism to explain observed clinical problems of phenytoin application in PTE.

Title: Pramipexole counteracts the outcomes of traumatic brain injury in wistar rat on oxidative stress and behavioral dysfunction

Authors: *M. SALMAN[1], S. PARVEZ[1], H. TABASSUM[2];
[1]Toxicology, Jamia Hamdard, New Delhi, India; [2]Indian Council of Med. Res., New Delhi, India

Abstract: Tissue damage and organelle dysfunction is the key event in traumatic brain injury (TBI) pathophysiology which leads to oxidative stress, neuronal dysfunction and cell death. There is no therapeutic medicine is available that could potentially hamper the neuronal death and dysfunction after TBI. Pramipexole (PPX) is a promising neuroprotective D2-agonist that

can work against various neurological disorders. The present study was aimed to elucidate to explore the mechanism of neuroprotection by PPX against oxidative stress induced neuronal damage and dysfunction after TBI. We hypothesized that neuroprotection by PPX may involve in amelioration of oxidative stress and mitochondrial dysfunction followed by TBI. PPX was injected intraperitoneally (0.25 & 0.5 mg/kg/b.wt.) after trauma. The behavioural assessment parameters were assessed for PPX neuroprotection at 48h and 7days post-TBI. The oxidative stress parameters glutathione (GSH), lipid peroxidation (LPO), superoxide dismutase (SOD) and catalase were analyzed spectrophotometrically at 48h after TBI. We used flow cytometry to analyze mitochondrial membrane potential (ΔΨm) which is a contributing factor of mitochondrial dysfunction after TBI. The expression level of apoptosis-inducing proteins was done by western blot analysis. Post-treatment of PPX improved neurobehavioral function and attenuates oxidative damage and ΔΨm collapse. We concluded that the neuroprotective effect of PPX is mediated by attenuating oxidative stress (LPO, SOD, GSH and catalase) and ΔΨm after TBI in experimental animals. This data provide evidence of PPX provides neuroprotection as a therapeutic approach for the treatment of TBI. **Keywords:** traumatic brain injury, control cortical impact, behavioural alteration, oxidative stress, recovery

Title: Effects of assessment timing and rat strain on auditory processing and spatial learning after mild traumatic brain injury

Authors: *S. W. THRELKELD[1], E. MORALES CESTERO[1], D. LAFLAMME[1], A. B. BRADFORD[1], J. SZMYDYNGER-CHODOBSKI[2], A. CHODOBSKI[2];
[1]Neurosci., Regis Col., Weston, MA; [2]Emergency Med., Rhode Island Hosp., Providence, RI

Abstract: Traumatic brain injury exacts significant neurobehavioral cost on nearly 1.7 million patients and their families in the United States each year. In patients with mild traumatic brain injury (mTBI), auditory impairments and deficits in learning and memory are common, often presenting at variable time windows post injury. Rodent models employing controlled cortical impact (CCI) techniques have been used to study cellular processes and behavioral outcomes linked to injury progression. Previous studies have also reported differences in learning across rat

strains with mTBI. In the current series of studies, mTBI was induced in male Long Evans (LE; n=48) and Sprague Dawley (SD; n=24) rats using the CCI method, along with sham procedures. Subjects were subsequently assessed for auditory processing and spatial learning abilities at multiple time-points post injury in order to identify windows for deficit emergence. Results showed LE mTBI rats (n=12) with intact pure tone detection. However, significant impairments in frequency modulated (FM) sweep detection were observed as compared to sham (n=12) subjects 32 days post (DP) mTBI. A second study utilizing LE rats revealed comparable performance between sham (n=12) and mTBI (n=12) subjects in pure tone discrimination and FM sweep detection when assessed 59 DP mTBI. In study two, LE subjects with mTBI showed no deficits in spatial learning as compared to sham subjects. In study three, SD rats showed no impairments in auditory processing across single tone or FM Sweep tasks when evaluated 43 DP mTBI. However, in contrast to both LE studies, SD rats with mTBI showed significant impairments in spatial learning as compared to shams. Our findings parallel strain differences in spatial learning observed across other models of TBI. Further, it appears that deficits in FM sweep detection, seen for LE subjects tested 32DP mTBI, may be mediated by the post TBI window of assessment and strain specific variations in sensory acuity. Specifically, auditory deficits appear to be most prominent within 32 days of mTBI in LE subjects but not at later days for LE or SD subjects. Our findings may help inform the selection of optimal assessment windows and appropriate strains when employing a CCI model of mTBI.

Title: Focal brain lesion induced by ultraviolet irradiation in a rhesus monkey

Authors: *M. NAKATA, A. TAKEMURA, K. MATSUDA, S. YAMAMOTO;
AIST, Tsukuba, Japan

Abstract: Creating focal brain lesions is an essential technique to investigate the function of a specific brain area. Because of the anatomical resemblance to the human brain and the ability to perform advanced cognitive tasks, non-human primates (NHPs) subjected to lesion experiments have played an important role in investigations of higher brain function. However, techniques

that enable removing all of the brain tissue at a targeted site (e.g. aspiration) in NHPs cannot be easily controlled. Pharmacological techniques inactivate only specific cell types. Thus, we previously developed a novel method for creating focal brain lesions using ultraviolet (UV) light in rodents (Nakata et al., 2018, *Sci Rep*). In this study, we applied the UV lesion method to a macaque monkey. An adult male rhesus monkey (*Macaca mulatta*) was anesthetized. UV irradiation was provided through an optical fiber connected to a UV LED light source (UV-A; wavelength 365 nm, 4.0 mW × 3.0 h = 12.0 mWh). After removal of the skull, the tip of an optic cannula (flat circle, 600 μm in diameter) was stereotaxically placed on the targeted brain site (parietal cortex) and contacted the dura mater. Four days after irradiation, we performed magnetic resonance imaging (MRI), and found that the UV lesion had higher signal intensity in a T2-weighted MRI. Thereafter, the animal was perfused for histological analysis the following day. Hematoxylin-eosin staining further revealed that the UV irradiation had induced an inverted-bell shaped lesion. Loss of brain tissue and hemorrhagia were also observed in the central part of the lesioned area. Neuronal marker-immunoreactive cells were absent, and Iba1-immunoreactive microglia/macrophages were congregated within the lesion. These observations indicate that UV irradiation to the monkey brain induced neural degeneration and an immunological response. Taken together, these results show that we succeeded in applying the UV lesion method to the primate cortical surface, which was performed with simple surgical procedures and without any expert skill.

Title: Selective activation of central thalamic pathways facilitates behavioral performance in healthy non-human primates

Authors: *A. JANSON[1,2], J. L. BAKER[4], N. D. SCHIFF[5], C. R. BUTSON[1,2,3];
[1]Biomed. Engin., [2]Scientific Computing and Imaging Inst., [3]Neurology, Neurosurgery, & Psychiatry, Univ. of Utah, Salt Lake City, UT; [4]Brain and Mind Res. Institute, Div. of Systems Neurol. and Neuroscienc, [5]Neurol., Weill Cornell Med. Col., New York, NY

Abstract: The central thalamus (CT) is an important component of the arousal regulation system in the brain and damage to this structure, as a result of severe brain injury, is linked to chronic cognitive impairment. Deep brain stimulation within the central thalamus (CT-DBS) has been proposed as a therapeutic strategy to improve arousal regulation and cognitive impairments in patients with severe brain injury. Our hypothesis is that fiber pathways in the central thalamus have a specific orientation, projecting to the cortex and striatum, which are robustly activated with stimulation configurations that facilitate behavioral performance and enhance cortical and striatal activity. We developed a biophysical computational model of the macaque central thalamus that includes these fiber pathway projections and correlated their activation with behavioral and physiological data collected from a single subject performing a vigilance task during CT-DBS. We found that the stimulation configurations that produced significant improvements in performance were also the configurations that activate fibers in the biophysical model based upon the subjects reconstructed lead locations, see Figure 1. Our findings provide evidence that activation of specific structural white matter pathway in the central thalamus is linked to improved performance and activation of striatal and cortical areas. We anticipate that the model-based predictions of fiber pathway activation in the macaque central thalamus will provide a direct translational target in human studies of DBS for the treatment of severe brain injury.

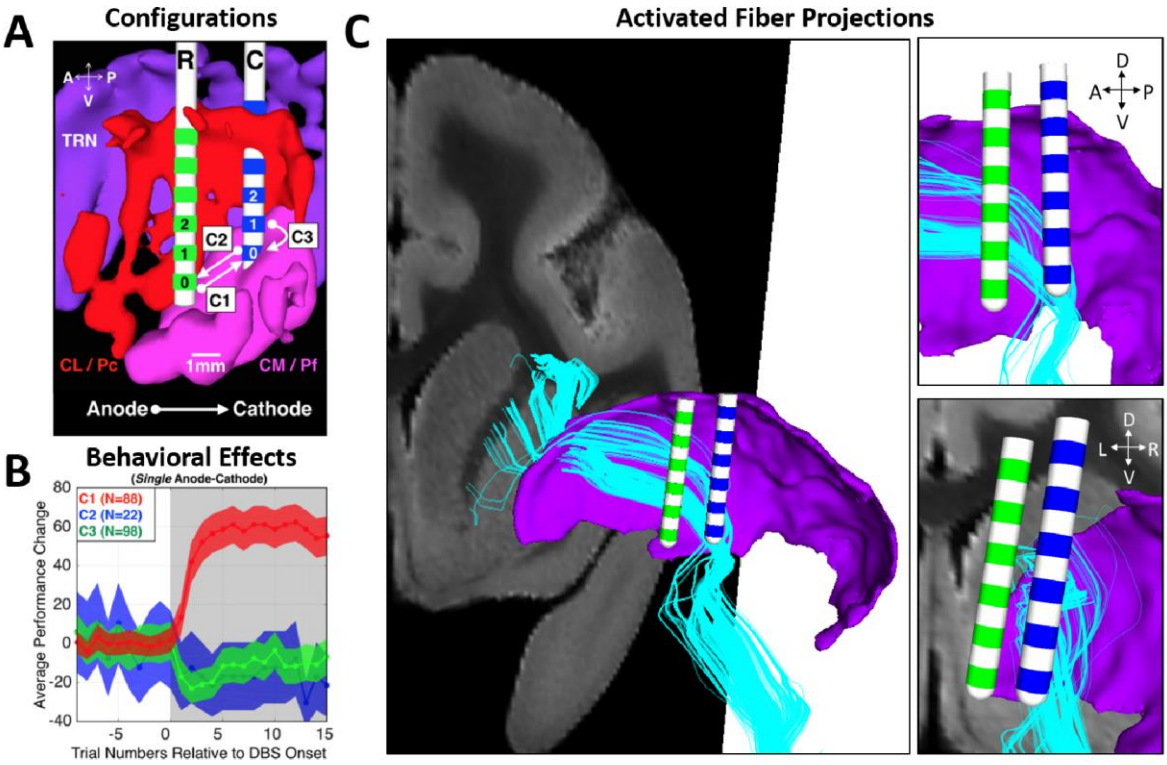

Figure 1. Configuration dependent effects of stimulation on behavioral performance and biophysical model of target fiber pathway. (A) Sagittal view of DBS lead placement in NHP subject and three different experimental stimulation configurations. Central lateral nucleus (CL) in red, central median nucleus (CM) in pink, and thalamic reticular nucleus (TRN) in purple. (B) Average performance change during stimulation for the three configurations +/- 95% CI. (C) Reconstructed fiber projections, from diffusion weighted imaging, through the central thalamus that are activated with configurations that strongly increase performance during stimulation.

Abstract: Concussion in humans is characterized by rapid onset and spontaneous resolution of a constellation of somatic, neuromotor, cognitive, and behavioral signs and symptoms precipitated by head injury with or without loss of consciousness. Neurological signs of acute concussion include confusion, altered mentation, slowed reaction time, motor weakness, impaired balance, incoordination, dystaxia, affect lability, and amnesia. Preclinical models of acute concussion have eluded development due to experimental requirements for anesthesia during injury. Recently, we showed that unanesthetized mice subjected to closed-head impact injury induced with a novel momentum transfer device reliably triggered abrupt onset and rapid recovery of a concussion syndrome similar to that in humans (Tagge CA *et al., Brain,* 2018). We developed the Boston University Concussion Scale (BUCS-1.0) as a multidimensional test battery for rapid, objective assessment of acute concussion in awake, unanesthetized mice. BUCS-1.0 comprises three 30-sec subtests (open-field, inverted wire mesh, beam walk) scored on standardized metrics (0-5) that capture graded task-specific deficits and summed as a composite score (BUCS range, 15-0). We conducted BUCS testing 2 min pre-injury (baseline), 2 min post-injury (post-injury), after 3-hr rest period (recovery). Most mice (166/203, 81.8%) exhibited mild neurological impairment (BUCS ≥10) after single impact. Fewer (32/203, 15.8%) showed moderate impairment (BUCS, 9-5). Severe impairment (BUCS ≤4) was rare (5/203, 2.5%). All mice recovered to baseline, typically in minutes and always by 3-hrs post-injury. In a revised format

(BUCS-2.0), we incorporated and validated a cognitive measure of spatial memory during the open-field subtest, which reveals that approximately 50% of impacted mice perform abnormally at 3 hours post injury compared to shams and the other subset of impacted mice. Surprisingly, we did not observe acute concussion (lowering of BUCS scores or abnormal spatial memory performance) in mice exposed to experimental blast.

Title: Variable changes in global brain connectivity resulting from traumatic brain injury

Authors: *J. NAKUCI[1], M. MCGUIRE[2], F. SCHWESER[3], D. POULSEN[3], S. E. MULDOON[4]; [1]Neurosci., Univ. At Buffalo, Buffalo, NY; [2]Dept. of Neurosurg., [3]Dept. of Neurol., Univ. at Buffalo, Buffalo, NY; [4]Dept. of Mathematics and CDSE Program, Univ. at Buffalo, SUNY, Buffalo, NY

Abstract: White matter tracts are important for efficient communication between distant brain regions and damage to these tracts can have significant impact on brain function. Traumatic brain Injury (TBI) can cause axonal injury beyond the site of the trauma, with white matter tracts exhibiting high vulnerability. Here we use network analysis to study changes in white matter reorganization in the lateral fluid percussion injury (FPI) model of TBI in rats. Structural brain networks were constructed from diffusion MRI and we observed heterogeneity in the connectivity of both healthy and injured animals. However, in injured rats, we find: (1) a subnetwork of connections, distributed throughout the brain, with increased connectivity strengths when compared to control networks; (2) a shift in the network backbone toward the inclusion of links with shorter distances between regions when compared to controls and; (3) a subset of regions in which the prevalence of network motifs was altered. These individual differences in structural connectivity across injured rats reflect different profiles of pathology induced changes. Finally, using an unsupervised clustering analysis, we identify two subpopulations within the TBI group that align with differences in the severity of the injury, as assessed using behavioral severity scores. These results suggest that measures of global brain network structure can be used to quantify changes in brain connectivity due to injury and to further differentiate subpopulations within an injured cohort.

Title: Electrographic, behavioral and peripheral blood biomarkers of post-traumatic epileptogenesis

Authors: *U. DEVARAJ[1], A. BRAGIN[1,2], J. ENGEL, Jr.[1,2,3];
[1]Neurol., Univ. of California, Los Angeles, CA; [2]Brain Res. Inst., Los Angeles, CA; [3]Neurobio. and Psychiatry and Biobehavioral Sci., Los Angeles, CA

Abstract: Objective: To identify electrographic, peripheral blood and behavioral biomarkers for prediction of post-traumatic epileptogenesis.
Method: Fluid percussion injury (FPI) was performed on 2 month old male Sprague-Dawley rats (n=9). 50um tungsten electrodes were implanted bilaterally into the rat (1) prefrontal cortex, (2) striatum, (3) anterior and posterior perilesional area and (4) hippocampus. Wideband electrical activity was recorded immediately after TBI and for the next 2-6 months. Anxiety level and memory were tested once a week. Blood samples (1ml) were drawn during the 1st and the 2nd week after TBI. After analysis of EEG data, animals were separated in to those, that developed spontaneous seizures (E+ group) and those that did not (E- group). Rate of high-frequency oscillations (HFOs), level of anxiety and memory were compared between E+ and E- groups. Concurrently, blood serum was analyzed for, 4-hydroxynonenal (HNE-4), Matrix Metalloproteinase 9 (MMP-9) and Aquaporin 4 (AQP-4) levels, before and after TBI.
Results: Thirty percent of rats became epileptic (E+) 70% did not (E-). The rate of HFOs increased in the prefrontal cortex and hippocampus areas in the E+ group within the first two weeks, but not in the E- group. 100% in the E+ and 80% in the E- showed a decline in memory;

2, 12 and 24 weeks after TBI. We found 100% of rats in the E+ group performed poorly in the anxiety-related behavior test; 2, 12 and 24 weeks after TBI. Only 50% of the E- group showed an increase in anxiety in week 2. Blood serum analysis showed upregulation of MMP-9 in 100% of rats in both the E+ and E- groups within the 1st and 2nd week after TBI. AQP-4 decreased in 70% of E+ rats and 100% in E- rats. Blood HNE-4 increased in all the rats in the E+ group within week 1 and in just 30% in E-. No changes were found in the 2nd week in either group. **Conclusion:** The increased rate of HFOs is, so far, the only stable biomarker of epileptogenesis after TBI. Further experiments are needed to confirm or reject preliminary data suggesting that anxiety level or changes of HNE-4 in the peripheral blood could also be biomarkers of post-traumatic epileptogenesis.

Title: *In vivo* spatiotemporal patterns of oligodendrocyte and myelin damage at the neural electrode interface

Authors: *K. CHEN[1,6], S. WELLMAN[1,6], F. CAMBI[2,7], J. R. ELES[1,6], T. D. KOZAI[1,6,3,4,5]; [1]Dept. of Bioengineering, [2]Dept. of Neurol., [3]Ctr. for Neurosci., [4]McGowan Inst. of Regenerative Med., [5]NeuroTech Ctr., Univ. of Pittsburgh, Pittsburgh, PA; [6]Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh and Carnegie Mellon Univ., Pittsburgh, PA; [7]Veterans Admin. Pittsburgh, Pittsburgh, PA

Abstract: Brain implantable electrodes are emerging as a powerful tool for understanding the patterns of brain circuitry and for therapeutic applications to neurological disorders, given their ability to record extracellular action potentials *in vivo* and/or deliver electrical signals into the local region. However, the longevity and performances of implanted electrodes have shown to be adversely affected by overwhelming biological responses, including severe neuronal loss and thick glial encapsulation. While glial responses, microglia activation and astrocytes reactivity have been thoroughly examined, oligodendrocytes and their extended structure, myelin, have not been extensively investigated in the neural interfacing field, especially their roles in acute inflammatory and chronic foreign body responses. It is well-established that oligodendrocyte make myelin wrapped around axons to provide electrical insulation. In addition,

oligodendrocytes provide metabolic support to neurons through cytoplasmic myelin channels and monocarboxylate transporters. Implantation of electrodes break the integrity of oligodendrocytes, exposing these vulnerable neuroglia to mechanical distortion, oxidative stress, pro-inflammatory cytokines, and chemokines. To gain insight into the impairment of oligodendrocyte and myelin structures at interfaces, we have characterized the spatiotemporal dynamics of oligodendrocyte and myelin damage at the tissue-electrode interface using multi-photon imaging microscopy. We showed that insertion of electrodes damage myelin structures leading to the formation of protruding structures called myelinosomes. This early myelin morphological injury was observed at the interface region and the spatiotemporal dynamics of myelinosome formation was traced over time. Preliminary analysis was performed to measure the effect of implantation-induced mechanical strain on myelin alignment at the electrode interface. A morphological opening operation with line structuring elements in 11 angles is programmed in MATLAB. Each pixel whose intensity higher than filter threshold is measured. Myelin angle is calculated between line structuring element and highest opening operation direction. The weighted averages in myelin angle were 89.4766 ± 58.6676 degree at the interface, 85.9003 ± 43.3848 degree in the distal region (300 μm away from implant), and 72.7215 ± 53.2499 degree on the contralateral side. Interestingly, preliminary results indicate that myelinosome formation does not always result in degradation of the attached myelin sheath, showing that myelin has the ability to repair early damage at the electrode interface.

Title: Effects of mild traumatic brain injury on widespread cortical function

Authors: *R. E. CARTER[1], E. SCOTT[1], L. S. POPA[1], J. ARONSON[1], J. DOMINQUEZ[2], L. GHANBARI[2], S. B. KODANDARAMAIAH[2], S. CRAMER[1], T. J. EBNER[1];
[1]Neurosci., [2]Mechanical Engin., Univ. of Minnesota, Minneapolis, MN

Abstract: Mild traumatic brain injury (mTBI) can have serious short- and long-term consequences including executive function and cognitive abnormalities. Also, focal injury may have widespread effects beyond the site of impact, suggesting a global disruption of cortical

networks. Here we deploy a novel optically clear, morphological conformant 3D-printed polymer skull to perform mesoscopic Ca^{2+} imaging to evaluate how mTBI alters patterns of interactions across the dorsal cerebral cortex. Transgenic mice (Thy1-GCaMP6f) were subjected to a modified controlled cortical impact model (0.4 m/s, 1 mm impact depth, 85 ms dwell time) using a 3 mm 3D-printed impact tip directly to the motor cortex, to simulate mTBI, and were then immediately implanted with the polymer skull to allow for chronic imaging in the same mice. Mice were head-fixed to a custom freely moving disk that allows for natural behaviors such as walking and grooming. We performed awake mesoscopic Ca^{2+} imaging (7 mm x 7 mm field of view, 20 Hz, 340 x 340 pixel resolution) of the dorsal cerebral cortex during spontaneous natural behaviors. High-speed infrared cameras recorded the behaviors simultaneously with the brain imaging, and limb movements were tracked using DeepLabCut, a machine learning algorithm. To assess changes in widespread cortical function, we first used spatial independent component analysis (ICA, SOBI and JADE algorithms) to segment the Ca^{2+} imaging data into functional independent components (ICs) in control mice and mice one month after mTBI. The data was separated into 1 min blocks for the analysis. The number, stability, and frequency of occurrence of ICs were compared between control and mTBI mice. Preliminary ICA using SOBI revealed a total of 468 unique ICs, 215 found only in control, 162 only following mTBI, and 91 that overlapped between control and mTBI. These ICs were composed of 48 unique domains that covered the majority of the visible dorsal cortical surface, with each IC comprised of 1-4 individual domains. The domains are relatively conserved, with only one domain specific to control mice, and 3 domains specific to mTBI mice. Next, we used both correlation matrix and graph theory approaches to assess changes in network connectivity following mTBI. Initial ICA data using JADE shows a large decrease in functional connectivity between ICs one month after mTBI, as quantified by a reduction in nodal degree (number of significant correlations/node), from an average of 20.3 ± 6.3 to 11.0 ± 3.1. These results suggest that a relatively mild cortical impact produces a chronic decoupling of functional network connectivity that could contribute to behavioral and cognitive dysfunction.

Title: The glymphatic function following repetitive mild traumatic brain injury: Risk for Parkinson’s disease?

Authors: *X. CAI[1,4], I. HARDING[1], J. QIAO[2], B. COLARUSSO[4], T. KNOX[4], P. P. KULKARNI[3,4], C. F. FERRIS[3,4];

Abstract: The glymphatic system (GS), a recently discovered waste clearance system in the brain, is described by the circulation of cerebrospinal fluid along glymphatic pathways penetrating to extracellular space, facilitated by aquaporin-4 (AQP4) water channels, allowing drainage throughout the brain. There is a growing literature that glymphatic system may play a critical role in the etiology and pathophysiology of CNS disorders. For example, recent work has suggested that the GS is largely impaired by 60% in moderate-to-severe traumatic brain injury (TBI). However, mild TBI (mTBI) characterized as a negligible loss of consciousness with minimal neuropathology is estimated to account for 75% of all TBI cases. While mTBI is difficult to detect, it causes chronic damage to the brain especially when exposed to repeated concussion, contributing to cognitive, motor and behavioral problems with an increased risk for Parkinson's disease. To date, little is known regarding how repetitive mild traumatic brain injury (rmTBI) impairs GS. This study aims to test the hypothesis that rmTBI causes reduced glymphatic flow(GF) in the midbrain dopaminergic system, altering AQP4 expression and localization in the perivascular domain, and reducing clearance efficiency in alpha-synuclein, a harmful protein forming Lewy bodies. Contrast-enhanced MRI experiments were performed through intracerebroventricular injection to follow brain-wide contrast agent dynamics over 2hs along the glymphatic pathway on fully awake rats exposed to rmTBI rats (n=7) as compared to non-concussed controls (n=7). TBI rats were hit on the forehead twice (48 hrs interval) with 7.4 m/s impact velocities and 30 psi based on momentum exchange model, three weeks prior to imaging. Behavior assays including Novel Object Preference and Barnes Maze were conducted to evaluate cognitive function a week after concussion. Immunohistochemistry on AQP4 co-stained with blood vessels were conducted to assess AQP4 expression/localization in the perivascular domain. Fluorescence conjugated alpha-synuclein proteins were intrastriatally administered in controls and rmTBI animals to assess clearance efficiency longitudinally with fluorescent imaging. Behavior results showed significantly reduced path efficiency in rmTBI rats compared to controls in Barnes Maze, indicating spatial memory deficits following repeated concussion. Altered glymphatic activity observed in the midbrain suggests a possible mechanism between mild head injury and PD that may lead to targeted treatments for neurodegenerative diseases.

Title: Does treatment with sleep aids following TBI alter the development of post-traumatic epilepsy?

Authors: *P. V. RODRIGUES[1], S. S. R. KONDURU[1], J. A. PFAMMATTER[2], M. V. JONES[3], R. K. MAGANTI[1];
[1]Neurol., Univ. of Wisconsin, Madison, Madison, WI; [2]Neurosci., [3]Dept Neurosci., Univ. of Wisconsin Madison, Madison, WI

Abstract: Traumatic Brain injury (TBI) leads to several sequelae including post-traumatic epilepsy (PTE), sleep-wake disturbances (SWD) and even mood disorders. Currently there are no preventive treatments for these sequelae.However, it is well established that lack of sleep triggers seizures, but it is unclear if SWD leads to PTE. We hypothesized that post-TBI SWD is linked to the development of PTE. Here, we aimed to investigate whether sleep aids-dual orexin antagonist (DORA-22) or Gaboxadol (THIP- an agonist of delta subunit containing $GABA_A$ receptor), when used early after TBI, will restore sleep and prevent development of PTE.We performed severe TBI (Controlled cortical impact-CCI) or sham injury (craniotomy only with no injury) in CD-1 mice and implanted epidural EEG electrodes in the right frontal and left parietal areas along with nuchal EMG under isoflurane anesthesia. After TBI/sham injury and EEG implantation animals were treated with either DORA-22, THIP, or control (vehicle control or no treatment) via oral gavage for 1 months from the day of surgery. We then conducted week long video-EEG recordings in week 1, and months 1, 2, 3 and 6. Acquired EEG data was transferred to a sleep scoring software (Sirenia Sleep) and was scored in 4 sec epochs. We then analyzed epileptiform events (seizures and interictal spikes) and sleep-wake patterns across time.Seizures occurred in ~ 25% of TBI animals whether untreated (9/40) or treated (3/12-for DORA-22 and 3/12 for THIP group). Normalized seizure counts (seizures per animal per hour of recording) indicate consistent seizure frequency across time in the untreated TBI animals(1.21 at week 1, 2.78 at month 2, 1.88 at month 3, and 2.08 at month 6). Interestingly, TBI mice treated with DORA-22 has no recorded seizures after the first week (2.78 at week 1and 0 at other time points)and we observed an increase in seizure rate of THIP animals as compared to controls (8.33 at week 1, 4.17 at month 1, 4.69 at month 2, and 0 at month 3). Seizures consisted of behavioral arrest, head nodding and hind limb stretching that sometimes progressed to Racine class V seizures. SWD consisted of “hypersomnia” in the first week, but “insomnia” at month 2

after TBI. Our preliminary results suggest no differences in sleep-wake patterns between DORA-22, THIP, or control treated TBI animals. A full analysis of seizures, interictal spikes (~80% of animals had interictal spikes), and sleep parameters is ongoing and further analysis is focused on understanding relationship between sleep disruptions, epileptiform events with or without treatment.

Title: Disruption of Sharp wave-Ripple and phase amplitude coupling across laminar hippocampal CA1 following traumatic brain injury

Authors: *C. COTTONE, K. G. GAGNON, C. D. ADAM, M. SERGISON, I. H. CHEN, A. V. ULYANOVA, J. A. WOLF;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Traumatic brain injury (TBI) is caused by mechanical insults to the head, often resulting in prolonged or permanent brain dysfunction including disruption of cognitive functions. The hippocampus is one of the most studied brain regions following TBI due to its central role in episodic and spatial memory and its demonstrated vulnerability during TBI. Sharp wave-ripples (SPW-Rs) are considered one of the most important hippocampal neural activity patterns that underlie cognitive functions. SPW-Rs are instrumental in stabilizing the spatial representation coded by place cells, refining hippocampal place fields and, by extension, for maintaining a stable cognitive map. Timing of hippocampal CA1 pyramidal cell spikes is tuned by the relative strengths of the cooperating/competing CA3 and entorhinal inputs and the strength of these upstream inputs are reflected by the gamma power in the appropriate lamina of CA1.We hypothesize that TBI may distort the timing of the upstream inputs towards CA1 compromising a proper formation of neuronal ensembles and consequently disrupt the SPW-R generation which may underlie aspects of post-TBI memory dysfunction.Cross-frequency coupling (CFC) and spike-local field potential (LFP) entrainment may support the organization of these neuronal ensembles and are present during a range of cognitive functions, including learning and memory. Using 64-channel silicon probes, we simultaneously recorded laminar hippocampal field structure and CA1 neurons in behaving rats during a familiar-novel

environment paradigm. Recordings were divided into moving and non-moving periods, and then phase-amplitude coupling (PAC) was calculated for every possible pair of channels using the 1-20 Hz band as the phase of the lower frequency oscillation and 1-300 Hz band as the power of the coupled higher frequency oscillation. Results show a reduction in PAC in injured subjects relative to sham, predominantly between radiatum and pyramidal layers in theta-gamma and delta-theta-ripple coupling, thus reflecting a loss of encoding synchrony between CA1-CA3 (low gamma (~30-60 Hz)), EC-CA1 (high gamma (~60-110 Hz)). Moreover, SPW-Rs rate is drastically reduced in injured group in both familiar and novel environments (~50% relative to the sham group), reflecting a reduction of memory retrieval and consolidation events.One interpretation of these results is that laminar afferent inputs into CA1, both from CA3 and entorhinal cortex, are no longer properly coupled to lower frequencies leading to a disruption of neuronal ensembles. In combination with the decrease of SPW-Rs generation, this may affect the proper memory and cognitive functionality.

Title: *In vivo* phage biopanning facilitates discovery of acute traumatic brain injury specific targeting peptides

Authors: *B. I. MARTINEZ, N. STEPHANOPOULOS, C. W. DIEHNELT, S. E. STABENFELDT;
Arizona State Univ., Tempe, AZ

Abstract: The heterogeneous injury pathophysiology of traumatic brain injury is a barrier to developing highly sensitive and specific diagnostic tools. Thus, biomarker discovery techniques that take advantage of mining this complexity are critical to the identification of biomarkers with high specificity. We employed a unique pipeline for biomarker discovery that entailed domain antibody (dAb) phage display, next generation sequencing (NGS) analysis, and nanotechnology strategies to generate truncated peptide-based motifs. Here we present the results where biopanning was conducted in an acute brain injury mouse model. For *in vivo* phage biopanning, adult C57Bl/6 mice were anesthetized and subjected to either controlled cortical impact (CCI) or sham surgery (n=3 per group/timepoint; approved by ASU IACUC). At 1 day post-injury (dpi), a

dAb phage library was intravenously injected and circulated for 10 minutes. Mice were promptly sacrificed, and phage eluted from injured brain tissue and amplified for a second biopanning round. Truncated peptide sequences were selected from NGS data analysis and developed using nanotechnology strategies. Control peptides were identified from dAb sequences specifically present in peripheral tissue. For validation, serial cryosections (20 µm) were collected from CCI or sham surgery mice at 1 (acute) or 7 (subacute) dpi. Immunostaining consisted of the biotinylated targeting or control peptides serving as a primary "antibody" followed by fluorescently-labeled streptavidin. NGS analysis revealed two select dAbs that were substantially enriched between biopanning rounds within the injury penumbra and not found in control libraries. Two truncated peptide sequences derived from the enriched dAbs, reflective of the unique dAb sequences, were generated to evaluate the specificity to acute neural injury via IHC. Only one peptide demonstrated notable positive recognition of the cortical injury penumbra at 1 dpi while no signal was observed in sham tissues. Furthermore, when testing this peptide on subacute tissue, no positive signal was observed. Negative control peptides did not bind to either injured or sham tissue, suggesting specificity of the injury targeting peptide. The pipeline of phage display followed by NGS analysis demonstrated a unique approach to discover motifs that are sensitive to the heterogeneous and diverse pathology present in neural injury. We successfully identified a unique motif that spatially homes to acute neural injury. Future studies will include immunoprecipitation mass spectrometry experiments to determine the specific antigen targets.

Title: Sleep spindles and its role as a potential biomarker for the development of secondary epilepsy post traumatic brain injury

Authors: *S. KONDURU, J. PFAMMATTER, P. RODRIGUES, M. JONES, R. MAGANTI; Univ. of Wisconsin - Madison, Madison, WI

Abstract: Epidemiological data shows that post-traumatic epilepsy (PTE) is seen in about 10-20% of patients with Traumatic Brain Injury(TBI). It can be as high as 50% in injured military personnel. Currently, it is uncertain as to who develops PTE after TBI. Sleep-Wake disturbances

are very common in TBI patients and there is a close relationship between sleep disorders and seizures. Here, we analyzed sleep spindles,(a hallmark of NREM sleep) in mouse models of TBI as a potential biomarker for the development of PTE.
We analyzed EEG data sets from 3 cohorts of CD-1mice. 1) TBI cohort (n=40) underwent severe TBI (controlled cortical impact) to the right parietal lobe. 2) Sham cohort (n=22) underwent craniotomy without TBI. TBI and sham cohorts were recorded at week 1, month 1,2,3,6 after surgery. 3) The third set of mice underwent surgery without craniotomy (n= 6). EEG was obtained at week 1 from this cohort to determine the baseline for CD-1 mice. All the obtained EEG signals were 1) Manually scored for sleep-wake patterns in 4s epochs (Sirenia sleep) and artifactual EEG was excluded 2) Manually scored for sleep spindles after bandpass filtering between 9- 15hz (1hour NREM segments) to compare with automated method. 3) TBI cohort manually scored for seizures (Natus Neuroworks). We used an automated spindle detection method based on Ferrarelli et al(2007) in Wonambi, Python. Automated analysis was done using multiple detection and selection thresholds and correlated with manual spindle scoring. The best possible match (~50%) was identified when the detection and selection thresholds were set to 3 and 2. The method will be further reviewed and validated to yield higher predictive value and F1 score. Other parameters used for spindle detection are frequency (9-15hz) and duration(0.5-2s). We compared spindle results from validated automated detection across groups, TBI with seizures (~25% of TBI recorded), TBI without seizures and Sham. Preliminary analysis showed a difference in mean peak amplitude and power between sham (108.35+/-28.06; 10.43+/-4.74) and TBI groups (84.95+/-17.39; 6.67+/-2.59). Within the TBI groups, there was no difference in average peak amplitude and power between TBI animals with seizures (84.99+/-23.96; 6.37+/-3.26) and TBI animals without seizures (84.91+/-10.82; 6.97+/- 1.92). Normalized spindle density/hour/animal showed an increase in spindle density in TBI animals with seizures (47.58) and TBI animals without seizures (43.24) compared to sham (25.23). There was no difference in the mean frequency(hz) and duration of the spindles(sec) across groups. Further analysis of our data is being done to determine the significance of these findings.

Autonoma de Puebla / Inst. de Fisiologia, Puebla, Mexico

Abstract: According to the statistics of the World Health Organization (WHO) about one million people commit suicide annually in the world, so it reaches a remarkable thirteenth place as cause of death. Suicide is a mental illness that can occur at any age, it is a behavior determined by a large number of complex causes, mainly depression and alcohol use disorders, substance abuse, violence and various cultural and social environments becoming in a public health problem that need to be studied. The prefrontal cortex (PFC) is functionally related to emotion, stress and cognitive functions, aspects involved in suicidal behavior. The lesions of the prefrontal cortex entail a certain loss of decision capacity, so it is possible that alterations in this region lead to the inability to make appropriate decisions. The dendritic spines are dendritic membrane modifications, whose morphology changes could suggest modifications in neural communication, also this changes in their morphology and spines density are associated with several pathologies. In this work we aim to describe the morphological modifications of dendritic spines in the PFC, specifically in the orbitofrontal cortex of human tissue samples we obtained at forensic autopsies, with informed consent and according to an institutional approved protocol. Coupled with this we measured levels of synaptophysin, this glycoprotein has an important function in the exocytosis of synaptic vesicles in neurons, and therefore a generalized marker of synapses. Likewise, we aimed to measure the concentration of α-synuclein (α -Syn), which is a nuclear and synaptic protein and it is the main component of Lewy bodies in some neurodegenerative pathologies. In addition, to the samples of suicide victims, we obtained samples of patients who died from other causes, with the aim of having a “control group”. With these two groups, we created another 2 subgroups, which were "young group" (13-29 years old) and "adult group" (31-65 years old). It should be noted that the information known about all the samples was the cause of death, age and gender. Our results suggest that suicide victims have a modification in dendritic spine morphology, a decrease in dendritic spine density that could be related to the decrease in synaptophysin levels that we found. In other hand, our results suggest α -Syn does not show significant changes. It is known PFC is critically involved in emotional and cognitive processes, the activity of this cerebral area could be a biomarker for this psychopathology, thus, post-mortem findings seem to illustrate a pathophysiological condition predisposing to the suicidal episode, follow-up could be useful for the prevention of suicide.

Title: *In vitro* simulated traumatic brain injury decreases tyrosine hydroxylase expression in human primary dopaminergic cells

Authors: *M. A. RAMIREZ-LEE, Sr, H. ROSAS-HERNANDEZ, S. M. LANTZ, E. CUEVAS, S. F. ALI, S. Z. IMAM;
Div. of Neurotoxicology, Natl. Ctr. for Toxicological Res., Jefferson, AR

Abstract: A large number of Americans live with traumatic brain injury (TBI)-related disabilities. TBI occurs when external mechanical forces cause tissue deformation sufficient to induce brain damage. One of the hallmarks of TBI is neuronal death, but it is related to the development of neurodegenerative disorders, including Parkinson's disease (PD). In PD, the loss of dopaminergic neurons as well as decreased tyrosine hydroxylase (TH) expression and activity contribute to dopaminergic dysfunction. The precise link between TBI and the development of PD is not known, but it has been hypothesized that the decrease in TH expression and activity may be contributing factors. However, it remains unclear if TBI worsens the neurodegeneration observed in PD. Here, we evaluated the effects of in vitro simulated TBI on TH expression. To model PD, human primary dopaminergic neurons were treated with 1 mM methyl phenylpyridinium ion (MPP^+) for 24 hours. To simulate TBI, control and MPP^+-treated neurons were subjected to 0%, 10%, 25% and 50% biaxial stretch deformation. TH protein expression was evaluated 1, 2, 7 and 14 days after injury. As expected, MPP^+ decreased TH expression at all time points, successfully modeling dopaminergic dysfunction observed in PD. In addition, TH expression decreased after 10, 25 and 50% of stretch at measured time points; however, this effect occurred only in control cells, not in MPP^+-treated cells. Our data suggest that TBI promotes PD-like dopaminergic dysfunction, but does not exacerbate the damage already observed in the PD in vitro model. These data also suggest that both, TBI and PD may have similar mechanisms of damage involving the expression and activity of TH. Further studies are underway analyzing additional mechanisms of dopaminergic toxicity.

Title: The influence of the val66met polymorphism of the brain derived neurotrophic factor gene on pathology in an isogenic human *in vitro* model of neurotrauma

Authors: C. K. FRANZ[1], J. K. PHILLIPS[2], K. Y. COTTON[1], J. GRAFMAN[3], M. J. QUEZADA[1], ***J. D. FINAN**[2];
[1]Physical Med. and Rehabil., Shirley Ryan Abilitylab, Chicago, IL; [2]Neurosurg., Northshore Univ. Healthsystem, Evanston, IL; [3]TBI Res. Lab., Kessler Fndn. Res. Ctr., West Orange, NJ

Abstract: Traumatic brain injury (TBI) outcomes vary widely between patients - even when patients have a similar severity of injury. Common, genetic variants cause some of this variation, but well-designed human experimental studies of the effects of genetic predisposition on TBI outcome are both rare and have obvious ethical limitations. Human in vitro models address these limitations. Human-origin neurons can be generated from human subjects for culture in vitro using induced pluripotent stem cell technology. These neurons can be genetically edited to create isogenic neurons i.e. neuron populations that differ by only one genetic variant. This study used isogenic neuron populations to study the influence of the val66met polymorphism of the brain-derived neurotrophic factor (BDNF) gene on neurotrauma pathology. Isogenic induced pluripotent stem cells carrying the 3 genotypes of this polymorphism (val/val, val/met or met/met) were differentiated into excitatory, cortical neurons. They were then cultured at 60,000 cells/cm^2 on silicone membranes for 48 hours before stretch injury. Cells were injured with a 28% biaxial stretch pulse lasting 30 ms. Differentiated neurons expressed green fluorescent protein. 4 hours after injury, they were stained with 5 μg/ml Hoechst 33342 to label nuclei and then fluorescently imaged. These images were analyzed to quantify neurite outgrowth. Trauma significantly reduced mean neurite outgrowth per cell. There was also a significant effect of genotype on mean neurite outgrowth per cell and a significant interaction between the effect of trauma and the effect of genotype (2 factor ANOVA, $p< 0.05$). These results show that in vitro neurotrauma experiments in human isogenic cells can isolate the influence of a genetic variant on neurotrauma outcomes. They therefore offer a powerful opportunity to explore the association between genotype and neurotrauma morbidity that continue to be reported in large-scale clinical

TBI studies. The resulting insights could inform efforts to personalize therapy, stratify clinical trials and assess patient-specific susceptibility to poorer outcomes after neurotrauma.

Title: The influence of mild traumatic brain injury on immune response and development of post-traumatic headache in healthy adults

Authors: J. A. SMITH[1], J. XIE[2], P. MALICKY[2], C. CAREY[4], J. M. SAXE[5], K. M. NAUGLE[4], ***F. A. WHITE**[2,3];

Abstract: Post-traumatic headache (PTH) is one of the most common and persistent symptoms following mild traumatic brain injury (mTBI), often disrupting recovery in civilian/military populations. PTH has to date no defining clinical features, and is subsequently classified as a secondary headache disorder. While PTH can be transient, some patients go on to experience long-term PTH as evidenced by daily or several times a week attacks of headache pain. Despite the prevalence of PTH following mTBI, the pathological mechanisms underlying the development of chronic PTH's remain poorly understood. Research now suggests that monocytic cell subpopulations have an underappreciated role in the evolution of mTBI-associated PTH and may contribute to both subacute and chronic PTH sequelae. To investigate potential contributions of monocytes, we examined the major subpopulations of human monocytes. These cell populations are divided into high CD14 but no CD16 expression (CD14+CD16−) termed classical monocytes. An intermediate subset consists of high CD16 and high CD14 (CD14+CD16+) and a nonclassical subset as high CD16 but with relatively lower CD14 expression (CD14lowCD16+). Importantly, these cell subpopulations are known to preferentially transmigrate across the blood brain barrier and may contribute to neuroinflammation. The aim of this study is to prospectively determine the preponderance of the different monocyte

subpopulations in mTBI patients for up to 4 months post-injury. Adult mTBI patients recruited from Level I Emergency Department Trauma Centers completed study sessions at 1-week, 1-month (sub-acute), and 4-months (chronic) post mTBI (n=31). Participants completed a health history questionnaire, psychological questionnaires (Pain Catastrophizing Scale, Center for Epidemiological Studies – Depression Scale), and a headache survey which included a 0-10 numeric pain rating scale (NRS) to measure average intensity of headache pain. Additional assays included quantitative sensory tests which were administered to participants to measure endogenous pain modulation. The biological methods used to conduct this study were flow cytometry and LPS stimulation of peripheral blood mononuclear cells followed by cytokine/chemokine quantification. Currently, experiments concerning monocyte subpopulations and cytokine secretion following LPS stimulation are ongoing. Our data to date suggests substantial dynamics in monocyte subset distributions over the 4-month time period which could contribute to the clinical outcomes of PTH pain and depression and may serve as biomarkers or as potential therapeutic targets.

Title: The role of deficient pain modulatory systems in the development of subacute and chronic post-traumatic headaches following mild traumatic brain injury: An exploratory study

Authors: *K. M. NAUGLE[1], C. CAREY[1], J. HACKETT[1], J. SAXE[2], F. A. WHITE[3]; [1]Kinesiology, Indiana Univ. Purdue Univ. Indianapolis, Indianapolis, IN; [2]Trauma Dept., St. Vincent Indianapolis Hosp., Indianapolis, IN; [3]Anesthesia, Indiana Univ. Sch. Med., Indianapolis, IN

Abstract: Post-traumatic headache (PTH) is one of the most common and persistent symptoms following mild traumatic brain injury (mTBI), often disrupting recovery in civilian and military populations. Despite the high prevalence of PTH following mTBI, the pathological mechanisms underlying the development of chronic PTH's remain poorly understood. Recent animal and cross-sectional human studies indicate that mTBI may exert deleterious effects of endogenous

pain modulatory function, potentially underlying the elevated risk for intense and chronic PTH's following injury. Thus, the primary purpose of this prospective pilot study was to evaluate whether early pain modulatory profiles (sensitization and endogenous pain inhibitory capacity) after mTBI predicted the development of PTH's sub-acutely and chronically in mTBI patients. Adult mTBI patients recruited from Level I Emergency Department Trauma Centers completed study sessions at 1-week, 1 month (sub-acute), and 4-months (chronic) post mTBI (n=31). During each session quantitative sensory tests were administered to participants to measure endogenous pain modulatory function including 1) the conditioned pain modulation (CPM) test to measure endogenous pain inhibitory capacity and 2) temporal summation of pain test and pressure pain thresholds (PPT's) of the head to measure sensitization of the head. Participants also completed a health history questionnaire, psychological questionnaires (Pain Catastrophizing Scale, Center for Epidemiological Studies - Depression Scale), and a headache survey which included a 0-10 numeric pain rating scale (NRS) to measure average intensity of headache pain. Hierarchical regression analyses were used to predict headache pain intensity at 1-month and 4-months post injury, with potential predictors including demographic variables and outcome measures assessed at 1-week post injury. The regression for sub-acute headaches indicated that after controlling for headache pain at 1 week post injury, PPT's of the head ($p=.023$; $\beta=-0.36$) predicted headache pain at 1-month. For chronic PTH's, the results indicated that headache pain at 1-week ($p=.009$; $\beta=.39$), pain catastrophizing score ($p=.013$, $\beta=0.375$), and pain inhibitory capacity on the CPM test ($p=.023$, $\beta=-0.34$) predicted headache pain at 4 months, account for 51% of the variance. These results suggest that pain sensitization of the head is a risk factor for sub-acute PTH's, while deficient pain inhibitory capacity and pain catastrophizing early after a mTBI are risk factors for chronic PTH's.

Abstract: Human neuroimaging and non-human primate neurophysiology studies demonstrate the role of the central thalamus in arousal regulation and executive function1,2. However, a direct human neurophysiological signature of the central thalamus's contribution to these functions has yet to be reported. Here, we report the first observation of an enhancement of ~10Hz alpha power in the human central thalamus during different rest conditions, a variable-delay visually-guided saccade task ("vigilance task"), and an autobiographical memory (AM) retrieval task. A 40-year-old female patient with a moderate-to-severe traumatic brain injury (msTBI) was bilaterally implanted with Activa PC+S (Medtronic) deep brain stimulation (DBS) electrodes in the central thalamus, allowing both stimulation and recording of local field potentials (LFPs). Post treatment phase, LFPs were recorded from the top- and bottom-most contacts of each electrode as the patient was at rest with eyes closed, eyes open free viewing, or eyes open fixating. Power spectral density (PSD) estimates showed state-dependent modulations in mean power in the 7-12Hz alpha band in the right electrode. Recordings were also taken while the patient performed interleaved blocks of a saccade task with a variable fixation vigilance period and of a word-cued AM task in which the patient pressed a button upon successfully retrieving a memory. PSD estimates showed small modulations in mean power at ~5Hz theta and ~15Hz beta frequencies in the saccade versus vigilance epochs of the vigilance task (n=92). A robust modulation of ~10Hz alpha power was observed in the AM task (n=33) after the button press indication of a memory retrieved. These preliminary results demonstrate the first potential neurophysiological markers of arousal in the human central thalamus, with potential roles in vigilance, eye movement, and AM retrieval.

Title: Assessing biomarker potential and cytotoxicity of neuronal and astrocyte derived exosomes from individuals with mild traumatic brain injury

Authors: *C. N. W. WINSTON[1], R. A. RISSMAN[2], V. B. RISBROUGH[3];
[1]UC San Diego, LA Jolla, CA; [2]Neurosci, UCSD Sch. of Med., La Jolla, CA; [3]Dept. Psychiatry, Univ. of California San Diego, La Jolla, CA

Abstract: The prevalence of TBI is high, but to-date it is difficult to diagnose; there is currently no diagnostic biomarker, in particular, for mild TBI (mTBI) with persistent post concussive symptoms. To examine the potential of neuronally - derived (NDE) and astrocytic-derived (ADE) exosome cargo proteins as biomarkers of chronic mTBI in younger adults, we examined plasma exosomes from combat-deployed Marine and Navy service personnel enrolled in a prospective longitudinal study of combat-related risk and resilience, Marine Resiliency Study II (MRSII). We focused on blood samples collected from participants that self-reported at >1 mTBI while on deployment [MOU1] (mean age, 21.7 ± 0.2), and age-matched, controls (deployed service members that did not endorse a deployment-related TBI or a history of TBI; mean age, 21.95 ± 0.3). Plasma exosomes were precipitated and enriched against a neuronal adhesion protein, L1-CAM, and an astrocyte marker, glutamine aspartate transporter (GLAST) using magnetic beads to immunocapture the proteins and subsequently selected by fluorescent activated cell sorting (FACS). Extracted protein cargo from NDE and ADE preparations were quantified for protein levels implicated in TBI neuropathology by standard ELISAs and on the ultra-sensitive Single molecule assay (Simoa) platform. Plasma NDE and ADE levels of Aβ42 were significantly higher while plasma NDE and ADE levels of the postsynaptic protein, neurogranin (NRGN) were significantly lower in participants endorsing mTBI compared to controls with no TBI history. Plasma NDE levels of Aβ40, total tau, and neurofilament light (NFL), P-T181-tau, P-S396-tau, were not significantly different between the two patient populations. Plasma ADE levels of P-T181-tau and P-S396-tau were not significantly different between mTBI and control samples. Lastly, plasma NDE but not ADE cargo proteins from mTBI samples were found to be toxic to neuron-like recipient cells *in vitro*.

Title: Upper alpha to theta ratio predicts duration of post traumatic amnesia following traumatic brain injury

Authors: *M. L. VINAO-CARL, N. GORGORAPTIS, D. J. SHARP;
Imperial Col. London, London, United Kingdom

Abstract: PTA is a transient neurological disorder characterised by marked retrograde amnesia following traumatic brain injury (TBI). Structural damage to white matter tracts known as diffuse axonal injury (DAI) disrupts large-scale connectivity and hampers integration and consolidation of information within functional brain networks. However, the electrophysiological substrates of this altered connectivity remain poorly understood. EEG offers excellent temporal and spectral resolution for the analysis of neuronal oscillatory processes, an intrinsic property of resting state networks. To investigate network connectivity inverse modelling of alpha and theta rhythms was implemented through DICS and PCC beamformers. Spectral analysis and source reconstruction was conducted within individual frequency bands due to distortions in frequency architecture within PTA subjects. Graph theory indices of coherence were used to compare changes in network topology between controls (n = 13), acute PTA subjects (n = 11) and PTA subjects at follow up (n = 5). Power analysis in channel space revealed a net increase in theta and decrease in alpha power in acute PTA. Source reconstruction confirmed attenuated of alpha within key nodes of the dorsal attention network (DAN), cingulo-insular thalamic system (CITS) and default mode network (DMN). Conversely theta power was abnormally high across multiple networks and co-localised with reductions in alpha power, most notably in medial temporal lobe structures. In acute PTA, we observed an increase in upper alpha to theta ratio (UATR) compared to lower alpha to theta ratio (LATR), while the opposite was true at follow-up. Additionally, UATR but not LATR or TATR correlated with PTA duration. Contrary to expectation total alpha to theta ratio (TATR) was higher than controls at follow-up while theta power normalised, suggestive of a divergent contribution of theta and alpha to acute and long-term PTA deficits. Graph theory analysis based on coherence compounded these findings by revealing chronic disorganisation of alpha and theta connectivity throughout mnemonic and attentional networks which normalised at follow-up. We hypothesise that the slowing of alpha and theta rhythms reflects changes in connectivity from DAI induced deafferentation resulting in a shift in global frequency architecture. We provide evidence that theta and alpha rhythms though propagating through homophilous networks make distinct contributions towards the symptomatology of PTA.

Title: The impact of subconcussive head injuries on cognition-linked electrophysiological markers in contact sport athletes

Authors: *N. M. RASO[1], M. MAZUREK[1], S. BECKER[2], I. KINLEY[2], L. IAFRATE[2], C. PIRES[2];
[1]Dept. of Psychiatry and Behavioural Neurosci., [2]Dept. of Psychology, Neurosci. & Behaviour, McMaster Univ., Hamilton, ON, Canada

Abstract: Concussion is a form of mild traumatic brain injury (mTBI). Sport-related concussions are some of the most common and significant injuries sustained by athletes, and are often accompanied by psychological sequelae such as impaired memory and attention. Recently, attention has been paid to potential cognitive effects of repetitive subconcussive head injuries (RSHI) which may result during contact sport participation in the absence of a sustained concussion. Changes in local spectral power on electroencephalography (EEG), particularly peak alpha frequency (PAF) slowing, have been reported in concussions and mTBI (Dunkley 2015). PAF has been shown to differentiate groups of adults with higher memory performance from those of lower performance, groups of children with advanced reading ability from matched controls, and to predict state-dependent working memory (Angelakis 2004). To our knowledge changes in local spectral power have not been specifically examined in a population that is sustaining RSHI. We initially assessed 35 male high impact university rugby players ages 18-21 three times during the course of their season (t1: pre-contact season, t2: mid-season [5 weeks after contact initiated], and t3: end-season [8 weeks after contact initiated]). At each time point, they underwent 5 minutes of eyes-closed resting state EEG using the Cognionics Quick-20 dry electrode EEG headset. We hypothesized that over the course of a season athletes would demonstrate lower PAF, when controlling for concussion. Abnormal EEG findings have also been reported in athletes with a remote history of concussion, thus we expected baseline PAF to be negatively correlated with prior concussive injuries. We observed PAF slowing from t1 to t2 ($p = 0.016$ two-sided), with no significant change from t2 to t3 ($p = 0.512$ two-sided). These changes coincided with the highest intensity of expected impact throughout the rugby season, suggesting a relationship between RSHI and PAF. We also observed a negative correlation between PAF and self-reported number of RSHI, specifically participants' response to how many times they had their "bell rung" (colloquial phrasing for cranial impact; $p = 0.02$ controlling for concussions). Interestingly, the same trend was not observed when asked about "hard hits" or "concussion." This reporting difference may be due to stigma or concern about athletic sequelae of reporting head injuries as "concussions." These results overall are suggestive of a possible link between repeated subconcussive cranial impact and impaired electrophysiological markers of cognitive function.

Title: Patterns of binocular horizontal and vertical saccade velocity abnormalities in mild TBI

Authors: *J. H. ANDERSON;
Otolaryngology, Minneapolis VA Hlth. Care Syst., Minneapolis, MN

Abstract: Mild traumatic brain injury (mTBI) can result in significant problems affecting vision and oculomotor function (Armstrong, 2018), vergence eye movements (Magone et al., 2014; Suhr et al., 2015), spatial orientation, movement, and balance (Wallace and Lifshitz, 2016; Hoffer et al., 2010), These issues can result in problems with gaze control, eye-head-coordination, and visual-motor transformations underlying goal-directed movements. This can occur after multiple head trauma events, and in some cases after a single mild TBI event. Also, symptoms can persist years after the original trauma (Danna-Dos-Santos et al., 2018) and can become progressively worse over time. Effects of the natural aging processes probably interact with the pathophysiology resulting from TBI. This ongoing research is part of an effort to evaluate oculomotor function (saccades and pursuit eye tracking) during binocular viewing in mTBI. The general aims are to characterize the coordinated movement of the two eyes during changes in gaze in response to movement of a visual target (e.g., during saccades and visual pursuit of an object in three dimensional space) and during attempted visual fixation when there is head movement, to compare the eye velocity profiles of the two eyes in the presence of convergence, and to relate the velocity trajectories of the two eyes to vergence dysfunction in mTBI. For this study, the horizontal/vertical position and velocity of the left eye versus the right eye were analyzed. Saccade targets were presented 5 to 25 degrees left/right of center, 5 to 15 degrees above/below center, and 10 to 15 degrees diagonally from center. Plots of left versus right horizontal eye velocity and vertical versus horizontal eye velocity were quantified with polynomial regressions of eye velocity toward and away from zero velocity. Cluster and discriminant analyses of the regression coefficients identified those subjects with abnormal velocity trajectories. Some patterns included the following. For large saccade amplitudes there could be different velocities for the adducting eye versus the abducting eye in mTBI subjects who have convergence insufficiency or convergence excess. Furthermore, there could be a velocity asymmetry for rightward versus leftward saccades. These preliminary results have identified eye velocity patterns that show promise for characterizing binocular eye movements in mTBI. Further work will evaluate gaze in three dimensions where there are changes in vergence. The results could provide further insight into the underlying pathophysiology affecting the control of gaze in mTBI and suggest possibilities for evaluating vision therapy.

Title: Slow potentials of spreading depolarizations in clinical electrocorticography of traumatic brain injury: Measurement and modeling

Authors: T. WATANABE[1], ***J. A. HARTINGS**[2];
[1]Vagalume, LLC, Palo Alto, CA; [2]Univ. of Cincinnati, Cincinnati, OH

Abstract: Spreading depolarizations (SDs) are a primary mechanism of lesion development in stroke and brain trauma. In extracellular micropipette recordings using a salt bridge and DC amplifier, they are recorded as a propagating (2-9 mm/min), large (up to 20 mV), negative DC shift, reflecting electrical sources and sinks of mass tissue depolarization. In clinical monitoring of patients, by contrast, SDs are recorded by subdural electrocorticography (ECoG) from platinum macroelectrodes, and DC waveforms are more variable, longer-lasting, and multiphasic than those recorded with laboratory techniques. Here we describe and model the DC waveforms of SDs in clinical recordings as a first step to understanding their physiologic basis. Continuous DC-ECoG recordings (median 72 hr) were obtained from 19 patients during neurointensive care after placement of subdural 6-contact electrode strips during neurosurgery for treatment of severe brain trauma. In expert visual review, 1,050 unique SD wavefronts were identified and yielded 2,904 unique recordings of SD on different electrodes. Semi-automated methods were used to measure SD waveforms after correcting for baseline drift. The negative DC shift had an amplitude of 3.35 mV (median; 5-95% range: 0.53-11.15) and duration of 155 sec (5-95%: 67-295), and was often followed by a prominent positivity. The positivity amplitude was 0.97 mV (5-95%: 0.30-3.92 mV) and the duration was 222 sec (5-95%: 69-735). The delay between positive and negative peaks was 142 sec (5-95%: 70-758). All measures were non-normally distributed, and amplitude distributions were multimodal. Waveforms were then modeled under the assumption that potentials reflect the sum of two competing, partially overlapping processes [-N(t) and P(t)] that drive the ECoG voltage [V(t)] in opposite directions: $V(t) = -N(t) + P(t) + e(t) + s(t)$, where e(t) is an error term corresponding to very low frequency activity, and s(t) is the DC trend. N and P were each modeled as the product of two logistic sigmoidal functions with different rise, peak, and decay parameters, with an offset between initiation times. The model robustly fit all waveforms and captured extreme, unexplained variations in morphology. These results suggest the hypothesis that the morphological heterogeneity of SDs can be explained as

variations in two competing physiologic processes that influence the recorded DC potential. While the nature of these processes has not been determined, we speculate the involvement of blood flow responses to depolarization and the sensitivity of platinum electrodes to affected molecular species.

Title: Large-scale receptor tyrosine kinase screening reveals dynamic signaling architecture; unveiling novel translational targets for therapy in blunt traumatic brain injury at acute time point

Authors: *R. REHMAN[1], M. MILLER[3], M. MULAW[2], A. CHANDRASEKAR[4], U. HASSAN[5], A. TAKEOKA[3], F. ROSELLI[1];
[1]Dept. of Neurol., [2]Dept. Of Exptl. Tumor Res., Ulm Universiy, Ulm, Germany; [3]Neuro-Electronics Res. Flanders (NERF), Leuven, Belgium; [4]Dept. of Cell. Neurobio., Tech. Univ., Braunschweig, Germany; [5]German Resilience Ctr. (DRZ), Mainz, Germany

Abstract: Traumatic Brain Injury (TBI) is a highly complicated pathology involving multiple events occurring simultaneously including, but not limited to, inflammation, blood brain barrier disruption, apoptosis and alterations in neuronal signaling. Due to limited understanding of complex protein interactions and therapeutic explorations so far in TBI, we focus on mapping large scale signaling architecture originating from key regulators of multiple signaling events (such as cell proliferation, differentiation, apoptosis); Receptor Tyrosine Kinases (RTKs), at therapeutically effective time point. We opted for an advanced unbiased approach to explore the spatial (cellular specificity) and temporal dynamics (control, 3 hours, 24 hours, 3 days and 7 days) of 14 different RTK families post TBI in wild-type B6SJL male mice, aged P60-P80 (n= 6/group). Based on Linear Models for Microarray and RNA-Seq Data (LIMMA) analysis (R software package) on protein expression, our initial investigation of temporal activation revealed that most signaling events initiate at 3-hours post-TBI, limiting our therapeutic window. After establishing the temporal significance and spatial relevance (histological evidence) of RTKs with therapeutic insight, we performed a large-scale in-depth analysis of 223 different tyrosine kinase proteins and identified activated signaling proteins that showed significant differences compared

to the control group to identify distinct signaling modules (n=4/ group). To explore the therapeutic significance of selected signaling modules (phosphorylated C-met, phosphorylated Btk and phosphorylated VEGFR1), we orally administered single dose of FDA approved (to ensure translational effectivity) RTK inhibitors (JNJ38877605 Medchem; specific inhibitor for p-Cmet - 40mg/kg, CC292 Selleckchem; specific Inhibitor against p-btk - 30mg/kg, and PTK787 Selleckchem; specific inhibitor for p-VEGFR 2 & 1 - 50mg/kg) 2 hours (time until reaches maximum receptor occupancy in brain) before trauma. Inhibiting p-Cmet and p-VEGFR1 revealed alteration in the downstream signaling and partial signaling convergence. Post inhibition behavioral analysis of pellet retrieval task revealed improvement in cognitive performance and motor recovery after single inhibitor treatment post trauma (n=4 per group). Prolonged treatment (starting 2 hours pre-TBI until 7 days, one dose/day) of p-Cmet inhibitor revealed significant behavioral improvement until withdrawal of inhibitor treatment (n=5). We conclude that pathological outcome can be mitigated as early as 1-day post TBI by signal specific RTK treatment during therapeutically effective time window.

Title: Elevating microRNA-125b to treat traumatic brain injury via multiple target genes in rats

Authors: *B. G. LYETH[1], X. CHENG[2], Z. YE[4], B. LYU[3], T. OMUNGUYE-GEORGE[3], D. LIU[3];
[1]Neurolog. Surgery, UC Davis, Davis, CA; [2]Neurol., UC Davis, Sacramento, CA; [3]Neurol., UC Davis, Davis, CA; [4]Neurol., Univ. of California, Davis, Sacramento, CA

Abstract: Our pilot miRNA expression study demonstrated that miR-125b is significantly decreased in blood as early as 3 hr and the decrease lasts for at least 14 days after lateral fluid percussion induced traumatic brain injury (TBI) in rats. It was recently reported that miR-125b is decreased in blood of military combat veterans with post-traumatic stress disorder (PTSD).
In this study, we hypothesized that miR-125b mimic improves outcome after TBI. Using experimental TBI models, our data show that miR-125b mimic (2.4 mg/kg, i.v. and i.c.v.) blocks leukocyte infiltration, reduces cognitive deficits, and decreases neuronal death in hippocampus after TBI. Our miR-125b targetome studies show that a set of miR-125b target genes (Mknk2,

Alkk3, Neu1, others) are responsible for the therapeutic efficacy of miR-125b mimic on TBI. The preliminary mechanistic study data show: 1) miR-125b binds to the 3' untranslated regions (3'UTR) of Mknk2 and Neu1; and 2) Morpholino Oligos (MOs)-miR125b-Mknk2 acts like antagonists to block the binding of miR-125 to 3'UTR of Mknk2. Our ongoing study is to determine whether MO-miR125b-Mknk2/Alpk3/Neu1 *in vivo* prevents miR-125b mimic-induced decrease of these target genes in blood cells (leucocytes, platelets), endothelium, and brain cells (neurons, astrocytes, microglia) after TBI in rats, and thus blocks the therapeutic effects produced by miR-125b mimic after TBI.
In summary, this experiment tested whether miR-125b mimic has both peripheral and central effects to improve TBI outcome via decreasing miR-125b target oncogenes/kinases (Mknk2, Alpk3, Neu1). The combined use of i.v. miR-125b mimic and liposomes to treat TBI in rats is novel, and can be translated to treat human TBI. Our future studies will determine if the long-term decrease of miR-125b in blood is associated with the progression of PTSD after TBI.

Title: Ketogenic diet ameliorates cognitive impairment in a mouse model of TBI

Authors: M. HAR EVEN[1], V. RUBOVITCH[1], S. SCHREIBER[2], ***C. G. PICK**[1];
[1]Tel Aviv Univ., Tel Aviv, Israel; [2]Psychiatry, Tel Aviv Med. Ctr., Tel Aviv, Israel

Abstract: Traumatic brain injury (TBI), is a brain dysfunction without present treatment, caused by a violent blow to the head. In models of various brain injuries, animals fed with ketogenic diet (KD) perform better on learning tasks than those fed standard diet (SD). The main goal was to examine whether KD has a neuroprotective effects on the cognitive deficits in the mTBI mouse model. Mice were fed ketogenic or standard diet starting immediately following the trauma. Cognitive and behavioral performance was assessed 7 and 30 days post injury using Elevated Plus Maze (EPM), Y-Maze and Novel Object Recognition (NOR) tasks. Tail blood was taken for determination of ketone bodies levels at 0, 3, 7 and 30 days post injury and SIRT1 levels in the cortex were assessed using western blot analysis 30 days post injury. The results of the Y-maze and NOR tasks showed that mTBI mice maintained on KD, showed better cognitive abilities than the mice fed SD. EPM analysis shows no difference between all groups, indicating that injury failed to cause any anxiety-like behavior. Relative to control + SD mice, mice received KD (with or without mTBI) demonstrated a prominent increase in ketone bodies at 3, 7 and 30

days after the KD was initiated. Mice maintained on SD; post injury demonstrated SIRT1 reduction when compared with control and KD groups. These results support accumulating evidence that KD may be an effective approach to increase brain resistance to damage, and suggest a potential new therapeutic strategy for treating mTBI.

Title: MiR-212-5p attenuates ferroptotic neuronal death after traumatic brain injury by targeting Ptgs2

Authors: *X. XIAO[1], L. ZHANG[1,2], S. CAO[1], Y. JIANG[1], H. YAN[3], W. LIANG[1], L. GAO[2]; [1]Dept. of Forensic Genetics, West China Sch. of Basic Med. Sci. & Forensic Med., [2]Lab. of Mol. and Translational Medicine, West China Second Univ. Hosp., [3]Dept. of Forensic Pathology, West China Sch. of Basic Med. Sci. & Forensic Med., Sichuan Univ., Chengdu, China

Abstract: Ferroptosis, a newly discovered form of iron-dependent regulated cell death, has been indicated to be involved in traumatic brain injury (TBI). MiR-212-5p has previously reported to be downregulated in the extracellular vesicles after TBI. Here, we aimed to investigate whether miR-212-5p is involved in the ferroptotic neuronal death in TBI mice. The mRNA and protein levels of ferroptosis-related molecules were examined using qRT-PCR and western blotting, and the levels of ferrous iron and malondialdehyde (MDA) were measured by corresponding detection kits at 6h, 12h, 24h, 48h and 72h following controlled cortical impact (CCI) in mice. Cell death was examined using the lactic dehydrogenase assay in HT-22 and Neuro-2a cell lines transfected with miR-212-5p mimic and inhibitor. Luciferase report assay was applied to determine the target gene of miR-212-5p. Finally, the learning and spatial memory were evaluated using morris water maze test after stereotactically injecting miR-212-5p into the right lateral ventricle of CCI mice. The mRNA levels of *Gpx4* and *Acsl4* were upregulated at 6h post injury. The mRNA levels of *Nox2* and *Sat1* were constantly upregulated from 6h to 72h and the mRNA levels of *Slc7a11* were upregulated from 12h to 72h post injury. The protein levels were also observed to be significantly upregulated, with Gpx4 at 6h, Nox2 from 6h to 72h, xCT from 12h to 72h, and Sat1 at 72h after CCI. Interestingly, ferrous iron and MDA were increased

whereas miR-212-5p was decreased in the CCI group compared to the sham group from 6h to 72h post injury. Overexpression of miR-212-5p would attenuate ferroptosis while downregulation of miR-212-5p would promote ferroptotic cell death by targeting Ptgs2. Administration of miR-212-5p in CCI mice significantly improved the learning and spatial memory. Collectively, these findings indicate that miR-212-5p may protect against ferroptotic neuronal death in CCI mice partially by targeting Ptgs2.

Abstract: Traumatic brain injury (TBI) is a form of mechanical insult to the brain leading to irreversible motor functional impairments in TBI patients. TBI remains as a leading cause of disability and morbidity in the globe. The injured neurons in the central nervous system (CNS) have limited regenerative capacity to regrow their damaged axons across the lesion for target reinnervation following injuries. The presence of extrinsic growth inhibitory molecules such as chondroitin sulfate proteoglycans (CSPGs) at the lesion further impede axon regeneration after injuries. Currently, there is no effective therapy aimed to improve functional restoration in TBI patients. In recent years, emerging evidence suggested that low dose of ionizing radiation (LDIR) exhibits a wide range of beneficial effects to irradiated individuals. For instance, single exposure to LDIR exerts neuroprotective effects in various neurological disorders including Parkinson's disease, retinitis pigmentosa, glaucoma and spinal cord injury. This prompted us to investigate the potential hormetic effects of LDIR on promoting CNS repair after TBI. We performed a stab wound injury in motor cortex of postnatal and adult C57BL/6 mice, respectively. The mice were then received a single whole-body exposure of LDIR immediately after injury. In both postnatal and adult mice, LDIR markedly accelerated wound closure with a

marked reduction in apoptotic neurons 7 days after cortical stab wound injury. More importantly, we observed a marked improvement in motor functions from irradiated mice as assessed by pole climbing test, grip strength test and beam walking test after injury. Further histological analysis revealed that LDIR markedly increased microglial density, associated with a marked reduction in CSPG deposition at the lesion 6 hours and 7 days after injury. We confirmed that the increased microglial density at the lesion was due to the promoted microglial migration towards the lesion, but not due to increase in microglial proliferation. Cytokine profiling and qPCR analysis on irradiated microglia suggested that LDIR promoted microglial M1-to-M2 switch, with increased expression of genes involved in neuroprotection, CSPG degradation and phagocytosis. Taken together, our study demonstrated for the first time that LDIR promoted CNS repair and functional restoration via immunomodulation of microglia after TBI, shedding new light in developing alternative therapeutic approaches for TBI patients to improve functional outcomes after injuries.

Title: Expression of brain cortex CB_1 and CB_2 cannabinoid receptors in rats with traumatic brain injury treated with repetitive low frequency transcranial magnetic stimulation

Authors: S. GARCIA-RIOS[1], S. VALADEZ-IBARRA[1], M. MARTINEZ-VARGAS[1], L. NAVARRO[2], *L. VERDUGO-DIAZ[1];

Abstract: Transcranial Magnetic Stimulation (rTMS) is a technique which uses an electromagnetic field to induce changes in excitability of brain tissue. This property results useful as a treatment against Traumatic Brain Injury (TBI), a disease in which, among other things, deregulates the excitability of the brain, leading to neural damage. Against a TBI, the brain activates endogenously protective mechanisms, such as the activation of the cannabinoid system, which will regulate the excitability of neurons via their CB1 and CB2 receptors. In this study we evaluated the effects of low frequency (1 Hz) rTMS on the expression of brain cortex CB1 and CB2 receptors in Wistar rats with TBI. TBI was induced using a closed skull weight-

drop injury, with a metallic piston at 40 psi pression on the exposed and unprotected skull at the level of the motor cortex (coordinates $P = -2$ and $L = 1.4$). To apply rTMS we used an In-House Electronic System (EMAGPRO 12). This system was designed and developed by engineers at the Center of Research and Advanced Studies, IPN (Mexico City). 1 Hz rTMS was applied for 7 days 10 minutes daily with a figure-eight coil. Furthermore, we evaluated the expression of cannabinoid receptors CB1 and CB2 through Western Blot and RT-PCR analysis. Additionally, we performed a behavior scale using the Neurobehavioral Severity Scale (NSS-R), to assess the effects that TBI had upon the motor skills of the rats and see if low frequency rTMS had a positive effect on this trait. The level of expression of the cannabinoid receptors, as well as the results of the behavioral scale differ within all our experimental and control groups. We concluded that the rTMS modifies the excitability of the brain cortex, thus altering the expression of CB1 and CB2 receptors, leading to changes in the outcome of the TBI.

Title: Effect of high frequency transcranial magnetic stimulation on the expression of brain cortex CB_1 and CB_2 cannabinoid receptors of rats with traumatic brain injury

Authors: S. VALADEZ-IBARRA[1], S. GARCÍA-RIOS[2], L. VERDUGO-DIAZ[3], M. MARTÍNEZ-VARGAS[2], *L. NAVARRO[4];
[1]Fisiología, Fac. Medicina, Univ. Naional Autónoma de México, CDMX, Mexico; [2]Fisiología, Fac. Medicina, Univ. Nacional Autónoma de México, CDMX, Mexico; [3]Fisiología, Fac. Medicina, Univ. Nacional Autonoma Mexico, Mexico DF, Mexico; [4]Fisiología, Fac. Medicina, UNAM, CDMX, Mexico

Abstract: Traumatic Brain Injury (TBI) is defined as an alteration in brain function or other evidence of brain pathology, caused by an external force. Neuroprotective therapy aims to minimize the activation of toxic pathways and enhance the activity of endogenous neuroprotective mechanisms. Endocannabinoid system has been found as a mechanism of self-protection with neuroprotective properties, and repetitive Transcranial Magnetic Stimulation (rTMS) has been propose as a potential treatment for TBI. However, there are no studies that

prove if rTMS affects the endocannabinoid system after a TBI. Therefore, the objective of the current study was to determine the effect of high frequency rTMS on the expression of CB1 and CB2 cannabinoid receptors in rats with traumatic brain injury. We used adult male rats of Wistar strain, which were subjected to a TBI using a closed skull weight-drop injury, with a metallic piston at 40 psi pression, was induced on the exposed and unprotected skull at the level of the motor cortex (coordinates $P = -2$ and $L = 1.4$). Subsequently treated with 10 Hz rTMS for 7 days, 10 minutes daily. To apply it, we used a figure-eight coil with an In-House Electronic System (EMAGPRO 12), that was designed and developed by engineers at the Center of Research and Advanced Studies, IPN (Mexico City). The behavior was analyzed with the Revised Neurobehavioral Severity Scale (NSS-R). The food consumption was recorded before and after the trauma. The expression of cannabinoid receptors in the cerebral cortex was analyzed by western blot and RT-PCR. Finally, the results were statistically analyzed by using the Prism program. There was no significant difference in food consumption, but there was a tendency to reduce food consumption after trauma. Preliminary results suggest that rTMS change the expression of CB1 and CB2 cannabinoid receptors. The results of NSS-R scale show an improvement in rats treated with high frequency rTMS compared to untreated animals. These results suggest that high frequency rTMS may be a potential treatment for TBI.

Title: Effects of the transient receptor potential cation channel 5 inhibitor on hippocampal neuronal death after traumatic brain injury

Authors: *M. PARK, B. CHOI, A. KHO, S. LEE, D. HONG, J. JEONG, B. KANG, D. KANG, S. SUH;
Hallym Univ., ChunCheon, Korea, Republic of

Abstract: Traumatic brain injury (TBI) occurs when an external force impacts the brain. Head injury encompasses a variety of injuries that may involve damage to other structures such as the

scalp and skull. Traumatic brain injury can cause physical, cognitive, social, and behavioral changes and even permanent disability or death. When traumatic brain injury occurs, vesicular zinc is excessively released into the synaptic cleft and is then translocated into post synaptic neurons through multiple receptors and channels, such as the AMPA receptor, transient receptor potential cation channels (TRPCs) and transient receptor potential melastatin (TRPM). After primary brain injury, translocated free zinc can accumulate in neurons and lead to secondary events such as oxidative stress, inflammation, edema, swelling and cognitive impairment. Transient receptor potential channel 5 (TRPC5) is one of the seven mammalian transient receptor potential cation channels (TRPCs) that regulate the influx of cations such as calcium and sodium. The predominant TRPC channels are the TRPC1,4, and 5 in the mammalian brain and they are expressed in the hippocampus and prefrontal cortex of the brain regions. Specifically, TRPC4 and TRPC5 are associated with the mechanism of mercury toxicity and neurological behavior. Under pathological conditions such as ischemia and traumatic brain injury, excessive zinc release and accumulation occurs in neurons. Excessive zinc leads to calcium influx via TRPC5, leading to neuronal cell death. Based on previous research, we hypothesized that TRPC5 would induce zinc as well as calcium entry. Therefore, we hypothesized that the suppression of TRPC5 would prevent neuronal cell death by reducing the influx zinc and calcium. To confirm our hypothesis, we used a TBI animal model and after the TBI, we immediately injected NU6027(1mg/kg, *i.p),*TRPC5 inhibitor, and then sacrificed animals 24 hours later. We conducted Fluoro-Jade B (FJB) staining in order to confirm degenerating neuronal death in the cornus ammonis 1 (CA1) and the dentate gyrus (DG) of the hippocampus. As a result, degenerating neuronal cell death was decreased in the NU6027-treated group compared to the vehicle-treated group after TBI. In conclusion, the present study suggests that the suppression of TRPC5 can open a new therapeutic window for reduction of the neuronal death that may occur after TBI. Key Words: traumatic brain injury, zinc, NU6027, transient receptor potential cation channel 5, neuronal death

Title: N-docosahexaenoylethanolamine (synaptamide) GPR110-dependently reduced gliosis and improved spatial memory deficit induced by mild repetitive traumatic brain injury

Authors: *H. CHEN, A. DESAI, H.-Y. KIM;
NIAAA/NIH, Rockville, MD

Abstract: Long-lasting complications of repetitive mild traumatic brain injury (rmTBI) has been linked with chronic neurodegenerative disorders, especially the development of chronic traumatic encephalopathy (CTE). To date, there have no effective treatments for the complications of rmTBI in clinic. N-docosahexaenoylethanolamine (synaptamide) is an endogenous metabolite of docosahexaenoic acid (DHA) that is highly enriched in the brain. Synatamide was shown to potently promote neurogenesis, neuritogenesis and synaptogenesis in developing neurons, and ameliorate LPS-induced neuroinflammation. Recently, we have demonstrated that GPR110 is the target receptor for synaptamide mediating synaptamide's bioactivity. We have also established that repeated Closed-Head Impact Model of Engineered Rotational Acceleration (rCHIMERA), a mouse model of traumatic brain injury (TBI), produces long-lasting neuropathology and memory deficit. Using this injury model, we investigated in this study the effects of synaptamide on biochemical and functional outcome of TBI. Adult C57BL/6 male wild-type (WT) and GPR110 knock-out (GPR110 KO) mice were subjected to CHIMERA injury or sham treatment for three consecutive days at 24 h interval. Immediately after each impact, mice were injected with synaptamide or vehicle intraperitoneally. They were euthanized at different time-points from the last injury. Immunohistochemical and Western blot analyses were performed for GFAP and Iba-1 to assess astrocyte and microglial activation, respectively. Morris water maze was conducted for functional outcome. rCHIMERA injury caused spatial memory deficit and prolonged activation of microglia and astrocyte in multiple brain areas including optic tract, corpus callosum, cortex and hippocampus from both WT and KO mice. After injury, gpr110 was elevated in the WT mouse brain and synaptamide significantly improved the spatial memory and suppressed the activation of microglia and astrocyte. In contrast, the synaptamide treatment following rCHIMERA produced no improvement in GPR110 KO mice. Our data indicate that synaptamide exerts GPR110-dependent specific neuroprotective effects, suggesting translational potential of GPR110 activation in repetitive mild TBI.

Abstract: There is a need to increase our understanding of TBI-induced long-term disability mechanisms, and to test the safety and efficacy of therapeutic measures that target these mechanisms utilizing approaches that have excellent potential for rapid translation. Acceleration/deceleration closed head traumatic brain injury (CH-TBI) induces damage of micro-vessels which results in endothelial shear injury, blood brain barrier (BBB) dysfunction, and micro-bleeding. Microbleed-derived iron can provide an enduring inflammation, further breakdown of the BBB tight junctions, and cell death through multiple inflammatory pathways. Thus, removal of toxic iron is potentially an important therapeutic design for TBI treatment and rehabilitation. Thus, the current studies tested the influence of injury and compared the therapeutic impact of 2 iron chelators on hallmark disabilities in a rodent model of CH-TBI. Mild/moderate CH-TBI was produced using our previously reported protocol (450 g/1.25m). NaHBED (n=10) and Deferoxamine (DFO; n=5) treatments were initiated PO Day-0 and continued through PO Wk-2 (50 mg/kg/day for 2 wks, SQ). The control animals received equal volume of saline (SQ; n=7). The outcome measures for spasticity, balance, gait, anxiety and cognitive functions were compared in the saline control and 2 iron chelators treated groups. Our data to date revealed long-term disabilities in motor/vestibulomotor, anxiety and cognitive behaviors following CH-TBI, and significant reductions in these disabilities by NaHBED treatment. By comparison, the DFO treatment was less effective in reducing spasticity. This difference in treatment efficacy might be due to the comparatively lower iron clearing potency of DFO. Immunohistochemistry studies of TBI tissues showed patterns of a) iron deposition and disruption of BBB, b) increased expression of markers for inflammation in each neural region essential for the studied behaviors, and c) loss of regulatory noradrenergic and trophic supports. Tissues from the NaHBED-treated animals exhibited robust normalization of each of these markers. Collectively, our studies demonstrate that: 1) iron deposited via TBI-induced BBB disruption accelerates neuroinflammation and neuronal cell death, and 2) these can be attenuated by an iron chelator treatment. Taken together, iron chelator treatment offers the potential for a mechanism-based therapy that addresses a significant contributor to long-term TBI disabilities, and contributes to trophic support for neuronal and vascular healing, and neuroplasticity for adaptive compensation. NaHBED revealed superior outcomes when compared with treatment using DFO.

Title: Induction of the NF-kB signaling pathway, proinflammatory cytokines, and pyroptosis in the sensorimotor cortex, central nucleus of amygdala and locus coeruleus following TBI in rats

Authors: *S. TSUDA[1,2], J. HOU[1,2], R. NELSON[1], A. SADEESHKUMAR[1], V. BAEZ[1], F. J. THOMPSON[1,2,3], P. BOSE[1,2,4];
[1]Brain Rehabil. Res. Ctr., North Florida/South Georgia Veterans Hlth. Syst., Gainesville, FL; [2]Physiological Sci., [3]Neurosci., [4]Neurol., Univ. of Florida, Gainesville, FL

Abstract: Over 10 million people in the world have annually been suffering from traumatic brain injury (TBI) morbidities. Most of these injuries are classified into mild/moderate closed-head TBIs (cTBIs) which reported to have risk factors for inflammation-induced further progressive diseases. Acceleration-deceleration cTBI can cause micro-vessel shear injury, blood brain barrier (BBB) dysfunction, and bleeding. Iron deposited by diffuse micro-bleeds fuels inflammation through reactive oxygen species, and multiple inflammatory pathways, which may induce progressive disabilities. Our laboratory has shown that the BBB was compromised in various brain regions following cTBI and activated the TLR4/NF-kB signaling pathway in the hippocampus. Importantly, these detrimental biological events were attenuated following an iron chelator (NaHBED) therapy, indicating that removal of toxic iron deposited in the brain is an effective anti-inflammatory therapeutic option following cTBI. However, in other brain regions, NF-kB-mediated inflammatory status has not well been studied following cTBI. Therefore, the purpose of this study was to investigate the cTBI-induced NF-kB signaling pathway, cytokine induction, and inflammation-induced programmed cell death (i.e., pyroptosis) in the sensorimotor cortex (SMCx), the central nucleus of amygdala (CeA) and the locus coeruleus (LC). Following mild/moderate cTBIs (450g/1.25m) in rats, the coronal brain sections of intact and cTBI animals were immnofluorescently labelled with antibodies against NeuN, toll-like receptor 4 (TLR4), and p-NF-κB (p65 phosphorylated at serine 536), proIL-1β, TNFα, caspase-1, cleaved IL-1β, gasdermin D, and dopamine beta-hydroxylase. Our data to date indicate that cTBI activated the NF-κB via TLR4, induced proinflammatory cytokines (proIL-1β, TNFα), and

triggered pyroptosis in the neuronal cells of the SMCx and LC. In contrast, NF-κB was activated only in non-neuronal cells without involving TLR-4 in the CeA. Nonetheless, expression of TNFα and pyroptosis was highly induced in neuronal cells of the CeA. These results together with our previous work suggest that iron deposited via cTBI-induced BBB disruption might partly be responsible for increased induction of NF-κB signaling, proinflammatory cytokines, and pyroptosis in the SMCx and CeA. Since the iron chelator, NaHBED, significantly attenuated cTBI-induced LC cell loss, iron chelator treatment could be a potential therapeutic option to improve TBI-induced progressive disabilities. The current study provides new information of cTBI-induced CNS pathology, which might contribute to the development of a novel therapy.

Col. of Wisconsin, Milwaukee, WI; [5]Feinberg Sch. of Med., Northwestern Univ., Chicago, IL; [6]Div. of Civil, Mechanical and Manufacturing Innovation, Natl. Sci. Fndn., Alexandria, VA

Abstract: Athletes in contact sports are at high risk for concussive events and often undergo cognitive baseline testing to aid in concussion diagnosis and recovery tracking. About 30% of athletes are suspected of intentionally suppressing baseline test scores. We developed a sensorimotor task that is sensitive to concussion and its recovery: participants reached repeatedly toward a spatial target while opposed by spring-like loads that changed unpredictably from trial to trial. We quantified the extent to which sensorimotor memories contributed to motor adaptation. The present study examines if our technique is resistant to intentional performance suppression. Eight subjects performed Cogstate computerized cognition testing and our reaching task. Subjects grasp the handle of a 2D horizontal planar robot and perform 190 ballistic out-and-back movements to a remembered target. During the reach, the robot applies a pseudorandom spring-like load that changes between trials. An ARX time series model was fit to the sequences

of reach errors and spring stiffness values to describe how implicit memories of reach performance contribute to sensorimotor adaptation. Between trials, subjects moved the handle to self-assess the accuracy of their prior reach. Subjects participated in two conditions. In one, they performed their best and in the other they attempted to intentionally suppress performance by simulating symptoms associated with concussion. We hypothesized that suppression will result in lower Cogstate scores as well as kinematic deficits in the robotic test, but will not show differences in how implicit memories contribute to sensorimotor adaptation. When suppressing the Cogstate tests, subjects scored below the normative range of healthy individuals. When suppressing the robot task, subjects took longer to reach the target, moved slower than normal, and performed with greater variability. Self-assessments during suppression had greater variability and took longer. Despite that, the time series model was resistant to the effects of suppression. The variance accounted for by the model was not different between conditions. Further, the model revealed no differences in how sensorimotor memories contribute to the rejection of errors caused by environmental uncertainty. These results provide preliminary evidence that the contributions of sensorimotor memories to motor adaptation cannot be intentionally suppressed, and that a robotic assessment of concussion severity based on sensorimotor adaptation will be resistant to intentional performance suppression.

Title: Growth differentiation factor 11 promotes survival of retinal ganglion cells *in vitro* and *in vivo*

Authors: *H. YOO, U. SHANMUGALINGAM, D. CHAN, M. LUI, P. SMITH;
Neurosci., Carleton Univ., Ottawa, ON, Canada

Abstract: The visual system is a well-established model system to study axon regeneration and cell survival *in vitro* and *in vivo*. The use of this model has resulted in the identification of a variety of factors that improve cell survival and axonal growth after axon injury. Growth differentiation factor 11 (GDF11), a transforming growth factor-β (TGF-β) family member, was previously identified as a rejuvenation factor that promoted neurogenesis in aging mice. Previous work has revealed that *gdf11* mRNA is expressed in the developing retina, and that GDF11

protein can signal *Xenopus* retinal ganglion cell (RGC) growth *in vitro*. Previous work has revealed a striking decline in intrinsic RGC growth potential with age. The mechanisms mediating this dramatic loss of axonal growth ability has fueled significant interest in defining the factors that could contribute to this limitation in growth ability. The potential regenerative effect of GDF11 on mammalian RGCs remain unclear. Experiments were designed to determine whether GDF11 treatment promotes RGC survival and axonal growth using *in vitro* RGC culture and *in vivo* optic nerve crush models. Our data revealed that GDF11 administration was sufficient in protecting RGCs both *in vitro* and *in vivo*, but did not promote axonal growth. Our data also suggest that GDF11 promotes its neuroprotective effects *via* activation of phospho-Smad2/3 *in vitro*.

Title: Regulating neuronal growth with structurally-defined glycans

Authors: *G. HARTMAN, H. LUI, A. A. VASCONCELOS, V. POMIN, J. SHARP, N. M. ASHPOLE;
Univ. of Mississippi, Oxford, MS

Abstract: Chondroitin sulfate proteoglycans (CSPGs) and keratan sulfate proteoglycans (KSPGs) play an important role in neural development. Aggrecan, a CSPG, operates in the neural extracellular matrix where it negatively regulates neurite outgrowth to prevent aberrant process formation. Unfortunately, this aggrecan or CSPG-rich/KSPG-rich barrier can also prevent neuronal regeneration, which contributes to the inability to repair brain and spinal cord injuries. Removal of CSPGs and KSPGs has been shown to increase neurite outgrowth. We extend these findings by testing the ability of structurally-defined glycans to outcompete aggrecan and allow neurite outgrowth. Our overall goal is to determine if there is a particular glycan structure which can overcome inhibitory CSPGs and KSPGs without inhibiting neurite outgrowth themselves. We utilized primary cultures of rat neurons and applied polydisperse structurally related mixtures of CSPGs, KSPGs and newly-isolated, novel glycans in the absence and presence of aggrecan. Several of these glycans successfully removed the aggrecan-induced blockade while not inhibiting neurite outgrowth on their own. We are currently investigating the

efficacy of these compounds in concentration-response curves and are testing additional glycans with different molecular weights and varying sulfation patterns to determine the structural requirements for the glycans as modulators of neurite outgrowth. By investigating the impacts of these glycans, we will increase the understanding of proteoglycan regulation of neural structure and function, and potentially identify compounds which could be used to treat spinal cord injuries.

Title: Dynamic causal modelling of methylphenidate effects in traumatic brain injury

Authors: *M. BALAET;
Imperial Col. London, London, United Kingdom

Abstract: Executive dysfunction (ED) after traumatic brain injury (TBI) is a major concern, since it impacts quality of life and independence. Corticostriatal networks are known to be impaired in disorders characterised by ED, and recent evidence suggests their disruption also underlies these symptoms in patients with head trauma. In particular, the structural and functional connectivity between the caudate and a distributed set of cortical regions appears to correlate with ED (De Simoni et al., 2017). Analysis was performed on multimodal DTI-fMRI data from 42 TBI patients and 21 age-matched controls. The results illustrate reduced integrity of the white matter tracts and reduced connectivity in these regions is associated with ED. The same cohort of patients underwent a placebo-controlled methylphenidate trial.
The aim was to use resting state fMRI data to assess the impact of TBI and that of methylphenidate on the functional connectivity between the caudate and the regions where methylphenidate produces an effect. We used a generative modelling technique called spectral dynamic causal modelling. We constructed fully connected four-node models comprising of the caudate self-connection, network to caudate connection, caudate to network connection and network self-connection. After testing the stability of the models, we contrasted them across groups and drug conditions. Correlations between the effect of the drug on the functional

connectivity and Stroop executive function neuropsychological measures were then performed. All directed connectivity patterns were reproducible across individuals and across baseline, drug and placebo sessions, different significantly across patient and control groups. There were reliable effects of drug, whereby the patient-control differences in functional connectivity were normalised. There was a significant effect of TBI on the right caudate and methylphenidate effect network four-node models. The connection between the methylphenidate effects network to the right anterior caudate which was impaired by TBI was normalised by methylphenidate. Similarly, the connection between the right posterior caudate to the methylphenidate effects network which was impaired in TBI was normalised by methylphenidate. There was also a significant effect of the drug on the left anterior caudate and methylphenidate effect network four-node model. There was no significant correlation between the drug normalisation effect and executive function measures.
These results pave the way towards understanding effective connectivity relating to ED in TBI. They also enable a better understanding of the mechanism of methylphenidate effects.

Title: Lumbosacral spinal cord epidural stimulation reduces systemic inflammation in an individual with neurologically complete chronic SCI

Authors: *O. BLOOM[1,2], A. V. OVECHKIN[3], C. A. ANGELI[4], A. ARCESE[1], S. J. HARKEMA[5];
[1]The Feinstein Inst. For Med. Res., Manhasset, NY; [2]Physical Med. and Rehabil., Zucker Sch. of Med. at Hofstra Northwell, Great Neck, NY; [3]Neurolog. Surgery, Univ. Louisville, Louisville, KY; [4]Frazier Rehab Inst., Louisville, KY; [5]Dept Neurol Surgery, Univ. Louisville, Frazier Rehab Inst, KSCIRC, Louisville, KY

Abstract: In individuals with severe spinal cord injury (SCI), the autonomic nervous system (ANS) is affected leading to cardiovascular deficits and other impairments, which may result in hypotension, autonomic dysreflexia, and increased risk of stroke. Persons with SCI rostral to T5, where sympathetic nervous system fibers exit the spinal cord and innervate the immune system, also have clinically significant systemic inflammation and increased infection risk. We recently

identified profoundly elevated systemic inflammatory gene expression in persons with SCI rostral to T5 (Herman et al J Neurotrauma 2018). Based on our recent finding that lumbosacral spinal cord epidural stimulation (scES), using targeted configurations that promote cardiovascular stability (CV-scES), can safely and effectively normalize blood pressure in persons with chronic SCI (Harkema et al 2018 JAMA Neurol, Harkema et al 2018 Front Hum Neurosci), we hypothesized that this intervention would improve the immunological profile for inflammation. We investigated if daily exposure to CV-scES, that successfully restored blood pressure stability, also altered whole blood gene expression in a person (female, age 27) with chronic clinically motor complete cervical SCI. Blood was collected before and after 8 months of 6-hour daily CV-scES training. RNA was isolated from blood, mRNASeq libraries prepared (Illumina TruSeq Stranded Total RNA with RiboZero Globin), and 100bp paired end reads were collected on the Illumina HiSeq 2500 platform. With Partek Flow software, trimmed reads were aligned using STAR to the *hg38*genome assembly. There were 1040 up- and 590 down-regulated genes that were differentially expressed after CV-scES (FDR=0.05). Functional analysis of differentially expressed genes was performed using Enrichr (Chen et al 2013). The Panther, Reactome and Biocarta databases indicated that expression of several inflammatory pathways were downregulated, including Toll-like receptor signaling, cytokine and chemokine pathways. Conversely, Biocarta and Reactome databases indicated that the IL-10 anti-inflammatory pathway was upregulated after CV-scES. To our knowledge, this is the first report of data consistent with the hypothesis that scES may improve the immunological functional state in persons with chronic SCI.

Title: Human spinal circuitry generates intentional individual joint flexion after clinically diagnosed motor complete spinal cord injury with subthreshold lumbosacral epidural stimulation

Authors: *C. A. ANGELI[1,2], E. REJC[2], C. FERREIRA[2], S. J. HARKEMA[2,1];

Abstract: Recovery of voluntary motor function several years after clinical diagnosis of motor complete spinal cord injury (SCI) is rare. Subthreshold network targeted lumbosacral epidural stimulation (scES) restored voluntary movement in 5 individuals with motor complete SCI (Angeli2014, Grahn2017). Suprathreshold spatiotemporal targeted scES elicited movement in motor incomplete SCI in muscles scored 0 (AIS scale) (Wagner2018). The aim of this study is to understand mechanisms of suprathreshold vs. subthreshold scES in generating joint flexion in individuals with motor complete SCI. Individuals with motor complete SCI (n=19) were implanted at L1-S1 SC level with an electrode and neurostimulator. These individuals (age: 29.5 ± 8.7 yrs; time post injury: 4.8 ± 2.7 yrs) were unable to move their legs voluntarily, stand or step independently. Neurophysiological mapping consisted of amplitude and frequency responses at 2Hz scES using adjacent bipolar electrode combinations providing threshold and activation patterns for lower extremity muscles. Next, voluntary movement mapping continued while asking individuals to attempt flexion movements of the first toe, ankle and hip. Further changes in parameters were dependent on observed EMG modulation and joint movements. We performed torque and EMG assessments in 6/19 cases and supine movement in 19/19. All individuals were able to modulate EMG activity in the presence of subthreshold scES and able to move at least one joint. Although suprathreshold scES could drive movement in all participants, all optimized scES were subthreshold to allow initiation and control of the movement. Six of 19 were able to move all six joints. Figure 1 shows the number of joints individuals were able to voluntarily move with optimized scES. Ability to move was not dependent on age, time since injury or neurological level. These results provide evidence the subthreshold scES modulates network excitability of the injured spinal cord to allow for the integration of afferent and supraspinal descending input to generate movement below the injury after motor complete SCI.

Title: Effects of epidural stimulation on splanchnic blood flow during tilt induced hypotension in an individual with chronic spinal cord injury

Authors: *J. D. GUEST[1], A. V. OVECHKIN[2], B. LEGG DITTERLINE[3], J. FISHER[4], S. WADE[4], J. M. WECHT[5], S. J. HARKEMA[6];

Abstract: Introduction. Ultrasonography is a dynamic imaging tool to examine blood flow provided technical issues are controlled. In persons with chronic spinal cord injury (SCI), lumbosacral spinal cord epidural stimulation targeted to increase systolic blood pressure (CV-scES) has demonstrated beneficial changes in blood pressure regulation during orthostatic stress. The mechanisms responsible for these CV-scES-triggered blood pressure and flow changes are unknown, however sympathetic nervous system activation may play a role. Sympathetic activation could be associated with increased vascular resistance and a shift in blood volume from capacitance vessels into the active circulation, thereby increasing venous return and cardiac output. It is known that a substantial fraction of total blood volume is within the splanchnic vascular bed, thus, we hypothesized that celiac artery flow velocity would decrease in tilt and increase during active CV-scES Methods. To quantify such effects, dynamic changes in blood vessel area and pulsatility must be imaged. These measurements must be feasible under conditions that are clinically relevant, such as induced postural hypotension on a tilt table. To examine these issues, we focused on the celiac artery in an individual with C5, AIS B SCI (7.5 years post-injury) with known postural hypotension who had an epidural stimulator implanted at L1-S1 spinal cord. The pulsatile waveform (studied with a Philips Epiq 7G and C5-1 curved array transducer) provides information related to resistance in the vessels. Results. While supine, the celiac trunk varied from 5.9-8.6 mm diameter across the cardiac cycle (BP=106/67 mm Hg, 45 BPM). Peak systolic velocity was 300 mm/s with a resistivity index (RI) of 0.81. When the participant was tilted to approximately 50 degrees, peak velocity fell to 105 mm/s and vessel caliber ranged from was 5.0-7.4 mm; automated RI did not change but the diastolic wave form was unstable (58/35 mm Hg, 73 BPM. With active CV-scES of .8-.9V during tilt, RI decreased to 0.73, peak velocity increased to 145 mm/s, and flow during diastole was both greater and stable (BP 126/82 mm Hg, 60 BPM). Conclusion. These observations demonstrate active CV-scES changes celiac artery blood flow during postural hypotension.

Louisville, Frazier Rehab Inst, KSCIRC, Louisville, KY

Abstract: **Introduction:** Lumbosacral spinal cord epidural stimulation (scES) can locate and activate autonomic and motor neuron pools by systematically changing individual electrode polarity, frequency, amplitude, and pulse burst. Muscle activation and blood pressure data obtained from neurophysiological spinal mapping provides targeted configurations to elicit voluntary motor behaviors (Motor-scES) or physiological responses (CV-scES) to elicit cardiovascular stability. This study evaluated the specificity of the spinal neural networks for modulating cardiovascular function by comparing the efficiency of Motor-scES daily training to CV-scES daily training for targeting chronic orthostatic hypotension and modulating cardiovascular function **Methods:** Seven individuals with chronic motor complete cervical SCI *having cardiovascular dysregulation* received CV-scES (n=4) or Motor-scES (n=3) spatial temporal neurophysiological mapping. CV-scES mapping for systolic blood pressure stability in the range of 110 -120 mmHg did not invoke any motor activation in the lower extremity or trunk. Before and after 80 sessions of CV-scES or Motor-scES training, blood pressure, heart rate (HR) without scES were recorded during orthostatic stress induced by sit-up test. Individuals lay supine for at least 15 minutes, passively moved to a seated position; finger plethysmography and ECG recorded beat-to-beat blood pressure and HR. **Results:** Before CV-scES training, mean sitting blood pressure (90±6/54±4 mmHg) significantly decreased compared to supine blood pressure (103±3/60±3 mmHg). Mean sitting HR (72±3 bpm) significantly increased compared to supine HR (51±3 bpm). After CV-scES training, mean sitting (107±6/63±4 mmHg, 66±5 bpm) outcomes compared to supine (103±3/60±3 mmHg, and 63±3 bpm) were not significantly different. Orthostatic blood pressure stability was maintained regardless orthostatic stress. Before

Motor-scES training, mean sitting blood pressure (100±13/54± 8) decreased compared to supine blood pressure (115±12/59±8 mmHg) and mean sitting HR (65±8 bpm) significantly increased compared to supine HR (53±5 bpm). After Motor-scES training mean sitting blood pressure (84±6/47±1 mmHg) compared to supine (110±19/59±8 mmHg) significantly decreased; mean sitting HR (55±7,66±6 bpm) significantly increased. **Conclusion:** Specificity of spinal cord networks elicit independent and unique temporal spatial maps for autonomic regulation. Motor-scES mapping is specific to motor pools with negative or no effect on cardiovascular function. This research has implications for intersystem networks for restoration of health and function after SCI.

Title: Epidural stimulation of the lumbosacral cord to promote storage and stimulate voiding in urethane-anesthetized transected female rats

Authors: *C. HUBSCHER[1], R. HOEY[1], D. MEDINA AGUINAGA[1], F. KHALIFA[2], S. ZDUNOWSKI[1], A. EL-BAZ[2], S. HARKEMA[1];

Abstract: Daily bladder management for conditions such as spinal cord injury (SCI) most frequently includes a combination of catheterization (either self-intermittent or suprapubic) and pharmacological approaches, which targets maintenance but does not promote recovery of function. We have exciting data from multiple individuals receiving spinal cord epidural stimulation (scES) that is optimized for stepping and standing, in combination with task-specific training, that shows improvements in lower urinary tract function. The overall objective of our current functional mapping pre-clinical animal studies is to identify scES configurations (electrode location, amplitude and frequency) at lumbosacral spinal levels that can promote and/or provide optimal neural control of urine storage (adequate bladder capacity at safe pressures without incontinence) and sufficient controlled emptying (high voiding efficiency at safe leak point pressures) after SCI. Initial mapping was done in acute anesthetized terminal preparations during cystometry (bladder filling) using a modified electrode array (Medtronic

Specify 5-6-5 epidural device) that is being used by our group in parallel human scES studies. The current data compares the response to scES in transected female rats 6 weeks post-injury at L3 (region with circuits related to external urethral sphincter [EUS] control) and L6 (level of bladder circuits) spinal segments. Results: 1) L3 stimulation through activation of EUS reduced void volume but did not prevent bladder contractions. 2) L3 stimulation showed a frequency and intensity dependent pattern of results, indicating the rate of stimulation is important for EUS function. 3) L6 stimulation immediately triggered contraction of the bladder and voiding. 4) L6 stimulation is intensity but not frequency dependent. Taken together these results suggest that the circuitry is dissociable and amenable to stimulation that seeks to promote either storage or voiding. Furthermore, our innovative approach and novel application of this Medtronic Specify 5-6-5 epidural device will generate functional maps that will lay the groundwork for expedient translation of this promising technology to individuals with SCI as well as provide a powerful tool for elucidating underlying circuits present in the lumbosacral cord that are involved in urogenital function.

Title: Response of distal colon and rectum to epidural stimulation of the lumbosacral cord in Wistar rats under urethane anesthesia

Authors: *R. F. HOEY[1], D. MEDINA AGUINAGA[1], F. KHALIFA[3], S. ZDUNOWSKI[2], A. EL-BAZ[3], S. HARKEMA[2], C. HUBSCHER[1];
[2]Kentucky Spinal Cord Injury Res. Ctr., [1]Univ. of Louisville Sch. of Med., Louisville, KY; [3]Univ. of Louisville Speed Sch. Engin., Louisville, KY

Abstract: Numerous complications arise after spinal cord injury (SCI) including bowel dysfunction, with up to 95% of individuals requiring at least one method of initiating a bowel movement (e.g. laxatives, digital stimulation). Bowel dysfunction after SCI is most often due to reduced gastric and colonic motility (constipation, fecal impaction, difficulty with evacuation) with the additional complication of incontinence due to lack of rectal/anal sensation and control. Our lab has been investigating the effect of spinal cord epidural stimulation (scES) on bowel function in an animal model utilizing spinal cord transection (T9) and spinally intact male and

female Wistar rats (contusion injuries planned) in an acute anesthesia (urethane, IV) terminal preparation. Using a modified Medtronic 5-6-5 electrode, the L5-S1 segments of the cord were targeted and numerous stimulus combinations (frequency, Hz; intensity, µA) were applied to determine the effect on distal colon, rectal, and anal sphincter function. To measure bowel function, pressure probes (Millar SPR-524, 3.5F tip) were positioned at depths of 2 cm (rectum) and 10 cm (distal colon) from the anal verge. Anal sphincter function was measured by implanting fine-wire electrodes bilaterally into the external anal sphincter. Baseline data collected prior to scES is compared to those data collected during stimulation periods to assess any effect on bowel contraction activity in these structures. Dependent measures for pressure recordings include: the presence of contractile waves, frequency of contractions, amplitude of contraction, and whether the contractions are stimulated or inhibited by the epidural stimulation. The data collected to date indicate 1) scES stimulation of the L5-S1 cord inhibits the contractile activity of both the distal colon and rectum, 2) this inhibition is intensity but not frequency-dependent, and 3) the inhibition is not sex dependent. Additionally, because data regarding bowel and bladder function can be collected concurrently, any interaction or dynamic interplay in these systems can be investigated. Furthermore, the ability to control multiple system dysfunctions with a single intervention is an exciting possibility for the treatment of human SCI using scES.

Title: Effects of wide pulse width neuromuscular electrical stimulation and afferent feedback on activation pattern modulation in individuals with severe spinal cord injury

Authors: *D. J. ARPIN[1], B. UGILIWENEZA[1], G. F. FORREST[2], S. J. HARKEMA[3], E. REJC[1];
[1]Univ. of Louisville, Louisville, KY; [2]Kessler Fndn., West Orange, NJ; [3]Dept Neurol Surgery, Univ. Louisville, Frazier Rehab Inst, KSCIRC, Louisville, KY

Abstract: Severe spinal cord injury (SCI) results in the inability to stand and step, primarily because of the loss of tonic supraspinal drive to the spinal circuits controlling posture and locomotion, compromising the level of excitability of this circuitry. In the last decade, spinal cord stimulation has been applied to enhance the excitability of the spinal circuitry to promote motor function recovery after sever SCI. Interestingly, wider pulse width neuromuscular electrical stimulation (NMES) has been proposed to favoring central (spinal) activation mechanisms. Thus, specific NMES parameters may modulate the excitability of the spinal circuitry, which could affect training-induced neural plasticity and consequent motor function recovery in individuals with sever SCI. Therefore, this study explored the effect of NMES pulse width on central activation in 10 individuals (female = 2, male = 8; age = 33.9 + 9.5 years) with motor complete SCI. To this end, NMES was delivered to the knee extensors and ankle plantarflexors starting with an amplitude of 5 mA, and increasing by 5 mA for every subsequent stimulation until either the participant requested to stop the stimulation or the maximum stimulation amplitude (140 mA) was reached. This stimulation protocol was repeated with two pulse widths (500 and 1000 us), which were randomized across participants and muscle groups. To investigate the effects on central activation, electromyographic (EMG) activity was concurrently recorded from the vastus lateralis during knee extension stimulation, and from the gastrocnemius medialis during plantarflexion stimulation. Our results show that the higher pulse width (1000 us) demonstrated a greater effect on central activation as quantified by more frequent occurrences of post-NMES EMG activity ($p = 0.002$) and a 37% higher EMG amplitude ($p = 0.003$) in contractions generating similar torque output. We also found inter-individual differences in how NMES amplitude and torque output affect central activation. These findings suggest that pulse width should be carefully selected, together with the other NMES parameters, to optimize the neuromuscular activation depending on the rehabilitative goal (i.e. maximizing torque generation or central activation). Furthermore, preliminary data suggests that wide-pulse NMES may be used to enhance central activation for a short time period, during which afferent information alone (i.e., movement of the knee joint) could enhance muscle activation. Further studies should examine whether this brief period can provide a time-window during which greater training-induced neural plasticity can be promoted.

Title: The human spinal cord can concurrently learn standing and stepping after chronic motor complete spinal cord injury

Authors: *E. REJC[1], C. A. ANGELI[2], S. HARKEMA[1];
[1]Univ. of Louisville, Louisville, KY; [2]Frazier Rehab Inst., Louisville, KY

Abstract: Increasing evidence suggests that spinal cord epidural stimulation (scES) and activity-based training can promote significant motor function recovery after chronic, motor complete spinal cord injury (SCI). Previous studies in complete animal models showed that the motor tasks that are repetitively practiced affect the characteristics of training-induced neural plasticity, leading to task-specific adaptations and also affecting the spinal cord ability to learn novel motor tasks. The aim of this study is to further explore the learning potential of the human spinal cord following motor complete SCI, understanding *i*) whether standing and stepping, two motor patterns that differ considerably in neural activation, can be concurrently learnt; and *ii*) which training characteristics are important to promote the recovery of standing and stepping. Eight individuals with chronic, motor complete SCI were implanted with a scES unit. Four individuals performed approximately 80 sessions of stand training (5 days/week; 1 hour per session) followed by ~80 sessions of step training (Cohort 1). Four other individuals (Cohort 2) alternated standing and stepping practice every session (stand-step training), achieving the same training volume as Cohort 1 (~160 sessions). Cohort 2 also gradually increased training frequency (i.e. 2 sessions/day), and was encouraged to volitionally contribute to the motor pattern generation. Training was always performed with individual- and task-specific scES. Stand training improved standing ability in all individuals enrolled in Cohort 1, with two of them achieving independent standing with self-assistance for balance. The subsequent block of step training impaired standing ability in three of these four participants. Also, Cohort 1 was unable to take independent steps on a treadmill at any time point. Cohort 2 showed progressive improvement in standing ability (less external assistance and less stable upper limb support) throughout stand-step training, and all individuals achieved independent standing holding the hands of a trainer to assist balance. Also, independence of different components of the step cycle progressed throughout stand-step training in Cohort 2, and three participants achieved independent steps on a treadmill; the intent to step was critical to generate this motor output. These findings suggest that, after motor complete SCI, the human spinal cord can concurrently learn standing and stepping while appropriate scES parameters are applied, and that varying the trained motor task as well as volitionally contributing to the motor pattern generation are key training features.

Title: Neurophysiological markers and machine learning to support the selection of epidural stimulation parameters for standing rehabilitation in humans with chronic motor complete spinal cord injury

Authors: *S. MESBAH[1], T. PISOLKAR[1], C. A. ANGELI[3], S. J. HARKEMA[4], E. REJC[2]; [1]Kentucky Spinal Cord Res. Ctr., [2]Univ. of Louisville, Louisville, KY; [3]Frazier Rehab Inst., Louisville, KY; [4]Dept Neurol Surgery, Univ. Louisville, Frazier Rehab Inst, KSCIRC, Louisville, KY

Abstract: Individual- and task-specific spinal cord epidural stimulation (scES) parameters can re-enable independent standing (with self-assistance for balance), which is a key achievement toward the recovery of functional mobility, in individuals with chronic motor complete spinal cord injury. The selection of scES parameters for standing is currently performed following dedicated guidelines based primarily on individualized maps of motor pool activation collected in supine position, resulting in an evidence-based process that relies substantially on the operators' expertise. We recently demonstrated that wavelet analysis can provide relevant EMG features contributing to the accurate classification (~96% by K-nearest neighbor) of assisted and independent standing. We also observed that independent standing was promoted by EMG activity characterized by lower median frequency, lower variability of median frequency, lower variability of activation pattern, lower variability of instantaneous maximum power as well as higher total power. In the present study, we initially took advantage of these findings to develop a prediction algorithm capable of ranking effectiveness of muscle activation for standing. We trained muscle-specific KNN models based on data sets related to different external assistance for standing. We then fed the prediction algorithm with 48 standing events performed by 6 individuals while different scES parameters were tested. Ranking scores varied substantially among scES parameters applied and investigated muscles. This approach can identify which muscle groups present poor activation and conceivably limit the achievement of independent standing, thus narrowing down subsequent scES parameters adjustments. Also, it can suggest which of the tested set of scES parameters promotes the activation pattern more effective for standing; this can be relevant when different sets of parameters result in the same need of external assistance for standing, and the decision on which parameters to apply for standing rehabilitation should be made. Additionally, we performed preliminary analysis on supine

stimulation mapping EMG data to determine the effects of scES parameters on time- and frequency-domain EMG characteristics related to standing ability. Preliminary analysis suggests that adjustments in scES parameters result in individual- and muscle-specific adaptations of these EMG characteristics. Future studies should assess whether scES parameters resulting in EMG characteristics more effective for standing during supine stimulation mapping may also promote better standing muscle activation and ability.

Title: Regulation of cardiovascular function with epidural stimulation maintains normative blood pressure responses to bladder distension in individuals with chronic spinal cord injury

Authors: *S. C. ASLAN[1], A. N. HERRITY[2], C. HUBSCHER[3], S. J. HARKEMA[4]; [1]Neurolog. Surgery, Univ. of Louisville, Louisville, KY; [2]Neurolog. Surgery, Univ. of Louisville, Louisville, KY; [3]Dept Anatom. Sci. & Neuro, Univ. Louisville Sch. Med., Louisville, KY; [4]Dept Neurol Surgery, Univ. Louisville, Frazier Rehab Inst, KSCIRC, Louisville, KY

Abstract: More than 1.5 million people live with spinal cord injury (SCI) in the USA. Many of them suffer from bladder dysfunction that significantly lowers their quality of life after SCI. Neural control of micturition requires complex coordination between supraspinal centers, autonomic (sympathetic and parasympathetic) and somatic (pudendal) pathways. Supra-sacral SCI disrupts voluntary and autonomic control of bladder function resulting in detrusor over-activity and uncoordinated bladder and external urethral sphincter contractions characterized by low overall compliance (low bladder capacity under high detrusor pressure). Furthermore, SCI above T6 can disrupt sympathetic control of the heart and the blood vessels, impairing cardiovascular autonomic regulation of blood pressure (BP) consistent with persistent hypotension and/or episodes of uncontrolled hypertension known as autonomic dysreflexia (AD). Both neurogenic bladder and cardiac autonomic impairment places individuals with cervical and upper-thoracic SCI at considerable risk for AD and, long-term cardiovascular diseases. Recently, we demonstrated that lumbosacral spinal cord epidural stimulation (scES) optimized for cardiovascular function restored autonomic cardiovascular function in individuals with cervical SCI. In this study, we investigated the effects of scES optimized for cardiovascular

and bladder storage function on BP responses in individuals with cervical and upper-thoracic SCI. Optimal scES configurations were identified to promote both the neural control of bladder storage and the maintenance of normative BP. Initial studies were conducted in two participants (AIS B; C4 and T2 levels of injury). Continuous BP and heart rate using the non-invasive BP monitoring system were acquired during cystometry (bladder filling) without scES at baseline and with scES, over a 5-month period. In addition, the first participant received scES training at home. Blood pressure was greater than 160/80 mmHg in both individuals at baseline and decreased to 120/78 mmHg and 110/65 mmHg, respectively, during urodynamics. Both individuals reported decreased or no AD symptoms during bladder filling when scES was in use. Moreover, improved control of BP regulation facilitated a further increase in bladder capacity, within normative range of 400-450 ml (per International Continence Society guidelines) with scES during cystometry. In conclusion, scES has potential to improve BP during bladder filling in individuals with SCI and reduce the number of daily catheterizations, which may improve their quality of life and lead to a decrease in the morbidity and mortality risk.

Title: Effects of epidural spinal cord stimulation on respiratory motor function in individuals with chronic spinal cord injury

Authors: *A. V. OVECHKIN[1], B. DITTERLINE[1], S. C. ASLAN[1], C. A. ANGELI[2,1], S. HARKEMA[2,1];

Abstract: Introduction: Respiratory and cardiovascular complications are listed as the leading causes of morbidity and mortality in individuals with chronic spinal cord injury (SCI). However, there is no clinical standard of care that has been established for individuals with these abnormalities. Respiratory and cardiovascular systems are inter-related and impact one another through respiratory-cardiovascular (also known as cardio-respiratory) coupling mechanisms. We

demonstrated that lumbosacral spinal cord epidural stimulation specifically configured to target cardiovascular function (CV-scES) can normalize the arterial blood pressure in individuals with SCI-induced cardiovascular deficits. We hypothesized that cardiovascular effects of the CV-scES are associated with respiratory modulations.
Methods: In six individuals with motor-complete SCI above T4, Spirometry (Forced Vital Capacity /FVC/; Forced Expiratory Volume in 1 sec /FEV_1/; Maximum Inspiratory and Expiratory Pressure /PI_{max} and PE_{max}/; and surface electromyography of upper trapezius, intercostal, rectus abdominus, and oblique muscles have been obtained with CV-scES "off" or "on" both at baseline and after 80 sessions of CV-scES.
Results: In response to stimulation, the participants demonstrated no acute changes in spirometrical and electromyographic outcomes. However, after exposure to 80 sessions of CV-scES, specifically configured to target the arterial blood pressure regulation, there were increase in spirometric measures in association with improved respiratory multi-muscle activation patterns.
Conclusion: These results indicate that CV-scES facilitates respiratory-cardiovascular remodeling within spinal autonomic and motor networks. This intervention may be used as a therapeutic option to improve respiratory-cardiovascular health in patients with SCI.

Abstract: Introduction: Spinal cord injury (SCI) results in profound cardiovascular dysfunction that results in persistent hypotension, orthostatic hypotension, and autonomic dysreflexia. Spinal

cord epidural stimulation (scES) has demonstrated the ability to acutely increase hypotensive blood pressure to a normal range and mitigate orthostatic hypotension even without stimulation. However, effects of scES on the heart are unknown. We sought to understand how the heart acutely responds to scES, and the role it plays in maintaining blood pressure after an scES intervention.Methods: Nine individuals with chronic, cervical SCI were included. Individuals were implanted with a stimulator over spinal segments L1-S1. Individual-specific scES configurations (electrode polarity, amplitude, frequency, and pulse width) were identified to maintain systolic blood pressure within 107-120 mmHg (CV-scES) without skeletal muscle contraction. Blood pressure was confirmed with brachial measurements. Echocardiography was performed before and after scES training by a registered diagnostic cardiac sonographer in the left-lateral decubitus position and while seated at a 45-degree incline to create a mild orthostatic stress.Results: Application of CV-scES increased blood pressure in the seated position and led to rapid increases in cardiac output, end diastolic volume, and systolic flow in the hepatic veins. There were also rapid increases to VTI of blood measured in the LVOT, ascending aorta, and descending aorta. After a prolonged scES intervention, measured without stimulation, there were significant increases to ejection fraction, end diastolic volume, LVOT VTI, and LV Mass. Despite increased mean arterial pressure and increased afterload, there were no increases to end systolic volume and stroke volume remained the same.Conclusions: Acute CV-scES rapidly increased venous return to the heart, increasing end diastolic volume and cardiac output during orthostatic stress. VTI of blood in the LVOT and ascending and descending aorta also rapidly increased. This indicates acute CV-scES promotes redistribution of blood from the capacitance vessels into the systemic circulation. After a prolonged scES intervention, even without stimulation, there were significant increases to ejection fraction, end diastolic volume, LVOT VTI, and LV mass, and no changes to end systolic volume. This indicates scES can lead to beneficial changes within the heart that improve cardiovascular function, which can lead to improved cardiovascular regulation.

Title: Subthreshold spinal cord epidural stimulation acutely restores voluntary movement control in individuals with motor complete spinal cord injuries

Authors: *J. M. D'AMICO[1], S. J. HARKEMA[1,2], E. REJC[1], C. ANGELI[2,1];

Abstract: Following human spinal cord injury (SCI) there is a marked interruption in descending inputs to the spinal cord which results in reduced voluntary motor activity and impaired motor function. However, the spinal cord can recover and exhibits considerable plasticity at various levels of the motor pathway. Because most human SCI are not anatomically complete, recovery of function most likely involves plasticity in circuitry above and below the lesion. Through the use of epidural stimulation (scES) and task-specific training we have provided a cellular environment that enables sensory-motor circuits to recover significant levels of function. The purpose of this study was to investigate whether subthreshold scES alone, prior to training, can restore voluntary activation below the lesion. Seven participants (33±13 years of age) with chronic motor complete SCI (5.3±2.8 years since injury) who were unable to voluntarily move their legs were implanted at L1-S1 with an electrode array and neurostimulator. Three initial sessions of spatiotemporal neurophysiological mapping and voluntary movement mapping was performed to determine the optimal stimulation configuration to elicit hip flexion, ankle dorsiflexion and hallux extension. Different configurations were used for each leg. Participants then performed a functional neurophysiological assessment which consisted of standardized mono-articular movements (unilateral hip flexion and extension, knee extension, ankle dorsi and plantar-flexion, hallux extension) in a supine position with and without delivery of scES. Surface EMG was recorded from sixteen lower limb muscles while participants were instructed to perform three attempts of each movement. EMG activity was detected in the agonist muscles during hip flexion (left: 33±13% of attempts, right: 43±19%), ankle dorsiflexion (left: 33±16%, right: 48±15%) and hallux extension (left: 43±16%, right: 38±17%). Interestingly, EMG activity was also detected in the appropriate agonist muscles during hip extension (left: 22±16%, right: 50±20%), knee extension (left: 50±15%, right: 28±12%) and ankle plantarflexion (left: 28±17%, right: 56±17%). These results indicate that subthreshold epidural stimulation can sufficiently alter the central state of excitability of the spinal cord to allow residual voluntary inputs to effectively elicit muscle activity below a complete spinal cord injury, even in the absence of training. Interestingly, it appears that even subthreshold scES that was not mapped for a specific movement can effectively restore voluntary control below a lesion.

Title: Correlation of radiographic spinal cord parameters with volitional movement after spinal cord epidural stimulation for chronic traumatic spinal cord injury

Authors: *T. BALL, C. ANGELI, E. REJC, S. MESBAH, S. HARKEMA, M. BOAKYE; Univ. of Louisville, Louisville, KY

Abstract: Background
Spinal cord epidural stimulation has been shown to enable volitional lower extremity movement in patients with chronic traumatic spinal cord injuries. The parameters correlating with successful stimulation are still not well understood. In particular, there is sparse literature on the radiographic predictors of success. Our goal in this study was to correlate radiographic parameters with the volitional motor responses post-operatively (number of joints moved)
Methods
For participants with appropriate imaging, we measured the following parameters: 1.) The cross-sectional area (CSA) of the spinal cord at the inferior endplate of C3. 2.) The CSA of the spinal cord at the superior endplate of T12. 3.) The ratio of the CSA of the residual neural tissue to the CSA of the cord at C3 inferior endplate was classified at <1/3, 1/3 to 2/3, or greater than 2/3. 4.) The position of the inferior-most aspect of the stimulator with respect to the inferior-most aspect of the conus medullaris (below, at, or above the termination of the conus medullaris).
Results:
1.) There was a positive correlation between the CSA of the spinal cord at the inferior endplate of C3 and the number of joints moved (R^2 of 0.35).
2.) Placement of the stimulator above the termination of the conus medullaris does not appear to adversely affect the number of joints moved and may be associated with slightly higher efficacy than placing the bottom of the stimulator at of below the termination of the conus medullaris, but this needs to be confirmed with more participants
3.) There is a poor correlation between the C3 CSA and the T12 CSA, and the C3 CSA seems to be a better predictor of number of joints moved.
4.) Even in participants who had less than 1/3 of the normal CSA compared to the normal cord, some were able to achieve a good functional status.
Conclusions:
Careful evaluation of pre-operative radiographic parameters may help identify patients that are more likely to benefit from spinal cord epidural stimulation with regards to regaining volitional movement of the lower extremities.

Abstract: The ability to regain motor activity, translating to improved functional activity, is extremely important to persons with spinal cord injury (SCI). However, there are many other critically important residua of SCI that significantly impact the health and quality of life of affected persons. These include cardiovascular dysfunction (hypotension and hypertensive episodes), thermoregulatory, respiratory, bowel, bladder, and sexuality related dysfunction as examples of what is often referred to as the “hidden impairments” of SCI. To date, 20 individuals with motor complete injury have undergone spinal cord epidural stimulation (scES) and training at one center. Results to date (either by defined tools (“measured”) or by patient report (“reported”) have shown improvements in respiratory function (n=16, measured); cardiovascular function (n=12, measured, n=17 reported); bladder and bowel function to varying degrees (n=18, reported; n=8, measured); improved temperature regulation and sweating (n=17, reported); improved cognition and alertness/well-being (n=9, measured; n=16 reported) and sexual function (n=4, reported). These results reveal benefits of scES in numerous domains of medical disturbances after SCI. However, to document improvement in each of these requires application of several scales which can create patient burden while still not fully capturing the significance of improvement in overall health and its impact on quality of life or activities of daily living. As such, a new measure linking different domains of physiological function is being developed that will document quantitative and patient-reported outcomes that can be used prospectively to

gauge an overall 'health profile' of persons with SCI. This poster will present both the medical benefits of scES to date on 20 implanted patients as well as the new measure developed for future use.

Title: Lumbosacral spinal cord epidural stimulation acutely improved cerebral blood flow regulation during orthostatic stress after chronic human spinal cord injury

Authors: *S. WANG[1], J. M. WECHT[2], A. V. OVECHKIN[1], B. DITTERLINE[1], J. D. GUEST[3], G. F. FORREST[4], O. BLOOM[5], S. J. HARKEMA[1,6];

Res., Manhasset, NY; [6]Frazier Rehab Inst., Louisville, KY

Abstract: Introduction: Severe spinal cord injury (SCI) causes cardiovascular dysfunction including orthostatic hypotension. As a result, cerebral hypo-perfusion can cause dizziness and lightheadedness and may be associated with decline of cognitive function and increased risk of stroke. We previously showed that epidural stimulation at lumbosacral spinal cord (scES), targeted for cardiovascular function (CV-scES), acutely and consistently mitigated orthostatic hypotension in individuals with chronic SCI. The goal of this study is to evaluate the acute effect of CV-scES on cerebral blood flow (CBF). **Methods:** Individuals (n=5) with chronic cervical motor-complete SCI and cardiovascular deficit were implanted with a 16-electrode array on the dura (L1-S1 cord segments, T11-L1 vertebrae). Specific CV-scES configurations (anode and cathode electrode selection, amplitude, frequency, and pulse width) for each individual were identified to maintain systolic blood pressure within a targeted normative range without lower extremity muscle activity. Orthostatic tolerance was tested with a 70°- head-up tilt maneuver lasting for 30 minutes until symptoms limited. Transcranial Doppler was used to assess CBF in

the middle cerebral artery, with simultaneous blood pressure and heart rate monitoring at supine and during the head-up tilt maneuver. The tilt test was performed without CV-scES and repeated with CV-scES. Beat-to-beat mean arterial pressure (MAP) and mean CBF velocity (mCBFv) were analyzed. Cerebrovascular conductance, as a measure of cerebral vasodialation, was estimated as mCBFv/MAP. Cerebrovascular autoregulatory function during tilt was estimated as the regression coefficient between mCBFv and MAP during MAP decline. **Results:** Orthostatic tolerance increased with CV-scES (duration of tolerated tilt: 30 ± 0 minutes) compared to without CV-scES (5.5 ± 3.9 minutes). Decreases in MAP (-12 ± 14 mmHg, 13 ± 14%) and CBFv (-4 ± 8 cm/s, 9 ± 20%) from supine to tilt with CV-scES were reduced compared to without CV-scES (-37 ±11 mmHg, 47 ± 12% and -17 ± 7 cm/s, 32 ± 10% respectively). Cerebrovascular conductance during tilt with CV-scES was unchanged from supine (104 ± 9 %) as compared to an increase during tilt without CV-scES (137 ± 47 %). The regression coefficient between mCBFv and MAP during tilt was 0.29 ± 0.19 cm/s/mmHg with CV-scES and 0.71 ± 0.36 cm/s/mmHg without CV-scES. **Conclusions:** Acute CV-scES increased orthostatic blood pressure and CBFv and improved orthostatic tolerance in individuals with chronic SCI. Cerebral vasodialation was restored to supine level, and cerebrovascular autoregulatory function was improved with CV-scES during orthostatic stress.

Title: Expanding target range boundaries: A new measure to evaluate continuous blood pressure stability in individuals with chronic spinal cord injury

Authors: *B. UGILIWENEZA[1], S. MESBAH[4], A. N. HERRITY[2], S. C. ASLAN[5], S. WANG[3], S. J. HARKEMA[6];
[1]Neurosurg., [3]Dept. of Neurolog. Surgery, Kentucky Spinal Cord Injury Res. Ctr., [2]Univ. of Louisville, Louisville, KY; [4]Neurosurg., Univ. of Louisvlle, Louisville, KY; [5]Neurolog. Surgery,

Univ. of Louisville, Louisville, KY; [6]Dept Neurol Surgery, Univ. Louisville, Frazier Rehab Inst, KSCIRC, Louisville, KY

Abstract: Profound dysfunction of the cardiovascular system occurs after spinal cord injury (SCI), particularly in motor complete injuries above T6, which is a leading cause of death in this population. Cardiovascular dysregulation leads to persistent hypotension, bradycardia, orthostatic hypotension and episodes of autonomic dysreflexia, which drastically impacts quality of life by affecting overall health and disrupting the ability to engage in daily activities. Our recent work has demonstrated that spinal cord epidural stimulation (scES), in the absence of descending input, can modify the excitability of the relevant spinal interneuronal pools allowing them to respond to peripheral autonomic input and approximate normal cardiovascular control. Current measures of cardiovascular function are limited, as they only focus on a static window of clinically recommended values. Therefore, there is a critical need to identify a sensitive measure that comprehensively captures the dynamic variability that participants experience in their day-to-day life and the effect of scES on blood pressure stability. In this study, our goal was to define and validate a measure of expanding target range boundaries that would quantify the stability of blood pressure within normative ranges as well as account for deviations outside of that range. Using the theory of cumulative density function, the expanding target range boundaries were defined as: 1) the percentage of systolic blood pressure values falling within clinically recommended ranges, and 2) the percentage of values occurring in symmetrically expanded boundary domains, above and below the clinically recommended range. Representation of range distribution and percentage of values within each range was calculated as area under the curve (AUC), distinguishing those individuals with a high percentage of values falling within recommended blood pressure ranges during scES targeting cardiovascular function. We demonstrated that this measure is valid (i.e. discriminatory, reliable and responsive) and was effective at evaluating the level of blood pressure variability and deviations from clinically recommended values in participants receiving scES optimized for cardiovascular function. This measure will improve our understanding of the cardiovascular profile in individuals with chronic SCI and represents a novel method to comprehensively and objectively quantify the effect of scES and training on the cardiovascular system.

Abstract: In the past few years, the use of epidural stimulation (scES) in individuals with clinically diagnosed motor complete spinal cord injury has been expanded from motor control to autonomic regulation, both of the cardiovascular system as well as bladder control. Although scES needs to be task-specific and integrated with training for prolonged effects to develop, more than one training intervention can be beneficial for the integration of multiple systems. The purpose of this study is to evaluate the integration of various task-specific scES training paradigms and its effects on motor, cardiovascular and bladder systems. We used a 5-6-5 electrode array and stimulator implanted epidurally from L1 - S1 spinal cord in individuals with chronic motor complete (n=4). Individuals underwent multiple training paradigms (motor, cardiovascular and/or bladder) with task-specific scES either concurrently or by adding one system at a time following a long training intervention within a single system. Epidural mapping for each system occurred prior to optimization of stimulation parameters and the beginning of any training. We show evidence that the spinal cord has the capacity to integrate and regulate more than one system following training with task specific scES. The addition of multiple scES training paradigms does not negatively affect previously scES trained systems while showing significant improvements in additionally trained systems. These results demonstrate that networks within the human spinal circuitry can drive motor movement and simultaneously integrate regulatory control of autonomic function. After spinal cord injury these circuits remain intact and are an untapped resource for therapeutic intervention.

Title: Development of regenerative therapy for spinal cord injury in dogs

Authors: W. HANYU, *N. FUJITA, J. CHEN, T. TAKEDA, R. NISHIMURA;
The Univ. of Tokyo, Tokyo, Japan

Abstract: Spinal cord injury (SCI) due to various cause such as intervertebral disc disease and trauma is a major neurological disability in dogs and canine SCI can be regarded as spontaneous and translational animal model for human research. Recently, we have established a novel canine MSC adhering to adipocytes in bone marrow (named as bone marrow peri-adipocyte cells, in short, BM-PACs) and developed cell-based regenerative therapy for canine SCI using BM-PACs. *In vitro*, BM-PACs showed superior ability to secrete hepatocyte growth factor (HGF) which possesses powerful healing effects on SCI in response to inflammatory cytokines. When transplanted into intravenously to SCI model nude mice in acute phase, BM-PACs showed homing ability and secrete HGF at the injured site. After transplantation, mice showed significantly better functional recovery and more myelinated areas retained. Further, BM-PACs showed secretion ability of VEGF and chemo-attractant property to CXCL12 upregulating at the SCI site in sub-acute phase. When transplanted intravenously to SCI model in sub-acute phase, cells could also migrate toward the injured site and functional recovery were significantly facilitated. Histological evaluation revelated increase of CD31 and NF-200 positive area at the injured site, which suggested angiogenesis and axonal repairing or regeneration were induced by intravenously transplanted cells. Based on these results, clinical application of cell-based therapy for severe canine SCI using BM-PACs are carrying out and can provide useful outcomes for translational research in similar MSC-based therapies for human SCI. On the other hand, we are also investigating a method to induce BM-PACs into neural cells to develop regenerative therapy for canine chronic SCI. When BM-PACs were cultured in neural differentiation medium after FGF-2 treatment, neuron-like morphological changes and MAP2 expression was enhanced. After neural induction, intracellular Ca^{2+} levels increased by KCl stimulation, thus BM-PACs can generate neuron-like cells possessing electrophysiological function and there is a possibility of cell replacement therapy for canine chronic SCI using these cells.

Abstract: [Background] Translational research develops human therapeutic methods based on data of basic research, and evaluations of the outcome of model animals should be equivalent to those of humans in clinical field. In spinal cord injury (SCI) research, many clinical trials have been performed in recent years, but there is contradiction that the method of outcome-evaluation differs between human and model animals. Our team has also performed translational research on SCI with neural stem cell transplantation. We, therefore, developed multiple evaluation-methods which could be common to animals and humans for scientifically-validated translational research. [Purpose] To establish evaluation-methods of model animals which are equivalent or superior to the clinical evaluation-methods for SCI treatment. [Method] (Animal) Female Black 6J mouse and NOD SCID mouse (Model) Infinite Horizon Impactor, moderate contusional injury on Th10 (Evaluation method) We examined the followings as evaluation method-candidates that can be used in clinical fields. Behavioral assessment: digital footprint, kinematic analysis. Electrophysiological evaluation: motor evoked potential, H reflex. Image evaluation: in vivo MRI tractography. [Results] In behavioral evaluation, parameters equal to or higher than those of human walking test were obtained. In electrophysiological evaluation, electromyography corresponding to human magnetic evoked potential was demonstrated, and H reflex was also performed with good reproducibility including habituation-phenomenon. For MRI, we firstly developed the method for quantifying fibers with in vivo spinal cord tractography by devising fixtures.

Title: Optimizing urinary continence with epidural stimulation after human spinal cord injury

Authors: *A. N. HERRITY[1], S. C. ASLAN[1], S. MESBAH[1], C. HUBSCHER[2], S. J. HARKEMA[1];
[1]Neurolog. Surgery, [2]Anatom. Sci. & Neurobio., Univ. of Louisville, Louisville, KY

Abstract: Deficits in urological function after spinal cord injury (SCI) include neurogenic detrusor over-activity and uncoordinated bladder and external urethral sphincter contractions, resulting in inefficient emptying and high bladder pressure. Clinical complications associated with high bladder pressure and chronic catheter use include, urinary tract infections, calculi, bladder cancer, and renal deterioration. Bladder distention also is a primary trigger of autonomic dysreflexia (AD) in individuals with cervical and upper thoracic SCI. Standard of care for bladder dysfunction includes the use of pharmacological agents to promote bladder storage and intermittent self-catheterization for bladder evacuation. However, there is a critical need for a successful treatment that restores normal lower urinary tract function as these management strategies and associated cardiovascular dysregulation, continue to diminish the capacity of the bladder and result in side effects that increase morbidity and mortality. In chronic motor complete SCI, we recently demonstrated that customized spinal cord epidural stimulation (scES) configurations targeted for cardiovascular function improved blood pressure regulation, and scES optimized for bladder emptying improved voiding efficiency. However, the direct effects of targeted scES for bladder storage and the ability to simultaneously regulate rising bladder and blood pressure has not yet been investigated. Thus, our overall goal in this study was to optimize scES for safely maintaining urinary continence and to test the effects of training with scES optimized for bladder function for at-home use. These initial experiments were conducted in two participants (AIS B; C4 and T2 levels of injury) during cystometry with continuous beat-to-beat measurements of blood pressure and heart rate (ADInstruments). Over a period of 4-6 weeks, optimal scES configurations (anode/cathode selection, amplitude, frequency, pulse width) were identified at the lumbosacral level (L1-S1) that promoted both the neural control of bladder storage (capacity) and normalization of blood pressure. While controlling blood pressure, successful bladder storage parameters were obtained for both subjects to date, which included capacity and detrusor pressure during filling within the recommended guidelines of the International Continence Society. Targeted scES for urinary continence provides a means for

mitigating AD associated with bladder distention and improving regular standard time intervals between bladder emptying under safe pressures without pharmacological treatments that have unwanted side-effects.

Title: Contribution of hypothalamic A11 dopaminergic neurons to pain modulation in the dorsal horn of the spinal cord

Authors: *M. PUOPOLO, J. LAUZADIS, H. LIU, M. NERANTZINIS;
Stony Brook Med., Stony Brook, NY

Abstract: Pain signals relayed to the dorsal horn of the spinal cord are subject to extensive modulation by local neurons and by neurotransmitters released from supraspinal nuclei. Hypothalamic A11 dopaminergic neurons project to all levels of the spinal cord and provide the main source of spinal dopamine. Electrical stimulation of the A11 nucleus support the anti-nociceptive effects of dopamine in the dorsal horn of the spinal cord. The aims of the present project were: 1) to test the hypothesis that dopamine inhibits the synaptic transmission from primary nociceptors to lamina I projection neurons; 2) to determine the contribution of A11 dopaminergic neurons to pain modulation in vivo in the spare nerve injury (SNI) model of neuropathic pain. In horizontal spinal cord slices in vitro, the excitatory postsynaptic currents (EPSCs) were recorded from lamina I projection neurons upon stimulation of the L4/L5 dorsal root. The external solution was (in mM): 125 NaCl, 2.5 KCl, 26 $NaHCO_3$, 1.25 NaH_2PO_4**,** 20 glucose), oxygenated with 95/5% O_2/CO_2. The internal solution was (in mM): 125 Cs-methanesulfonate, 10 NaCl, 2 $MgCl_2$, 14 phosphocreatine, 4 Mg-ATP, 0.3 Na-GTP, 10 EGTA, 10 HEPES, 5 mM QX-314, pH 7.2 with CsOH. The Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) were selectively expressed in A11 dopaminergic neurons by injecting pAAV-hSyn-DIO-hM3D(Gq) close to the A11 nucleus in TH-Cre rats subjected to the SNI model of neuropathic pain. After three-four weeks post-injection of the AAVs, DREADDs were activated in vivo by intraperitoneal injection of clozapine-N-oxide (CNO) to increase the activity of A11 dopaminergic neurons. Mechanical sensitivity (g) was assessed with the von Frey anesthesiometer. Dopamine strongly inhibited (by ~70%) the EPSCs recorded from lamina I projection neurons upon stimulation of nociceptive Aδ- and C-fibers. Dopamine increased the paired pulse depression ratio (PPR) of paired EPSCs suggesting a presynaptic effect.

Pharmacological experiments proved that the inhibitory effects of dopamine were mediate by D3 and D4 receptors. Immunohistochemistry analysis showed that DREADDs were selectively expressed in TH positive neurons in the hypothalamic A11 nucleus. Activation of DREADDs in vivo with CNO rescued the mechanical pain threshold by about 40% in the ipsilateral hindpaw, while had no effect on the contralateral hindpaw. Taken together, our data show that dopamine strongly inhibits the synaptic transmission between primary nociceptors and lamina I projection neurons, and suggest that activation of A11 dopaminergic neurons in vivo can rescue the mechanical pain threshold in the SNI model of neuropathic pain.

Title: Sex differences in the link between endogenous pain modulation, resilience, pain unpleasantness and salience

Authors: *S. FIROUZIAN[1,2], N. R. OSBORNE[1,2], J. C. CHENG[1,2], J. A. KIM[1,2], R. L. BOSMA[1], K. S. HEMINGTON[1,2], A. ROGACHOV[1,2], K. D. DAVIS[1,2,3];
[1]Krembil Brain Institute, Krembil Res. Inst., Toronto Western Hospital, Univ. Hlth. Network, Toronto, ON, Canada; [2]Inst. of Med. Sci., [3]Dept. of Surgery, Univ. of Toronto, Toronto, ON, Canada

Abstract: Background: A “one-size fits all” approach to pain management fails in part due to individual variability in the brain circuitry associated with pain modulation. The effectiveness of the endogenous pain modulation system can be evaluated by the conditioned pain modulation (CPM) test. CPM may be impacted by an individual’s inherent resilience, the affect and attention-grabbing impact of the conditioning stimulus. Therefore, this exploratory study determined the relationship between CPM capacity and 1) resilience, and 2) pain unpleasantness and salience of the modulating stimulus. We also tested whether there were sex differences in these relationships. **Methods :** Healthy adults (51 female, 55 male) completed the Resilience Scale (25-175 scores) and underwent psychophysical testing. We used a familiarization protocol to determine each subject’s Pain50 (temperature to evoke pain intensity rated 50/100). To evaluate CPM, a thermode on one volar forearm (Medoc, QSense) delivered 10s test stimuli (TS) without (TS1) and concurrent with (TS2) a 100s conditioning stimulus (CS) delivered by a thermode to the other arm. All stimuli were at Pain50. Subjects rated TS and CS pain, and CS

pain unpleasantness and salience from 0-100. CPM was calculated as: [(TS2 pain-TS1 pain)/TS1 pain]x100. Thus, negative scores represent pain inhibition (CPM capacity). **Results:** Subjects exhibited a wide range of scores for resilience (83-175), pain unpleasantness and salience (0-100). Subjects also exhibited a wide range of CPM capacities (-100% to +112.5%), and were grouped into those showing pain inhibition (CPM group, n=53), and those lacking thereof or showing pain facilitation (no-CPM group, n=53). At the whole group level, there was no correlation between CPM and resilience (P>0.05). However in males, CPM scores were negatively correlated with resilience in the no-CPM group, but not in the CPM group. There was no statistically significant relationship between CPM and resilience in females. However, pain unpleasantness and salience of the CS were significantly higher in the no-CPM group compared to the CPM group. **Conclusion:** The unpleasant and attention-grabbing nature of a conditioning stimulus may diminish CPM capacity resulting in low CPM capacity (i.e., pain facilitation instead of inhibition). However, high resilience, a positive attribute inherent to subjects, may serve as a protective factor against further pain amplification; this was observed in males lacking CPM.

Title: Loss of endogenous analgesia leads to delayed recovery from incisional pain in a rat model of chronic neuropathic pain

Authors: *J. OHTA[1], T. SUTO[2], T. HIROKI[3], H. OBATA[4];
[1]Dept. of Anesthesiol., Gunma Univ. Grad. Sch. of Med., Meabashi-Shi, Japan; [2]Dept. of Anesthesiol., Gunma Univ. Grad. Sch. of Med., Maebashi-Shi, Japan; [3]Dept. of Anesthesiol., Gunma Univ. Grad. Sch. of Med., Maebashi-shi, Japan; [4]Dept. of Anesthesiol. and Ctr. for Pain Mgmt., Fukushima Med. Univ., Fukushima-Shi, Japan

Abstract: Preceding pain and impaired endogenous analgesia are recognized as risk factors of chronic postsurgical persistent pain (CPSP). It is not clear if restoring endogenous analgesia can prevent CPSP. We have shown that a rat model of chronic neuropathic pain, the spinal nerve ligation model 6 weeks after surgery (SNL6W), shows significantly impaired noxious stimulus-induced analgesia (NSIA). It has also been shown that repeated treatment with amitriptyline, a tricyclic antidepressant can restore the NSIA in SNL6W rats. In the present study, we investigated whether SNL6W rats exhibited persistent pain after plantar incision and the effects of perioperative treatment with amitriptyline on postsurgical pain recovery process in SNL6W rats. The rats underwent right L5 and L6 SNL surgery. A plantar incision was made on the contralateral to the nerve ligation at SNL6W. Paw withdrawal threshold was evaluated with von Frey filament postoperatively. Preliminary experiments confirmed that NSIA reversed by five daily treatment with amitriptyline (10 $mg \cdot kg^{-1} \cdot d^{-1}$) was maintained for at least one week. Perioperative amitriptyline (10 $mg \cdot kg^{-1} \cdot d^{-1}$) was administered for consecutive 13 days (-5 to 7 days after incision). To investigate the role of noradrenergic and cholinergic signals in the spinal dorsal horn, pharmacological antagonism was performed. Noradrenaline and acetylcholine content, and density of neuroaxonal fibers synthesizing them, were analyzed to examine the effects of amitriptyline on spinal neuroplasticity. Recovery of the withdrawal threshold of SNL6W rats to pre-incision values required 28 days after plantar incision, while naive rats recovered within 14 days (POD14; $P < 0.0001$, POD21; $P < 0.0001$, POD28; $P = 0.0047$ vs SNL6W). Intrathecal injection of alpha2 adrenoceptor antagonist (idazoxan) or muscarinic cholinergic receptor antagonist (atropine) decreased the withdrawal threshold on POD14 and 21 in naive rats (idazoxan; POD 14, 21, $P < 0.0001$ vs baseline, atropine; POD 14, $P = 0.0038$ vs baseline), but not in SNL6W rats. Perioperative amitriptyline attenuated the delayed recovery in SNL6W rats (vehicle treated SNL6W; POD 28, amitriptyline treated SNL6W; POD 14), and the effect was antagonized by atropine (POD 14, $P < 0.0001$ vs baseline). The concentration of acetylcholine and its synthetic enzyme were not altered by amitriptyline treatment. Noradrenergic and cholinergic analgesia, which is necessary for normal recovery, is lost in the SNL6W rats. A strategy to enhance endogenous analgesia using antidepressants may help to prevent CPSP in chronic pain patients.

Title: Orofacial inflammation with stress induces hyperalgesia through down-regulation of 5-HT_2 receptors

Authors: *Y. XUE[1], S.-Q. WEI[1], P.-X. WANG[1], E.-Q. LIU[2], R. TRAUB[3], D.-Y. CAO[1]; [1]Xi'an Jiaotong Univ. Col. of Stomatology, Xi'an, China; [2]Xi'an Jiaotong Univ. Hlth. Sci. Ctr., Xi'an, China; [3]Univ. of Maryland Sch. of Dent., Baltimore, MD

Abstract: Aim of Investigation: Patients with temporomandibular disorders (TMD) and fibromyalgia syndrome (FMS) have some similar symptoms, but the mechanism is still unclear. The purpose of this study was to investigate whether the impairment of descending pain inhibition system through down-regulation of 5-HT_{2A} and 5-HT_{2C} receptors in the spinal cord contributes to somatic hyperalgesia induced by orofacial inflammation combined with different patterns of stress. **Methods:** Female Sprague-Dawley rats were ovariectomized and injected subcutaneous with 17-β-estradiol (E2, 50 μg in 100 μL safflower oil) every 4 days. Injection of complete Freund's adjuvant (CFA, 150 μL) into bilateral masseter muscles with to induce orofacial inflammation pain. Three or 11 day forced swim stress (FSS 3d or 11d) and 11 consecutive days of a heterotypic stress protocol were used after injection of CFA. The heterotypic stress protocol comprised 3 stressors randomly arranged included FSS, water avoidance stress (WAS), or restraint stress (RS) each day. Somatic sensitivity was assessed with thermal and mechanical stimulation of the hind paw before (baseline) and after stress. The expression of 5-HT_{2A} and 5-HT_{2C} receptors in the L4-L5 dorsal spinal cord was examined by Western blot. The 5-HT_{2A} receptor agonist TCB-2 (100 μg) or 5-HT_{2C} receptor agonist MK212 (100 μg) were injected intrathecally for 5 consecutive days starting at the last 4 days of stress and 1 day after in the heterotypic group, and beginning one day prior to the 3 day FSS group. **Results:** Orofacial inflammation combined with 11 day FSS induced persistent mechanical hyperalgesia till 15 days after FSS and thermal hyperalgesia for 2 days. The mechanical and thermal hyperalgesia lasted for 43 days and 30 days respectively in the heterotypic stress group. 5-HT_{2A} receptor expression significantly decreased in the heterotypic stress group compared to the control (oil+saline+non-stress) group. The expression of 5-HT_{2C} receptor significantly decreased in the orofacial inflammation with stress groups compared to the control group. Intrathecal injection of 5-HT_{2A} or 5-HT_{2C} receptor agonist blocked both mechanical and thermal hyperalgesia evoked by orofacial inflammation pain combined with 3 day FSS or heterotypic stress in E2 treated rats. **Conclusions:** The impairment of descending pain inhibition system through down-regulation of 5-HT_{2A} and 5-HT_{2C} receptors contributes to somatic hyperalgesia induced by orofacial inflammation combined with stress, indicating that 5-HT_{2A} and 5-HT_{2C} receptors may be potential targets in the treatment of TMD comorbid with FMS.

Abstract: Background: Valproate (VPA), a histone deacetylase inhibitor, is analgesic in clinical and experimental studies, but the mechanisms are still unclear. Chronic stress evokes and exacerbates functional pain syndromes such as fibromyalgia, irritable bowel syndrome (IBS) and temporomandibular disorder (TMD). The present study investigated whether repeated administration of VPA attenuated the somatic hyperalgesia and visceral hypersensitivity evoked by 3 day forced swim stress and whether 5-HT_{2C} receptor in the spinal cord contributed to the anti-hyperalgesia effects of valproate. **Methods:** Subchronic stress was produced by forced swim (FS) for 3 consecutive days (10, 20, 20 min) in female Sprague-Dawley rats. Somatic sensitivity was assessed by thermal withdrawal latency to radiant heat and mechanical withdrawal threshold to von Frey filaments. Visceral sensitivity was assessed via visceromotor response to colorectal distension. The expression of 5-HT_{2C} receptor in the L4-L5 and L6-S1 dorsal spinal cord was examined by Western blot. VPA (300 mg/kg) or its vehicle saline was intraperitoneally injected 30 min before each FS and 1 day after FS for 4 consecutive days. 5-HT_{2C} receptor antagonist RS-102221 (30 μg, 10 μL) was intrathecally injected 30 min after VPA injection in the RS-102221 group. **Results:** Repeated FS significantly reduced the thermal withdrawal latency and mechanical withdrawal threshold, as well induced visceral hypersensitivity in the intraperitoneal injection of saline group. The somatic hyperalgesia and visceral hypersensitivity were accompanied by significant down-regulation of 5-HT_{2C} receptor expression in the L4-L5 and L6-S1 dorsal spinal cord. Intraperitoneal administration of VPA prevented the development of thermal and mechanical hyperalgesia, visceral hypersensitivity, and down-regulation of 5-HT_{2C} receptor in the spinal cord. The reversal of somatic hyperalgesia and visceral hypersensitivity by VPA in FS rats was blocked by intrathecal administration of the selective 5-HT_{2C} receptor antagonist RS-102221. **Conclusion:** VPA attenuated FS-induced somatic hyperalgesia and

visceral hypersensitivity in part by restoring down-regulated function of 5-HT_{2C} receptor in the spinal cord, suggesting that VPA may be a potential drug for the treatment of stress-induced somatic hyperalgesia and visceral hypersensitivity, which are characteristic symptoms of fibromyalgia and IBS, respectively.

Title: Descending serotonergic facilitation of latent pain sensitization is suppressed by μ-opioid receptor constitutive activity in the rostral ventromedial medulla

Authors: *A. H. COOPER, N. S. HEDDEN, B. K. TAYLOR;
Dept. of Anesthesiol. and Perioperative Med., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Tissue or nerve injury induces latent sensitization (LS) of spinal nociceptive signaling that lasts several months, even after tissue damage and overt signs of hyperalgesia have resolved. Spinal μ-opioid receptor constitutive activity (MOR_{CA}) opposes LS and may prevent the transition from acute to chronic pain (Corder et al, Science, 2013). Opioid receptor inverse agonists unmask LS, leading to pain reinstatement. Hypersensitivity and neuronal activation occur robustly on the side contralateral to injury, suggesting that neuronal sensitization occurs not only at the dorsal horn (DH), but also in the brain. The observation that descending serotonergic projections from the rostral ventral medulla (RVM) facilitate nociceptive processing in the DH forms the premise for the current study. We predicted that inhibition of MOR_{CA} in the RVM would reveal LS and inhibition of $5HT_3$Rs in DH would reduce LS. Adult male C57BL/6 mice underwent hindpaw plantar incision (PI) or sham surgery followed 14 days later by unilateral guide cannula implantation into the RVM. PI induced mechanical hypersensitivity at the plantar hindpaw (tested using the up-down von Frey method) lasting less than 21 days. Following resolution of hypersensitivity, intra-RVM administration of the MOR-selective inverse agonist CTAP (300 ng/0.3 μl) reinstated mechanical allodynia but had no effect in sham-operated mice ($n = 7$; 2-way RM ANOVA with Bonferroni post-tests; $P < 0.05$). This lasted at least 2 hours, with a peak decrease in mechanical threshold occurring 90 mins after injection. In a separate cohort of mice, 21d post-PI, intra-RVM 6β-naltrexol (a neutral opioid receptor

antagonist; 3 µg/ 0.3 µl), abolished intra-RVM CTAP-induced reinstatement of mechanical allodynia but had no effect by itself (n = 8; $P < 0.001$); this demonstrates that a ligand-independent MOR_{CA} mechanism, rather than opioid peptide signaling, suppresses LS in the RVM. We also tested whether descending serotonergic facilitation, mediated by spinal 5-HT_3R signaling, drives LS. 21 days after PI, intrathecal administration of the 5-HT_3R antagonist ondansetron (10 µg/5 µl) attenuated systemic naltrexone-induced reinstatement at both the ipsilateral and contralateral hindpaw ($P < 0.01$, n = 5-7). Ondansetron had no effect in sham-operated mice or in those that did not receive systemic naltrexone ($P > 0.05$). We conclude that inhibition of MOR_{CA} unmasks descending serotonergic $5HT_3$R-mediated facilitation of spinal dorsal horn neurons, leading to pain reinstatement. We propose that descending serotonergic projections from the RVM may be a target for therapeutic intervention to prevent the transition from acute to chronic pain.

Abstract: Typically, endogenous pain modulatory systems are less efficient in chronic pain patients. DNIC or conditioned pain modulation (CPM) is a form of endogenous pain modulation. CPM is compromised in the elderly population, making them more vulnerable to chronic pain conditions. Sex differences in CPM have also been reported, though inconsistently. In any case, neurobiological mechanisms underlying age and sex differences in CPM are relatively unknown. In this study, we used a DNIC behavioral assay and resting state functional magnetic resonance imaging (rsfMRI) to assess the effect of age and sex on endogenous pain modulation and related brain circuitry in rats. Groups of male and female Fischer 344 rats, consisting of both young (3-6 mo) and aged (20-24 mo) rats were used. DNIC was assessed with capsaicin in the forepaw as the conditioned stimulus and noxious heat on the hindpaw as the test stimulus. Changes in thermal thresholds before and 15, 30, 60, 90, and 120 min after capsaicin treatment were

assessed. For rsfMRI, rats were scanned using a Bruker 7T MRI and under isoflurane anesthesia ≤ 1.5%. Functional scans (TR = 1500 ms, in plane resolution = 400 μm, slice thickness 1 mm) were acquired 15 min before and 45 min after the capsaicin treatment. rsfMRI scans were analyzed to examine the effects of DNIC on anterior cingulate cortex (ACC) connectivity to the whole brain. Young males exhibited stronger DNIC responses than young females. DNIC responses were significantly impaired in both old male and old female rats. Young males' greater DNIC responses were associated with strong PAG-ACC connectivity, while young females strongly engaged circuitries implicated in the noradrenergic descending pain modulation, such as the retrosplenial cortex (Rs), pontine nuclei (Pn), and locus coeruleus (LC). The decreased DNIC responses in old females were associated with greater ACC connectivity to the PAG and the limbic system. Comparisons in ACC connectivity between young males and old males did not show statistical differences, suggesting that deficient DNIC responses in old males may involve brain structures other than ACC. Our findings showed that DNIC and brain networks are modulated in age- and sex-dependent manners. Sex differences in DNIC primarily involved connectivity of ACC-PAG whereas age differences in DNIC were associated with the limbic system and other distinct brain areas.

Title: Differential endogenous pain inhibition between male and female rats contribute to sex differences in development of temporomandibular joint osteoarthritis pain

Authors: *V. E. EATON[1], C. DALY[1], J. LEE[2], I. D. MENG[3], T. E. KING[1];
[1]Biomed. Sci., Univ. of New England, Biddeford, ME; [2]Dept. of Complete Denture Prosthodontics, Nihon Univ. Sch. of Dent., Tokyo, Japan; [3]Biomed. Sci., Univ. of New England, Biddeford, ME

Abstract: Males rats develop chronic ongoing pain and central sensitization at a five-fold higher dose of monosodium iodoacetate (MIA) than females in a model of temporomandibular joint osteoarthritis (TMJOA). We propose that this sex difference in susceptibility to development of ongoing pain and central sensitization are due to differences in descending pain inhibition. A measure of endogenous pain inhibition used in the clinical and preclinical setting is diffuse

noxious inhibitory control (DNIC), also referred to in humans as conditioned pain modulation (CPM). This measure demonstrates analgesia to a noxious stimulus in the presence of a secondary noxious stimulus applied elsewhere on the body. We assessed hindpaw analgesia to noxious mechanical stimulation induced by forepaw capsaicin injections to measure CPM in male and female Sprague Dawely rats. Rats received left TMJ injection of high (80 mg/ml, males only) or low (16 mg/ml, males and females) concentrations of MIA or equivolume saline (50 μl). Day 14 post-injection, rats were tested for capsaicin-induced mechanical analgesia (CPM) using the Randel Silletto test. Baseline withdrawal thresholds to noxious mechanical stimulation of the hindpaw were recorded followed by an intraplantar injection of capsaicin (125ug/ 50ul) into the right forepaw under light isoflurane anesthesia. Paw withdrawal thresholds were again measured 15, 30, 45, and 60 minutes post-capsaicin. Saline-treated males demonstrated longer-lasting capsaicin-induced analgesia compared to female rats. MIA diminished capsaicin-induced analgesia in a dose dependent manner in the male rats. To determine whether endogenous opioids protect males from low dose MIA-induced TMJOA pain, we assessed whether systemic naloxone (3 mg/kg, i.p.) induced conditioned place aversion (CPA) and FOS expression in the medullary dorsal horn. Our results demonstrate that naloxone produces CPA and FOS expression in the medullary dorsal horn of low-dose MIA treated males and not in saline treated controls. In conclusion, male rats show stronger capsaicin-induced analgesia compared to females and naloxone unmasked TMJOA pain resulting in CPA and FOS expression in the medullary dorsal horn of low-dose MIA treated male rats. These observations indicate that endogenous opioids protect male rats from developing TMJOA-induced ongoing pain. These findings suggest that males and females inherently differ in descending pain modulation with males having stronger descending pain inhibitory systems than females and that blocking endogenous opioids in males unmasks TMJOA-induced pain. This research was supported by a COBRE award (P20GM103643).

Title: Evaluation of descending endogenous pain-modulating system in daughters of patients with fibromyalgia

Authors: *L. F. MEDEIROS[1,2], R. MUNIZ[2], R. H. PALUDO[2], J. DUSSAN-SARRIA[1], W. CAUMO[1], A. SOUZA[2];

Abstract: Introduction: fibromyalgia syndrome is characterized by pain and widespread sensitivity, neural changes, and alterations in the peripheral and the central physiology mechanisms. This syndrome can be related with genetic, neurobiological and environmental factors. It is known that, in different chronic pain processes, descending modulation of pain pathways can present some dysfunctions. The Conditioned Pain Modulation (CPM) task has been used to assess the descending endogenous pain-modulating system in clinical research field. And, data from literature has described the role of the brain-derived neurotrophic factor **(**BDNF) in the maintenance mechanism, sucha as survival, growing, neuroplasticity, neural reparation, and neuronal differentiation, and also in the pain process mechanisms. Thus, our objective was to characterize differences in the pain response between case and control groups, which consisted by daughters of fibromyalgia patients and daughters of women pain-free, respectively. Methods: this is a case-control study, approved by IRB#140635. Seventy-six women were enrolled after signed the informed consent form, 38 daughters of patients with fibromyalgia diagnosis (case group), and 38 daughters of women without this syndrome (control group). Psychophysical tests were: pain threshold by quantitative sensory testing (QST) and conditioned pain modulation (CPM). Sociodemographic questionnaire was applied and blood serum sample was collected. BDNF (ng/ml) and estradiol (pg/ml) serum levels were measured. Data were analyzed by SPSS; $P<0.05$ was considered significant and considering the non-normal distribution data, Mann-Whitney test was used. Results: no differences were found in BDNF and estradiol serum levels between case and control groups ($P>0.05$). However, we found interesting results, the case group presented lower delta response in CPM-task than control group taking into account levels of BDNF and estradiol ($P<0.05$), suggesting a descending endogenous pain-modulating system less efficient. Conclusion: our results showed that the case group already presents changes in the descending endogenous pain-modulating system assessed by CPM. Important to highlight that all women enrolled in the current study were healthy (without fibromyalgia syndrome). And, further studies needs to be encouraged to analyze possible changes in pain modulation mechanisms in daughters of fibromyalgia patients, for example, a cohort design study.

Abstract: Cancer pain remains a major area of unmet medical need. One common form of chronic cancer pain, affecting 400,000 people each year in the US alone, is associated with skeletal metastases. These pains are typically mechanoceptive in nature and poorly managed by available analgesics. Here, we employed *in vivo* imaging using GCaMP6s to assess the properties of the nerve fibres that transduce bone cancer pains. We show that a subclass of nociceptors, those that are normally mechanically insensitive, are recruited and activated in a rodent model of bone cancer, and that this dramatically increases sensory input from the diseased tissue to the central nervous system. The recruitment of these so-called silent afferents was shown to be Piezo2-dependent.
Next, utilising *in vivo* spinal electrophysiology, we show that the increased peripheral input described above leads to the reorganization of descending noradrenergic controls, potently increasing inhibitory tone. We hypothesise the existence of a spino-pontine-spinal loop that modulates spinal excitability in a noradrenergic fashion and is strongly altered in the advanced metastatic disease. This changes the spinal pharmacology of α_2-adrenoceptor antagonist atipamezole, which now has inhibitory actions at the level of the spinal cord.
Diffuse Noxious Inhibitory Controls (DNIC), a unique form of descending noradrenergic controls, was studied also. This phenomenon, whereby application of a noxious stimulus to one part of the body inhibits pain perceived in a remote body region, acts through inhibitory descending pathways. Interestingly, DNIC were found dynamic with the progression of bone tumours. We hypothesise that DNIC originate from brain regions separate to those that govern tonic noradrenergic controls, and we conclude that the expression status of DNIC can be used clinically as a diagnostic tool to tailor pain pharmacotherapy in patients suffering from chronic bone cancer pain.
The unique properties of bone silent afferents, which show plasticity in pain chronicity, combined with ensuing central events offer several novel opportunities for targeting metastatic bone pain. Due to the dynamic nature of the disease and resulting pains, it is crucial to match pain therapy with the stage of the disease.

Title: Characterization of the widespread sensitization in trigeminal nerve-mediated inflammatory pain model of rats

Authors: *M. YAJIMA, M. SUGIMOTO, Y. K. SUGIMURA, Y. TAKAHASHI, F. KATO; Dept. of Neurosci., Jikei Univ. Sch. of Med., Tokyo, Japan

Abstract: Ectopic/widespread sensitization, an augmented nociceptive sensitivity in (multiple) parts of the body distinct from the site of primary injury or inflammation, is one of the hallmark symptoms of the chronic/centralized pain. It is generally assumed that plastic changes in the central nervous system for processing and controlling the pain-associated signals underlie this symptom, which would provide the basis for "primary chronic pain" (ICD-11, 2018), a type of chronic pain without apparent causes of pain. We have already demonstrated that pharmacological degeneration of the spinal noradrenergic terminals (Kinoshita et al., 2014), artificial activation of the right central amygdala (CeA) neurons (Sugimoto et al., 2016) and orofacial inflammation (Sugimoto et al., 2016) lead to mechanical allodynia in the bilateral hind limbs, suggesting that aberrant perturbation of the ascending and descending pain regulatory loop causes wide-spread sensitization. Using this orofacial inflammation model in rats, we characterized the mechanisms underlying this sensitization. Injection of formalin into the upper lip lowered the paw withdrawal threshold (PWT) in bilateral hind limbs, lasting for >72 hours. Administration of acetaminophen (100-200 mg/kg, i.p.) at 3.5 h post-formalin elevated the PWT to levels not significantly different from the pre-formalin level. This effect of acetaminophen lasted for ~6 h. As recent lines of evidence suggest acetaminophen exerts its analgesic effects by indirectly activating endocannabinoid receptors (Klinger-Gratz et al, 2018), it is suggested that the widespread sensitization following orofacial inflammation would involve up-regulation of the descending pain modulatory system from the CeA to the spinal dorsal horn, which is under control by endocannabinoids and CB1 receptors.

Title: Resting brain connectivity underlying conditioned pain modulation analgesia

Authors: *E. P. MILLS[1], A. M. YOUSSEF[1], P. M. MACEY[2], L. A. HENDERSON[1]; [1]Univ. of Sydney, Sydney, Australia; [2]UCLA Sch. of Nursing, Univ. of California at Los Angeles, Los Angeles, CA

Abstract: Conditioned pain modulation (CPM) is an analgesic mechanism where pain at one site is inhibited by a second, remote, noxious stimulus. It is important to understand why some individuals express CPM analgesia and others do not. Indeed, the risk of developing chronic pain is greater in individuals with reduced CPM abilities, suggesting that resting activity within CPM neural circuits predisposes an individual to developing chronic pain. We have shown that the subnucleus reticularis dorsalis (SRD) in the medulla is important for CPM in humans. In the present study, we used functional magnetic resonance imaging (fMRI) to explore whether CPM ability is related to the strength of resting SRD signal coupling with other pain-modulation regions. We recruited 46 healthy subjects (19 males; mean[±SEM] age: 34±2 years). First, we applied 8 noxious thermal stimuli to the subject's forearm using a 3x3cm thermode (Medoc, Israel) (*test stimulus, TS*). The subject rated their pain intensity to each TS (0=no pain, 10=worst pain imaginable) using a Computerised Visual Analogue Scale (Medoc). After the fourth stimulus, the subject immersed their foot in noxious cold water (*conditioning stimulus, CS*) and continued to rate pain evoked by the TS. Based on the change in pain ratings during simultaneous TS and CS compared to those during TS alone, subjects were grouped as either showing CPM analgesia ("CPM"; n=22) or no CPM analgesia ("NoCPM"; n=24). Additionally, each subject underwent a 6-minute resting state fMRI scan. Using SPM12, fMRI images were realigned, physiological noise removed and the brainstem spatially normalized to a brainstem-only template using the SUIT toolbox. The SRD was selected as a "seed" region in a functional connectivity analysis using the DPARSF toolbox. Using the brainstem-only and whole-brain images separately, the SRD connectivity with each voxel was compared between CPM and NoCPM subjects in voxel-by-voxel analyses ($p<0.05$, small volume corrected). Compared to the NoCPM group, CPM subjects showed significantly greater resting SRD functional connectivity with the spinal trigeminal nucleus (mean[±SEM] connectivity strength in arbitrary units, CPM: 0.32±0.03, NoCPM: 0.15±0.04). Further, CPM participants demonstrated greater SRD connectivity with higher regions involved in modulating pain, including the mid-cingulate cortex (CPM: 0.12±0.02, NoCPM: -0.02±0.03). The results suggest that resting connectivity between pain-modulation areas underlies an individual's ability to engage analgesic mechanisms during

two noxious stimuli. This may confer a protective advantage in CPM individuals that reduces their likelihood of developing chronic pain.

Abstract: Descending control of the spinal neurons is poorly understood, despite being crucial for the motor and sensory information processing. Since the area around the central canal (lamina X) is the spinal region participating in both these functions, it is interesting to study how descending regulation affects lamina X neurons. For this, we did the patch-clamp recordings in the hemisected spinal cord preparation from P12 rats while stimulating the dorsolateral funiculus and the ipsilateral dorsal root. Such approach allowed investigating the inputs from descending fibers and their impact on the primary afferent-driven responses. We found that more than a half of the tested lamina X neurons responded with polysynaptic EPSCs and/or IPSCs to a single descending tract stimulation. The putative monosynaptic inputs were rare, suggesting little direct synaptic contacts between descending fibers and lamina X neurons in young animals. Meanwhile, in a number of neurons continuous activation of the descending fibers (2-10 Hz) diminished mono- and polysynaptic components of the primary afferent input evoked by the dorsal root stimulation. Taken together, these findings indicate that descending regulation of the spinal lamina X circuitry involves both pre- and postsynaptic mechanisms.

Title: PEBP detects incoming nociceptive information to enhance endogenous opioid tone from descending inputs

Authors: *J. LAVIGNE[1], C. KIM[2], K. A. EDWARDS[4], J. M. STREICHER[3];
[1]Pharmacol., Univ. of Arizona Col. of Med., Tucson, AZ; [3]Pharmacol., [2]Univ. of Arizona, Tucson, AZ; [4]Dartmouth Col., Hanover, NH

Abstract: The United States has roughly 100 million people suffering from chronic pain, which has been poorly managed by opioid treatment with attendant side effect and abuse liabilities. Recent efforts to create novel therapies that avoid these problems are promising, however none have been truly successful. A likely reason for this is due to a lack of understanding of the mechanisms of ascending and descending pain pathways. Although the general mechanisms and circuits are well known, less is known about the micro-circuitry, cell types, receptor distribution and receptor signaling mechanisms within these pain pathways. Our lab has identified a novel regulator of MOR signaling, phosphatidylethanolamine-binding protein (PEBP), and characterized its role in MOR signaling and MOR mediated behavior. PEBP in its unphosphorylated monomeric form binds and inhibits Raf-1, and when phosphorylated by PKC it will dimerize, bind, and inhibit GRK2. We hypothesized that inhibiting PEBP will increase free GRK2 and thus βarrestin2 recruitment to the MOR and decrease morphine-induced antinociception. Indeed, inhibition of PEBP with an inhibitor, locostatin, reduced βarrestin2 recruitment *in vitro*. Conversely, activating PKC resulted in phosphorylation of PEBP and a subsequent decrease in βarrestin2 recruitment. Moreover, inhibiting PEBP in the spinal cord with locostatin or using CRISPR resulted in substantial decreases (>50%) in morphine-induced antinociception via the tail flick assay. We next sought to investigate the specific physiological role of PEBP in regulating endogenous antinociception. To do this we injected locostatin intrathecally (*it*) and then injected DAMGO intracerebroventricularly (*icv*) to activate OFF-cells, promoting descending endogenous opioid release in the spinal cord. We then performed [^{35}S]-GTPγS coupling for MOR on these spinal cords and found *icv* DAMGO treatment alone caused a 29% decrease in [^{35}S]-GTPγS coupling; *it*locostatin treatment alone caused a 34% decrease; The combination of *it* locostatin followed by *icv* DAMGO resulted in a 73% decrease. These

results suggest a gating mechanism whereby incoming nociceptive information sensitizes the MOR through a PEBP-dependent regulation, thus promoting endogenous opioid antinociception from descending inputs.

Title: The neural basis of opioid-mediated conditioned analgesia in chronic neuropathic pain

Authors: *C. CHO, V. MICHAILIDIS, A. FATIMA, H. PARK, B. PRESSWALA, N. DZIEKONSKI, A. LEONETTI, L. J. MARTIN;
Univ. of Toronto, Mississauga, ON, Canada

Abstract: Objective: Chronic pain can be interpreted as a maladaptive pain memory that is susceptible to alterations through learning such as conditioning. In support, conditioned analgesia represents a phenomenon where an inert treatment induces pain relief. The objective of the study was to identify the neural pathways of the central nervous system responsible for conditioned analgesia using a mouse model of chronic neuropathic pain.
Methods: Mechanical pain thresholds were measured in 6-8wk old male CD-1 mice, before and following spared nerve injury (SNI). The SNI mice then underwent a four-day conditioning phase where contextual and tactile stimuli were coupled with an unconditioned drug stimulus (morphine, 10mg/kg). Following the conditioning period, the SNI mice were administered either saline or an opioid receptor antagonist. Following behavioural testing, neuronal activity was mapped in the spinal cord and brain by probing for c-fos expression using immunoblotting and immunohistochemistry.
Results: Saline administration following pharmacological conditioning induced analgesia comparable to that of morphine, which was reversed by naloxone. Systemic administration of antagonists for opioid receptor subtypes mu, delta and kappa demonstrated that inhibition of mu-opioid receptor (MOR), but not delta- or kappa-opioid receptors, blocked saline-induced analgesia, suggesting that opioid-mediated placebo analgesia occurs via MOR. Immunoblotting and immunohistochemical analyses revealed significant changes in c-fos expression in the spinal cord and the pain processing regions of the brain.
Conclusions: We demonstrate a novel animal model of conditioned analgesia within the context

of chronic neuropathic pain. This is accompanied by corresponding changes of neuronal activities in the central nervous system similar to those observed in humans, warranting further investigations in order to elucidate the underlying neural basis for conditioned analgesia.

Title: Local administration of a CB1 antagonist reveals endocannabinoid tone regulating pain-modulating neurons in the rostral ventromedial medulla

Authors: *Y. ZHANG[1], M. E. MARTENSON[1], M. M. HEINRICHER[1,2];
[1]Dept Neurol Surgery, [2]Behav Neurosci, Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Systemic administration of cannabinoids produces analgesia that is mediated in part through brainstem pain modulating systems. These systems have a major output through the rostral ventromedial medulla (RVM). Blocking cannabinoid receptor 1 (CB1) in the RVM suppresses analgesia produced by CB agonists or stress. *In vitro* studies have shown that blocking presynaptic CB1 receptors in RVM disinhibits GABA release, suggesting a local endocannabinoid tone. However, how this endocannabinoid tone influences the pain-modulating circuitry within the RVM *in vivo*, and implications of this tone for pain processing remain to be determined. The aim of these experiments was to test the hypothesis that endocannabinoid tone in the RVM modulates activity of distinct classes of pain modulating neurons: pro-nociceptive ON- and anti-nociceptive OFF-cells. Activity of identified ON- and OFF-cells and heat-evoked paw withdrawal were recorded in lightly anesthetized male and female Sprague-Dawley rats. Microinjection of a CB1 receptor antagonist, SR141716 (200 pmol/200 nL), in the RVM unexpectedly increased the ongoing firing of ON-cells, while vehicle injection did not change neuronal activity. Activity of OFF-cells was unchanged. NEUTRAL-cells, RVM neurons without a known role in pain modulation, also showed no change in activity following CB1 receptor block. These data indicate that, at least under basal conditions, endocannabinoid action in RVM limits activity of pro-nociceptive ON-cells, and thus provides an ongoing restraint of nociceptive transmission.

Title: Functional and anatomical characterization of descending periaqueductal gray (PAG) projections and their role in pain modulation

Authors: *J. G. GRAJALES-REYES[1], V. K. SAMINENI[1], A. LEGARIA[1], C. E. PEDERSEN[2], M. R. BRUCHAS[2], R. W. GEREAU, IV[1];

Abstract: Endogenous analgesic pathways embody an alternative target for the development for chronic pain therapies. Previous studies have demonstrated the role of the ventrolateral periaqueductal gray (vlPAG) in descending pain modulation. It has been proposed that tonic GABAergic neurotransmission at the level of the vlPAG serves to inhibit efferent excitatory projections that mediate descending analgesia. Disinhibition of these projection neurons allows subsequent activation of rostral ventromedial medulla (RVM) neurons that inhibit nociception at the level of the spinal cord. However, lack of cell-type specificity in these studies has prevented the determination of the role of specific subsets of vlPAG neurons in analgesia. We have utilized recently developed genetic tools to selectively manipulate and monitor the activity of subclasses of vlPAG neurons to identify the circuit components critical for analgesia. Our data suggest that increasing the activity of glutamatergic vlPAG neurons or decreasing the activity of GABAergic vlPAG neurons results in increases in sensory thresholds in uninjured animals, while ameliorating hyperalgesia associated with chronic pain states. We hypothesized that efferent projections to the RVM from the vlPAG are partially responsible for the observed analgesia in our previous study. Population-specific anatomical tracing revealed that the nearly all neurons projecting from vlPAG to the RVM (nucleus raphe magnus) are glutamatergic. Optogenetic stimulation of these vlPAG-RVM neurons results in elevation of thermal thresholds in uninjured animals and reverses thermal hyperalgesia associated with inflammatory states. Our results provide direct experimental evidence supporting the GABA disinhibition hypothesis, highlighting the role of descending glutamatergic neurotransmission at the level of the PAG-RVM as a key component of endogenous analgesic pathways. Abstract: Transcranial direct current stimulation (tDCS) over the primary motor cortex (M1) has shown promise as a novel analgesic therapy for chronic pain patients. However, the top-down analgesic mechanisms at the spinal level remain unknown. This study therefore used the capsaicin model of ongoing pain in healthy volunteers to investigate the top-down effects of M1-tDCS on spinal cord measures of central sensitisation (i.e. secondary hyperalgesia). Using a within-subject design, 13 subjects were recruited and underwent baseline electrical pain perception (EPP) threshold and mechanical stimulus response (S/R) function testing before topical application of 1% capsaicin cream over the L5 dermatome. Ongoing pain ratings were assessed using visual analogue scale (VAS) ratings. EPP thresholds were used to determine severe and mild areas of secondary hyperalgesia by measuring the degree of change in pain threshold at 4 points within an area covering 98.9 cm2 around the neurogenic flare response (severe: 62.21 ± 4.70% of baseline versus mild: 93.45 ± 6.97% of baseline; $p<0.0001$). Mechanical S/R function was then re-assessed in the severe area of secondary hyperalgesia. ANOVA revealed an effect of mechanical stimulus ($F = 19.57$; $p<0.001$) and time (pre and post-capsaicin, $F = 9.87$; $p<0.01$) resulting in a leftward shift of the S/R curve. The analgesic effects of tDCS over M1 (20 mins anodal, 2mA) or sham stimulation were then investigated in a randomised, double-blind manner. tDCS reduced ongoing VAS ratings (post-tDCS: 43.18 ± 5.15 versus post-sham: 52.32 ± 3.57; $p < 0.05$), increased EPP thresholds (post-tDCS: 82.8 ± 12.7% of baseline; $p < 0.01$) and caused a rightward shift in the mechanical S/R curve, which was not evident in the sham condition. There was a significant correlation between the tDCS-induced change in EPP threshold and change in mechanical sensitivity in the area of secondary hyperalgesia ($r2 = 0.45$; $p<0.01$). These data demonstrate that EPP can be used to map mild and severe areas of secondary hyperalgesia and that M1-tDCS can modulate the severity of secondary hyperalgesia.

Title: Changes in the balance of pro-versus anti-nociception during the development of capsaicin-induced secondary hyperalgesia in healthy volunteers

Authors: *Y. RHO, A. REDDY, S. HUGHES, P. STRUTTON;
Imperial Col. London, London, United Kingdom

Abstract: Changes in the levels of spinal cord facilitation and inhibition are fundamental mechanisms associated with the development of chronic pain. However, it is currently unknown whether similar changes occur during the development of experimentally-induced ongoing pain and secondary hyperalgesia in human pain models. In this study, we explored temporal changes in the balance of pro- (i.e. facilitation) and anti- (i.e. inhibition) nociception using well validated psychophysical measures of spinal cord excitability and endogenous inhibitory pathways. Twenty-four healthy subjects were recruited and underwent baseline conditioned pain modulation (CPM), wind up and electrical pain perception (EPP) threshold testing before application of 1% topical capsaicin cream over an area of the L5 dermatome. Responders to capsaicin (n=13) had their EPP thresholds and wind up ratios re-measured at time points during the development and following the onset of secondary hyperalgesia. CPM was measured again at the end of the study protocol. Capsaicin caused a gradual decrease in EPP thresholds (pre-capsaicin: 8.30 ± 0.73 mA; early development: 7.83 ± 0.95 mA; late development: 7.17 ± 0.96 mA; post-capsaicin: 6.88 ± 0.78 mA; $p<0.01$) within a 98.9 cm2 area surrounding the neurogenic flare response and an increase in wind up ratio (pre-capsaicin: 2.86±0.39; early development: 2.77 ± 0.35; late development: 3.44 ± 0.51; post-capsaicin: 3.74 ± 0.44; $p<0.01$) during the development and onset of secondary hyperalgesia. There was also a change in CPM following the onset of secondary hyperalgesia (pre-capsaicin: 19.00 ± 3.48%; post-capsaicin: 1.98 ± 4.23%; $p<0.01$). Non-responders to capsaicin (n = 11) showed no changes in either CPM or windup. These data suggest that the changes observed in the responders to capsaicin are mediated by a gradual shift in the balance of pro- versus anti-nociception during the development of secondary hyperalgesia. It may be possible to reduce the severity of capsaicin-induced pain sensitivity by modulating the balance of endogenous pro- versus anti-nociceptive drive.

Title: Attenuation of capsaicin-induced ongoing pain and secondary hyperalgesia by virtual reality stimulation is related to the activity within endogenous pain inhibitory pathways

Authors: S. HUGHES, H. ZHAO, E. AUVINET, ***P. H. STRUTTON**;
Imperial Col. London, London, United Kingdom

Abstract: Virtual reality (VR) interventions have shown promise as a novel distraction-based analgesic therapy for use in painful medical procedures and during acute pain states. There is now a growing body of evidence that suggests VR can be used in the management of chronic pain. However, there has been limited investigation into the analgesic mechanisms associated with VR and whether it can modulate the altered nociceptive processing associated with chronic pain. We examined the relationship between psychophysical measures of endogenous analgesia and the effects of VR on capsaicin-induced ongoing pain perception and secondary hyperalgesia in healthy volunteers. Nineteen subjects had baseline conditioned pain modulation (CPM) and electrical pain perception (EPP) thresholds measured prior to the application of 1% topical capsaicin cream over the L5 dermatome. Visual analogue scale (VAS) ratings were measured to track the development of an ongoing pain state and changes in EPP thresholds outside of the neurogenic flare indicated the presence of secondary hyperalgesia. Responders to capsaicin (n=15) had analgesic effects measured during and after a randomised 10-minute exposure to either real or sham (i.e. 2D computer monitor screen) VR stimulation. VR was associated with a reduction in ongoing pain ratings (mean±SEM post capsaicin VAS: 62.17 ± 2.07 versus during VR VAS: 47.67 ± 2.94; $p<0.001$) and an increase in EPP threshold (post capsaicin EPP threshold: 5.33 ± 0.47 mA versus during VR EPP threshold: 6.78 ± 0.54 mA; $p<0.0001$) which both returned to a sensitised level following removal of the VR headset. CPM showed a significant correlation with changes in secondary hyperalgesia ($r2 = 0.68$, $p<0.001$), but not with changes in ongoing pain perception ($r2 = 0.063$, $p > 0.05$). These results indicate that VR stimulation may be a promising new behavioural and analgesic therapy for use in chronic pain patients. We demonstrate that the analgesic effects are mediated through two distinct endogenous analgesic pathways; one of which is CPM-dependent and likely involves the interaction between cortical regions mediating top-down modulation of descending inhibitory pathways and the other is CPM-independent and is likely to be mediated through cortical areas involved in distraction.

Title: Correlation between pain-related behaviors and synaptic transmission in amygdala CRF neurons in a neuropathic pain model

Authors: *T. KIRITOSHI[1], V. A. YAKHNITSA[1], V. NEUGEBAUER[1,2,3];
[1]Pharmacol. and Neurosci., [2]Ctr. of Excellence for Translational Neurosci. and Therapeut., [3]Garrison Inst. on Aging, Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: The amygdala is an important contributor to pain-related emotional-affective conditions and pain modulation. The central nucleus of amygdala (CeA) serves as a major output nucleus of the amygdala. CeA activity is increased and mechanistically linked to pain-related behaviors in different pain conditions. Evidence suggests that a subset of CeA neurons containing corticotropin releasing factor (CRF) is critically involved in the modulation of pain and affective disorders. Here we used optogenetic activation or silencing of CRF-CeA neurons to determine their contribution to pain related behaviors. Elevated plus maze test performance and vocalizations evoked by innocuous and noxious stimuli of the hind paw were measured in adult neuropathic rats (4-6 weeks after spinal nerve ligation, SNL) and control rats. For optogenetic activation or silencing of CRF neurons, a Cre-inducible viral vector (DIO-AAV) encoding channel rhodopsin 2 (ChR2) or enhanced Natronomonas pharaonis halorhodopsin (eNpHR3.0) was injected stereotaxically into the right CeA of transgenic Crh-Cre rats, kindly made available to us by Dr. Robert Messing's group, UT Austin. Animals were allowed to recover for channel expression. For wireless optical stimulation of ChR2 or eNpHR3.0 expressing CRF-CeA neurons, an LED optic fiber was stereotaxically implanted into the right CeA in control and neuropathic rats. Optical activation of CRF-CeA neurons increased the vocalizations under normal condition, whereas optical silencing of CRF-CeA neurons decreased vocalizations and ameliorated anxiety like behaviors in the neuropathic pain model. Subsequent patch-clamp recordings in brain slices confirmed that functional ChR2 and eNpHR3.0 were expressed in CRF-CeA neurons. No response to light stimulation was observed in CRF-negative CeA neurons. The data provide evidence for an important contribution of CRF-CeA neurons to neuropathic pain-related behaviors and for their ability to generate pain behaviors in the absence of injury under control condition.

Title: Kappa opioid receptor blockade restores inhibition of amygdala CRF neurons in a functional pain model

Authors: *M. HEIN[1], G. JI[1,2], E. NAVRATILOVA[4], F. PORRECA[4], V. NEUGEBAUER[1,2,3]; [1]Pharmacol. and Neurosci., [2]Ctr. of Excellence for Translational Neurosci. and Therapeut., [3]Garrison Inst. on Aging, Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX; [4]Pharmacol., Univ. of Arizona Col. of Med., Tucson, AZ

Abstract: Neuroplastic changes in the central nervous system have been implicated not only in pain conditions associated with an identifiable injury, but also in functional pain syndrome (FPS), in which the pain cannot be attributed to tissue pathology. Mechanisms of FPS remain to be determined, but these conditions are typically triggered by stress, which can create a chronic pain condition. Corticotropin releasing factor (CRF) and its CRF1 receptor in the amygdala have been linked to emotional-affective behaviors and pain modulation. The amygdala is also a major site of opioid receptors. The central nucleus of the amygdala (CeA), in particular, serves as a major site of amygdala output, and exhibits high levels of expression of the Gi/o-coupled kappa opioid receptor (KOR). KOR activation by its endogenous ligand, dynorphin, or agonists can have adverse effects and oppose mu-opioid receptor-mediated actions. Here we tested the hypothesis that blockade of KOR signaling restores inhibitory control of CRF neurons in the central nucleus (CeA) in a rat model of FPS. Brain slice electrophysiology was used to determine the effects of a KOR antagonist (Nor-Binaltorphimine, nor-BNI) on CRF-CeA neurons. These neurons can be visualized in brain slices from transgenic Crf-Cre rats, kindly made available to us by Dr. Robert Messing's group, UT Austin. AAV5-ChR2-CaMKII-eYFP was injected into the lateral parabrachial area (LPB) to allow optical activation of glutamatergic synaptic input to CeA neurons. The FPS model was induced by morphine priming for 7 days (using subcutaneously implanted mini osmotic pumps) followed 4 weeks later by one hour of restraint stress on two consecutive days. The control group received morphine without stress. Whole-cell

patch-clamp recordings of CRF-CeA neurons found that in the FPS model, nor-BNI increased LPB-evoked glutamate-driven inhibitory synaptic currents (IPSCs, feedforward inhibition) as well as spontaneous and miniature IPSC frequency, but not amplitude, while decreasing neuronal excitability (frequency-current F-I relationship). The data suggest that blockade of KOR signaling in a rodent model of FPS restores synaptic inhibition of CRF-CeA neurons through a presynaptic mechanism of action.

Abstract: The dynorphin/KOR system has emerged as a novel target for the treatment of stress-related mood disorders including anxiety, depression, drug seeking and relapse. KOR is widely, but specifically, expressed in both rodent and human brain neuronal circuits including the amygdala. The amygdala is part of the limbic brain and plays an important role in mediating emotional responses to pain as well as fear, anxiety and stress. The central nucleus of the amygdala (CeA) is an important output structure that may sustain chronic pain through descending pain facilitatory outputs to brain/brainstem areas for behavioral modulation. Our previous studies showed that stress-induced activation of KOR promotes sensory and affective pain behaviors, and blockade of KOP signaling in the right CeA blocks stress-induced pain responses, suggesting enhanced descending facilitation from the amygdala as a mechanism to amplify nociceptive input following stress. In this study, systems electrophysiology was used to determine the effects of stress-induced activation of KOR signaling on CeA neurons. Extracellular single-unit recordings were made from CeA neurons in anesthetized adult rats that were morphine-primed and exposed to restraint stress (functional pain model) compared to

controls. Background activity and evoked responses to brief (15 s) test stimuli (compression of the hindpaw) were measured. Background activity and evoked responses of CeA neurons were increased in morphine-primed, stressed rats compared to controls. Administration of a KOR agonist (U-69593) by microdialysis into the CeA increased the responses of CeA neurons to noxious and innocuous stimuli in control rats, but not in the functional pain model. Administration of a KOR antagonist (nor-BNI) by microdialysis into the CeA reduced the responses of CeA neurons to noxious and innocuous stimuli in morphine-primed, stressed rats, but not in control rats. The data suggest that KOR signaling mediates activation of CeA neurons in stress-related functional pain conditions.

Title: Group II metabotropic glutamate receptors modulate synaptic transmission in CRF-CeA neurons in an arthritic pain model

Authors: *M. MAZZITELLI[1], V. NEUGEBAUER[1,2,3];
[1]Pharmacol. and Neurosci., [2]Ctr. of Excellence for Translational Neurosci. and Therapeut., [3]Garrison Inst. on Aging, Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: The amygdala plays an important role in the regulation of emotional-affective components of pain and in pain modulation. The central nucleus of amygdala (CeA) serves major output functions. The CeA receives nociceptive information via the external lateral parabrachial nucleus (PB). The CeA is also the main source for extra-hypothalamic corticotropin releasing factor (CRF), which is involved in several neuropsychiatric disorders. CRF-CeA containing neurons project to other brain regions involved in behaviors and pain. Gi/o-coupled group II metabotropic glutamate receptors (mGluR2 and mGluR3) are expressed in different brain regions, including the amygdala. Their activation can decrease neurotransmitter release and regulate synaptic plasticity, but effects of the modulation of group II mGluRs and subtypes on CRF-CeA neurons remains to be determined. In this study we address this question in a rodent model of arthritic pain. Brain slice physiology was performed to determine the effects of a group II mGluR agonist (LY379268 disodium salt) and a positive allosteric modulator (PAM) selective for mGluR2 (LY487379 hydrochloride) on CRF-CeA neurons from normal rats and arthritic rats

(5-6 h postinduction of a kaolin/carrageenan-monoarthritis in the left knee joint). In order to visualize CRF-CeA neuron in brain slices, we used transgenic Crh-Cre rats, kindly made available to us by Dr. Robert Messing's group, UT Austin. Whole-cell patch-clamp recordings were used to investigate monosynaptic excitatory postsynaptic currents (EPSCs) and glutamate driven inhibitory postsynaptic currents (IPSCs) evoked from PB inputs. Activation of group II mGluRs by LY379268 resulted in a reduction of EPSCs and IPSCs in the arthritic condition. Similarly, selective activation of mGluR2 by LY487379 decreased the synaptic responses evoked by PB stimulation. These results suggest that group II mGluRs, and particularly mGluR2, in the amygdala can regulate synaptic transmission of CRF neurons, which could explain the anxiolytic and antinociceptive properties of pharmacological agents acting on group II mGluRs.

Title: Phenotypic differences in potassium (SK) channel dysfunction in the amygdala in a rat model of neuropathic pain

Authors: *V. A. YAKHNITSA[1], T. KIRITOSHI[1], V. NEUGEBAUER[1,2,3];
[1]Pharmacol. and Neurosci., [2]Ctr. of Excellence for Translational Neurosci. and Therapeut., [3]Garrison Inst. on Aging, Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: The amygdala is an important limbic structure for the emotional-affective dimension of pain. Small-conductance calcium-activated potassium (SK) channels are expressed in the central amygdala (CeA) and inhibit neuronal excitability under normal conditions. We discovered dysfunction of SK-channels in neuropathic pain conditions that contributes to increased CeA neuronal activity and pain behaviors. Here we tested the hypothesis that the magnitude of neuropathic pain behaviors predicts and correlates with the amount of SK-channel dysfunction in CeA. Mechanical sensitivity (von Frey test) and audible (nocifensive response) and ultrasonic (affective response) vocalizations were measured in neuropathic rats (L5 spinal nerve ligation model, SNL) and in sham controls 4 weeks after surgery. Anxiety-like behaviors were evaluated using the open field and elevated plus maze tests, and depression-like behaviors were measured on the forced swimming and sucrose preference tests. SNL rats showed reduced

withdrawal thresholds and increased vocalizations compared to sham controls. Anxiety-like behaviors occurred in 58% while depression-like behaviors were observed in 30% of SNL rats. Comorbidity of anxiety and depression was found in 18% of rats. Patch-clamp recordings of regular firing lateral CeA neurons in brain slices from SNL rats with anxiety/depression comorbidity found reduced mAHP, increased action potential frequency-current (F-I) relationship, and enhanced excitatory synaptic transmission compared to sham controls and to the SNL phenotype with low anxiety and without depression-like behavior. The data suggest close interaction between amygdala plasticity and neuropathic pain. SK channel dysfunction contributes to maladaptive neuropathic pain-related amygdala plasticity that correlates with anxiety- and depression-like behaviors.

[3]Shanghai Univ., Shanghai, China; [4]Guangdong Pharmaceut. Univ., Guangzhou, China

Abstract: *Radix angelicae pubescentis* (RAP) has been used in Chinese traditional medicine to treat painful diseases such as rheumatism and headache for centuries. A previous study has reported that columbianadin (CBN), a major coumarin in RAP inhibits acute and inflammatory pain behaviors. However, the effects of CBN on neuropathic pain behaviors have not been reported. Moreover, it has not been reported what might be the potential mechanism underlying the anti-nociceptive effects of CBN, nor if CBN modulates any ion channels. In the present study, we studied the effects of CBN, compared to another major coumarin of RAP osthole (OST), on nociceptive behaviors in a neuropathic pain model of mouse induced by a chemotherapy drug oxaliplatin. We also studied the effects of CBN, compared to OST, on voltage-gated calcium and sodium currents in small dorsal root ganglion (DRG) neurons of mice. We found that CBN largely inhibited both mechanical and cold hypersensitivity induced by oxaliplatin while OST largely inhibited the mechanical hypersensitivity. Using whole-cell patch

clamp recordings, we further found that both CBN and OST significantly inhibited calcium currents (*Ica*), but not sodium currents in small-sized DRG neurons. However, CBN displayed a stronger inhibitory effect on *Ica* compared to OST. Moreover, our data suggested that CBN selectively inhibits the L-type *Ica* while OST inhibits all types of *Ica* non-selectively. These results suggest that CBN inhibits neuropathic pain behaviors through an inhibition of L-type calcium currents in nociceptive DRG neurons. In addition, the inhibition of different types of calcium currents in DRG neurons might contribute to the different pattern of anti-nociceptive effects of coumarins.

Abstract: Chronic pain is more prominent in women than in men, yet until relatively recently most preclinical pain research was done almost exclusively in male animals. Recent studies have shown profound sex differences in mechanisms of chronic pain. Many of these findings have been in the chemotherapy-induced neuropathic pain (CIPN) area. We tested the hypothesis that AMPK activators could be effective in reversing established CIPN in male and female mice. The indirect AMPK activator metformin has been previously shown by our lab to cause a reversal of neuropathic pain induced by spared nerve injury (SNI), but only in male mice. However, metformin is effective in preventing, but not reversing, CIPN in female mice. These discrepant findings suggest a complex interaction of metformin and sex-specific anti-neuropathic pain effects. We sought to gain more clarity around this issue by using different classes of AMPK

activators in a common CIPN model in mice. Therefore, we used structurally distinct AMPK activators narciclasine (NCLS) and MK 8722 to treat paclitaxel-induced mechanic hypersensitivity and hyperalgesic priming in male and female mice. Efficacy of these compounds to both prevent and reverse hypersensitivity were tested by giving the drug treatment concurrently and following paclitaxel respectively. Paclitaxel (4 mg/kg) was given every other day for a week while AMPK activators were given every day for 7 consecutive days. We found that indirect AMPK activator NCLS (3 mg/kg) was able to prevent and reverse mechanical hypersensitivity as well as block hyperalgesic priming in male and female mice while the direct AMPK activator MK-8722 (30 mg/kg) only blocked priming. We interpret our findings as evidence that indirect AMPK activators are more effective for treating pain hypersensitivity in paclitaxel-induced neuropathy and that both direct and indirect AMPK activators can be effective in male and female mice. These findings have important implications for the development of AMPK-targeting therapeutics for pain treatment.

Abstract: Neuropathic pain (NeuP) describes a heterogeneous group of chronic pain disorders arising from lesion or disease of the somatosensory system. Gabapentin (GBP) and pregabalin (PGB) are among the first line treatments, however, both are associated with poor efficacy and undesirable side-effects. Identifying a plasma biomarker to track disease progression or predict pharmacological efficacy will facilitate drug discovery in NeuP. We have used the chronic constriction injury (CCI) model to investigate plasma cytokine/chemokine profile after NeuP induction and following GBP and PGB treatment. The CCI model was induced in male Sprague-Dawley rats (n=16) by unilateral ligation of the sciatic nerve. Paw withdrawal threshold (PWT; mechanical allodynia) was assessed using von-Frey hairs. PWT was measured at baseline (day 0), day 20 following nerve ligation, 2h (day 27) post-GBP (100mg/kg, PO) and, 2h and 24h (day

42/43) post-PGB (30mg/kg, PO). Plasma IFN-γ, IL-1β, IL-4, IL-5, IL-6, KC/GRO, IL-10, IL-13 TNF-α were analysed at these time points. CCI resulted in increased mechanical sensitivity as measured by PWT. This was reversed by both GBP and PGB at the 2h time point only. Plasma IL-5 was increased following CCI and this was reversed by GBP treatment only. IL-13 was unaffected by CCI and was increased 2h following PGB treatment. TNF-α was decreased by CCI and further decreased by PGB only, at both time points. CCI had no effect on IL-6 and IL-10, both drugs increased these targets. KC/GRO was unaffected by CCI but decreased by GBP and PGB. This study demonstrates the acute efficacy of both GBP and PGB in the rat CCI model of NeuP. Reversal of increased plasma IL-5 following CCI induction was specific to GBP treatment only. IL-13, a cytokine associated with suppression of NeuP, was acutely increased by PGB consistent with its efficacy. The plasma cytokine/chemokine profile here suggests a complex interaction between NeuP disease progression, pharmacological intervention and inflammatory signalling. This study has identified potential plasma markers of NeuP progression and treatment efficacy. Future studies will be designed to further explore the translational potential of these inflammatory markers.

Title: Sex-dependent antiallodynic effect of α_5GABA$_A$ receptors and differences in α_5GABA$_A$ receptors regulation in neuropathic rodents

Authors: *Ú. FRANCO-ENZÁSTIGA[1], A. B. SALINAS-ABARCA[1], R. GONZÁLEZ-BARRIOS[3], B. SÁNCHEZ-HERNÁNDEZ[4], P. BARRAGAN-IGLESIAS[5], G. GARCÍA[2], J. MURBARTIAN[2], T. J. PRICE[5], R. Abstract: It has been shown that the gene *GABRA5* coding for the extrasynaptic α_5 subunit-containing $GABA_A$ (α_5GABA_A) receptors is expressed at higher levels in striatum of women. Moreover, positive allosteric modulators selective for α_5GABA_A receptors reduce stress only in female mice. These data suggest sex differences in the regulation and/or function of α_5GABA_A receptors in the nervous system. It is currently known that α_5GABA_A receptors are expressed in dorsal root ganglia (DRG) and spinal cord (SC) participating in chronic pain. The aim of this study was to investigate whether α_5GABA_A receptors actions are sex-dependent in neuropathic rats and mice. We also evaluated the role of estrogen on the action of α_5GABA_A receptors in neuropathic rats. Moreover, we examined the changes in protein and mRNA levels of α_5GABA_A receptors in DRG and SC of neuropathic animals. Finally, we investigated the influence of epigenetics on the profiles of *Gabra5* expression by analyzing DNA methylation levels in *Gabra5* CpG island in DRG from female and male neuropathic rats. L-655,708, α_5GABA_A receptors inverse agonist (0.15-15 nmol, i.t.), produced an antiallodynic effect in neuropathic female rats and mice. However, L-655,708 elicited a lower effect in male animals. Ovariectomy abrogated the antiallodynic effect of L-655,708 in neuropathic female rats, while 17β-estradiol (14 days, 20 µg/kg, s.c.) restored it. The recovered effect of L-655,708 by 17β-estradiol was lost in rats injected with the specific antagonist of estrogen receptor ICI 182,780 (3 days, 50 µg/kg, i.t.). Nerve injury increased α_5GABA_A receptors protein and mRNA in DRG and SC in female rats and mice and decrease it in males. Moreover, nerve injury increased DNA methylation levels in *Gabra5* CpG island in males but no changes were found in females. Together, these results suggest that α_5GABA_A receptors mediate neuropathic pain in a sex-dependent fashion in rodents, which could be related to a sex-dependent *Gabra5* gene regulation in response to nerve injury. Estrogen receptor activation by 17β-estradiol is involved in α_5GABA_A receptors actions in neuropathic pain possibly through the modulation of epigenetic mechanisms to regulate *Gabra5*. The use of inverse agonists of α_5GABA_A receptors may be a viable strategy for treating neuropathic pain in women.

Title: Anti-allodynic effect of the combination tramadol and N-palmitoylethanolamide in rats with chronic constriction of the sciatic nerve

Authors: *Y. BLANCO HERNANDEZ, L. C. MENA VALDÉS, F. J. LÓPEZ MUÑOZ; CINVESTAV, Mexico City, Mexico

Abstract: Neuropathic pain (NP) is a chronic disorder with a complex and multifactorial etiology. Among drugs used in the NP treatment is tramadol (TRAM), a prototype of analgesic opioid drug. Moreover, it has recently described the antinociceptive effects of the cannabinoids for example N-palmitoylethanolamide (PEA). **Objective.** To evaluate the anti-allodynic effects of TRAM, PEA and the combination in rats with chronic constriction of the sciatic nerve (CCI model). **Methods**. Single doses of TRAM (3.16-31.62 mg/Kg, p.o), PEA (0.316-10.00 mg/Kg, p.o.) and the corresponding combinations were administered, from which the dose response curves were constructed. The antiallodynic effect was determined using the cold allodynia test in the CCI model. The evaluations were made up to 10 days after the surgery at 30, 60, 90, 120 and 180 minutes after the administration of the drugs. **Result.** It was found that TRAM, PEA and the combination showed anti-allodynic efficacy significative respect as the control group ($p<0.05$). Different combinations have been evaluated which have shown additive and potentiation effects. Of them the combination of TRAM 3.16 mg/Kg +PEA 0.316 mg/Kg presents an effect of potentiation which does not present significant differences ($p> 0.05$) with higher doses evaluated of the combination. **Conclusions.** These results demonstrate that the TRAM, PEA and the combination have anti-allodynic effect in rats with NP induced by CCl, and the combination of TRAM 3.16 mg/Kg +PEA 0.316 mg/Kg evidence potentiation effects.

Title: Inhibition of neuropathic pain via NPY Y1 receptor activation in the dorsal horn

Authors: *T. S. NELSON[1], D. F. S. SANTOS[1], K. E. MCCARSON[2], B. K. TAYLOR[1]; [1]Dept. of Anesthesiol. and Perioperative Medicine, Pittsburgh Ctr. for Pain Research, Pit, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA; [2]Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Neuropeptide Y (NPY) exhibits long-lasting inhibitory control of nociceptive transmission after injury (Solway et al., 2011) but the specific receptor targets of NPY in the spinal cord have not been well characterized, particularly in the setting of neuropathic pain. Dorsal horn neurons that express the neuropeptide Y1 receptor (Y1R), an inhibitory G protein-coupled receptor, are well positioned to mediate the anti-nociceptive actions of NPY. We hypothesized that **f**ollowing peripheral nerve injury, Y1Rs maintain their functional G-protein coupling and that selective Y1R agonists will reduce behavioral symptoms of neuropathic pain and immunohistochemical markers of central sensitization in cells in the dorsal horn. Male and female C57BL/6 mice underwent spared nerve injury surgery (SNI), a model of neuropathic pain. First, [^{35}S]GTPγS binding assays in lumbar spinal cord sections of both sham and SNI mice suggest that Y1R signaling efficacy remains intact within spinal neurons as neither the EC_{50} nor the E_{max} were affected by SNI ($p<0.05$, n=6-9). Second, intrathecal (i.t.) administration of the selective Y1R agonist, $Leu^{31}Pro^{34}$, dose-dependently reduces both mechanical (von Frey method) and cold (withdrawal duration to acetone droplet evaporation) hypersensitivity 14-28 days after SNI ($P<0.05$, n=8-11). Third, Y1R specific activation was determined by coadministration of $Leu^{31}Pro^{34}$ with a Y1R antagonist, which blocked the antihyperalgesic effects of $Leu^{31}Pro^{34}$ ($P>0.05$, n=4-7), whereas coadministration with a Y2 receptor antagonist did not ($P<0.05$, n=6-10). Lastly, pERK expression was assessed after the following steps: i.t. administration of drug (Y1 agonist, Y1 antagonist, Vehicle, or Y1 Agonist +Y1 Antagonist); 30-minute wait, 5 minutes of light brush mechanical stimulation of the injured hindpaw, and then perfusion. Spinal cord sections were processed for immunohistochemistry and the number of pERK-expressing cells in laminae I-III of L4 dorsal horn was quantified. $Leu^{31}Pro^{34}$ significantly reduced the number of pERK-expressing cells in the superficial dorsal horn ($P<.05$, n=4-6) but not when coadministered with a Y1R antagonist ($P>.05$, n=4-6). These results suggest that following SNI, the Y1R maintains the capacity to inhibit pain and that i.t. administration of a Y1R specific agonist reduces behavioral and molecular signs of central sensitization of pain-related dorsal horn neurons. In combination with previous studies these results support the Y1R as a promising target for the treatment of neuropathic pain and warrant clinical trials for the i.t. administration of Y1R-selective agonists.

Title: Analgesic effects of a fish skin preparation on chemotherapy-induced neuropathic pain in rats

Authors: *H. KIM[1], S.-H. HWANG[1], P. YANG[2], J. M. AL-HASSAN[3], S. ABDI[1];
[1]Pain Med., [2]2Department of Palliative, Rehabil. and Integrative Med., The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX; [3]Kuwait Univ., Safat, Kuwait

Abstract: Advances in the treatment of cancer using various types of chemotherapy agents have led to improvement in the survival rate of cancer patients. However, many chemotherapeutic drugs including taxanes, vinca alkaloids, and platinum complexes produced chronic neuropathic pain, called chemotherapy-induced neuropathic pain that is a dose-limiting adverse effect which affects the quality of life of the cancer patients and survivals. The catfish *Arius bilineatus, Val.* secretes a proteinaceous epidermal secretion, preparations from which were reported to produce wound healing and anti-inflammatory activity. Fraction-B is a preparation from the skin secretions. The purpose of study was to determine the analgesic effects of Fraction-B on paclitaxel (PAC)-induced neuropathic pain (PINP) in rats. PINP was produced by intraperitoneal injections of PAC at a dose of 2 mg/kg on days 0, 2, 4, and 6 (total 8 mg/kg) in adult male Sprague Dawley rats. The pain behavioral test was measured by using a set of von Frey filaments and then calculated a 50% mechanical threshold. Western blotting of the L1-6 dorsal root ganglia (DRGs) was performed for the measurement of protein levels of pro-inflammatory mediators. Fraction-B was intraperitoneally injected after fully developed pain behavior. PAC induced mechanical allodynia, which began to manifest on days 7-10, peaked within 2 weeks, and plateaued for at least 2 months after the first PAC injection. PAC also increased the levels of pro-inflammatory mediators including phosphorylated nuclear factor κB and monocyte chemoattractant protein-1 in the DRGs. Systemic injection of Fraction-B ameliorated pain behaviors at doses of 3, 5, and 10 mg/kg. The 10 mg/kg of Fraction-B significantly increased mechanical threshold for 2 hours. Fraction-B decreased PAC-induced pro-inflammatory mediators. We conclude that Fraction-B alleviates chemotherapy-induced neuropathic pain in rats by reducing the levels of pro-inflammatory mediators in the DRGs.

Title: Effect of 5-HT7 receptor agonist on chronic pain associated co-morbid disorders in neuropathic rats

Authors: *V. GOURA[1,2], P. JAYARAJAN[1], A. KISHORE[2], R. ABRAHAM[1], A. VUYYURU[1], R. NIROGI[1];
[1]Suven Life Sci. Ltd., Hyderabad, India; [2]Pharmaceut. Sci., Manipal Acad. of Higher Educ., Manipal, India

Abstract: Chronic pain is a debilitating syndrome. Patients also suffer from mood disorders like depression, anxiety and cognitive deficits. Thus, treating chronic pain is becoming difficult task with the existing therapy. It is important to treat both pain and its associated disorders concurrently in co-morbid populations. Preclinical research is concentrated on G-protein coupled receptor (GPCR) classes in treating pain and associated depression. We have sought to put our efforts in characterizing a newly identified GPCR, the serotonin receptor subtype 7 (5-HT_7). As per literature survey LP-211, a 5-HT_7R agonist showed its therapeutic effects on sleep, anxiety, depression and pain in preclinical animal models. But till date, no data is available on pain co-morbidities. In the current study we tested LP-211, 1 and 3 mg/kg, i.p. and LP-211, 3 mg/kg, i.p. + Gabapentin 10 mg/kg, i.p. on partial sciatic nerve induced neuropathic pain (PSNL), streptozocin induced diabetic neuropathic pain (DNP) models and associated co-morbidities like anxiety, depression and cognitive deficits. Von Frey monofilaments were used for evaluating pain, elevated plus maze (EPM) for anxiety, forced swim test (FST) for depression and novel object recognition test (NORT) for cognition. LP-211, 3 mg/kg, i.p. showed mild analgesic effects in PSNL and DPN rats. LP-211, 3 mg/kg, i.p. + Gabapentin, 10 mg/kg, i.p. showed significantly synergistic analgesic effect in the current tested models for pain and in treating its associated disorders. Thus, LP-211 a 5-HT_7R agonist in combination with gabapentin would be a promising therapy for treating chronic pain.

Title: Assessment of the efficacy of different pharmacological treatments in a model of partial meniscectomy-induced osteoarthritis in female rats

Authors: A. ZANON, V. MAFFRE, Y. DARBAKY, *L. DIOP;
ANS Biotech, RIOM, France

Abstract: Osteoarthritis (OA) is a degenerative disease involving several joint tissues, characterized by damages to the articular cartilage. The partial meniscectomy model presents similarities to human OA with cartilage damage, subchondral bone remodeling, and presence of osteophytes. Symptomatically, the partial meniscectomy model has been described as inducing evoked pain (tactile allodynia). The objective of this study was to evaluate the activity of different pharmacological treatments (opioid receptor agonists, nonsteroidal anti-inflammatory drug (NSAID) and local anaesthetic) on mechanical allodynia in a model of partial meniscectomy-induced OA in female rats.
Methods: Adult female Lewis rats were anesthetized before partial resection of medial meniscus. On week 3 after surgery, animals received an acute administration of Morphine, Diclofenac or 0.9% NaCl. On week 6 after surgery, animals received an acute administration of Tramadol, Bupivacaine or 0.9% NaCl. Tactile sensitivity of both hindpaws was measured before and after treatment, on week 3 and 6, using electronic Von Frey.
Results: Partial meniscectomy surgery induced, from 3 weeks to 6 weeks after partial resection of medial meniscus, a reduced and stable paw withdrawal threshold in the vehicle-treated group as compared to the sham-operated controls. On week 3, a single subcutaneous administration of Morphine 3 mg/kg induced, in dose and time related manner, an antiallodynic effect in a model of partial meniscectomy-induced OA. In the same experimental conditions, Diclofenac 30 mg/kg po exhibited moderate antiallodynic effect. On week 6, a single oral administration of Tramadol 100 mg/kg produced, in dose and time related manner, a marked antiallodynic effect. Bupivacaine intra-articularly administered at 0.01 mg/kg did not induce any significant effect in a model of partial meniscectomy-induced OA.
Conclusions: In the model of partial meniscectomy-induced OA, opioid receptor agonists showed marked antiallodynic effects. The hypersensitivity was reduced by treatment with a NSAID but not with local anaesthetic in the model of OA.

Title: Investigation of the temporal plasma cytokine/chemokine profile of the monosodium iodoacetate rat model of osteoarthritis: Relevance to pharmacological reversal of hyperalgesia

Authors: *J. A. PRENDERVILLE[1], E. SOKOLOWSKA[1], M. BIANCHI[1], A. L. THOMAS[2], C. MONTAGUT-BORDAS[3], A. S. FISHER[2], N. UPTON[2], A. H. DICKENSON[4]; [1]Transpharmation Ireland Ltd, Dublin, Ireland; [2]Transpharmation Ltd, London, United Kingdom; [3]Neuroscience, Physiology, Pharmacol., Univ. Col. London, Dublin, Ireland; [4]Univ. Col. London, London, United Kingdom

Abstract: Osteoarthritis (OA) is estimated to affect 10-15% of individuals over the age of 60 (WHO, 2013). OA primarily affects load bearing joints, including the knee, often leading to pain and disability. Identification of a plasma biomarker to predict pharmacological efficacy will facilitate drug discovery in OA. We have used the monosodium-iodoacetate (MIA) rat model of OA to investigate plasma cytokine/chemokine profile after OA induction. The OA model was induced in 3 cohorts of male Sprague-Dawley rats (n=105) by intra-articular injection (knee joint) of MIA (glycolysis inhibitor; 80mg/ml, 25ul). Weight-bearing was measured using an incapacitance meter at baseline and hyperalgesia induced by MIA was calculated. Cohort 1 received daily injections of vehicle, celecoxib (50mg/kg) or pregabalin (30mg/kg) on days 3-7 (early phase). Cohort 2 received the same treatments on days 24-28 (late phase). Hyperalgesia was measured daily and compared with sham control. In cohort 3 plasma was sampled at baseline and 4, 7 and 14 days after MIA administration. IFN-γ, IL-1β, IL-4, IL-5, IL-6, KC/GRO, IL-10, IL-13 and TNF-α were analysed. MIA resulted in an approximate 70% reduction in weight-bearing on the ipsilateral side. In cohort 1, the reduction in weight-bearing was reversed by celecoxib, pregabalin had no effect. In cohort 2, the reduction in weight-bearing was reversed by pregabalin, celecoxib had no effect. In cohort 3, plasma KC/GRO was increased at day 4 in comparison to baseline. TNF-α was decreased on day 7 and day 14 in comparison to day 4. IL-4 and IL-10 were increased at day 14. This study supports the previously reported biphasic nature of the MIA model, characterised by the early inflammatory phase where hyperalgesia is reversed by the non-steroidal anti-inflammatory drug (NSAID) celecoxib and the late neuropathic phase showing sensitivity to pregabalin. Consistent with this, we show acute early elevation of the chemokine KC/GRO and a progressive decrease in the inflammatory cytokine TNF-α across the inflammatory phase. The anti-inflammatory cytokines IL-4 and IL-10 were increased after the inflammatory phase. These data suggest that plasma inflammatory markers may indicate OA disease progression and could be used to inform treatment strategy.

Abstract: *Montanoa tomentosa* is widely known in Mexico for treating female health disorders since hundreds of years, yet there are no scientific report about its use on pain or inflammation even when certain population of the country has given the plant this use. Thus, in this study we used the formalin test and the carrageenan-induced edema to test the antinociceptive and anti-inflammatory effect of an ointment containing hidroalcoholic extract of *M. tomentosa;* furthermore, we performed the histological examination of tissue from all treatments to describe the inflammatory response and the histopathologic changes on each treatment. Our results showed that topical administration of MT (*M. tomentosa*) ointment diminished flinching behavior induced by formalin and significantly reduced the carrageenan-induced edema. Besides, we observed a significant reduction in tissue disruption as well as less infiltration of leucocytes when the dose 50 mg/paw was administered. These data suggest that MT ointment has interesting and potential antinociceptive and anti-inflammatory activities.

Title: Antihyperalgesic and antiallodynic activities of the rosmarinus officinalis oil nanoemulsion in a fibromyalgia model in rats

Authors: *A. HERNÁNDEZ LEÓN[1], M. E. GONZÁLEZ-TRUJANO[1], J. C. TAVARES-CARVALHO[2], A. NAVARRETE[3];
[1]Inst. Nacional de Psiquiatría Ramón de la Fuente Muñiz, Ciudad de Mexico, Mexico; [2]Ciencias Biológicas e da Saude, Univ. Federal do Amapa, Macapa, Brazil; [3]Facultad de Química, Univ. Nacional Autónoma de México, Ciudad de Mexico, Mexico

Abstract: Fibromyalgia (FM) is a musculoskeletal chronic pain syndrome in humans due to an altered processing of somatosensory information. No efficacious current therapy strongly promotes strategies for its treatment or attenuation. *Rosmarinus officinalis* is an ancient medicinal plant with a long history and scientific studies supporting its potential antinociceptive properties. The aim of this study was to investigate the effects of *R. officinalis* essential oil alone and prepared in a nanoemulsion formulation, to compare Mexican and Brasilian plants, using the reserpine (RES)-induced FM like pain model in rats. Male Wistar rats weighing 200 to 250 g were grouped in n=6 animals. The behavioral thresholds of nociceptive response in the experimental FM were analyzed in parameters of muscular hyperalgesia, and tactile and cold allodynia. Groups consisted in: (a) No treatment (healthy control), (b) FM, (c) FM + nanoemulsion *R. officinalis* essential oil (RO) from Mexican plant (NEMEX), (d) FM + nanoemulsion RO from Brazil plant (NECHA), both at 5% concentration, compared to the (e) RO without nanoemulsion at a dosage of 100 mg/kg as reference sample or a standardized nanoemulsion (NECULT) at 5% and 20%. Our results demonstrated that conventional obtention of RO from Mexican plant produced significant antihyperalgesic and antiallodynic responses. The antihyperalgesic but not antiallodynic response was resembled by nanoemulsions of RO obtained from Brazil or Mexican plants. In conclusion, our results give evidence that *R. officinalis* oil possesses potential as alternative treatment for FM-like pain which antihyperalgesic dosage might be improved by using a nanoemulsion formulation

Title: Potential analgesic-like effects of Tilia americana var. mexicana in an experimental animal model of fibromyalgia

Authors: *Y. E. QUINTO-ORTIZ[1], A. HERNANDEZ-LEON[2], L. D. PALOMINO-NAVARRETE[3], M. E. GONZALEZ-TRUJANO[2];
[1]Natl. Inst. of Psychiatry "Ramón de la Fuen, Mexico city, Mexico; [2]Neurosci. department, Natl. Inst. of Psychiatry Ramón de la Fuente Muñiz, Mexico city, Mexico; [3]Fac. of Chem., Natl. Autonomous Univ. of Mexico, Mexico city, Mexico

Abstract: Fibromyalgia (FM) is a painful syndrome characterized by chronic generalized pain and central nervous system comorbidity. Its prevalence is higher in women than in men. Although drugs are available to alleviate most of the symptoms, their adverse effects promote discontinuation of drug therapy. Therefore, it is preponderant to find alternatives of therapy efficacious and safety. In the present investigation, a methanol extract of *Tilia americana* var. *mexicana* was studied to give evidence of its potential as therapeutic alternative for FM. Ethno-pharmacological knowledge of this species in traditional Mexican medicine have described significant analgesic and anxiolytic and sedative-like effects because of the presence of flavonoid compounds. The experimental model of reserpine-induced FM was applied using female Wistar rats (200-250 g). Analgesic-like effect of *Tilia* (10, 30, and 100 mg/kg i.p.) and their fractions (AB: 100 mg/kg i.p., F: 10, 30, 100, and 300 mg/kg) obtained by chromatographic analysis were explored compared to those observed with the reference drug fluoxetine (10 mg/kg s.c., 3 injections -24, -5 and 0 h before the test) and tramadol (10 mg/kg i.p.). The combination of AB-fraction (rich in terpenes) or F-fraction (rich in flavonoids) with fluoxetine (2.5 mg/kg s.c. 3 injections -24, -5 and 0 h before the test) or tramadol (3 mg/kg i.p.) was also explored to look for a pharmacological synergistic interaction. Data demonstrated that *Tilia* extract and fractions alone produced antihyperalgesic and antiallodynic-like effects since they increased thresholds to the muscular pressure in about 56-91%, tactile allodynia in 80-87%, and in cold allodynia in 82-100%. Combination of AB or F- fractions with fluoxetine or tramadol produced lower effects than those observed in individual administration suggesting an antagonic pharmacological interaction. In conclusion, this study gives evidence that *Tilia americana* var. m*exicana* extract

possess constituents with potential properties to alleviate pain-like FM, however caution is important in combination of alternatives of therapy since a drug interaction is highly probably.

Title: Spinal dopaminergic receptors contribute to nociception in a rat model of fibromyalgia

Authors: *Y. E. DE LA LUZ-CUELLAR[1], F. MERCADO[2], V. GRANADOS-SOTO[1]; [1]Dept. de Farmacobiología, CINVESTAV Sede Sur, Ciudad de Mexico, Mexico; [2]Dirección de Investigaciones en Neurociencias, INPRFM, Ciudad de Mexico, Mexico

Abstract: Fibromyalgia patients have reduced levels of monoamines in cerebrospinal fluid and this could lead to a dysfunction of descending pain modulation systems. Spinal dopaminergic projections from the hypothalamic A11 nucleus modulates nociceptive transmission in dorsal horn of spinal cord. Activation of central and peripheral D2-like receptors produces anti-nociceptive effects while stimulation of D1-like receptors increase neuronal excitability and has pro-nociceptive effects in models of inflammatory and neuropathic pain. However, the role of spinal dopaminergic receptors in functional pain is unknown. The aim of this study was to investigate the role of spinal dopamine receptors in a reserpine-induced model of fibromyalgia. Fibromyalgia-type nociception was induced by a reserpine injection (1 mg/kg) for three consecutive days in female Wistar rats. Tactile allodynia (TA) and muscular hyperalgesia (MH) were assessed with Von Frey filaments and the Randall-Selitto test, respectively. Reserpine-treated rats were intrathecally injected with the selective D2-like agonists quinpirole (1-10 nmol), and pramipexole (0.15-15 nmol), or the D1-like receptor antagonist SCH-23390 (10-100 nmol). Rats also were treated with intrathecal co-treatments of quinpirole or pramipexole and selective antagonists for D2 (L-741,626), D3 (PG01037) and D4 (L-745,870) receptors. Similarly, reserpinized rats received intrathecal co-treatment of SCH-23390 with the D1-like agonist SKF-38393. Experimenter was blinded to all treatments. Intrathecal quinpirole and pramipexole, but not vehicle, partially reversed reserpine-induced TA and MH in a dose-dependent manner. Co-treatment with L-741,626 totally reversed the anti-allodynic and anti-hyperalgesic effects of quinpirole and pramipexole, whilst co-treatments with PG01037 and L-745,870 moderately blocked the anti-nociceptive effects of these compounds. These data suggest

that activation of spinal D2-like receptors has anti-nociceptive effects in fibromyalgia-like nociception, with a major role of D2 receptor-subtype. Moreover, intrathecal SCH-23390, but not vehicle, completely reversed TA and partially reversed MH in reserpinized rats. Co-treatment with SFK-38393 completely reversed the anti-allodynic effect of SCH-23390, suggesting that activation of D1-like receptors has a pro-nociceptive effect in fibromyalgia-like nociception. The D1-like agonist and all D2-like antagonists had no effect *per se*. Results suggest that spinal dopaminergic receptors, mainly through the activation D1-like receptors, contribute to the nociceptive hypersensitivity induced by reserpine in female rats.

Title: Protein kinase C-beta isoform as a mechanism promoting chronic pain in sickle cell disease

Authors: *Y. HE[1], Z. J. WANG[2];
[1]Univ. of Illinois at Chicago, Chicago, IL; [2]BPS, Univ. Illinois, Chicago, IL

Abstract: As a marker of disease severity and mortality predictor, pain is one of the most dreadful symptoms in sickle cell disease (SCD) and is refractory to currently available analgesics. Besides acute painful vaso-occlusive crises, SCD is also accompanied by intractable chronic pain. This persistent, and often unrelieved, pain starts early in childhood and continues throughout life. The neurobiological mechanisms of chronic pain in SCD remain unclear, which markedly limits effective pain management and the quality of life in patients with SCD. Taking advantage of a humanized mouse model of SCD, this study aimed to investigate protein kinase C (PKC)-beta isoform mechanism for chronic pain in SCD. We characterized pain phenotypes in the Townes' mouse model (TOW) of SCD that exclusively expresses human alleles encoding normal α- and sickle β-globin. TOW mice exhibited ongoing spontaneous pain as well as hypersensitivity to evoked pain stimuli compared with littermate control mice. We then examined spinal and nociceptor PKCbeta-mediated signaling and behavioral consequences. Prominent activation of PKCbeta was identified in the superficial laminae of the spinal cord dorsal horn as well as in the nociceptors in TOW sickle mice. Functional inhibition and genetic silencing of the PKC isoform attenuated sickle cell pain phenotypes, abolishing PKC activation,

spontaneous pain, mechanical allodynia, and heat hyperalgesia in the sickle cell mice. Taken together, these data suggest PKCbeta as one of the mechanisms for the generation and maintenance of ongoing and evoked pain in SCD. These findings offer insights into sickle cell pain mechanisms, which may become a potential target for pharmacological interventions.

Title: Opioid-induced hyperalgesia by chronic administration of morphine is caused by serotonin in spinal dorsal horn and, in part, through the 5HT-3 receptor

Authors: *Y. KAMIYA, M. SASAKI, M. TANAKA, K. BAMBA, T. OHNISHI;
Anesthesiol., Niigata Univ. Hosp., Niigata, Japan

Abstract: [Introduction] We conducted the following experiments to clarify the involvement of serotonin and the 5HT-3 serotonin receptor in hyperalgesia induced by chronic opioid administration. [Method] This study was approved by the Niigata University Animal Experiment Ethics Committee (Approval No. H27-203). We created the following groups using male C57BL / 6 mice (6-9 weeks old); a group that received 20 mg / kg of morphine hydrochloride intraperitoneally twice a day for 4 days, a group in which serotonin synthesis inhibitor para-chlorophenylalanine (PCPA) 150 mg / kg was administered once a day from 4 days before morphine administration through the morphine administration period, a group in which a 5HT-3 receptor antagonist ondansetron (OND) 2 mg / kg was administered 30 minutes before morphine administration. The Paw withdrawal thresholds were measured by von Frey test for these groups. Moreover, in the spinal dorsal horn of the above three groups, expression levels of phosphorylated ERK and glial fibrillary acidic protein (GFAP), which are known to be activated by nociceptive stimuli at spinal dorsal horn, and serotonin were compared using immunostaining. [Results] Four days of continuous administration of morphine produced paw withdrawal hyperalgesia, but no hyperalgesia occurred in the PCPA-treated group. Moreover, pre-administration of OND suppressed hyperalgesia (control group (n = 9): 1.04 ± 0.1 g, morphine group (n = 11): 0.34 ± 0.06 g, morphine + PCPA group (n = 8): 1.04 ± 0.08 g, morphine + OND 2 mg / kg: 0.73 ± 0.11 g, $p < 0.001$ by Kruskal -Wallis test). Continuous administration of

morphine apparently increased serotonin expression in the spinal dorsal horn, but PCPA administration completely suppressed the increase of serotonin expression by morphine administration. On the other hand, co-administration of OND did not suppress the increase of serotonin by the morphine administration. Morphine administration significantly increased phosphorylated ERK and GFAP but was significantly suppressed by PCPA and OND treatment. [Conclusion] The present study suggested that chronic administration of morphine to mice causes hyperalgesia, which involves serotonin, and a part of which is mediated by the 5HT-3 receptor.

Title: The role of cannabinoids and terpenes in cannabis-mediated analgesia in rats

Authors: *K. J. SUFKA[1,2], H. M. HARRIS[1], M. A. ROUSSEAU[2], A. S. WANAS[1], M. M. RADWAN[1], S. CALDWELL[2], *K. J. SUFKA[3,1], M. A. ELSOHLY[1,4];

Abstract: Cannabis sativa has been used for centuries in treating pain. However, the analgesic role of many of its constituents including the terpenes is unknown. This research examined the contributions of terpenes (volatile oil) and cannabinoids in cannabis-mediated analgesia in rats. Animals received intraperitoneal administration of either vehicle, 10.0 or 18.0 mg/kg morphine, or various doses of the extract without terpenes, isolated terpenes, THC, or the full extract. 30 m later animals were tested on hotplate and tail-flick tests of thermal nociception. One week later, rats received a second administration of test articles and tested 30 m later in the abdominal writhing test of inflammatory nociception. In the thermal assays, hotplate and tail-flick latencies for morphine treated rats were dose-dependent and significantly higher than vehicle treated animals. All of the cannabinoid compounds except for the isolated terpenes produced dose-dependent increases in hotplate and tail-flick latencies. In the inflammatory nociceptive assay, animals treated with vehicle and isolated terpenes demonstrated increased abdominal writhing

while all of the cannabinoid compounds significantly decreased abdominal writhing responses. Overall, THC alone produced robust analgesia equivalent to the full cannabis extract while terpenes alone did not produce analgesia. These data suggest the analgesic activity of cannabis is largely mediated by THC while terpenes alone do not cause alterations in cannabis-mediated analgesia.

Title: The marijuana-derived terpene β-Caryophyllene reverses mechanical allodynia and thermal hyperalgesia in a mouse model of neuropathic pain

Authors: *J. L. WILKERSON[1], J. S. FELIX[2], L. R. MCMAHON[1];
[1]Pharmacodynamics, [2]Univ. of Florida, Gainesville, FL

Abstract: Pain is one of the most common reasons to seek medical attention and chronic pain is a worldwide epidemic. Under some circumstances, incoming protective nociceptive signaling is prolonged leading to behavioral sensory alterations common to pathological neuropathic pain. As marijuana contains numerous terpenes, we hypothesized that the terpene β- Caryophyllene would reverse behaviors associated with pathological neuropathic pain. We used the chronic constriction injury of the sciatic nerve (CCI) model of neuropathic pain, which produces robust increases in sensitivity to light mechanical touch, or allodynia, as assessed with von Frey filaments, and increased thermal sensitivity, or thermal hyperalgesia, as assessed in the hotplate test. To examine the involvement of cannabinoid receptors, we also tested this compound in mice that had undergone the CCI surgery that lack either functional cannabinoid type 1 receptors (CB_1R (-/-)) or mice lacking functional cannabinoid type 2 receptors (CB_2R (-/-)).
First, we assessed the ability of β- Caryophyllene to reverse mechanical allodynia and thermal hyperalgesia. Male and female wildtype mice on a C57BL/6J background underwent CCI surgery with chromic gut suture used to ligate the sciatic nerve. Sham mice underwent surgical procedures but without nerve ligation. Starting seven days after surgery, mice were injected intraperitoneally (i.p.) with a single dose of vehicle (1 part ethanol / 1 part emulphor/ 18 parts saline) or β- Caryophyllene (56, 100, 178 mg/kg) and 20 min later mice were tested for

mechanical allodynia and thermal hyperalgesia. Mice in the CCI - Vehicle group displayed robust mechanical allodynia and thermal hyperalgesia when compared to Sham - Vehicle mice. The terpene β- Caryophyllene produced dose-dependent reversal of mechanical allodynia at the doses of 100 and 178 mg/kg, and dose-dependent reversal of thermal hyperalgesia at the dose of 178 mg/kg. Next, we tested β- Caryophyllene at the dose of 178 mg/kg (i.p.) in male and female CB_1R (-/-), CB_2R (-/-) mice. In CB_2R (-/-) mice this dose was not sufficient to reverse mechanical allodynia, or thermal hyperalgesia. Meanwhile, in CB_1R (-/-) no attenuation of β-Caryophyllene's effects on mechanical allodynia or thermal hyperalgesia was observed. This demonstrates that CB_2R are necessary for β- Caryophyllene's anti- allodynic and thermal hyperalgesic effects, with CB_1R being dispensable. These findings suggest that β- Caryophyllene acts via CB_2R and may be an attractive therapeutic for the treatment neuropathic pain.

Title: The role of spinal endocannabinoids in a rat model of oro-facial neuropathic pain

Authors: *K. NAKAI[1], A. NAKAE[2], Y. MINEGISHI[1], R. URABE[1], M. MIYAMAE[1], T. YANAGIDA[2], K. HOSOKAWA[3], T. KUBO[4];
[1]Univ. of Fukui Hosp., Eiheiji-Cho, Japan; [2]Osaka Univ. Grad. Sch. of Frontier Biosci., Suita-Shi, Japan; [3]Osaka Univ. Grad. Sch. of Med., Suita-Shi, Japan; [4]Osaka Univ. Grad. Sch. of Med., Suita-shi, Japan

Abstract: Background: Endocannabinoids are decomposed by enzymes such as fatty acid amide hydrolase (FAAH) and monoacylglycerol lipase (MAGL). Inhibitors for FAAH and MAGL increase amounts of endocannabinoids. The manipulation of endogenous cannabinoids (CBs) is an alternative to the direct targeting of CB receptors for the treatment of pain. The contribution of spinal endocannabinoids in the oro-facial neuropathic pain remains unclear. Chronic constriction injury to the infraorbital nerve (ION-CCI) has proven to be a useful model for oro-facial neuropathic pain. The present study evaluates the role of spinal endocannabinoids in a rat model of oro-facial neuropathic pain. Material and Methods: Male Sprague Dawley rats underwent unilateral CCI to the right ION. The ION was dissected free in the orbital cavity. Two nylon (5-0) ligatures were loosely tied around the ION. 14 days after the initial surgery, tactile allodynia of the territory of the ligated nerve was confirmed by measuring the mechanical

response threshold in response to application of von Frey filaments. Only rats with hyper-responsiveness to mechanical stimulation were used. An intrathecal catheter was implanted for upper cervical spinal injection of drugs. The polyethylene tube (PE10) was advanced 10 mm caudally through a tiny hole in the atlantooccipital membrane and the dura. The animals were allowed to recover 7 days before drug testing. The time course of analgesic effects of intrathecally administered a FAAH inhibitor JNJ1661010 and a MAGL inhibitor JZL184 were examined. We evaluated the antagonizing effect of intrathecal pretreatment with a CB1 receptor antagonist SR141716A or a CB2 receptor antagonist AM630, on the analgesic action of the FAAH inhibitor or the MAGL inhibitor. The time course data for the dose-response effects were analyzed by two-way analysis of variance and Tukey-Kramer multiple-comparison test. Results: Intrathecal administration of JNJ1661010 and JZL184 significantly increased mechanical thresholds in a dose dependent manner. AM630 significantly reduced the analgesic effects of JNJ1661010 and JZL184. SR141716A did not alter the analgesic effects of JNJ1661010 and JZL184. Conclusions: The increase of spinal endocannabinoids reduced the pain-related behavior in a rat model of oro-facial neuropathic pain. The pain modulation was mediated by CB2 receptors.

Title: High capacity *in vitro* disease modelling of chronic pain

Authors: *P. KARILA, C. NODIN, S. LARDELL, M. KARLSSON;
Cellectricon AB, Mölndal, Sweden

Abstract: Rodent models have been used extensively to provide insight into the mechanisms underlying many diseases, and to explore the efficacy of candidate drugs. Despite recent questioning of rodent models, they still bring immense value to the scientific community. For example, using a high capacity optical electrophysiology approach where up to 96 neuronal cultures can be probed in parallel, we have demonstrated that changes in neuronal excitability induced by long-term inflammation *in vivo* clearly persists after establishment of primary mouse dorsal root ganglia (DRG) cultures (Bersellini Farinotti et al. Abstract number 10283, Neuroscience 2018). Chemotherapy-induced peripheral neuropathy (CIPN) is a common adverse effect of commonly used chemotherapeutic drugs and there is a need for efficient and physiologically relevant screening methods to identify compounds reversing the neuropathy-

related adverse effects. In the current exploratory study, the purpose was to establish a high capacity testing approach for CIPN-inducing chemotherapeutic agents on neuronal excitability *in vitro*.Successful assay development would enable efficient screening of compounds reversing the effects induced by CIPN-inducing compounds and ultimately aid in understanding adverse effects of commonly used chemotherapeutic drugs such as platinum drugs and taxanes.
Rat DRGs were prepared according to previously described methods (Sidders et al. J Mol Biol. 2018 Sep 14;430(18 Pt A):3005-3015) and plated into 384-well plates. The CIPN-inducing compounds oxaliplatin and paclitaxel were added to the cultures up to seven days prior to evaluating the compound effects on an optical electrophysiology platform. The cultures were subsequently fixed to enable immunocytochemical investigation of neuronal morphology.
Oxaliplatin induced increased neuronal excitability in the rat DRG cultures. The effects were most pronounced after seven days. In contrast, in presence of paclitaxel, neuronal excitability was reduced in a concentration- and time-dependent manner. In addition to the functional effects, morphological parameters such as changes in the number of neurons and the extent of the neurite network were investigated for the two drugs.
In conclusion, by using our high capacity plate-based optical electrophysiology platform, we have developed models to explore and understand underlying conditions in the excitability properties of sensory neurons in disease conditions. The models can be used for large scale screening for compounds that are reversing the effects induced by CIPN-inducing compound. The translational aspects of the results will also be discussed.

Title: Spinal calcitonin gene-related peptide promotes chronic pain plasticity and depolarizes dorsal horn chloride reversal potentials in female but not male mice

Authors: *C. A. PAIGE[1], I. P. FERNANDEZ[2], M. KUMEO[1], M. PAPALAMPROPOULOU-TSIRIDOU[2], L.-E. LORENZO[2], G. L. MEJIA, JR[1], F. M. FERRINI[3], Y. DE KONINCK[4], G. DUSSOR[1], T. J. PRICE[1];

[1]Sch. of Behavioral and Brain Sci., Univ. of Texas At Dallas, Richardson, TX; [2]Cell. and Mol. Neurobio., Laval Univ., Quebec, QC, Canada; [3]Univ. of Turin, Grugliasco, Italy; [4]Cell. & Mol. Neurobio., Laval Univ. / IUSMQ, Quebec, QC, Canada

Abstract: The majority of patients impacted by chronic pain are women. In our study, we aimed to investigate the potentially sexually dimorphic role of Calcitonin Gene-Related Peptide (CGRP) in three mouse models of chronic pain: hyperalgesic priming, incision, and spared-nerve injury (SNI). Based on emerging findings from the migraine field, we hypothesized that CGRP antagonists would block all three forms of chronic pain specifically in female mice. We induced hyperalgesic priming with an injection of the human IL-6 receptor (IL-6r) or through an incision of the hindpaw. The spared nerve injury was used to induce neuropathic pain. In the hyperalgesic priming experiments CGRP8-37, a CGRP receptor antagonist, was given intrathecally (I.T.) at either the time of IL-6r/incision or PGE2 injection in order to determine if CGRP8-37 could block the establishment of or reverse hyperalgesic priming. For animals with SNI, CGRP8-37 was administered I.T. and PWT was measured following the I.T. injection. In priming induced by IL-6r injection, CGRP8-37 both blocked and reversed hyperalgesic priming specifically in females. In the incision model, CGRP8-37 blocked priming in female mice following PGE2 injection. In the SNI model, there was a transient effect of the CGRP antagonist on mechanical hypersensitivity in female mice only. Our findings demonstrate that blocking CGRP receptors with CGRP8-37 is effective in reducing mechanical hypersensitivity in all 3 models, but only in female mice. Consistent with these findings I.T. CGRP caused a long-lasting mechanical sensitivity specifically in female mice. This CGRP-induced mechanical hypersensitivity was reversed by the KCC2 activator, CLP-257. However, in the IL-6r induced hyperalgesic priming model I.T. CLP-257 reversed hyperalgesic priming in both male and female animals. In spinal dorsal horn electrophysiology experiments CGRP shifted chloride reversal potentials to significantly more positive values but, again, only in female mice. Therefore, CGRP may regulate KCC2 expression and/or activity specifically in females but KCC2 clearly plays a role in promoting mechanical pain hypersensitivity in both sexes. We conclude that CGRP promotes pain plasticity in female mice, but has a limited impact in male mice, suggesting that CGRP antagonists may be an effective treatment for many forms of chronic pain in females.

Title: HC-030031, TRPA1 antagonist, produced efficacy in AITC-induced pain despite low theoretical receptor occupancy

Authors: M. HAJOS[1], R. GILFILLAN[1], J. P. GILBERT[1], M. CHAMBERS[2], A.-M. KÄRKKÄINEN[3], S. ROBJOHNS[2], E. LOWE[2], G. CLARK[2], S. WILLIAMS[2], S. MAIDMENT[2], ***D. MISZCZUK**[3];
[1]Biogen, Cambridge, MA; [2]Charles River Discovery, Saffron Walden, United Kingdom; [3]Charles River Discovery, Kuopio, Finland

Abstract: Effective treatment of chronic pain remains an unmet medical need. Growing evidence supports the role of the transient receptor potential cation channel, sub-family A, member 1 (TRPA1) in the pathophysiology of neuroinflammatory and neuropathic pain. TRPA1 is highly expressed in primary nociceptive neurons of the trigeminal ganglion, and dorsal root ganglia, and is activated by noxious cold and natural irritants such as allyl isothiocyanate (AITC). HC-030031, a widely used TRPA1 antagonist, has demonstrated efficacy in acute and neuropathic pain models such as chemotherapy-induced polyneuropathy, spinal nerve ligation, Complete Freuds Adjuvant-induced pain and AITC-induced flinch in mice and rats.
In the current study we set out to characterize the pharmacological performance of HC-030031 against human and rat TRPA1 using robust *in vitro* screening assays. This data was used alongside plasma and brain concentrations to determine the theoretical receptor occupancy (%RO) required for an efficacious response in the AITC-induced flinch pain model.
The inhibitory properties of HC-030031 were tested in human and rat TRPA1 *in vitro* screening assays, with the FLIPR^{TETRA} calcium influx assays providing IC_{50} values of 5.2 and 12 µM, respectively. Electrophysiology assays using both automated (Sophion Qube) and manual patch-clamp confirmed HC-030031 potency. Selectivity against family members, TRPV1, TRPV4 and TRPM8, was observed using the FLIPR^{TETRA} (IC_{50} > 30 µM). Efficacy assessment of HC-030031 (3, 10, 30, 100 and 300 mg/kg, PTT 2h) in AITC-induced flinch in rats showed a decreased duration of flinch behavior following dosing at 10, 30, 100 and 300 mg/kg. Whilst HC-030031 displayed a dose proportional increase in plasma and brain exposure between 10 and 300 mg/kg there was no increase in PD response. Free plasma concentrations were 5-410 ng/ml (93% bound) and brain concentrations were 4-416 ng/g (91% bound).
The %RO based on free concentrations of HC-030031 was estimated to be <3% in both plasma and brain at all dose levels. Additionally, receptor occupancy was also low when calculated from total HC-030031 levels, with a PD response observed after 10 mg/kg dosing where <1% RO was predicted (free concentrations).
In conclusion, this data suggests that the *in vivo* efficacy based on the free plasma concentration in the AITC-induced flinch in rats cannot be explained by the TRPA1 inhibitory effect in isolation. The possible off-target mechanisms for HC-030031 efficacy remains to be investigated.

Title: Antinociceptive profile of substituted phthalimides with aspartate enantiomers in rats

Authors: *E. RAMIREZ-SAN JUAN[1], C. CAMPOS-RODRIGUEZ[1,2], I. CUMBRES-VARGAS[1], A. PINEDA-PINEDA[1], R. M. AGUILAR-SANCHEZ[1], J. G. TRUJILLO-FERRARA[3];

Abstract: Pain is related with almost all the clinical pathologies across all ages and sex, implicating a decrease in the quality of life of the patients and an economic problem within the countries. Consequently, finding new therapies or strategies to relief pain is relevant for the population. Pain could be defined as an unpleasant emotional and sensory experience, which is a direct output of nociception. In the market, a wide-variety of analgesic drugs have been sold but they are not solving the main problem. In the last decade, phthalimides derivatives called the attention due to their analgesic and anti-inflammatory properties. Thalidomide is the prototype of those molecules that have been emerged. An inhibition of the tumor necrosis factor alpha, interleukin 6 and 12 and the inhibition of the cyclooxygenases (mainly COX-2) are some of the implicated mechanisms of action suggested for the N-substituted phthalimide molecules. Previous studies in the lab, showed that symmetric phthalimides have antinociceptive and anti-inflammatory activity. Additionally, N-substituted phthalimides with aspartate demonstrated an NMDA antagonist profile in silico and in vivo. With this basis the aim of the study was to evaluate the antinociceptive and anti-inflammatory activity of N-substituted phthalimides with R or S aspartate (RTASP, STASP) in an acute (Tail-Flick test) and inflammatory (Formalin test) model of pain in rats. For this purpose, groups of adult Wistar male rats (250-300 g; n=8) were treated: a) dimethyl sulfoxide (DMSO) 2% in phosphate buffer solution (PBS, pH = 7, control), b) indomethacin 5 mg/kg (positive control) c) RTASP or STASP 100 mg/kg, d) RTASP or STASP 316 mg/kg, e) RTASP or STASP 421.7 mg/kg. After 45 min of the intraperitoneal administration, the tail flick test or formalin test were run. For the Tail-Flick test, the latency to the tail flick were measure, while for the formalin test, the number of flinches and area under a curve of flinches (AUC) were analyzed. The results evidenced that RTASP and STASP has antinociceptive effect due probably to their anti-inflammatory property. At the three proven

doses, both molecules decreased the acute phase and inflammatory in the formalin test. Moreover, STASP antinociceptive effect seems to be dose-dependent. RTASP and STASP do not have antinociceptive effect on the thermal stimuli evoked by the tail-flick apparatus. Other studies were needed to determine the mechanism of action of these molecules, however we speculate that they might be inhibiting at least COX-pathway and having some interaction in the excitatory transmission as NMDA antagonists.

Title: Analgesic efficacy of highly selective and biologically stable neurotensin type 2 receptor (NTS2) analogs

Authors: *M. VIVANCOS[1], R. FANELLI[2], A. RENÉ[2], J.-M. LONGPRÉ[1], F. CAVELIER[2], P. SARRET[1];
[1]Pharmacol. and Physiol., Univ. de Sherbrooke, Sherbrooke, QC, Canada; [2]Inst. des Biomolécules Max Mousseron, IBMM, UMR-5247, CNRS, Univ. de Montpellier, Montpellier, France

Abstract: Endogenous neurotensin and the chemically modified NT(8-13) analogs inhibit the nociceptive transmission by interacting with two class A G protein-coupled receptors, namely NTS1 and NTS2. However, the binding of NT to NTS1 not only induces analgesia but also results in hypotension and hypothermia, which may represent barriers to adequate pain management. As opposed to NTS1, there is now substantial evidence indicating that NTS2-selective agonists may mediate analgesia without exerting changes in blood pressure or body temperature. Here, our goal was thus to design and characterize novel NT(8-13) analogs exhibiting high affinity and selectivity toward NTS2. To this aim, we synthesized a series of NT(8-13) analogs harboring site-specifically modified unnatural amino acids and reduced amide bonds. To target preferentially NTS2, Tyr^{11} was replaced by a *N-Homo*-Tyrosine (*N-h*Tyr) or by a *N-Homo*-Tryptophane (*N-h*Trp). Then, Pro^{10} and Leu^{13} were respectively substituted by the non-natural silylated amino acids, silaproline (Sip) and (trimethylsilyl)alanine (TMSAla).

Finally, a reduced amide bond (Ψ[CH_2NH]) was incorporated between the two Lys^8-Lys^9 residues to minimize peptide degradation. Our binding data revealed that these NT(8-13) analogs, codenamed JMV5297 (H-Lys-Ψ[CH_2NH]Lys-Pro-*N*-*h*Tyr-Ile-TMSAla-OH), JMV5298 (H-Lys-Ψ[CH_2NH]Lys-Sip-*N*-*h*Tyr-Ile-TMSAla-OH) and JMV5335 (H-Lys-Ψ[CH_2NH]Lys-Pro-*N*-*h*Trp-Ile-TMSAla-OH) showed good affinity for NTS2 (IC_{50}: 9.5 ± 2.1 nM; 11.9 ± 3.4 nM and 1.31 ± 0.17 nM, respectively) without binding activity at NTS1 (IC_{50}: > 20 µM for all analogs tested). In addition, these analogs were much more stable in plasma with half-lives exceeding 24 hours. Then, JMV5297 and JMV5335 were tested *in vivo* in acute (tail-flick test) and tonic (formalin test) pain models. We found that intrathecal (i.t.) injection of these two compounds at 90 µg/kg produced a significant analgesic response compared to saline-treated rats. At this dose, both compounds were also effective in reversing the nociceptive behaviors induced by intraplantar formalin. Importantly, both JMV5297 and JMV5335 did not produce hypothermia at the effective analgesic dose and did not induce hypotension after intravenous delivery. In conclusion, targeting the NTS2 receptor with selective NT analogs represents a promising alternative to opioids for pain management.

Title: A transgenic model with humanized TRPA1 pore domain enables study of human-selective TRPA1 inhibitors in the rat

Authors: M. DOURADO[1], K. L. STARK[2], R. M. REESE[4], P. KARILA[5], S. LARDELL[5], K. ANDERSON[3], S. WARMING[3], *D. H. HACKOS[1];

Abstract: Aim of investigation: The TRPA1 channel has been studied as a target for pain as well as respiratory conditions such as asthma. As such, the pharmaceutical industry has identified many small-molecule selective inhibitors of TRPA1 with the aim of testing these in clinical trials. Unfortunately, many otherwise potent drug-like TRPA1 inhibitors bind poorly to rodent TRPA1 channels due to amino acid differences in the binding site region within the pore domain. To enable pre-clinical testing of such compounds, we have developed a mutant rat model that fully humanizes the pharmacology of this binding site region.

Methods: Using CRISPR technology, we first developed a humanized TRPA1 rat where the entire human cDNA was inserted at the rat TRPA1 start site. Unfortunately, this led to a hypomorph with severely-reduced TRPA1 expression. We then constructed a mutant rat where we replaced only 10 amino acid residues that fully humanizes the small-molecule binding site within the pore domain. We used expression analysis, calcium imaging, high throughput calcium fluorimetry, and behavioral analysis to determine whether the expected humanized pharmacology was properly installed in this animal model.
Results: We found that our novel humanized binding-site knockin (KI) rat showed active functional expression of TRPA1 in DRG neurons with the expected cell body size distribution. Furthermore, these rats showed normal behavioral responses to AITC when applied to the hind paw, which is known to be TRPA1-dependent. Calcium fluorimetry experiments demonstrate that the expected humanized pharmacology is present in DRG neurons in culture. Finally, we show that AITC-induced behavioral responses can be blocked by a human-selective TRPA1 inhibitor.
Conclusions: Here we demonstrate a novel humanized rat model that allows pre-clinical testing of human-selective TRPA1 inhibitors. Our hope is that this model will facilitate the clinical development multiple classes of human-specific TRPA1 inhibitors.

Title: Pharmacological effect of hydrogen sulfide on the hypersensitivity to pain in male Wistar rats with insulin resistance

Authors: *J. H. BELTRÁN-ORNELAS, D. CENTURIÓN, D. L. SILVA-VELASCO, A. SÁNCHEZ-LÓPEZ, F. J. LÓPEZ-MUÑOZ;
Pharmacobiology, CINVESTAV, Mexico City, Mexico

Abstract: Several lines of evidence have shown the potential role of hydrogen sulfide (H_2S) in insulin resistance and pain. However, up to date, the effect of H_2S in the hypersensitivity to pain during fructose-induced insulin resistance has not been evaluated. Thus, the aim of this study was to determine the effect of NaHS (sodium hydrosulfide; H_2S donor), DL-propargylglicine (DL-PAG; cystathionine-Ɣ-lyase inhibitor) and hydroxylamine (AOOA; cystathionine-β-synthase inhibitor) on the allodynia and hyperalgesia. For this purpose, 48 rats were divided into two groups. The first group (n=40) was treated with fructose (15% in drinking water) during 20 weeks, while the second group (control; n=8) received tap water. 16 weeks after the treatment with fructose, the first group was divided into 5 subgroups (n=8 each), which received daily i.p. administration during 4 weeks with: (1) nothing; (2) phosphate buffer saline (PBS; 1 ml/kg); (3) NaHS (5.6 mg/kg); (4) DL-PAG (10 mg/kg); and (5) AOOA (10 mg/kg). Next, oral glucose tolerance test and insulin levels were determined before and after administration of glucose (2 g/kg, p.o.). The rats were placed in acrylic cages on top of a wire mesh grid that allowed their paws access to the von Frey filaments. Bending forces of 8 and 60 g to the mid-plantar skin of right hind paw were applied. The filament was placed on the skin until it bowed slightly, each filament was presented ten times at a rate of about 1 second. A response was recorded if the rat withdrew its hind paw from the filament. Responses were converted into a frequency percent (%=number of responses/10 × 100). Animals treated with fructose showed hyperinsulinemia and insulin resistance. Interestingly, fructose-induced insulin resistance was reverted by AOOA and DL-PAG but not by PBS. NaHS only diminished the glucose basal and HOMA index. Control rats rarely withdrew its paw from 8 g stimuli and usually withdrew its paw from 60 g stimuli. Chronic treatment with fructose during 20 weeks: (1) presented response with 8 g stimuli, which indicates tactile allodynia, and (2) increased level of response seen with
60 g stimuli which indicates tactile hyperalgesia. Chronic treatment with NaHS did not modify the tactile allodynia and hyperalgesia. However, AOOA and DL-PAG reverted both tactile allodynia and hyperalgesia induced by insulin resistance. These data suggest that endogenous H_2S could be implicated in the pathophysiology of the insulin resistance and in the development alterations in nociception during this metabolic state.

Autónoma Metropolitana, Unidad Xochimilco, Ciudad de México, Mexico; [4]Área Académica de Química, Inst. de Ciencias Básicas e Ingeniería, Univ. Autónoma del Estado de Hidalgo, Pachuca, Mexico

Abstract: Ipomoea stans belongs to the convolvulaceae family, it is commonly known as "tumbavaquero" or "campanita". It is used in traditional medicine for muscular and visceral pains, epileptic attacks, as well as to calm the nerves, however, there is no scientific evidence to corroborate its analgesic effect, in this sense **the objective** of the present study was to evaluate the antinociceptive effect of the methanolic extract of *Ipomoea stans* in a nociceptive pain model in CD1 mice. **Methods**. The vegetal material was collected in the municipality of Mineral de la Reforma, State of Hidalgo, Mexico. The methanolic extract of *I. stans* was obtained by maceration of the aerial part (stem and leaves). The antinociceptive activity was evaluated using the Writhing model. **Results**. The intragastric administration of *I. stans* (300 mg/kg) showed effects in the temporal course, observing the maximum effect at 15 min post-administration. This effect was maintained over time, almost constantly during the 30 min. When evaluating the overall effect of antinociception, it was shown that *I. stans* had a similar effect to indomethacin. **Conclusion**. Our results indicate for the first time the antinociceptive activity of *I. stans* in a visceral pain, therefore this study contributes in part to the validation of the use of the species *I.stans* in traditional medicine with analgesic effect.

Title: Differential effects of opioid versus alcohol dependence on pain avoidance behavior and regional endocannabinoid system deficiency

Authors: *J. A. CUCINELLO[1], M. E. BERNER[2], A. R. PAHNG[1], K. N. EDWARDS[1], S. EDWARDS[1];
[1]Dept. of Physiol., LSU Hlth. Sci. Ctr., New Orleans, LA; [2]Loyola Univ., New Orleans, LA

Abstract: In contrast to their analgesic effects, chronic use of either opioids or alcohol produces the paradoxical emergence of a heightened state of pain sensitivity, termed hyperalgesia, during withdrawal. A hallmark symptom of hyperalgesia is the development of motivational strategies to avoid painful stimuli, and our lab has shown that adult male Wistar rats will display pain avoidance behavior using the mechanical conflict avoidance system during withdrawal from morphine (n=10-11/group) or alcohol (n=8-9/group). The present study sought to identify how morphine and alcohol differentially affect pain avoidance behavior and endocannabinoid signaling within pain- and avoidance- associated brain regions, including the periaqueductal grey (PAG) and basolateral amygdala (BLA). Western blotting was conducted for protein quantification of endocannabinoid system-related proteins cannabinoid receptor type 1 (CB_1R), diacylglycerol lipase alpha (DAGL*a*), monoacylglycerol lipase (MAGL), and fatty acid amide hydrolase (FAAH). We found that morphine and alcohol dependence produced distinct patterns of pain avoidance behavior, where morphine dependence produced more hyperalgesic behavior and ethanol dependence produced more allodynic behavior. Morphine dependence appears to cause hyperalgesia through deficient PAG endocannabinoid signaling, with pain avoidance behavior negatively correlating with PAG CB_1R levels across both saline- and morphine- treated groups. We also found that alcohol dependence may facilitate allodynic behavior through a similar dysregulation of endocannabinoid signaling within the BLA, were pain avoidance was negatively correlated with the ratio of BLA DAGL*a*:MAGL. Overall, we found evidence that endocannabinoid deficiency within the PAG and BLA is associated with increases in pain avoidance behavior in dependent animals, suggesting that exogenous cannabinoid treatment may be an effective therapy for substance-induced hyperalgesia.

Title: Different mechanisms mediate endogenous and exogenous opioid analgesia in inflammatory pain

Authors: *Y. DOU[1], X. ZHANG[1], M. ZHAO[2], Q. LI[1], A. LI[2], Y. SUN[1];
[1]Inst. of Neurosci., Shanghai, China; [2]Huazhong Univ. of Sci. and Technol., Hubei, China

Abstract: Mu-opioid receptors (MORs) are widely expressed in the central nervous system and are crucial for opioids analgesia. However, the functional role of the MORs expressed in different types of neurons in opioid analgesia still remains largely unknown. Here, we demonstrated that distinct neuronal populations mediate analgesic effects of exogenous and endogenous opioids on inflammatory pain. We took advantage of the fluorescence micro-optical sectioning tomography (fMOST) serial technology to provide a global view of the distribution of MOR^+ neurons in the brains. Using of a new genetic mouse model, we selectively expressed MORs in different subsets of neurons and examined their roles in opioid analgesia. We found that morphine-induced analgesia of both acute and chronic inflammatory pain is mediated by MORs in glutamatergic but not GABAergic neurons. In contrast, the analgesic effect of endogenous opioids on inflammatory pain is mediated by MORs in GABAergic neurons but not glutamatergic neurons. Thus, our study demonstrated that the MORs expressed in excitatory and inhibitory neurons are differentially involved in exogenous and endogenous opioid analgesia.

Title: Effect of protein kinase C inhibition within the periaqueductal gray on morphine antinociceptive tolerance

Authors: A. RAM, *E. N. BOBECK;
Utah State Univ., Logan, UT

Abstract: The ventrolateral periaqueductal gray (vlPAG) is an important midbrain region that regulates the descending pain modulatory system and is implicated in the development of antinociceptive tolerance to opioid analgesics. Protein Kinase-C (PKC) is a Ser/Thr kinase that phosphorylates the μ-opioid receptor (MOPr) following morphine agonism. This phosphorylation is responsible for desensitization of the receptor, resulting in the termination of G-Protein signaling. It is speculated that PKC-mediated desensitization of the MOPr does not readily lead to the internalization of the receptor, thus contributing to tolerance. Previous studies have shown that intracerebroventricular administration of PKC inhibitors prevented the development of morphine tolerance in mice. Further, a non-specific PKC/GRK inhibitor was able to block the development of morphine tolerance in the vlPAG. However, the contribution of PKC to morphine tolerance in the vlPAG has not been directly explored. Using immunofluorescence staining, we observed increased phosphorylated PKC that is co-localized with the MOPr at the cell membrane of vlPAG neurons in morphine-tolerant animals. Further, we assessed the development of morphine antinociceptive tolerance following pre-treatment with the PKC inhibitor, Gö-7874, which targets conventional PKC isoforms. The compound was bilaterally microinjected into the vlPAG of wild-type mice prior to the commencement of a chronic morphine tolerance paradigm. The analgesic effects of morphine were assessed using Hot Plate and Tail Flick tests, which are respectively representative of supra-spinal and spinal thermal nociceptive responses. This study contributes to the understanding of PKC-mediated MOPr desensitization processes leading up to morphine tolerance.

Abstract: Oxytocin (OT) is a 9-amine neuropeptide that plays an essential role in mammalian labor, lactation, maternal bonding, and social affiliation. OT has been reported to exert an analgesic effect in both humans and animals, and the results of certain animal experiments have shown that the analgesic effect of OT is partially blocked by opioid receptor antagonists. To investigate the relationship between OT and μ opioid receptor (MOR), we evaluated how OT affects MOR in vitro by performing an electrical impedance-based receptor biosensor assay (CellKey™ assay), an intracellular cAMP assay, and a competitive receptor- binding analysis by using cells stably expressing human MOR and OT receptor. In both the CellKey™ assay and the intracellular cAMP assay, OT alone exerted no direct agonistic effect on human MOR, but treatment with 10^{-6} M OT markedly enhanced the MOR signaling induced by 10^{-6} M endomorphin-1, β- endorphin, morphine, fentanyl, and DAMGO. Moreover, in the competitive receptor-binding assay, 10^{-6} M OT did not alter the affinity of endomorphin-1 or morphine for MOR. These results suggest that OT could function as a positive allosteric modulator that

regulates the efficacy of MOR signaling, and thus OT might represent a previously unrecognized candidate analgesic agent.

Title: OPRM1 transfection reduces nociception and mortality in oral cancer mouse models

Authors: ***N. H. TU**, K. INOUE, H. WILLIAM, M. S. AHMAD, R. X. DANG, H. D. TRAN, D. H. KIM, E. DOWSE, I. KENTARO, S. YAMANO, B. L. SCHMIDT;
Bluestone Ctr. For Clin. Res., New York, NY

Abstract: Oral squamous cell carcinoma (SCC) is debilitating and painful. Novel treatment for oral cancer pain is needed. We previously showed that the mu-opioid receptor is downregulated in human oral cancer patients due to OPRM1 methylation. Upregulation of OPRM1 via viral-mediated gene transfection shows promise for analgesic treatment. However, there are safety concerns associated with viral vectors including a strong immune response and cytotoxicity. To overcome these concerns, we developed a non-viral hybrid vector: HIV-1 Tat peptide sequence modified with histidine and cysteine residues combined with a cationic lipid. We utilized a mouse oral cancer model induced through 16 weeks of exposure to 4-Nitroquinoline 1-oxide (4NQO) in the drinking water. After tongue cancer developed, we quantified gnawing activity in a dolognawmeter. Extended gnaw-time in the dolognawmeter was used as a behavioral index of oral nociception. We transfected OPRM1 with our non-viral vector once mouse gnaw-time in the dolognawmeter was statistically longer in duration than baseline values for each mouse. OPRM1 transfection significantly reduced gnaw-time at post-transfection day 8 (73.8 ± 73.7 vs 94.3 ± 71.2), 16 (27.7 ± 44.0 vs 112.4 ± 66.2) and 24 (47.2 ± 25.7 vs 114.7 ± 81.2). We infer from these results that OPRM1 transfection reduced nociception secondary to oral SCC. Additionally, OPRM1 transfection increased the survival rate compared to control mice at day 24 (100% vs 44.4%). Furthermore, the transfected mice showed no signs of systemic inflammation.

Title: Daily intermittent fasting in mice enhances morphine induced anti-nociception while mitigating multiple side effects

Authors: *D. I. DURON, J. M. STREICHER;
Pharmacol., Univ. of Arizona, Tucson, AZ

Abstract: The opioid epidemic has continued to plague the United States with high levels of abuse and poor quality of life for chronic pain patients requiring continuous use of opioids. Many potential solutions have been proposed to mitigate this epidemic including new medications to reduce the abuse and side effect profiles of opioids; however, new medications are plagued by low efficacy, abuse potential, and toxicities. These limitations suggest that non-pharmacological interventions could be more efficacious with low side effect profiles. Intermittent fasting (IF) is a time restriction diet which has recently grown in popularity over the past decade in the prevention and mitigation of a variety of pathological states. Numerous animal and human studies have shown the benefits of IF in these disease states, but not in opioid treatment paradigms. We thus subjected male and female CD1 mice to 18-hour fasting intervals followed by 6-hour feed periods with standard chow for 1 week. Mice which underwent this diet displayed an enhanced anti-nociceptive response to systemic morphine both in efficacy and duration using thermal tail flick and post-operative paw incision pain models. While showing enhanced anti-nociception, IF mice also demonstrated a reduction in the development of anti-nociceptive tolerance using the thermal tail flick assay paired with daily systemic morphine treatment. We also found a reduction in the development of opioid induced constipation using both fecal mass and fecal pellet count in IF mice. Seeking a mechanism for our behavioral findings, we performed ^{35}S-GTPγS assays to assess the functionality of mu opioid receptors within the spinal cord and periaqueductal grey (PAG) tissues from IF mice with and without chronic morphine treatment. The resulting DAMGO concentration-response curves demonstrated an increased efficacy of mu opioid receptors within the spinal cord in IF mice and an absence of the development of tolerance within the PAG in IF mice, suggesting site-specific receptor mechanisms for the behavioral effects we observed. These data suggest that a daily IF diet may improve the therapeutic index of acute and chronic opioid therapies for pain patients in the clinic, both in improved analgesia and reduced tolerance and constipation.

Title: Kappa opioid receptors mediate TRPA1 analgesia

Authors: *E. SEMIZOGLOU, C. GENTRY, S. BEVAN, D. A. ANDERSSON;
King's Col. London, London, United Kingdom

Abstract: The available therapies for chronic pain fail to provide permanent relief to patients and are often associated with severe side effects. Chronic pain has led to over-prescription of opioid analgesics and has contributed to the increasing rates of opioid addiction and deaths. The need for novel analgesics devoid of side effects in the central nervous system is therefore urgent. The aim of this study is to explore the modulation of nociception, mediated by a crosstalk of opioid receptors and TRP (Transient Receptor Potential) channels in the peripheral nervous system.Transgenic mice lacking TRPA1 (Transient Receptor Potential Ankyrin 1) have reduced sensitivity to mechanical stimulation. We discovered that this sensory loss is related to peripheral KOR (Kappa Opioid Receptors) which are engaged in the absence of TRPA1. Administration of KOR antagonist normalizes this phenotype in *Trpa1*$^{-/-}$ mice but has no effect on nociception in wild type mice. *In vivo* calcium imaging experiments of the L4 DRGs (Dorsal Root Ganglia) reveal that less neurons respond to mechanical stimulation in *Trpa1*$^{-/-}$ mice, compared to wild type. This sensory abnormality is reversed by administration of the opioid receptor antagonist naloxone but not by saline. *In situ* hybridization experiments in lumbar DRGs from wild type mice show that approximately 40% of the KOR positive neurons also express *Trpa1*. Transcriptomic and protein levels of KOR in DRGs from wild type and *Trpa1*$^{-/-}$ mice are unaltered according to RNA sequencing, qPCR, western blot and ELISA assays. We are currently studying the interactions between KOR and TRPA1 in HEK293 cells. To conclude, the sensory deficits of *Trpa1*$^{-/-}$ mice are not directly related to the loss of TRPA1 but are explained by increased activity of KOR in the periphery. Ongoing studies will identify the molecular mechanisms for TRPA1 modulation of KOR activity. Our results may facilitate identification of molecular targets for new analgesic therapies for chronic pain.

Title: A role for dopaminergic signaling in opioid resistance following spinal cord injury

Authors: *H. M. RODGERS, R. PATTON, J. YOW, S.-A. LIM, S. CLEMENS, K. L. BREWER;
Brody Sch. of Medicine, East Carolina Univ., Greenville, NC

Abstract: Opioids are not universally effective in treating neuropathic pain following spinal cord injury (SCI). We have shown in a rat model of SCI that 2/3 of the animals do not respond to morphine, but adjuvant addition of a dopamine (DA) D1R antagonist or D3R agonist was able to restore the lost morphine response, suggesting that morphine resistance after SCI involves DA-ergic signaling. The aim of this study was to determine the analgesic response of morphine-responsive and nonresponsive SCI rats to DA modulators alone and in combination with morphine and determine if changes in CNS DA levels were associated with the altered morphine response. Baseline nociceptive thresholds were measured in uninjured (n = 8) and SCI (n = 25) adult female rats before and after injection of morphine (2mg/kg) or saline (control). Rats then had thresholds re-assessed after injection of morphine + pramipexole (D3 agonist; 0.1mg/kg), morphine + SCH 39166 (D1 antagonist; 0.1mg/kg), pramipexole, or SCH 39166. Lumbar spinal cord and striatum samples were collected from a subset of rats in all groups and processed for metabolomics and targeted mass spectrometry to identify metabolite differences and quantify levels of DA. Morphine alone increased sensory thresholds in all uninjured rats but only 1/3 of SCI rats responded to morphine. SCI animals, regardless of response to morphine, showed improved analgesia with morphine + D3R agonist. However, only SCI nonresponsive rats showed improved analgesia with morphine + D1R antagonist compared to morphine alone. Metabolomics principal component analysis identified three clusters that corresponded to uninjured, SCI morphine-responsive and SCI morphine-nonresponsive groups. Preliminary analysis suggests differences in DA, prostaglandin and endogenous opioids pathways. Striatal DA levels were decreased in SCI morphine-nonresponsive rats compared to SCI morphine-responsive animals. In the lumbar spinal cord, DA levels were decreased in both morphine-responsive and nonresponsive SCI rats compared to uninjured rats. These data suggest that differences in DA pathways may affect morphine responsiveness following SCI.

Abstract: Effective opioid therapies to treat chronic pain are compromised by several inter-related drug-induced phenomena, such as opioid-induced hyperalgesia (OIH), antinociceptive tolerance and withdrawal. Novel opioid-sparing approaches are needed as the broad use of opioids and rates of opioid-related addiction and mortality have risen to constitute the current ”opioid epidemic.” However, the underlying mechanisms of OIH, antinociceptive tolerance and withdrawal remain poorly understood. We identified a novel mechanism whereby sustained opioid administration drives OIH and tolerance through adenosine kinase (ADK)-dependent dysregulation of adenosine signaling at the A_3 adenosine receptor (A_3AR). Subcutaneous infusion of morphine in rodents led to the development of OIH and tolerance that was associated with increased expression of adenosine kinase (ADK; the major enzyme determinant of extracellular adenosine concentrations) in the dorsal horn of the spinal cord. Intrathecal administration of the ADK inhibitor, ABT-702, attenuated the development of OIH and tolerance and these beneficial effects were lost when A_3AR was blocked with intrathecal administration of the A3AR antagonist, MRS1523. This suggests that A_3AR activation counter-regulates the adverse effects of morphine. Indeed, administration of A_3AR agonists (IB-MECA, MRS5698 or MRS5980) prevented the development of OIH and tolerance. Moreover, A_3AR agonists also reduced naloxone-precipitated withdrawal behaviors. At the molecular level, A_3AR agonists inhibited NLRP3 inflammasome activation and expression of the neuroexcitatory and

inflammatory cytokine, interleukin-1β. Our results demonstrate that the loss of adenosine/A_3AR signaling is critical to the development of opioid-induced adverse effects and provide the pharmacological rationale to support clinical evaluation of A_3AR agonists as adjunct therapy to opioids.

Title: Effects of oxycodone on striatal direct and indirect pathway medium-sized spiny neurons in dorsal striatum

Authors: ***J. BARRY**[1], K. D. OIKONOMOU[1], E. DONZIS[1], S. CHOPRA[1], C. Y. YANG[3], P. GOLSHANI[3], C. J. EVANS[2], M. S. LEVINE[1], C. CEPEDA[1];

Abstract: Opioids, in particular oxycodone, are currently the treatment of choice for severe pain. Opioid effects are mediated principally by the μ-opioid receptor (MOR) class of G protein-coupled receptors. MORs are abundant in various brain regions, including the ventral and dorsal striatum. However, little is known about potentially differential effects of opioids on direct and indirect pathway medium-sized spiny neurons (MSNs) in dorsal striatum. As the main effect of MOR activation is cell membrane hyperpolarization, we hypothesized that action potential firing and Ca^{2+} transient activity of MSNs would be reduced after oxycodone administration. To test this hypothesis, we combined viral expression of a genetically-encoded Ca^{2+} indicator, GCaMP6f with a miniaturized microscope (miniscope) to image spontaneous Ca^{2+} activity in

direct and indirect pathway MSNs of freely-moving mice before and after systemic injection of oxycodone (10 mg/kg) or control vehicle. D1- and A2A-Cre mice (aged 3-4 months) were injected with GCaMP6f and after 2 weeks the cortical tissue overlying the striatum was removed to allow implantation of a GRIN lens. 2-3 weeks later, a baseplate to hold the miniscope was affixed to the skull. Ca^{2+} activity was correlated with mouse behavior using a time-synced videocamera. Miniscope movies were analyzed using custom-written MATLAB scripts. In control conditions MSNs of the direct and indirect pathway displayed Ca^{2+} transients in close association with movement initiation and exploratory activity. Oxycodone injection induced typical MOR activation signs including hyperactivity, Straub tail, and gait disturbances. Interestingly, the number of MSNs displaying Ca^{2+} transients was reduced. Similarly, the amplitude and frequency of Ca^{2+} transients decreased after oxycodone. There also appeared to be a major dissociation between Ca^{2+} transient activity and behavior after oxycodone treatment as movements were no longer correlated with increased Ca^{2+} activity. Following imaging experiments, mice were used for slice electrophysiology to investigate the effects of oxycodone on GCaMP6f-expressing direct and indirect pathway MSNs. Whole-cell patch clamp recordings in current clamp mode indicated that bath application of oxycodone (10μM) induced cell membrane hyperpolarization and reduced the number of action potentials evoked by depolarizing current pulses. These results demonstrate that oxycodone reduces Ca^{2+} transient activity and favors membrane hyperpolarization as well as decreased firing regardless of MSN subtype. Findings also suggest that hyperactivity after opiates is mediated by a pathway other than the dorsal striatum.

Title: Acupuncture attenuates neuropathic pain and opioid tolerance in mice via orexin-initiated endocannabinoid signaling in the periaqueductal gray

Authors: *M.-T. LEE[1,2], L.-C. CHIOU[1,2,3];
[1]Dept. of Pharmacol., [2]Grad. Inst. of Brain and Mind Sci., Col. of Medicine, Natl. Taiwan Univ., Taipei, Taiwan; [3]Grad. Inst. of Acupuncture Sci., China Med. Univ., Taichung, Taiwan

Abstract: Opioids are indispensable in pain management, but their long-term efficacy in suppressing chronic pain is hindered by the development of tolerance. Clinically, opioid tolerance can be delayed by co-administration of non-opioid analgesics. We have recently revealed a nondrug, non-opioid analgesic mechanism induced by electroacupuncture at the PC6 (Neiguan) acupoint (EA-PC6), which overlays the median nerve, in mice.[1] Briefly, EA-PC6 at low frequency (2 Hz, 2 mA, 0.15 ms) can trigger orexin release from the lateral hypothalamus into the ventrolateral periaqueductal gray (vlPAG), a midbrain region for initiating descending pain inhibition. Orexin then activates postsynaptic orexin 1 receptors (OX1Rs), a Gq protein-coupled receptor family, in the vlPAG, resulting in synthesis of 2-arachydonoylglycerol (2-AG), an endocannabinoid that produces retrograde inhibition of GABA release by activating presynaptic cannabinoid 1 receptors (CB1Rs), leading to disinhibition of the vlPAG, and ultimately inducing analgesia. Here, we further examined whether repeated administrations of EA-PC6 can attenuate chronic pain without developing tolerance, and prevent the development of opioid tolerance in mice with neuropathic pain induced by chronic constriction injury (CCI) at the right sciatic nerve. The CCI-mice were left to develop neuropathic pain for 7 days. Their allodynia responses of were evaluated by the paw-withdrawal threshold to the von Frey filaments. From day8 to day14, CCI-mice were daily treated with morphine (10 mg/kg, *i.p.*), EA-PC6 or morphine+EA-PC6. We found that repeated treatments with EA-PC6 significantly suppressed mechanical allodynia in CCI-mice. However, repeated EA-PC6-induced analgesia (rEA-PC6-IA) did not develop tolerance as compared with repeated treatment of morphine for 7 days, and opioid tolerance (OT) in these mice were reversed by EA-PC6. Moreover, EA-PC6 co-administered with daily morphine injection significantly prevented the development of OT, for 7 days. Mechanistically, the OT-reversal and OT-preventive effects of EA-PC6 were prevented by either SB334867 (an OX1R antagonist, 15 mg/kg, *i.p.*) or AM251 (a CB1R antagonist, 1.1 mg/kg, *i.p.*), suggesting the involvement of OX1Rs and CB1Rs. These results suggest that EA-PC6 can either reverse or prevent OT via the disinhibition mechanism mediated by OX1R-initiated endocannabinoid-CB1R signaling in the vlPAG. Thus, EA-PC6 is a potential novel pain management strategy in OT-inflicted patients, such as terminal cancer patients. [1]Chen YH, Lee HJ, Lee MT, et al. Title: Effect of hyperbaric oxygen (HBO_2) on withdrawal-induced hyperalgesia during spontaneous withdrawal in morphine-dependent mice

Authors: *A. L. BREWER[1], D. Y. SHIRACHI[2], R. M. QUOCK[1];
[1]Psychology, Washington State Univ., Pullman, WA; [2]Physiol. and Pharmacol., Univ. of the Pacific, Stockton, CA

Abstract: With the opioid epidemic showing few signs of abating, new strategies for treating both pain and opioid dependence are needed. Hyperalgesia occurs as a result of opioid withdrawal and plays a role in relapse [Carcoba et al., *J Addict Dis 30(3): 258-70,* 2012]. Hyperbaric oxygen (HBO_2) is 100% oxygen administered at higher-than-atmospheric pressure. HBO_2 has shown promise in reducing pain in both preclinical animal models and in clinical conditions [Gibbons at al., *Brain Res. 1537:111-6,* 2013; Zhang et al., *Brain Res. 1711:41-*4, 2019; Efrati et al., *PLOS One 10(5)1-25,* 2015]. Furthermore, HBO_2 effectively reduced somatic signs of opioid withdrawal in animal models [Nicoara et al., *Brain Res. 1648:434-7,* 2016]. Collectively, these results indicate that HBO_2 may be effective for reducing hyperalgesia associated with opioid withdrawal. We assessed the effect of HBO_2 treatment on hyperalgesia in mice undergoing spontaneous withdrawal. Male and female NIH Swiss mice were made dependent upon morphine by twice daily *s.c.* injections of escalating doses of morphine for 4 consecutive days (50-125 mg/kg morphine). Following a final injection of morphine on Day 5, morphine injections ceased. Mice were treated with either HBO_2 or room air (RA) using two different treatment designs. The first treatment design featured a single 30-min treatment of 3.5 atmospheres absolute (ATA) HBO_2 or RA 60 min prior to hyperalgesia assessment at 10 h after the last morphine injection. The second treatment design consisted of multiple treatments of 2.5 ATA HBO_2 or RA prior to the 11, 25, 35, 49, and 59 h time points. Hyperalgesia was assessed by taking paw withdrawal thresholds to increasing paw pressures were recorded prior to the first injection and at 5, 10, 24, 34, 48, 58, 72, 82, 96 and 106 h after the final injection for one set of experiments (single high pressure exposure) and at 5, 11, 25, 35, 49, 59, 72 and 82 h for the second set of experiments (multiple lower pressure exposures). Both treatment paradigms effectively reduced hyperalgesia during withdrawal in both male and female mice. This data indicates that HBO_2 may be an effective way to treat hyperalgesia associated with opioid withdrawal.

Title: Chinese herbal extract attenuates morphine tolerance and dependence

Authors: *K. NUSEIR[1], I. MARMOUZI[2], A. ALACHKAR[3], O. CIVELLI[4];
[1]Jordan Univ. of Sci. and Technol., Irbid, Jordan; [2]Univ. of California at Irvine, Irvine, CA; [3]Pharmacol., [4]Univ. of California Irvine, Irvine, CA

Abstract: The opioid epidemic is a global problem that attracted the attention of authorities worldwide. In order to solve this problem, research had focused on finding alternatives. Unfortunately, until now, there are no better replacements for opioids; which still is the gold standard when it comes to analgesia. Traditional herbal medicine has been rising in popularity; and traditional Chinese medicine (TCM) gained most recognition globally. One of these TCM is an extract (YHS) of a plant traditionally used to treat pain and inflammation for thousands of years in China. The combination of opioids and herbal medicine for the treatment of pain is not highly explored. In order to examine the outcome of combining YHS with opioids on acute and inflammatory pain, we are proposing experiments to evaluate this effect. Morphine with YHS in varying concentrations will be administered to mice and acute as well as inflammatory pain responses will be measured using well-established models of pain. In addition, the combinations of YHS and morphine given to mice over a long term (1 week) in order to study tolerance and addiction development. Results of this study will supplement our knowledge about opioids and their use to treat pain. Furthermore, results of this study will elucidate more regarding tolerance to opioids. Most importantly, results of this study might bring us one-step closer to combat the opioid epidemic.

Title: Upregulation of the μ-opioid receptor in response to naltrexone occurs via an endoplasmic reticulum exit site-dependent pathway

Authors: *S. GRANT[1], A. K. MUTHUSAMY[1], H. A. LESTER[2];
[1]Chem., [2]Biol. and Biol. Engin., Caltech, Pasadena, CA

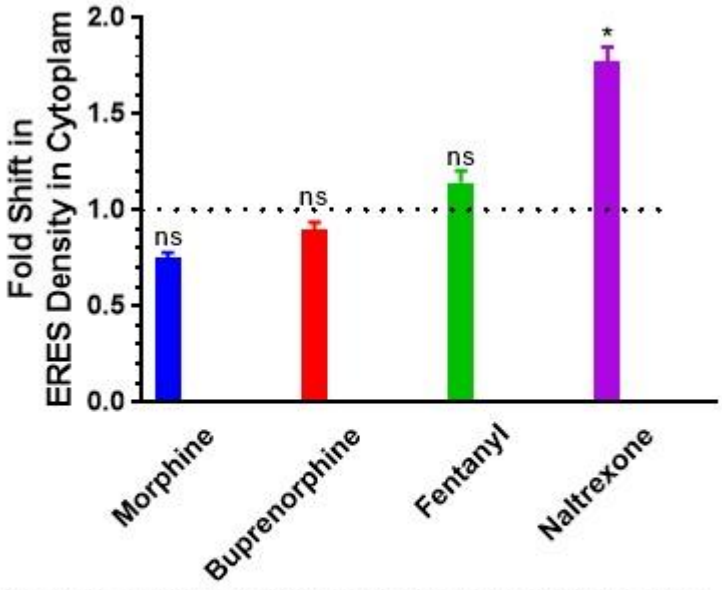

Figure 1. Changes in ERES density after opioid receptor ligand incubation. Each compound was used at 10 μM and incubated in the SH-SY5Y cell media for 12 h. Normalized to vehicle-treated cells (dotted-line). For each condition, n > 20 cells. Data are the mean ± S.E.M. *,p<0.05; ns, p>0.05 (unpaired t-test).

Abstract:

Understanding the mechanisms of μ-opioid receptor (MOR) sensitivity will be vital to fighting the global opioid epidemic. The most common opioid antagonists, naltrexone (Ntx) and naloxone, increase surface levels of MOR, causing individuals to become more sensitive to opioid agonists. Following antagonist treatment, any relapse to opioid agonist use presents a risk of overdose. In contrast, many opioid agonists, including fentanyl and the endogenously expressed MOR agonist peptides, decrease the levels of surface MOR protein. The mechanisms regulating MOR surface levels are incompletely known. We hypothesize that endoplasmic reticulum exit sites (ERES) participate early in the pathway of antagonist-induced upregulation of MOR surface levels, but not in agonist-induced downregulation. Using fluorescently tagged Sec24, a component of ERES, and super-resolution microscopy, we observe ERES in living SH-SY5Y cells. To describe details of cellular ERES levels, we take z-stacks using the Zeiss® Fast Airyscan module. In cells transfected with the ER-retained MOR N190K, we found that the

fraction of cytoplasm occupied by ERES increased after 12 hr incubation in 10 µM Ntx, but not in morphine, fentanyl, or buprenorphine (Figure 1). We also assessed whether ERES levels change with morphine and fentanyl using a MOR mutant that lacks the ability to become phosphorylated at S375 (a critical phosphorylation site for MOR function). We observed no differences in ERES levels under these conditions, suggesting that the lack of ERES change by agonists is not due to S375 phosphorylation. We also measured changes in cyclic adenosine monophosphate (cAMP) levels due to Ntx, to test the hypothesis that ERES levels change in response to cAMP levels. We show that Ntx does not change cAMP levels. These results support the hypothesis that the upregulation event proceeds via ERES while the downregulation event does not (agreeing with evidence that downregulation proceeds via endocytosis). These data suggest that Ntx is entering the cell, entering the ER, and serving as a pharmacological chaperone of the MOR.

Title: Positive allosteric modulation of cannabinoid type-1 receptors (CB1R) attenuates the anti-hyperalgesic effects of a mu opioid receptor (MOR) agonist in theperiaqueductal gray (PAG) of morphine-withdrawn rats

Authors: *J. W. MIDDLETON[1], U. DATTA[3], L. K. KELLEY[2], T. D. LOBELL[2], N. W. GILPIN[4];
[1]Cell Biol. and Anat., [2]Physiol., LSU Hlth. Sci. Ctr., New Orleans, LA; [3]Dept. of Physiol., LSUHSC, New Orleans, LA; [4]Physiol., Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA

Abstract: Chronic opioid drug use produces tolerance to the analgesic effects of opioids and cessation of opioid use can produce or exaggerate hyperalgesia. Cannabinoids are a potential alternative to opioids for the treatment of pain because they modulate pain in central pathways, and cannabinoid receptors (CBRs) are found in many of the same brain regions as opioid receptors. Nociception and pain are mediated by a complex set of circuits, and molecular and cellular brain processes. One critical site for pain modulation is the periaqueductal gray (PAG),

which receives ascending pain information and modulates pain via projects to the medulla. Activation of pre-synaptic mu-opioid receptors (MORs) in the PAG suppresses inhibitory synaptic transmission, thereby disinhibiting medulla-projecting neurons to promote anti-nociception. Positive allosteric modulators (PAMs) of CB1Rs modulate the functional effects of cannabinoid receptor activation; GAT211, a CB1R PAM, exhibits anti-nociceptive effects in animal models of chronic inflammatory pain. We used a combination of brain slice electrophysiology and behavioral pharmacology to test the interaction effects of GAT211 and the MOR agonist DAMGO on PAG synaptic transmission and thermal nociception in rats treated with chronic morphine and tested (or sacrificed) during withdrawal. Some rats were implanted with cannulae aimed at the PAG for four behavioral pharmacology experiments (GAT211 dose-response, DAMGO dose-response, DAMGO timecourse, and GAT211-DAMGO dual treatment). Separate rats were sacrificed after the 7thday of morphine treatment for cellular recordings in ventrolateral PAG brain slices. In the slice, GAT211 alone did not affect synaptic inhibition in vlPAG neurons, and GAT211 attenuated DAMGO-induced suppression of synaptic inhibition in the same neurons. *In vivo*, intra-PAG GAT211 treatment did not affect thermal nociception in morphine-treated rats or saline-treated controls. Intra-PAG DAMGO treatment produced robust dose-dependent anti-nociceptive effects in morphine-treated and saline-treated rats. Intra-PAG GAT211 treatment attenuated the anti-nociceptive effects of DAMGO in morphine-withdrawn rats, but did not alter DAMGO effects on thermal nociception in saline-treated controls. These findings support the conclusion that CB1R positive allosteric modulation antagonizes the cellular and behavioral effects of the MOR agonist DAMGO in the PAG. This suggests that opioid-sparing effects of cannabinoids may occur outside the PAG, and lays the foundation for future work on CB1R-MOR interaction effects in PAG microcircuits.

Title: Chronic opioids and cannabinoids in models of chronic pain and pathologic bone fracture

Authors: *A. L. THOMPSON, H. CICCONE, D. MOHTY, A. SMITH, J. CONTRERAS, A. LANE, J. SORENSON, T. M. LARGENT-MILNES, T. W. VANDERAH;
Pharmacol., Univ. of Arizona, Tucson, AZ

Abstract: Fractures, both pathologic and traumatic, can result in severe chronic pain that leads to decreased quality of life and functional status. Opioids are a main therapy used to control bone pain but, have off target, detrimental effects on the bone itself. We explored the role of chronic opioids and cannabinoids in two models of murine fracture to assess their effects on bone health. In our cancer induced bone fracture model, female C57BL/6J mice (15-20g) underwent implantation of 80,000 breast adenocarcinoma cells (E0771) into the right femoral cavity. Sham operated animals underwent the same procedure, but were injected with cell media only. Spontaneous pain behaviors were measured by blinded observer, flinching and guarding, at baseline, 7, 10 and 14 days post-surgery. Morphine or saline was administered via osmotic minipump from days 7 to 14 post surgery. In our traumatic fracture model, C57BL/6J mice (15-25g) underwent femoral implantation of a stainless-steel pin into the right femoral cavity. A mid-diaphyseal fracture was initiated using a three-point bending device. Sham animals received the femoral pin alone. Spontaneous and evoked pain behaviors were taken at baseline, 1, 7, 14, 21 and 28 days post-fracture by a blinded observer. Ambulation measurements were also obtained at weekly intervals to assess activity. Animals were treated with morphine or cannabinoids from days 1-28 post fracture via minipump. Inflammatory cytokines (e.g. IL-1, IL-6, TNFalpha) were measured by quantitative PCR and ELISA, bone degradation was analyzed via radiographs and micro-computed tomography (μCT) and cell quantifications were done using flow cytometry. Opioid hyperalgesia and tolerance were observed in our models, while cannabinoids maintained their efficacy over the study. Significant changes in gene expression of inflammatory cytokines and bone metabolic regulators were observed in the bone tissue in animals chronically treated with morphine, with the cannabinoids modulating this change in gene expression. In addition, the animals treated with sustained morphine had accelerated bone loss as measured by both radiograph and μCT. Cannabinoid agonists helped mitigate morphine -induced bone loss. Chronic morphine administration modulated healing time and attenuated callus bridging. Cannabinoid compounds were effective in pain control and did not affect healing time of fracture. This suggests that chronic opioids have negative effects on bone in addition to their other deleterious side effects, while cannabinoids are worth investigating for pain control in bone disease due to their efficacy in pain management, as well as their potential benefits to bone healing.

Title: Roles of Wnt signaling in physical dependence on morphine in mice

Authors: M. WU[1,2,3], Z.-H. LI[2], L. LIANG[2], P. MA[1], D. LIU[1], F. RAO[1], ***X.-J. SONG**[1,2]; [1]SUSTech Ctr. for Pain Med. and Med. Cancer Hosp. & Inst., Beijing, China; [3]Dept. of Neurobio., Northwestern Univ., Evanston, IL

Abstract: Wnts are a family of secreted lipid-modified signaling proteins that act as short- or long-range signaling molecules in the regulation of cellular processes like proliferation, differentiation, migration, cell polarity during the development of nervous systems, as well as cardiac differentiation and development. We have recently demonstrated that Wnt signaling plays critical roles in the development of chronic pain after nerve injury or bone cancer through the canonical β-catenin-dependent and noncanonical β-catenin-independent pathways as well as the transcription factor YAP/TAZ nuclear-gate control. We hypothesized that a prolonged morphine exposure may serve as a severe stress that elicits neuronal alterations and activates Wnt signaling. Preventing and treating opioid dependence and withdrawal is a major clinical challenge and the underlying mechanisms of opioid dependence and withdrawal remain elusive. Here, we report that activation of Wnt signaling in the primary sensory neurons and the spinal cord plays critical roles in the development of opioid dependence. Our experiments were performed in a well-characterized mouse model of repeated using of morphine. The results show that Wnt5b is produced and accumulated in the dorsal root ganglia following repeated morphine treatment and that, following naloxone-precipitated withdrawal, the accumulated Wnt5b can be quickly transmitted to the spinal cord. In the spinal dorsal horn, Wnt5b, through the atypical Wnt-Ryk receptor and alternative Wnt-YAP/TAZ signaling pathways, contributes to the naloxone-precipitated opioid withdrawal-induced behavioral symptoms and hyperalgesia as well as the neurochemical alterations. Spinal blockade of Wnt-Ryk receptor and Wnt-YAP/TAZ signaling axes can greatly suppress the behavioral and neurochemical alterations after naloxone-precipitated withdrawal. These findings indicate a critical mechanism underlying the opioid dependence and naloxone-precipitated opioid withdrawal and suggest that targeting Wnt5b synthesis in the primary sensory neurons and Wnt signaling pathways in Wnt-Ryk and Wnt-YAP/TAZ signaling axes may be an effective approach for prevention and treatment of opioid dependence and the withdrawal syndromes.

Title: The combination of morphine and haloperidol reduces allodynia and side effects of morphine in rats with neuropathic pain

Authors: *L. C. MENA-VALDÉS[1], Y. BLANCO-HERNÁNDEZ[1], A. MÉNDEZ-BERNAL[2], I. MARTÍNEZ-RACINE[2], J. V. ESPINOSA-JUÁREZ[1], F. J. LÓPEZ-MUÑOZ[1];

Abstract: Haloperidol has been described as anti-nociceptive drug mediated by sigma 1 receptors antagonism. The morphine is an opioid drug currently used in the neuropathic pain (NP) treatment. **Objectives.** To determine the anti-allodynic effects of the combined therapy of haloperidol/morphine in rats with NP induced by chronic constriction injury (CCI),to evaluate the tissular damage produced in the CCI model and to detect the side effects of this combination. **Methods.** The anti-allodynic effects of haloperidol (0.01778mg/kg, s.c.) and morphine (0.0316mg/kg, s.c.) combination were determined after multiple-doses, using the cold allodynia test. The evaluations of cold allodynia were done until 10 days post-surgery every day, during one week andtissue samples (sciatic nerve and spinal ganglia) were taken on days 3, 6 and 9 to assess the severity of the damage before treatments. The rotarod test was used to evaluate motor coordination and for evaluate the effect of constipation was carried out a gastrointestinal transit test by using charcoal. **Results.** The time courses analysis indicated that morphine (0.0316mg/kg, s.c.) reached its maximum effect (≈60%) at day 4, which decreases abruptly from day 5 until values similar to the control. These results indicates that tolerance to the opioid was developed. However, the combination achieves a maximum anti-allodynic effect at day 2 (≈90%), which was maintained the next 5 days of evaluation, being significantly ($p < 0.0100$) greater than the maximum effect achieved by morphine. Histological analyse showed that CCI in control animals was characterized by several neutrophils, lymphocytes, macrophages and multinucleated cells in sections of the peripheral nerve and the spinal ganglia sections L5, L6 exhibit neuronal soma variably degenerate. On the other hand, the combination analysed did not show adverse effects of constipation or motor incoordination. **Conclusion.** The combination evaluated showed significant antiallodynic effects and did not present adverse effects, which suggest the use of this combination in NP treatment.

Title: Spinal PGC-1a suppressed morphine tolerance through reducing oxidative stress

Authors: Y. KASHIWAGI[1,2], H. YI[1], K. TAKAHASHI[1,2], K. HAYASHI[1], S. LIU[1], T. IIDA[1,2], J. GU[1], T. KUNISAWA[2], ***S. HAO**[1];

Abstract: Long-term use of opioid analgesics is limited by the development of unwanted side effects, such as tolerance, and dependence, which contributes to the current epidemic of opioid abuse and overdose-related deaths in the U.S. The exact molecular mechanisms of morphine antinociceptive tolerance (MT) is still not clear yet. Previous evidence showed that MT induces neuroinflammation and oxidative stress in the spinal neurons. Peroxisome proliferator-activated receptor-γ coactivator-1α (PGC-1α) is crucial to mitochondrial function. It is not clear about the role of PGC-1a in morphine tolerance (MT) state. We hypothesize that spinal PGC-1α suppressed morphine tolerance through reducing mitochondrial superoxide. MT was induced by repeatedly intrathecal morphine twice daily for 7 days. Mechanical threshold and thermal latency were measured using von Frey test and hot plate test. MT lowered expression of spinal PGC-1α using western blots, and increased mitochondrial superoxide using mitochondrial superoxide image. Immunohistochemistry shows that the expression of PGC-1α and mitochondrial superoxide localized in the neurons of the spinal cord dorsal horn in MT rats. MT also induced the loss of the anti-oxidative SIRT3-MnSOD system. Intrathecally recombinant PGC-1α or Mito-Tempol (a mitochondrial scavenger) was given before morning morphine once daily for 7 days. Intrathecal recombinant PGC-1α, SIRT3, or Mito-Tempol reduced MT development in the von Frey test and hotplate test, left-shifted the curve of accumulated morphine. Intrathecal recombinant PGC-1α reduced the number of mitochondrial superoxide positive cells. The present findings suggest that PGC-1α, SIRT3-MnSOD, mitochondrial superoxide are involved in spinal MT, and that PGC-1α mediated mitochondrial superoxide in MT.

Title: Diverse cell types within the vlPAG exhibit opioid-induced GIRK currents

Authors: *K. B. MCPHERSON, K. L. SUCHLAND, S. L. INGRAM;
Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The periaqueductal grey (PAG) is an important integration site within the descending pain modulatory pathway that receives diverse inputs—the ventrolateral region in particular (vlPAG) is a key target for opioid induced analgesia. The disinhibition theory for descending pain modulation proposes that opioids selectively inhibit GABAergic interneurons within the vlPAG, disinhibiting glutamatergic output neurons that project to the rostral ventromedial medulla (RVM). However, the vlPAG is a highly heterogeneous region with diverse cell types. Using whole-cell patch-clamp recordings of membrane firing properties in naïve rats we defined 5 distinct cell-types within the vlPAG: onset-firing, tonic firing, phasic firing, random-firing, and pacemaker neurons. These cell types are observed throughout the rostral-caudal axis without any obvious topographical distribution or morphological distinction. The firing properties were found to be intrinsic by removing GABAergic and glutamatergic tone. We examined opioid activation of G-protein coupled inwardly-rectifying potassium channel (GIRK) currents using the selective mu-opioid receptor agonist DAMGO. Unexpectedly, opioid-induced GIRK currents were observed in all of the cell types, and opioid-insensitive cells were also observed in all groups suggesting further heterogeneity within the vlPAG. Additional studies will use retrograde fluorescent CTb labeling from the RVM to examine the intrinsic properties of vlPAG neurons that project to this key downstream target for pain modulation and whether these cells are directly affected by acute or persistent inflammation. Collectively, these findings indicate that aspects of the disinhibition theory are over-simplified and that careful delineation of the circuits between the vlPAG and RVM will enhance our understanding of the descending control of pain.

Title: A suite of knockin mouse lines to resolve the functional organization of opioid receptors in neural circuits

Authors: *W. M. MCCALLUM[1], D. WANG[2], A. SHUSTER[3], D. J. BERG[4], S. LOW[6], G. SCHERRER[5];
[1]Anesthesia, Stanford Univ. Sch. of Med., Palo Alto, CA; [2]Dept. of Anesthesiology, Perioperative and Pain Med., Stanford Univ., Palo Alto, CA; [3]Stanford Univ., Fremont, CA; [4]Anesthesiol., [5]Stanford Univ., Palo Alto, CA; [6]CA-2, Dept of Anesthesia, Critical Care and Pain Med., Massachusettes Gen. Hosp., Boston, MA

Abstract: Investigating opioid receptor-expressing neurons has been hampered by the lack of tools to gain specific genetic access to these cells. To address this issue, we generated knockin mouse lines in which we targeted the *Oprd1* and *Oprm1* genes that encode the delta and mu opioid receptors (DORs and MORs, respectively) to express the DNA recombinases Cre, CreERT2, Flp or Dre. These mouse lines can be used independently or combinatorically to selectively manipulate neurons expressing DOR, MOR, or both receptors. Here, we describe the characterization of *Oprd1*^{Cre} mice. To identify CNS neurons with Cre activity in adult mice, we first used either intra-cranial and -spinal injections of rAAV5-CAG-FLEX-GFP or intravenous (iv) injections of AAVPHP.eB-CAG-DIO-GFP. In the brain, we found that the Cre activity distribution pattern in *Oprd1*^{Cre} mice is remarkably consistent with the known expression pattern of DOR in wildtype mice, for example with GFP+ layer II/III and V cortical neurons, basolateral amygdala neurons, and striatal neurons. In the spinal cord, we observed GFP+ neurons throughout the grey matter, including in the ventral horn, and with a particularly high density at the ventral border of lamina II inner, confirming our recent findings (Wang et al., 2018) with an independent tool. To examine *Oprd1* expression in DRG neurons, we made iv injections of AAVPHP.S-CAG-DIO-GFP to *Oprd1*^{Cre} mice. We also crossed *Oprd1*^{Cre} mice with Ai14 (*Rosa26* $^{LSL\text{-}tdTomato}$) and *Oprd1*^{GFP} mice to compare the *Oprd1* expression fate map (*Oprd1* lineage) and *Oprd1* expression pattern in the adult mouse. These studies revealed the remarkably dynamic expression of DOR through embryonic development, during which considerably more

DRG neuronal types express *Oprd1*, including peptidergic C nociceptors that express *Oprm1*, before DOR expression in these cells is extinguished postnatally. Thus, in the adult, Cre activity is largely restricted to myelinated mechanosensory neurons, as evidenced by the presence of tdTomato+ and GFP+ large diameter DRG neurons with axons that project both to spinal laminae III-IV and to medullary cuneate and gracile nuclei through the dorsal column pathway. Collectively, our data establish the utility of *Oprd1*^{Cre} mice to investigate and manipulate DOR-expressing neurons, and begin to define the temporal and spatial characteristics of *Oprd1* and *Oprm1* (co)-expression for elucidating the functional organization of the opioid system.

Title: Architecture of opioid-mediated neuromodulation of sensory, motor, and respiratory brainstem circuits

Authors: N. F. HUG, *N. MERCER LINDSAY, W. M. MCCALLUM, G. SCHERRER; Stanford Univ., Stanford, CA

Abstract: Opioids profoundly alter sensory responses, motor behaviors, and respiratory activity. However, the distribution pattern of opioid receptors in brainstem circuits has not been clearly elucidated. Here we examined the expression patterns of mu and delta opioid receptors (MOR and DOR respectively) in sensory and motor circuits in the brainstem using antibodies and MOR-mCherry/DOR-eGFP reporter mice.
We found that that DOR and MOR are expressed in oral sensory and motor nuclei. We observed notable labeling in the secondary sensory neurons in the dorsal part of the principal sensory nucleus as well as in the motor neurons for the esophagus, lips, and tongue. These findings in oral circuits prompted us to look in detail at labeling of MOR and DOR in other brainstem structures involved in breathing, with an emphasis on the pre-Bötzinger Complex (PBC), the central pattern generator for breathing.

Opioid-induced respiratory depression (OIRD) is the leading cause of opioid-related overdose deaths in the United States. While there is significant evidence for the direct impact of opioids on respiration, there is little agreement on where the site of action is within the brain. Therefore, we next aimed to identify MOR+ and DOR+ neurons in the PBC area.
Specifically, we examined the PBC MOR+ neurons for overlap with other classic markers of PBC rhythmic respiratory neurons: somatostatin (SST) and neurokinin-1 receptor (NK1R). Using immunohistochemistry (IHC), we found that MOR+ neurons are present in the PBC in a partially overlapping but distinct population from the canonical rhythmogenic neurons. Further, we found a distinct DOR+ neuron population in the PBC that also partially overlaps with MOR+ neurons. To validate these findings, we also performed in situ hybridization experiments in wildtype mouse tissue with probes against *Oprm1* (gene encoding MOR) and *Sst* transcripts and found the same pattern of expression as in IHC experiments.
Taken together, these results suggest that opioids may act both on cranial motor nuclei and PBC circuits to impair breathing. The studies begin to elucidate opioid receptor organization in brainstem to resolve the circuit and molecular mechanisms that underlie OIRD.

Title: PD1 modulates nociceptive synaptic transmission and mu opioid receptor signaling in the spinal cord dorsal horn

Authors: *C. JIANG[1], Z. WANG[2], M. MATSUDA[2], Q. HE[2], R.-R. JI[3];
[1]Dept. of Anesthesiol., Duke Univ. Med. Ctr., DURHAM, NC; [3]Pain Res. Division, Anesthesiol., [2]Duke Univ. Med. Ctr., Durham, NC

Abstract: Programmed cell death ligand-1 (PD-L1) is typically produced by cancer cells and has been shown to suppress immunity through PD-1 receptor expressed on T cells. However, neuronal signaling of PD-1 is largely unknown. Recently we demonstrated that PD-1 is also expressed by primary sensory neurons and mediates PD-L1-evoked synaptic transmission (Chen et al., 2017). Here we tested if PD-1 is involved in neurotransimminon induced by opioid. One key mechanism for opioid analgesia is to decrease neurotransmitter release and nociceptive

synaptic transmission in the spinal cord dorsal horn (SDH), which is mainly mediated by an activation of mu opioid receptor (MOR). Double staining revealed co-localization of PD-1 and MOR immunoreactivity in SDH axons and axonal terminals. We prepared mouse spinal cord slices to record spontaneous excitatory postsynaptic currents (sEPSCs) in out lamina II neurons. Bath perfusion of morphine (10 μM) in spinal cord slices of WT mice led to a significant reduction of sEPSC frequency. However, in P*d1*-deficient spinal slice, this inhibition was suppressed. Next, we compared morphine-evoked outward currents in SDH neurons in WT and KO mice. We found that the average amplitude of outward currents was changed from 15.8 ± 1.5 pA in WT mice to 7.8 ± 1.8 pA in KO mice ($P < 0.05$). To confirm that MOR signaling needs PD-1, we also tested morphine effect on synaptic transmission in spinal slices treated with Nivolumab, a clinically used anti-PD-1 monoclonal antibody or control IgG. We found that Nivolumab treatment also reduced morphine's inhibition on EPSC. Finally, we found that PD-L1 (0.075 nM), a major ligand of PD-1, and morphine (0.01 nM) produced synergistic actions in synaptic
transmission inhibition. Taken together, our data demonstrate that PD-1 is an essential signal imponent of MOR signaling in nociceptive synaptic transmission in the spinal cord dorsal horn.

Title: Neuronal PD-1 (programmed cell death protein-1) is required for morphine analgesia and mu opioid receptor signaling

Authors: *Z. WANG, C. JIANG, M. MATSUDA, K. WANG, J. ZHAO, R.-R. JI;
Duke Univ., Durham, NC

Abstract: Opioids such as morphine produce analgesia via mu opioid receptor (MOR). Despite extensive research in last several decades, opioid receptor signaling is not fully understood. Programmed cell death ligand-1 (PD-L1) is an immune checkpoint inhibitor and suppresses immunity through PD-1 receptor expressed on immune cells. However, PD-1 signaling in

neurons is largely unknown. We recently reported that primary sensory neurons of dorsal root ganglion (DRG) express PD-1 receptor, and activation of PD-1 by PD-L1 inhibits neuronal excitability and pain[1]. This study was undertaken to investigate the interactions between PD-1 and MOR, two inhibitory and analgesic receptors in the peripheral and central nervous system. We used *Pd1* knockout mice and anti-PD-1 monoclonal antibody, nivolumab to investigate the PD-1 effects on morphine analgesia in tail-flick and hot plate tests, CFA induced inflammatory pain, SNL induced neuropathic pain and bone cancer pain models. Our results indicated that morphine induced antinociception in tail-flick and hot plate tests, and anti-allodynic effects in CFA induced inflammatory pain, SNL induced neuropathic pain and bone cancer pain models was impaired in *Pd1* knockout mice. Moreover, morphine analgesia was also abrogated in adult wild-type mice after treatment with Nivolumab, a clinically used anti-PD-1 monoclonal antibody. Notably, PD-1 and MOR are highly colocalized in DRG neurons and have functional interactions. The suppressing effects of morphine in calcium currents in DRG neurons was also impaired in *Pd1* knockout mice. Finally, PD-L1 and morphine produce synergistic analgesia. Our findings suggested that anti-PD-1 immune therapy may interfere opioid analgesia in cancer patients via disrupting the PD-1-MOR interaction in the peripheral nerve and DRG tissue. On the other hand, PD-L1 might be used to treat clinical pain and enhance opioid analgesia in cancer and non-cancer patients.

Title: Peripheral nerves are invoved in human skin elasticity

Authors: *M. TSUTSUMI, K. TAKAGAKI, S. NOMIYAMA, K. KAJIYA;
Shiseido Global Innovation Ctr., Yokohama, Japan

Abstract: Cutaneous innervation is essential for the perception and maintenance of skin homeostasis. Until now, intra epidermal nerve fibers have been studied as a potential cause for symptoms like itchiness, pain, and abnormal sensations. Previous reports describe peripheral nerve fibers as having a crucial role on epidermal functions. Detailed morphologies of nerve

fibers in the dermis and their role remain unclear. The dermis provides tissue integrity and elasticity. Collagen is the major structural protein of the extracellular matrix and is synthesized by dermal fibroblasts. We have demonstrated the 3D structure of peripheral nerves in the dermis and investigated how they affect dermal elasticity.
Light Sheet Fluorescence Microscopy (LSFM) is superior to conventional microscopy for precise imaging of large specimens with exceptional light efficiency and speed. First, we used LSFM to construct 3D images of peripheral nerve fibers in the facial skin of healthy subjects. Skin tissues were clarified and immunolabeled for PGP9.5. This method allowed us to observe their 3D structure in a dermal area almost 2 mm below the epidermis. Deeper in the dermis, nerves bundle vertically toward the epidermis and formulate dense networks by branching in the upper region of the dermis. To investigate the change of density in nerve fibers during aging, we quantified the volume of nerve fibers (PGP9.5 and Neurofilament H) using 50 μm cross sections. Nerve fibers were denser in younger groups (mean age 34.8±8.0. 27, 33, 33, 46 years) compared to older groups (mean age 75.5±15.1. 57, 70, 84, 91 years). Next, to explore the effects of neuro-mediators released from neurons on fibroblasts, Human iPSC-Derived Sensory Neuron Progenitors were cultured. Cultured fibroblasts were treated with a neural conditioned medium and collagen I mRNA was measured. As a result, the medium upregulated collagen mRNA expression. In addition, we observed continuous procollagen synthesis in skin explants using immunohistochemistry. Since procollagen is the precursor molecule of collagen, it suggests collagen synthesis is newly occurring, not there for the maintenance of existing collagen I. These results suggest that the degradation of nerve fibers from aging would lead to be a reduced skin elasticity. In conclusion, the peripheral nervous system has a crucial role in skin homeostasis, not only for epidermal functions but also in dermal elasticity.

Title: Human fingertip sensitivity to local coding variables of vibrotactile stimuli

Authors: A. BHATTACHARJEE, C. BRAUN, *C. SCHWARZ;
Univ. of Tuebingen, Tuebingen, Germany

Abstract: Vibrotactile skin deflections are the basis for texture identification. Classically, it has been assumed that global temporal variables ‘intensity’ (time-averaged kinematics), or ‘frequency’ (best frequency inferred from spectral analysis) dominate vibrotactile discrimination. Here, driven by the idea that short lived frictional skin deflection, so called ‘stick-slip’ movements, may be instrumental (Schwarz 2016, TINS 39:449), we test the alternative idea that local temporal aspects of the vibrotactile signal (instantaneous kinematics) support vibrotactile discrimination.
We used pulsatile stimuli (pulse frequency, pf), in which a pulse consists of a single-period cosine. By choosing the pulse’s waveform frequency (wf) and amplitude (a), we varied local kinematics while being able to disentangle the global variables pf and intensity. In a Yes/No detection of change psychophysical paradigm the participants’ task was to determine whether a 1s series of pulses changed its character in the middle. In a first approach we designed pairs of discriminanda (first stimulus always a=40micron, pf=90Hz and wf=170 Hz) that differed solely in pf and thus not containing any local cue. Five out of 7 participants detected these changes at a threshold level of $\Delta pf \sim 15 \pm 5\%$ (mean±SD, i.e. at pf=103.5 Hz) showing that humans are able to use global variables in absence of local ones. Next, keeping pf and a constant, wf (and local variables) could be changed without affecting the mean speed. Six out of 7 participants mastered the task at an average threshold of $\Delta wf \sim 25 \pm 5\%$ (i.e. at wf= 212Hz) suggesting that - assuming intensity is measured as mean speed - humans can base their perception purely on local variables. Finally, aiming at relaxing the assumption that intensity is only measured as mean speed, we systematically examined the 8-dimensional stimulus space spanned by local velocity and acceleration; and global parameters mean(absolute(velocity^x)) and mean(absolute(acceleration^x)) (with x=[1,2,3]) to identify pairs of discriminanda that would disentangle these versions of intensity and local velocity. A favorable situation was found at wf=198Hz, where two test stimuli were available, distinguishing the effect of local velocity. All participants’ performance was better at detecting stimuli that included local velocity cues vs those excluding it (percent correct: 72% vs. 40%; paired t-test; p=0.002). In summary, our data provide first evidence that humans are sensitive to local tactile coding features, opening the possibility that they may use frictional movements as a basis of texture identification.

Title: Characterizing the tactile sensitivity of the breasts

Authors: *K. R. MCLELLAN[1], K. H. LONG[2], A. K. SURESH[1], S. LINDAU[1], S. J. BENSMAIA[3];

Abstract: Simple (or total) mastectomy, the most common mastectomy procedure for women with breast cancer, involves amputating all of the breast tissue, including the cutaneous branches of intercostal nerves III-VI. The resulting loss of sensation in the breast leads to a feeling of disembodiment and can cause sexual dysfunction. To develop strategies for preserving or restoring breast function, we characterize the neural basis of breast sensation in healthy women. First, we assess which classes of tactile nerve fibers innervate the breast. Second, we identify the role of individual intercostal nerves in carrying sensory signals from the breast. To these ends, we designed and constructed an experimental apparatus to passively deliver diverse, well-controlled tactile stimuli to the breast and nipple-areolar complex (NAC). We then present a variety of tactile stimuli - including vibrations and textures - and have subjects perform perceptual judgments adapted from well-established psychophysical paradigms used to investigate the tactile sensitivity of the hand. After establishing the baseline sensitivity of the breast, we pharmacologically block individual intercostal nerve fibers to assess each nerve's contribution to sensation.

Title: Differential effects of potassium channel blockers on mechanical responses of three types of mechanoreceptors in whisker hair follicles of mice

Authors: M. SONEKATSU[1,2], A. YAMADA[1], J. LING[1], *W. TANIGUCHI[2], J. G. GU[1];
[1]Dept. of Anesthesiol. and Perioperative Med., Univ. of Alabama at Birmingham, Birmingham, AL; [2]Wakayama Med. Univ., Wakayama, Japan

Abstract: Mechanoreceptors are essential in tasks such as environmental exploration, social interaction and tactile discrimination. Using our newly developed pressure-clamped single-fiber recording technique, we have recently identified in whisker hair follicles of mice three functional types of mechanoreceptors, the rapidly adapting (RA), slow adapting type 1 (SA1) and slowly adapting type 2 (SA2) mechanoreceptors. In the present study we explored the role of K^+ channels in tuning impulse firing of these mechanoreceptors by testing effects of different K^+ channel blockers on mechanically evoked whisker afferent impulses. We tested tetraethylammonium (TEA) and found that neither RA nor SA1 impulses were affected by bath application of 10 mM TEA, but SA2 impulses were significantly increased by TEA at the concentrations of 5 mM and 10 mM. However, SA2 impulses were suppressed by TEA at the lower concentrations of 200 µM and 1 mM. We tested 4-aminopyridine (4-AP) and found that RA impulses were not affected by bath application of 1 mM 4-AP, but both SA1 impulses and SA2 impulses were suppressed by 1 mM 4-AP. At a lower concentration of 100 µM 4-AP, SA2 impulses but not SA1 impulses were suppressed. We tested Ba^{2+} and found that both RA and SA1 impulses were increased but SA2 impulses suppressed by bath application of 5 mM Ba^{2+}. When these K^+ channel blockers were focally applied to whisker afferent nerves but not applied to whisker hair follicles, they did not have any effects on the impulses of these mechanoreceptors. These findings suggest that different types of K^+ channels may be differentially expressed at the afferent terminals of these mechanoreceptors in whisker hair follicles to tune their functions.

Title: Impairment of slowly adapting type 1 mechanoreceptors in mice following vincristine treatment

Authors: *M. S. SONEKATSU, J. G. GU;
Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Loss of the sense of touch or numbness in fingertips and toes is one of the most common sensory dysfunctions in patients receiving chemotherapy with anti-cancer drugs such as

vincristine. Whisker hair follicles functionally resemble human fingertips and contain several types of mechanoreceptors including lanceolate endings, Merkel discs and Ruffini-like endings. Electrophysiologically, Lanceolate endings, Merkel discs and Ruffini-like endings in whisker hair follicles mediate rapidly adapting (RA), slowly adapting type 1 (SA1), and slowly adapting type 2 (SA2) responses, respectively. In the present study, we investigated effects of vincristine treatment on each type of mechanoreceptors in whisker hair follicles of mice. Nerve impulses of each type of mechanoreceptors were elicited by mechanical stimulation to whisker hair follicles and recorded using our newly developed pressure-clamped single-fiber recording technique. *In vitro* short-term treatment of whisker hair follicles with 2 μM vincristine for 2 hours increased mechanically evoked impulses of RA and decreased SA1 significantly, but did not affect the impulses of SA2. *In vivo* treatment of animals with vincristine at a daily dose of 0.3 mg/kg for 10 days significantly decreased mechanically evoked impulses of SA1, but had no significant effects on impulses of RA and SA2. Collectively, our results suggest that Merkel discs, the mechanoreceptors mediating SA1 responses in whisker hair follicles, are main targets by vincristine to cause the impairment of tactile sensitivity.

Title: Integrin alpha1 beta1 increases mechanosensation and decreases cold perception in the mouse hind paw

Authors: J. MICHAUD[1], S. LEE[1], V. WAI[1], A. POZZI[2], L. BENT[1], *A. L. CLARK[1];
[1]Univ. of Guelph, Guelph, ON, Canada; [2]Vanderbilt Univ., Vanderbilt, TN

Abstract: Objective: To measure the effect of integrin α1β1 on mechanical and temperature sensation in the mouse hind paw.
Rationale: Integrin α1β1 is a collagen receptor expressed by keratinocytes in the basal layer of the epidermis. Merkel cells and Meissner's corpuscles (MCs) are low-threshold mechanoreceptors found in close proximity to integrin α1β1 in the basal epidermis. Furthermore, MCs are tethered to the basal epidermis by collagen fibres. Transient receptor potential vanilloid 4 (TRPV4) is highly expressed by epidermal keratinocytes, Merkel cells and MCs. TRPV4 is activated by warm temperatures (>27°C) and osmotic stress, and TRPV4 deficient mice show

deficits in heat detection. Interestingly, integrin α1-null cells are insensitive to osmotic stress, suggesting that integrin α1β1 is necessary for the function of TRPV4. Therefore we hypothesize that integrin α1-null mice have reduced mechanical and heat sensation in the hind paw.
Methods: All animal procedures were approved by the University of Guelph ACC. 20 adult wildtype (WT) and integrin α1-null (KO) mice (10 of each sex) were exposed to 3 assays for mechanosensation (ramping Von Frey, static Von Frey (0.8-7.5g hairs) and cotton swab) and 2 assays for thermosensation (hot plate (50°C) and ice pack (-20°C)). For ramping Von Frey, an electronic anesthesiometer was applied and the force output recorded when a response was elicited. For all assays, flicking, licking or withdrawal of the hind paw constituted a response. ANOVA with genotype and sex as factors were conducted for all data except the static Von Frey where a repeated measures ANOVA was applied.
Results: KO and female mice had a lower threshold of response to ramping Von Frey compared to WT ($p=0.03$) and male ($p=0.04$) mice respectively. There were fewer responses ($p=0.001$) to the 7.5g hair by KO mice compared to WT, and no effects on the cotton swab assay. There was a significant ($p=0.004$) sex and genotype interaction effect for the cold plate test, with male KO mice showing 5s less tolerance compared to male WT and female KO mice. Heat tolerance was less in females compared to males ($p=0.03$), with no genotype effect.
Conclusions: Integrin α1β1 increases the force threshold for mechanosensation by 1g, but does not influence light touch. This suggests that integrin α1β1 influences the function of Merkel cells but not MCs. Surprisingly, integrin α1β1 increases cold tolerance but only in male mice, and does not influence heat sensation. This suggests that compensatory mechanisms are at play to restore the lost heat responses due to TRPV4 dysfunction in KO mice.
Significance: Integrin α1β1 plays an important role in hind paw mechanical and temperature sensation.

Title: The density of Meissner's corpuscles varies with anatomical location across the sole of the hind paw, but is not affected by integrin alpha1beta1

Authors: *V. WAI, L. ROBERTS, L. BENT, A. L. CLARK;
Univ. of Guelph, Guelph, ON, Canada

Abstract: Introduction: Balance and motor control are influenced by mechanoreceptors in the glabrous skin of the foot. Studies utilizing microneurography show a concentration of afferent responses in the anterolateral human foot sole, however mechanoreceptor density at the afferent terminals is unknown. Meissner's corpuscles (MCs) are mechanoreceptors responsible for sensing light touch, grip and low frequency vibrations, whose function is conserved across mammalian species. MCs are located in the dermal papillae where they are tethered to the stratum basale by collagen fibres. The collagen receptor, integrin α1β1, is expressed by keratinocytes in the basal layer of the dermis. The proximity of integrin α1β1 to MCs may suggest interplay between them, affecting mechanosensation. We hypothesize MC density will be greatest in the anterolateral hind paw footpads and will be increased in integrin α1-null (KO) compared to wild type (WT) mice.
Methods: Animal procedures were approved by the University of Guelph ACC. 16 right hind paws were harvested from WT and KO mice (8 of each sex). Hind paws were fixed (4% PFA), processed, embedded (paraffin) and serially sectioned (8μm) in the sagittal plane. Every third slide was stained using hematoxylin and eosin, and imaged using light microscopy. MCs were counted every 90μm and density was calculated as a function of foot pad or phalanx surface area. Repeated measures ANOVA with genotype and sex as factors were conducted for MC density in footpads and distal phalanges, and footpad surface area.
Results: The surface area of footpad 5 was three times greater than the other footpads ($p<0.001$). MCs were found exclusively in the dermal papillae of the footpads and the tips of the distal phalanges. On average, MC density was at least five times greater in the footpads ($12.5mm^{-2}$) than the phalanges ($2.2mm^{-2}$). MC density was on average at least three times greater in footpads 1, 3, 4 ($19.4mm^{-2}$) compared to footpads 2, 5, 6 ($5.7mm^{-2}$), and three times greater in phalanges 2 and 5 ($3.2mm^{-2}$) compared to phalanges 3 and 4 ($1.0mm^{-2}$). Genotype and sex had no effect on MC density or footpad size.
Conclusion: MC localization to the footpads and distal phalanges suggests that these are critical contact regions providing mechanosensation feedback in mice. Larger MC density in footpads 1, 3, and 4 may suggest the importance of these pads in anteroposterior balance control while larger MC density in phalanges 2 and 5 may suggest their role in mediolateral gripping and balance control.
Significance: Differences in MC density across the footpads and distal phalanges suggests their anatomical location is critical in anteroposterior and mediolateral balance respectively.

Title: Dependence of texture-elicited skin vibrations on scanning speed

Authors: *C. M. GREENSPON, K. R. MCLELLAN, J. D. LIEBER, S. J. BENSMAIA; Organismal Biol. & Anat., Univ. of Chicago, Chicago, IL

Abstract: We are exquisitely sensitive to surface microstructure and to the material properties of objects. To sense the finest elements of a texture - measured in the tens of nanometers - requires movement between the skin and a surface, which elicits vibrations in the skin that are dependent on both the texture and the way it is explored. These vibrations can be measured using a laser Doppler vibrometer that measures the movement of the skin along the axis perpendicular to its surface. With this technique, texture-elicited vibrations have been shown to depend on the speed at which the skin moves over the surface. Indeed, the vibrations dilate or contract with increases or decreases in scanning speed, respectively. While the effect of scanning speed on the frequency composition of skin vibrations has been characterized, its effect on their intensity has not. To do so requires that textures be scanned at different speeds within the same experimental block, so that the effective gain of the measurement remain consistent across speeds. To fill this gap, we presented textures to the fingertips of human participants scanned over a range of speeds (10 - 160 mm/s) and measured the skin vibrations using a laser-Doppler vibrometer. We replicated the result that, as speed increases, the frequency composition of the vibrations shifts systematically towards higher frequencies, leading to a constant frequency when expressed in spatial units. Furthermore, vibratory intensity - as gauged by root mean squared displacement - increased with speed. We found that the warping of the frequency composition of the vibrations - its shift toward the left or the right with decreases or increases in scanning speed - could account for the bulk of the effect of scanning speed on intensity. We could further improve the fit by taking into account the resonance of the skin, which selectively modulates frequencies. Our model allows us to predict the vibratory power at any speed for any texture given the power spectrum of that texture at any one speed.

Title: Imaging the fingerpad deformations during vertical oscillations of a hand-held object

Authors: *B. P. DELHAYE[1], F. SCHILTZ[1], J.-L. THONNARD[1], P. LEFEVRE[2];
[1]Univ. Catholique de Louvain, Brussels, Belgium; [2]Univ. Catholique de Louvain, Louvain-la-Neuve, Belgium

Abstract: Dexterous object manipulation critically relies on the feedback provided by the tactile afferents innervating the fingertips. Indeed, disruption of this feedback severely impairs our ability to properly coordinate the fingertip forces exerted on the object. The interactions between the fingertips and the object continuously generate complex spatiotemporal skin deformations that are in turn faithfully encoded by the afferents. To better understand the exact nature of those deformations and therefore the information that could potentially be captured by the skin afferents during active movements, we imaged the contact area between the index fingertip and a transparent object while subjects (n=6) performed vertical oscillations using a precision grip. A total of 300 oscillations were recorded for each subject, split into 15 blocks of 30 seconds. The oscillations peak-to-peak amplitude was 20 cm, and a metronome guided the pace at 1.5 seconds per cycle. From the images, we could then track fingerprints and evaluate skin strains in the contact area. We also monitored the interaction forces (i.e. the grip force and the load force) and torques, the fingerpad moisture before and after each block, and the coefficient of friction. Two major fingertip deformations took place at each oscillation cycle. First, due to fingertip compliance, the bulk of the fingerpad oscillated up and down, following the load force acting as a pulling force. This was characterized by rolling and associated motion of the center of pressure of the fingertip. Second, when the bulk movement approached its maximum, we observed the systematic occurrence of partial slips at the periphery of the contact area between the fingerpad and the object. Those partial slips occurred even though the object was still securely held between the fingers and resulted in patterns of skin strains that were highly stereotyped during an oscillation cycle. While the amount of partial slip was consistent across trials, it varied a lot across subjects due to various factors including the level of grip force, the coefficient of friction, the fingerpad moisture and the compliance of the skin. We argue that those partial slips and the

resulting strain patterns might provide essential information to adjust the grip force and avoid complete slip.

Title: Consistency and discrepancy between reported direction and trajectory: Layered mechanisms of tactile motion perception

Authors: *S. KUROKI;
NTT Communication Sci. Labs., Kanagawa, Japan

Abstract: By sensing direction and trajectory of the motion across the skin, we are able to identify relative positional relationship of hand and touching object and local shape of the object. Motion direction perception has been well studied, and involvement of slow, high-level feature tracking mechanism has been suggested. Tactile motion aftereffect occurs at spatiotopic frame rather than somatotopic frame [Watanabe et al., EBR 2009; Kuroki et al., EBR 2012], and the threshold of direction detection is well beyond that of motion detection [Holcombe et al., Vision Res 2008; Kuroki et al., JNP 2016]. These studies indicates lack of low-level motion energy detector as observed for visual motion perception. On the other hand, motion cue is also essential for object manipulation, where not only accuracy but also rapidity is essentially required. Indeed, neurophysiological/computational studies suggested existence of tactile low-level motion/shape detectors [Delhaye et al., JNP 2019; Pei et al., PLoS Biol 2010; Pruszynski et al., NatNeurosci 2014]. Here we try to consider whether not only slow/high-level feature tracking but also fast/low-level mechanism of motion detection can contribute to motion feature perception. In the experiment, participants put their palm or medial side of the forearm on the braille display (32×48 array). One of four tilted motion stimuli (upward or downward, rightward or leftward) was presented. Participants were asked to report two questions: motion direction (up or down) and resulting shape of its trajectory (diagonal line between bottom left to top right or line between bottom right to top left). If our perceptual access is limited to position tracking mechanism, the shape of motion would be correctly answered only when the tracking is succeed, i.e., when the direction of motion is correctly detected. If, we can also access to the motion feature information extracted from low-level mechanism perceptually, then the proportion correct of these two questions does not necessarily correlated. We found that accuracies for direction and shape questions were not correlated when experiment was done with the palm, suggesting multiple mechanisms of tactile motion perception. Interestingly, the correlation was

found when the same task was conducted with arm, where is not frequently used for object manipulation. Note that the size of stimuli on the arm was quadruple of that on the palm, which was normalized based on the ability of two-point discrimination. These results support the idea that the brain uses multiple mechanisms depending on the situation and body site.

Title: Fine orientation processing in the tactile periphery

Authors: *V. SUKUMAR[1], E. HAY[2], A. PRUSZYNSKI[3];
[1]Univ. of Western Ontario, London, ON, Canada; [2]Dept. of Psychiatry, Krembil Ctr. for Neuroinformatics, CAMH, Toronto, ON, Canada; [3]Physiol. and Pharmacol., Western Univ., London, ON, Canada

Abstract: First-order tactile neurons signal information about touched objects. Previously, we showed that these neurons extract the geometric features such as edge orientation. Here, we probed the robustness and fidelity of this edge orientation processing for finely spaced edges presented over a wide range of stimulation speeds. We recorded from 56 human first-order tactile neurons - 32 fast-adapting Type-1 (FA-1) innervating Meissner corpuscles and 24 slow-adapting Type-1 (SA-1) innervating Merkel endings. The stimuli were edges embossed on a rotating drum, oriented 5 to 20 degrees relative to the fingertip, presented at 12 speeds from 2.5 to 270 mm/s speeds. Responses of both FA-1 and SA-1 neurons robustly discriminated the edges at slow and medium speeds using the temporal code. Intensity codes performed poorer. Contrary to previous notions about the relative specialization of SA-1 neurons for signaling fine spatial details, we found that FA-1 neurons carried more information about fine differences in edge orientation. Our results suggest that first-order tactile neurons signal fine edge orientations robustly across a broad range of speeds used during normal hand function, and that FA-1 neurons are particularly important for processing finer details of touched objects.

Abstract: Cutaneous feedback from the foot sole is crucial for gait and balance control. Four classes of specialized afferents innervate the skin of the soles of the feet and had their electrophysiological properties recently explored in detail with the aid of microneurography. Nevertheless, in order to fully understand their role in balance control and walking, and to devise more natural feedback for prosthetic limbs, afferent responses need to be studied at the population level.
Here, we present a computational model that simulates neural spiking responses from the combined population of mechanoreceptive afferents innervating the sole of the foot. Our work takes into account the unique mechanics of the skin tissue in the foot (including depth and hardness), and includes all relevant afferent classes (both slowly and rapidly adapting) that signal skin indentation, slip, vibration, and stretch. Single-unit recordings of afferent firing characteristics were used for validation and fitting. The work builds on previous research in our group on mechanotransduction in the hand.
We used the model to calculate receptive field sizes and thresholds (absolute and tuning) across afferent types and show that they match their empirical counterparts closely. We also quantified how skin mechanics affects the tactile responses across different regions of the foot.
In future work, we plan to use the model to improve somatosensory feedback in prosthetic devices through neural interfaces with lower limb nerves.

Title: Different cell groups encode stimulus intensity and direction in insect mechanosensory system

Authors: *H. OGAWA[1], K. TANAKA[2], M. SOMEYA[3], H. SHIDARA[1];
[1]Dept. of Biol. Sciences, Fac. of Sci., [2]Biosystems Sci. Course, Grad. Sch. of Life Sci., Hokkaido Univ., Sapporo, Japan; [3]Lab. for Circuit Mechanisms of Sensory Perception, RIKEN CBS, Wako, Japan

Abstract: The sensory system extracts various characteristics of stimulus including intensity, frequency, and direction and encodes the sensory information by spike trains of cell population. Many neurophysiological studies have focused on neural codes of various sensory parameters. However, it remains unclear whether individual neurons encode only specific sensory parameter of the stimulus or are involved in representation of multiple stimulus characteristics. To address this issue, we used cricket cercal sensory system to detect airflow dynamics surrounding animal. The sensory information of airflow such as airflow speed and stimulus orientation is processed by local circuit within the terminal abdominal ganglion and conveyed to higher center via several identified projection neurons such as the giant interneurons (GIs). The previous study revealed that the direction of airflow is encoded by two pairs of GIs (Miller and Theunissen, 1991), but it is unknown what impacts the stimulus intensity has on the directional encoding. We measured the spike responses of individual GIs to airflow stimulus of various velocities from different angles using intracellular recording method and reported that the impacts of the stimulus intensity on the directional tuning varied by the type of GIs at last year's meeting. This result suggested that encoding of the stimulus direction by GIs is different in its robustness against the stimulus intensity among the cells which play different roles in sensory processing. In addition, the accuracy of direction or velocity encoding for individual and population of cells was analyzed by using cross-validation based on the maximum likelihood estimation method. The stimulus direction was represented by the population activity of three pairs of GIs, which are LGI, GI 10-2, and GI 10-3, whereas the airflow speed was encoded by the cell group consisting of MGI, GI 9-2, and GI 9-3. This result suggests that the stimulus direction and intensity are separately conveyed by different groups of GIs, which may be related to their behavioral functions.

Title: A three-dimensional dynamical model of the rat vibrissal array

Authors: ***N. O. ZWEIFEL**, N. E. BUSH, I. ABRAHAM, T. D. MURPHEY, M. J. Z. HARTMANN;
Northwestern Univ., Evanston, IL

Abstract: The rat vibrissal system is one of the most commonly used models to study how the brain encodes and processes somatosensory information. And yet, methods to accurately predict the three-dimensional (3D) dynamics of rat whiskers and the mechanical signals generated at the base of each vibrissa are still not available. In order to close this gap, we developed a simulation framework that incorporates a realistic 3D model of the full rat whisker array to predict the complete sensory input to the rat vibrissal system. The model for each individual whisker in the array is based on previous work, extending a two-dimensional rigid-link model to three dimensions. The whisker is approximated as a chain of conical frustums connected by equidistant joints with three degrees of freedom, modeled as torsional springs. We optimized the stiffness and damping parameters of the springs such that resonance frequency and damping behavior matched those of a real whisker. Then, we extrapolated the single-whisker model to the full rat whisker array taking into account the typical morphology and whisker geometry across the array. Our simulations show that the motions of the dynamically-optimized whisker model closely match data from real whiskers for multiple trials, achieving Pearson correlation coefficients of 0.91 and 0.94 for horizontal and vertical deflections, respectively. Results from simulation experiments with a single whisker colliding against a straight edge reproduced results from analytical models published in other studies. Resonance experiments with the whiskers of the extrapolated array approximated previous experimental results, validating generalizability of the model across different whisker geometries. Lastly, simulation experiments of the full rat whisker array under various conditions, including passive collisions and active whisking against a peg, demonstrate how the array morphology and the whisker geometry across the array shape the tactile input to the whisker system. Our simulations show that our model approximates the behavior of real whiskers with small error. Thus, we provide a new three-dimensional dynamical model of the rat vibrissa that can accurately simulate the mechanical signals at the whisker base,

including during collisions. In addition, our model generalizes to a full whisker array and provides the means to simulate the complete sensory input to the rat vibrissal system.

Title: Simulating deformation of the whisker shaft within the follicle

Authors: *Y. LUO[1], J. W. RUDNICKI[2], M. J. HARTMANN[1,3];
[1]Dept. of Mechanical Engin., [2]Dept. of Civil and Envrn. Engin., [3]Dept. of Biomed. Engin., Northwestern Univ., Evanston, IL

Abstract: During active whisking behavior, the deformation profile of the vibrissal shaft within the follicle-sinus complex (FSC) is critical to determining the mechanoreceptor response. Current anatomical evidence suggests that the follicle wall is relatively stiff, that the follicle-vibrissal junction is relatively rigid, and that the hair bulb at the base of the vibrissal shaft is relatively soft. A simplified beam-and-spring mechanical model was constructed for the FSC based on this anatomical evidence. The model was validated against an experimental study that measured tissue displacement during passive touch (Whiteley et al., 2015). The model was then used to predict the deformation profile of the vibrissal shaft during active whisking. Results suggest that the vibrissa will pivot around a fulcrum near the follicle entrance, and form a "C-shape" between the level of the ring sinus (RS) and the level of the rete ridge collar (RRC). This C-shape suggests that both RS-Merkel and RRC-Merkel cells will experience similar deformations during whisker deflection. We then modeled the effects of intrinsic muscle activation and the effects of an increase in blood pressure within the RS. The model predicts that both muscle activation and blood pressure increase will enhance the tactile sensitivity of RS-Merkel cells by increasing the static pressure in the tissue within the FSC. We discuss the assumptions required to determine whether this sensitivity enhancement will be biased towards large or small contact deflections. Finally, the model suggests that the deformation profile during active whisking does not qualitatively differ from that during passive touch. This result may allow future qualitative study of mechanoreceptors within the FSC to be conducted during only passive touch (e.g., in the anesthetized animal) and then generalized to active whisking.

Title: Complex, three-dimensional whisker stimulation reveals functional tiling of both adaptation and stimulus encoding properties in whisker responsive trigeminal ganglion neurons

Authors: *N. E. BUSH[1], S. A. SOLLA[2], M. J. Z. HARTMANN[3,4];
[1]Interdepartmental Neurosci. Program, Northwestern Univ., Evanston, IL; [2]Physiol., Northwestern Univ., Chicago, IL; [3]Mechanical Engin., [4]Biomed. Engin., Northwestern Univ., Evanston, IL

Abstract: In order to reveal the full representational capabilities of sensory neurons, it is crucial to observe their responses to a variety of complex and naturalistic stimuli. In the rodent whisker system, mechanical information at the base of the follicle drives the activity of primary sensory neurons in the trigeminal ganglion (Vg). To date, studies of the encoding properties of these neurons have primarily been limited to whisker motion in two-dimensions (2D), often employing restricted stimulus sets. In the present work we quantified the full three-dimensional (3D) shape of whiskers during complex and naturalistic stimulation while recording from Vg neurons. We fit generalized linear models (GLMs) with multiple input filters to predict neural activity in response to mechanical variables at the base of the whisker caused by the 3D deflections. Our results show that individual Vg neurons simultaneously represent multiple mechanical features of a given stimulus, and that rapidly/slowly adapting populations (RA/SA) are not distinct during complex stimulation. When tuning properties of recorded neurons are examined as a population, feature representations are observed to vary continuously and to tile the mechanical stimulus space. Together, these results suggest that Vg neurons employ a distributed code to account for all available mechanical information. Consistent with some earlier studies from the 1960's through the 1980's, as well as some more recent studies, we find that the adaptation properties of Vg neurons do not segregate into clean functional classes.

Title: Using biomimetic robotic whiskers to simultaneously extract 3D contours and texture: An approach for modeling neural responses in the whisker-trigeminal system

Authors: *Y. YI[1], H. M. EMNETT[1], K. J. KLECZKA[1,2], M. J. Z. HARTMANN[1,2];
[1]Mechanical Engin., [2]Biomed. Engin., Northwestern Univ., Evanston, IL

Abstract: We built a robot with artificial whiskers (vibrissae) that can sense 3D contours and textures. The material for the artificial whiskers was carefully chosen to ensure that deformations stay in the elastic regime (i.e., the whiskers do not "kink" or stay deformed after contact). The artificial whiskers are scaled to be either 5x or 10x the size and shape (including taper) of real rat whiskers. The base of each artificial whisker is attached to a robotic "follicle" (a set of sensors) that is designed to measure the mechanical components necessary for accurate 3D contact point extraction. We use the robot to show three results: (1) Consistent with prior work, the 3D whisker-object contact point can be estimated using mechanical signals and their rates of change (time derivatives). This first result is scientifically unsurprising, although it is always exciting to see an algorithm work in hardware. (2) As predicted by simulation, the 3D whisker-object contact point can also be estimated using judicious combinations of the mechanical signals alone, without their time rates of change. This second result holds as long as the whisker is tapered, but does not hold if the whisker is cylindrical. (3) The same whisker can also be used to classify textures based on higher frequency (vibration) signals. Different frequency ranges are used for contour extraction and texture discrimination, so the two can be performed simultaneously. At the same time as we have been building the robot, we have also been performing neurophysiological recordings in the trigeminal ganglion of the real rat. We have developed models for how these (real, biological) neurons respond to mechanical signals at the base of (real, biological) whiskers. We now plan to use the mechanical output from the robot's whiskers as input to the models of neural responses in the trigeminal ganglion. We anticipate that this hybrid robotic/biological approach will ultimately be useful for constraining the kinds of processing that occurs at the level of the brainstem trigeminal nuclei.

Title: Coordination of head and whisker kinematics in rats during a three-dimensional tactile search task

Authors: *A. RESULAJ[1], K. J. KLECZKA[2,3], M. J. Z. HARTMANN[2,3];
[1]Interdepartmental Neurosci. Program, [2]Biomed. Engin., [3]Mechanical Engin., Northwestern Univ., Evanston, IL

Abstract: Rodents are crepuscular creatures who search and sense their natural tactile surroundings using rhythmic protraction and retractions of their vibrissae arrays (whiskers) in a behavior referred to as “whisking”. The importance of this sensory modality to rodents is accentuated by the expansion of brain areas dedicated to processing whisker mediated information, and by fast sensorimotor loops passing through the rodent trigeminal brainstem nuclei. Whisking behavior is thus widely studied in neuroscience as an excellent model for active sensing and sensorimotor integration. Spatiotemporal control of whisker movements occurs in a complex three-dimensional (3D) world. As rodents burrow, climb, and navigate in their 3D habitats, individual whisks can vary considerably in amplitude and frequency. This exquisite spatiotemporal control of whisking can be seen in the changes in symmetry (a spatial parameter) and synchrony (a temporal parameter) between right and left whisker arrays. Previous studies have shown that the change in symmetry between the left and right whisker arrays is related to the rotational velocity of the head. The degree to which this symmetry is under top-down vs. reflexive control is poorly understood, in part, because most rodent behavior studies utilize either a head-fixed experimental configuration, or behavioral tasks in a planar, two-dimensional (2D) environment (e.g., Y-maze, linear track). We designed a task which employs a naturalistic 3D search behavior. Using recent techniques in machine vision and machine learning, we track head and whisker array position in 3D, exploring the degree to which head/whisker coordination is reflexive versus learning-dependent. We trained rats to stretch from a perch in order to search for a reward within a 3D volume of space, and quantified 3D head position and velocity along with whisker movement. (1) We reconstruct the animal’s head movements in 3D and quantify the effect of head pitch on whisking patterns. (2) We test the effect of modifying the task so that the animal can form a prior expectation of reward location within the 3D volume of space. (3) We

examine the extent to which the animal's learned experience of the environment modifies its tactile exploration strategy so as to maximize its reward. (4) We test whether head velocity and whisking asymmetry coupling is state-dependent and under putative top-down control. This naturalistic 3D task and the kinematic data it generates offers an opportunity to test models of sensorimotor integration. This novel paradigm and methodology can be useful for inactivation studies of sensorimotor structures.

Title: Cerebral fNIRS hemodynamic response encodes the velocity of patterned tactile stimuli

Authors: *M. HOZAN[1,2,3], J. GREENWOOD[1,2,3], S. M. BARLOW[1,2,3];
[1]Ctr. for Brain, Biology, and Behavior, [2]Biol. Syst. Engin. Dept., [3]Special Educ. and Communication Disorders, Univ. of Nebraska-Lincoln, Lincoln, NE

Abstract: BACKGROUND:
The cerebral hemodynamic response (HR) can be non-invasively measured using functional near-infrared spectroscopy (fNIRS) while participants passively receive patterned somatosensory stimulation, or actively perform repetitive motor tasks.
OBJECTIVE:
Whether and to what extent the evoked cerebral HR encodes the velocity of the stimulus pattern when neurotypical adults are presented with paced tactile stimuli at 3 distinct traverse velocities (10, 25 and 45 cm/s) on the dominant glabrous hand.
METHODS:
The fNIRS signal was collected from 11 right-handed neurotypical adults (19-35 yrs, 5F/6M) in two paradigms: passive (sensory) and active (sensorimotor). In the passive task, saltatory pneumotactile stimulation (60 ms pulses, 8-chan) traversed the glabrous hand (D1-D5) at 10, 25 and 45 cm/s. The active paradigm is similarly implemented, except the subjects are asked to perform precision grip at a matching velocity. A randomized block design was used for stimulus presentation (20s stim ON; 20s stim OFF; 10 reps/velocity) during data acquisition (NIRx Scout), [16 dual-tip LED sources (760 nm, 850 nm) and 20 detectors (7.8 Hz sampling rate)] placed bilaterally over motor/somatosensory cortices. HR signals from up to 104 links between sources and emitters were analyzed via the Maximum Likelihood Estimation (MLE) method to

classify the 3 distinct velocities. Common Spatial Pattern (CSP) methodology is used for dimensionality reduction and feature extraction.

RESULTS:

Preliminary results show an average accuracy of nearly 60% in detecting the correct velocity (chance level 33%) when analysis is performed on the raw fNIRS data without preprocessing. The classifier is more accurate in detecting HR features for the lowest (10 cm/s) and the highest (45 cm/s) velocity conditions.

CONCLUSION:

1) Cerebral fNIRS reveals encoding of sensorimotor stimulus features such as saltatory velocity. 2) Methodological differences in the analysis of fNIRS data can lead to different statistical results. Automated algorithms for feature extraction and classification can be beneficial, particularly when there is lack of consensus on signal processing methods.

Title: Does spike timing in somatosensory cortex code for vibratory frequency?

Authors: *T. CALLIER[1], Q. HE[1], S. J. BENSMAIA[2];
[2]Dept. of Organismal Biol. and Anat., [1]Univ. of Chicago, Chicago, IL

Abstract: Mounting evidence suggests that the precise timing of spikes in cortex plays a role in neural coding. In somatosensory cortex, information about the frequency of skin vibrations has been shown to be carried in both the rates and the timing of the neuronal response. The causal role of spike timing in frequency coding has thus been called into question in this context. To address this ambiguity, we trained monkeys to discriminate the frequency of skin vibrations while simultaneously manipulating stimulus amplitude to decouple rate and timing. Indeed, increases in frequency and increases and amplitude both lead to an increase in firing rate. We also recorded the activity evoked in somatosensory cortex using chronically implanted microelectrode arrays while the animals performed the task. We found that, while firing rate was informative about stimulus frequency at some recording sites, spike timing was informative over a greater proportion of electrodes. When both rate and timing carried frequency information, timing did so more faithfully than did rate. When the two candidate codes - rate and timing -

yielded conflicting signals, the animal's behavior was consistent with the timing code in the vast majority of cases. We conclude that the timing of the response of somatosensory neurons encodes information about vibratory frequency and guides frequency discrimination behavior.

Title: Sensory and lick-related neuronal activity in mouse somatosensory cortex underlying recognition of elementary tactile sequences

Authors: M. R. BALE, M. BITZIDOU, E. GIUSTO, ***M. MARAVALL**;
Sch. of Life Sci., Univ. of Sussex, Brighton, United Kingdom

Abstract: Temporal patterning is a key feature of natural signals and is used by the brain to decode stimuli and perceive them as sensory objects. When we hear or touch a sequential stimulus, such as a melody or passage of speech or a texture scanned by our fingertips, the order, timing and context of its concatenated elements are crucial. We sought to dissect how neuronal activity distinguishes between behaviorally relevant sequential patterns.
We developed a GO/NOGO discrimination task in which mice must distinguish between tactile "words" constructed from distinct whisker vibrations assembled in different orders. A sequence or "word" could potentially be recognized through several cues, including the arrival of a specific vibration or the presence of transitions between adjacent vibrations. Adult male mice (n = 30) were trained for several weeks in the task and could reach performance levels > 90%. In this elementary form of sequence recognition, animals sometimes responded to the earliest possible cues allowing discrimination, but enhanced their performance when deliberating for longer (n = 122 sessions, Spearman rho = 0.24, p = 0.0083).
To track the flow of activity during task performance, we optogenetically inactivated cortical regions on interspersed trials, using laser stimulation of inhibitory neurons in VGAT-ChR2 mice (n = 10-11 inactivation sessions per region). Inactivating primary somatosensory "barrel" cortex (S1BF) or secondary somatosensory cortex decreased licking responses in a manner consistent with a loss of sensory input to decision-making stages. Inactivating posterior parietal cortex had no discernible effect. Inactivating primary motor cortex resulted in an increase in licking responses consistent with a motor disinhibition.
Two-photon imaging in layer 2/3 of S1BF and higher areas (n = 7 mice, 31 sessions) revealed

heterogeneous neurons with mixed selectivity to task variables including sensory input, the animal's decision to lick, and the subsequent action and rewards. Neurons selectively responsive to a specific sequence were strikingly rare. In contrast, a large number of neurons, even in primary sensory cortex, were selectively activated preceding goal-directed licking.
These results show that recognition of elementary sequences is cortex-dependent and follows a hierarchical scheme with information flowing serially through somatosensory cortex. Consistent with evidence from other task designs, responses to task variables including licking were plentiful even at the initial cortical stage. These results reveal features of cortical activity that sequence recognition shares with other goal-directed sensory behaviors.

Title: Rapid sensory adaptation in the thalamocortical network of the mouse and the relative contribution of synaptic depression

Authors: ***N. C. WRIGHT**, P. Y. BORDEN, Y. LIEW, M. F. BOLUS, W. STOY, C. R. FOREST, G. B. STANLEY;
Wallace H Coulter Dept. of Biomed. Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: Adaptation has been studied extensively in the context of shaping sensory percepts, but the underlying neural mechanisms mediating adaptation remain poorly understood. In the early stages of sensory processing, persistent sensory inputs adapt the thalamocortical network. This phenomenon likely involves a range of mechanisms, including the modulation of thalamic properties such as ongoing and sensory-evoked firing rate, tonic/burst firing, and population synchrony, collectively referred to here as thalamic "state", as well as thalamocortical and intracortical synaptic depression. However, the relative contribution of each remains unclear. Here, we address this question in the whisker pathway of the lightly-anesthetized mouse by obtaining silicon probe and patch clamp recordings in layer 4 (L4) of primary somatosensory cortex (S1), and extracellular recordings in ventral posteromedial (VPm) nucleus of thalamus. We delivered precise punctate whisker stimulus features either in isolation, or embedded in adapting sensory white noise. We found that white noise reduced the amplitude and spatial extent of L4 S1 population feature responses, while reducing theoretical detectability of the whisker deflection and enhancing whisker velocity discriminability. In VPm, sensory white noise

reduced feature-evoked response amplitudes and bursting, suggesting the downstream effects in S1 could primarily reflect changes in thalamic state. Next, we more directly assessed the role of rapid synaptic adaptation at the level of cortex using a transgenic mouse expressing Channelrhodopsin in VPm neurons. We substituted the sensory feature with direct optogenetic stimulation of layer 4 thalamocortical terminals (thus bypassing the effects of thalamic state on the S1 response), and recorded spiking and subthreshold S1 activity. In contrast to sensory feature responses, S1 responses to terminal stimulation exhibited almost no adaptive effects when the stimulus was embedded in sensory white noise. Taken together, these results suggest that the sensory environment may primarily shape cortical responses to embedded sensory features by adapting thalamic firing properties, adding to a growing body of evidence for a more prominent role of thalamic coding than historically thought.

Title: Effects of transcranial direct current stimulation on tactile perception in musicians and non-musicians

Authors: L. DADASHEV[1], A. A. KARIM[1,2], ***B. GODDE**[1];
[1]Jacobs Univ., Bremen, Germany; [2]Univ. Clin. of Psychiatry and Psychotherapy, Tübingen, Germany

Abstract: Brain plasticity in sensory regions can be facilitated by brain stimulation. The relationship between the magnitude of plasticity and tactile performance with tactile expertise is not yet fully understood. We investigated the effects of transcranial direct current stimulation (tDCS) on tactile perception in tactile experts (musicians) and novices. We hypothesized that anodal, but not cathodal tDCS over contralateral somatosensory cortex would facilitate performance. We further expected these effects would be stronger in experts than in novices. At three separate days, 33 participants (age range: 18-27 years) received 15 minutes of 1 mA anodal, cathodal or sham tDCS in a pseudorandomized design. Pre and post tDCS, tactile sensitivity (Touch Detection Threshold; TDT) and discrimination performance (Grating Orientation Task; GOT) were assessed. Participants were divided into experts (17; semi-professional musicians) and novices (16; no prior instrumental experience). Computer-

typewriting hours per day was assessed as a control variable. In a second analysis, the amount of instrument-playing and computer-typing hours were combined into a 'tactile expertise' variable. Musicians performed marginally better than non-musicians in GOT, only. A significant session by condition interaction effect indicated that only anodal tDCS stimulation facilitated tactile performance. This effect was found for both analysis: with musical expertise as between groups factor and with tactile expertise as continuous covariate. Neither kind of expertise modulated the stimulation effect, but the effect on TDT was stronger in participants with higher baseline performance.

Title: Inter- and intrahemispheric resting-state functional connectivity alterations associated with upper limb somatosensory recovery early post stroke

Authors: *N. DE BRUYN[1], L. SAENEN[1], L. THIJS[1], E. CEULEMANS[1], S. MEYER[2], K. ALAERTS[1], G. VERHEYDEN[1];
[1]KU Leuven- Neurorehabilitation Sci., Leuven, Belgium; [2]Rehabil. Campus Sint-Ursula, Jessa Hopsital, Herk-de-Stad, Belgium

Abstract: Background: Sensorimotor deficits in the upper limb are present in more than 50% of subacute stroke patients. Knowledge concerning associations of changes in functional connectivity and clinical sensorimotor recovery is warranted. **Aim:** To investigate changes in functional connectivity of the sensorimotor resting-state network associated with clinical recovery of sensorimotor function in the early rehabilitation phase. **Methods:** We recruited 9 subacute stroke patients within 4 months post stroke. Resting-state functional magnetic resonance imaging (rs-fMRI) and a clinical sensorimotor profile was obtained at two time points with four weeks in between, consisting of Perceptual Threshold of Touch (PTT; somatosensory measure) and Stroke Upper Limb Capacity Scale (SULCS; motor activity measure). Three network indices of functional connectivity were created based on individually averaged connectivity values (z-transformed r-values) of a region of interest-to-region of interest analysis: interhemispheric, contralesional intrahemispheric and ipsilesional intrahemispheric index. Non-parametric partial correlations with time since stroke and mean framewise displacement as

nuisance regressors were obtained for the change scores of these three network indices with the clinical recovery scores. **Results:** We included 4 male and 5 female subacute stroke patients with mean age of 64 years (range: 47-79) and mean time post stroke of 82 days (range: 65-113)**.** Somatosensory (PTT) recovery was highly correlated to a decrease in interhemispheric index (r=0.82) and moderately correlated to an increase in contralesional intrahemispheric index (r=-0.53). Motor activity (SULCS) recovery was moderately correlated with an increase in ipsilesional intrahemispheric index (r=0.63). **Conclusion:** Changes in inter-and intrahemispheric connectivity seem to play distinct roles in motor and somatosensory recovery with motor recovery associated with ipsilesional intrahemispheric connectivity alterations and somatosensory recovery linked to inter- and contralesional intrahemispheric connectivity changes. Associations between increased contralesional intrahemispheric connectivity and PTT suggest a supporting role of the contralesional connectivity for somatosensory recovery in early rehab.

Title: Cortical map remodeling in the intact hemisphere and functional recovery after focal ischemic stroke to the primary somatosensory cortex

Authors: *J. FACCHINI, C. A. XERRI, N. CATZ, Y. ZENNOU-AZOGUI;
Aix-Marseille University, CNRS, Marseille, France

Abstract: After ischemic injury to S1, most studies have focused on the remodeling of perilesional areas and its role in functional recovery. In contrast, consequent alterations within the contralesional cortex remain poorly understood despite its involvement in the functional recovery. Our study investigates in rats the time-course of cortical cutaneous map remodeling in the intact hemisphere following unilateral focal ischemic damage to S1. In parallel, behavioral deficits are assessed to better understand the role of hemispheric interactions in the functional restoration. Using electrophysiological mapping, we explored the post-lesion reorganization of the non-affected forepaw cutaneous representation at several time points during four weeks after the cortical damage induction. We also used behavioral tests assessing tactile sensitivity and sensorimotor coordination. Cortical maps in the intact hemisphere show a representational dedifferentiation inducing a degradation of the somatotopic organization starting from 1 hour and worsening until 14 post-injury days. These changes are underpinned by a dramatic enlargement

of cutaneous receptive fields accompanied with an increase of neuron sensitivity to mechanical stimulation of the skin. Our behavioral observations show a strong impairment of tactile sensitivity and sensorimotor adjustments for the forepaw contralateral to the injured hemisphere, that gradually abated. No impairment was observed for the intact forepaw during behavioral assessments. Interestingly, a substantial, yet incomplete, restoration of somatotopic organization was found to occur at the end of the first postlesion month. This partial restoration appeared to be temporally related to the time course of the functional recovery.These data are in line with the model of lesion-induced alterations of the interhemispheric imbalance, as they are compatible with the transitory decrease of inhibition of the intact cortex originating from the injured side. Our findings underscore the critical role of hemispheric interactions in maintaining a fine somatotopic organization of cutaneous maps in the intact hemisphere and suggest a major implication of the interhemispheric balance in the functional recovery following focal stroke.

Title: Preserved individual finger representations in tetraplegia

Authors: *S. KIKKERT[1,2], M. VERLING[1], D. PFYFFER[2], P. FREUND[2], N. WENDEROTH[1]; [1]Dept. of Hlth. Sci. and Technol., ETH Zürich, Zürich, Switzerland; [2]Spinal Cord Injury Ctr. Balgrist, Univ. of Zürich, Zürich, Switzerland

Abstract: Following spinal cord injury (SCI) or limb amputation, the brain is deprived of sensory input and motor output to the limb(s). Non-human primate studies previously demonstrated that this leads to extensive reorganisation in the primary somatosensory cortex (S1), such that neighbouring body-part representations invade the “deprived” cortex. However, we previously demonstrated that functional representations of amputees’ missing hand are preserved in the “deprived” S1 area, a finding that questions widely held assumptions of brain organisation and reorganisation. Still, since amputees have a relatively intact motor output system (i.e. they can still activate the muscles that used to control the missing limb), it remains unclear how a retained functioning of the motor system contributes to preserving somatotopy. In this study, we used neuroimaging to characterise the somatotopic layout of hands with diminished or absent sensory and motor function in tetraplegic SCI patients.

We used 3T fMRI to investigate whether finger somatotopy is preserved following tetraplegic SCI. We asked 13 chronic cervical SCI patients and matched healthy controls to perform (attempted) individual finger movements in a travelling wave paradigm to uncover finger selectivity. To quantify somatotopic finger representations patterns, we also obtained blocked design data and used representational similarity analysis. To understand which determinants allow sensory representations in S1 to be maintained, we characterised patients' sensory and motor impairments using behavioural measures.
Our preliminary results revealed detailed somatotopy maps of SCI patients' hand, in which neighbouring clusters showed selectivity for neighbouring fingers in contralateral S1, similar to those observed in healthy control participants. This was true even in a patient with complete paralysis and sensory deprivation of the hands. However, inter-finger overlap was increased (i.e. finger separability was diminished) in patients compared to controls, an effect that tended to be more pronounced in patients with greater sensory and motor hand impairments.
Our results show that the functional finger layout of S1 is preserved even if both sensory *and* motor hand function are impaired. Such stable cortical somatotopy suggests that preserved somatotopic representations may be hardwired or maintained through intracortical mechanisms, though they might be shaped further through use-dependent plasticity. Our results further shed light on the determinants that allow sensory representations in S1 to be preserved, which may facilitate the development of individually-tailored neuroprosthetics.

Title: Somatosensory brain mapping

Authors: *S. LEE[1], M. LEE[1], J. KIM[3], S.-W. PARK[3], J.-H. AHN[3], S. YANG[4], S. YANG[2]; [2]Nano-Bioengineering, [1]Incheon Natl. Univ., Incheon, Korea, Republic of; [3]Yonsei Univ., Seoul, Korea, Republic of; [4]City Univ. of Hong Kong, Kowlong, Hong Kong

Abstract: The shaping and responsiveness of brain map, an indicative of cognitive status, is drastically influenced by experience. Previous representative mapping tools such as penetrating electrodes and magnetic resonance methods have limitation to clinical use largely due to pervasiveness and low spatiotemporal resolution, respectively. Here, our recently develops graphene-based epidural electronics are integrated into an electrocorticography (ECoG) array, therein having a large scale, real-time, and safe recording/stimulation with desirable resolution.

This system is empirically tested for cortical representation of somatosensory maps. Also, electrical stimulation in a subset of graphene spots enables to enhance sensory responses, demonstrating activity-dependent plasticity in a large scale. We propose that this technology heralds a new generation of brain-machine interfaces for studying brain map, map plasticity, and map-related diseases.

Title: Assessing plasticity of somatotopy and receptive field specificity of digit representations in primary somatosensory cortex after injury

Authors: *D. HULSEY[1], J. K. MATHEW[1], M. P. KILGARD[2], S. A. HAYS[3];

Abstract: Peripheral nerve injuries of the upper limb often result in persistent sensory deficits despite surgical repair. Extensive reinnervation does not ensure functional central organization. Here we study effects of transection and repair of the median and ulnar or radial nerves on S1 representation of the digits in the rat. We use four electromagnetic devices to deliver independent mechanical stimulation of digits 2-5 while recording multiunit activity across the digit region of S1. Using quantitative measure of receptive field specificity and cortical somatotopy, we report extensive disorganization after PNI. We additionally assess effects of pairing vagus nerve stimulation with tactile input on S1 representations. Developing therapies with potential to direct plasticity during reinnervation could help to restore normative cortical and sensory function.

Title: Malleability of the cortical hand map following single digit nerve block

Authors: *D. B. WESSELINK[1,2], Z.-B. SANDERS[2], H. DEMPSEY-JONES[1,2], P. KIELIBA[1], A. THEMISTOCLEOUS[2], S. KIKKERT[3,2], J. DIEDRICHSEN[4], U. E. EMIR[2,5], T. R. MAKIN[1,2];

Abstract: Classical primate studies demonstrate that following single digit amputation, the deprived cortical territory becomes responsive to passive input from its neighbouring digits, demonstrating the capacity of the primary somatosensory cortex (SI) to reorganise. Yet, little research has been carried to characterise the impact of such local reorganisation on the entire hand map, known to comprise of lateral inhibitory circuitry. Here we investigated the malleability of the SI hand map in the acute phase of deprivation. 15 participants attended two 7T MRI scanning sessions (1 mm3 resolution) involving both active and passive stimulation of single digits. ~1 hour prior to one session, participants received a localised pharmacological nerve block of digit 2 (D2). We first used univariate approaches to study digit remapping. D2 activity was significantly decreased in its native territory. Contrary to classical findings, on this short timescale, no significant activity increase was found for the neighbouring digits in the blocked territory, using both passive and active stimulation. Instead, we identified a significant decrease in digit selectivity across the entire hand map with passive stimulation, i.e. in the non-blocked territory. With active stimulation, no selectivity changes were found in the digit map. This indicates that in the acute phase of input loss, activity changes for passive stimulation extend well beyond the deprived cortical region, but additional input associated with the active task can offset this change. To further characterise larger-scale effects to local input loss, we interrogated inter-digit similarity using multivariate pattern analyses, extensively used to characterise human hand representation. We found that both active and passive stimulation resulted in significant reduction of inter-digit dissimilarity, indicating blurring of individuated digit representation, akin to the selectivity reduction mentioned above. However, this collapse in hand structure was also present in the active stimulation condition. Therefore, here we identify more extensive changes to hand representation that cannot be rebalanced with motor input. Our results demonstrate that local deprivation triggers rapid large-scale activity changes, resulting in profound changed to hand representation.

Title: Encoding and decoding bimanual vibration frequency information in human sensorimotor cortex

Authors: ***M. RAHMAN**, J. M. YAU;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Vibration frequency perception is a crucial capacity that enables humans to recognize and manipulate objects. While vibration frequency sensing has been extensively studied using behavioral paradigms, little is known about their neural representations in the human brain. Here, we used computational neuroimaging approaches to address two questions. First, how is vibration frequency information - experienced on one hand or both hands simultaneously - represented and combined in the human brain? Second, how do cortical frequency representations differ across different levels of the somatosensory cortical system? We measured and characterized whole-brain BOLD signal changes in participants experiencing a battery of vibrotactile stimulation on their hands. We fitted invertible voxel-wise encoding models to test specific hypotheses regarding population-level vibration frequency tuning and bimanual cue integration. We identified brain regions in parietal and frontal cortex that displayed preferential responses to particular frequency ranges which could be recapitulated by our encoding models which comprised frequency-tuned channels. We inverted the encoding models to successfully decode information about the stimulated hands and vibration frequency from multi-voxel time series patterns. Our findings offer a preliminary view of how bimanual vibration frequency information is represented and integrated in human sensorimotor cortex.

Abstract: Neuroprosthetic systems remain limited in capability and poorly embodied by users due to their inability to provide naturalistic touch feedback. A long history of work in nonhuman primates has demonstrated that intracortical microstimulation (ICMS) of S1 is able to be reliably perceived. ICMS trains of different amplitudes and frequencies can be discriminated from each other and mapped to mechanical stimuli of varying intensities in a predictable one-to-one fashion. However, the subjective experience of these stimulated perceptions remains poorly understood, since very few human participants have been stimulated in this way. Two previous human S1 ICMS studies have demonstrated a range of cutaneous and proprioceptive perceptions in fingers, forearm, and upper arm.
In this study, one participant with incomplete quadriplegia (including some retained finger sensation) was implanted with three stimulating arrays (Blackrock Microsystems; Salt Lake City, UT) in S1 - two in the dominant (left) hemisphere, one in the non-dominant (right) hemisphere. Preoperative structural and functional MRI imaging were performed and fused into an array placement plan. Intraoperative high-density ECoG (hdECoG) mapping of vibrational fingertip stimulation was performed using custom real-time software to determine placement locations for the stimulating arrays.
At 25 and 35 days post-surgery, our team performed a survey of sensations perceived during ICMS of the implanted electrodes. ICMS was performed electrode-wise at a fixed pulse frequency of 100 Hz with a stimulation amplitude of 60 μA. Stimulation of electrodes in the two

left hemisphere arrays elicited percepts on the right hand ranging in location from thumb to ring finger, from the top of the palm to the fingertip. Stimulation of right hemisphere electrodes elicited percepts predominantly in the left thumb and index fingertip areas. Reported sensations were consistent with both the expected somatotopic gradient of somatosensory representations in postcentral gyrus and the intraoperative ECoG mapping results. The reported finger phalanx of perceived sensation showed a gradient on the two left hemisphere arrays, with percepts closer to the central sulcus being reported as more proximal to the palm. Percepts were predominantly reported as electrical in nature and localized to the palmar side of the hand.
This study further demonstrates the potential for ICMS to provide useful feedback for neuroprosthetic systems. Furthermore, it shows that preoperative imaging and intraoperative ECoG mapping are an effective strategy for targeting sensory array placements for subjects with some retained finger sensations.

Title: Long-term stability of projected fields evoked via intracortical microstimulation in a human with chronically implanted electrodes

Authors: *V. KARAPETYAN[1], C. HUGHES[1], S. FLESHER[3], M. BONINGER[2], J. L. COLLINGER[2], R. A. GAUNT[2];

Abstract: The development of sophisticated neural prostheses, which interface directly with the sensorimotor cortex, hold the promise of restoring sensorimotor functions to patients with spinal cord injury or brainstem infarcts, who otherwise have limited options for recovery. Dexterous motor control in healthy individuals relies on intact somatosensory feedback, especially for the

execution of complex tasks. Intracortical microstimulation (ICMS) of the somatosensory cortex is being explored as a means to deliver such sensory feedback in bidirectional neuroprosthetics in hopes of augmenting performance. Animal studies have shown that signal stability of chronically implanted microelectrode arrays may degrade over time due to a multitude of factors. For ICMS to be viable as a feedback source, it must elicit stable sensory percepts in the face of such changes, since failure to do so may result in the need for regular remapping of pulse train parameters and percepts. Studies in nonhuman primates have demonstrated that ICMS thresholds can remain stable over 3 years. However, animal studies are limited in fully characterizing elicited sensory percepts in terms of their quality, location and extent.
In our study, a human participant with a cervical spinal cord injury was implanted with four microelectrode arrays, two in primary motor cortex and two in primary somatosensory cortex. Over the course of 4 years, regular assays were conducted with 100 Hz, 60 μA stimulus trains to characterize the quality, spatial extent, and location of the elicited sensory percepts.
The spatial locations sensory percepts remained stable for the vast majority of electrodes (5.9 ± 3.6 mm spatial drift), with the top 10% most mobile electrodes demonstrating only 13.0 ± 3.1 mm drift. Projected field sizes varied by 28 ± 14%. A small proportion (7/61) of electrodes produced two spatially distinct projected sensory fields over the course of the implant , but once identified, these too remained stable over time.
We demonstrate, in a long-term experiment in humans, that ICMS with microelectrode arrays can generate sensory percepts which remain stable in their size and location over 4 years. This suggests that, even with prolonged use, the electrodes remain functional, and that any movements of the electrode arrays within the cortex that might occur do not meaningfully change the location of the evoked percepts. These results suggest that ICMS could be used as a stable sensory channel in bidirectional brain-computer interfaces.

Title: Neural responses in human primary somatosensory cortex to vibrotactile stimulation suggest more overlap in afferent representations of individual digits than sensory perceptions elicited by ICMS

Authors: *T. M. THOMAS[1], M. S. FIFER[3], D. N. CANDREA[1], D. P. MCMULLEN[5], R. W. NICKL[2], M. C. THOMPSON[4], E. A. POHLMEYER[4], M. ANAYA[2], G. L. CANTARERO[2], W. S. ANDERSON[6], F. V. TENORE[4], B. A. WESTER[4], P. A. CELNIK[2,7], N. E. CRONE[7];

Abstract: Intracortical microstimulation (ICMS) is being increasingly studied as a means for restoring tactile perception to patients with spinal cord injuries (SCI). Studies in SCI patients have shown that ICMS in primary somatosensory cortex (S1) can elicit sensations in localized regions of the hand. While the goal of ICMS in SCI patients is to provide sensory feedback during upper-limb neuroprosthetic control using a brain machine interface, the extent to which ICMS can activate native representations of tactile information is still being investigated. In this study, we compared individual finger representations in S1 at the resolution of microelectrode arrays during vibrotactile stimulation of individual digits and during ICMS. A participant with incomplete quadriplegia was implanted with two microelectrode arrays (Neuroport Arrays, Blackrock Microsystems) in dominant S1 (left hemisphere) and one array in non-dominant S1 (right). To guide the placement of arrays, we used electrocorticography (ECoG; 3x21 high-density grid, 3 mm spacing) to record neural responses intra-operatively while vibrotactile stimulation (500 ms) was applied to individual fingertips. During post-recovery sessions, we recorded single and multi-unit activity from the arrays using this same vibrotactile stimuli. We also performed a survey of the sensations perceived while ICMS (100Hz, 60 μA) was applied to individual microelectrode contacts. Surprisingly, somatosensory perceptions elicited by ICMS at individual electrodes were localized to small areas on only one or two digits, even though the same electrodes recorded neural responses from vibrotactile stimulation of up to four digits. Neural responses recorded within each array, however, still presented a somatotopic gradient of the finger representations in agreement with ECoG recordings from the same areas. These findings suggest that somatosensory perceptions elicited by ICMS do not bear a one-to-one relationship to afferent representations of vibrotactile stimuli, and do not simply arise from activation of these representations. Instead, these perceptions may arise from additional processes that select from a subset of activated representations. Further investigation is needed to determine how ICMS-elicited perceptions compare to afferent representations of other sensory modalities, and whether alternate ICMS parameters can elicit perceptions more similar to these native representations. A better understanding of the neural mechanisms responsible for ICMS-elicited perceptions is needed to design effective strategies for providing tactile feedback for neuroprosthetic control.

Title: Dynamical coupling between primary somatosensory cortex and primary motor cortex during active grasping of a soft compliant object

Authors: *H. G. CU[1], W. TRUCCOLO[2], L. LYNCH[1], K. HUANG[1], D. BORTON[1], A. NURMIKKO[1];
[1]Biomed. Engin., [2]Neurosci., Brown Univ., Providence, RI

Abstract: We investigated the neural dynamics underlying the coupling between primary somatosensory (S1) and primary motor (M1) cortices in a non-human primate (Macaca mulatta) during a compliant object grasp discrimination task. Our motivation derives from current state-of-the-art intracortical brain-computer interface (BCI) systems which have allowed tetraplegic patients to control robotic arms and computer keyboards using neural signals from M1 or dorsal premotor cortex (PMd) (Hochberg et al. 2012; Ajiboye et al. 2017). These BCIs currently do not provide tactile sensory feedback as in a closed-loop system capable of sensory-motor integration (Bensmaia and Miller 2014; de Lafuente 2018). The animal was trained on a hand squeeze-and-hold task to actively grasp and maintain a grasping force on a soft rubber manipulandum within a fixed deformation range of the object based on the animal's sensory feedback. After training, we implanted two 96-channels IrOx microelectrode arrays in S1 and M1. For this initial study, we first decoded the softness of object from neural population data alone by calculating the relative similarity between spike trains (SSIMS) (Vargas-Irwin et al. 2015) and applying t-SNE visualization tools to reduce dimension. Then, we classified the different stiffness levels of the object using neural data from either S1 or M1, and from their joint activity. Second, to assess the information flow between these two areas, we applied a Variational Latent Gaussian Process (vLGP) algorithm (Zhao and Park 2017) to infer their low-dimensional dynamics and then computed conditional Granger causality measures, which assess the time causal interaction between these two areas low-dimensional dynamics in both time and frequency domains. We found that combined S1-M1 activity provided the best result in classification, which directly implicates the importance of S1-M1 co-activation in compliant object grasp discrimination. The low-dimensional representations from vLGP captured the overall population neural firing rate in each area and Granger causality indicated a bidirectional coupling between S1-M1. We are currently leveraging these preliminary results, especially the decoding sensory motor dynamics

during controlled grasp of a soft object, to develop new encoding experiments using intracortical patterned microstimulation toward the long term goal of BCIs that incorporate tactile sensory feedback.

Title: Task-specific training to promote earlier cortical reactivation and hand use recovery in monkeys after incomplete dorsal column spinal cord injury

Authors: *J. L. REED, H.-X. QI, J. H. KAAS;
Psychology, Vanderbilt Univ., Nashville, TN

Abstract: After nearly complete unilateral lesions of the dorsal columns (DC) in the cervical spinal cord of monkeys, the deprived hand is greatly impaired and the contralateral somatosensory cortex hand representation is deactivated. However, hand use and considerable reactivation of hand cortex recovers over 5-12 post-lesion weeks. Here, we compare the reactivation of hand cortex in area 3b, as measured with functional magnetic resonance imaging (fMRI), with the recovery of hand use in monkeys with and without task-specific behavioral training. We hypothesized that task-specific behavioral training promotes earlier hand use recovery and functional somatosensory cortex reactivation, detected at approximately the same time after injury. Nine adult male squirrel monkeys (*Saimiri boliviensis*, 4; *S. sciureus*, 5) were randomly assigned to a training or testing group. Monkeys received intensive training on a food pellet retrieval task, or were only tested weekly on the task. Lesions at C4-C6 disrupted some inputs from the digits and palm, while sparing some inputs from digit 1. Time course and extent of cortical reactivations in response to tactile stimulation on the digits were evaluated before DC lesion and 2-3 times post-lesion for 12 weeks with 9.4T fMRI in monkeys under isoflurane anesthesia. Final-stage somatotopic maps of reactivation were compared to patterns of fMRI activation in each monkey. After data collection, brains and spinal cords were processed, and the DC lesions were estimated to range from 60% to 95% complete. Analysts blinded to the conditions processed the fMRI and behavioral data. With generalized linear mixed modeling, we

found an interaction between the DC lesion extent, post-lesion time, and training group contributing to cortical activation, such that greater activation was estimated in the training group monkeys with minor (< 70% complete) lesions for all scan times as early as 2-4 weeks after injury compared to monkeys without training. By 5-6 weeks, greater activation was estimated in the training group across all lesion extents ($p < 0.0001$). Training alone was not a significant factor, while time and DC lesion alone and together tended to affect most measures of hand use and cortical activation. Differences in fMRI signals were modestly correlated with some, but not all, behavioral measures (e.g., grasp time, rho = 0.490, $p < 0.0001$; attempts per successful trial, rho = 0.111, $p = 0.261$). Overall, we found that task-specific training contributes to earlier cortical reactivation and hand use recovery when injuries are incomplete, but cannot overcome all impairments after nearly complete lesions.

Title: Morphometry, topology and structural plasticity in trigeminal nuclei of adult rats exposed to an enriched environment

Authors: *Y. MARTIN[1], C. AVENDANO[2], P. NEGREDO[2];
[1]Francisco De Vitoria Univ. CIF – G80480197, Pozuelo de Alarcon, Spain; [2]Univ. Autonoma de Madrid, Fac. Medicina, Madrid, Spain

Abstract: Brain is able to adapt structurally to changes in the environment even in adulthood. In recent years it has been shown that input- or experience-dependent plasticity is not an exclusive capability of the cerebral cortex, but also occurs at subcortical levels. The trigeminal system of rodents is an excellent substrate to study this type of plasticity. We investigated the morphometry and topology of the dendritic trees of two different populations of primary afferents-targeted trigeminal nuclei neurons, trigeminothalamic 'barrelette' neurons of the principal nucleus (Pr5) and trigeminal intersubnuclear neurons in the caudal division of the spinal trigeminal nucleus that project to the principal nucleus (Sp5c-Pr5). These neurons were retrogradely labeled with dextran amines from injections in the ventral posteromedial nucleus of the thalamus and Pr5, respectively, in controls and after exposing daily the rats to an environmental enrichment (EE) for two months. Fully labeled neurons were digitally reconstructed with Neurolucida and analyzed with NeuroExplorer. In controls, Pr5 neurons showed remarkable side asymmetries in

the number of low-grade trees and the total dendritic length (which was greater on the left side), as previously reported[1]. Sp5C-Pr5 neurons exhibited a more discrete degree of asymmetry mainly consisting of a larger number of spines and shorter distal segments on the right. Exposure to EE neutralized these lateral differences in both neuronal populations, and resulted in a substantial increase in the complexity of dendritic patterns in Pr5 and Sp5c-Pr5 neurons: greater dendritic branching, without total dendritic length increase in Pr5, and increased spatial expansion (as revealed by 3D Sholl analysis) and greater tortuosity of dendrites in Sp5c-Pr5. In the latter, the number of spines also increased, but this increase reached significance only on the left side. In addition, preliminary findings indicate that the changes observed in Pr5 neurons are only partially reversed by returning animals for an additional 2 months to standard housing after EE. These changes could reflect homeostatic processes directed at endowing the system with a convenient structural design that enables an optimal sensory processing when the conditions imposed create a new level of equilibrium.

Title: VIP neurons receive less ipsi- but more contralateral cortical long-range input in the absence of cortical layers

Authors: *G. HAFNER[1], J. GUY[1], M. WITTE[1], E. M. CALLAWAY[2], J. F. STAIGER[1];
[1]Inst. of Neuroanatomy, Goettingen, Germany; [2]Salk Inst., La Jolla, CA

Abstract: The inhibition exercised by GABAergic neurons is essential for controlling the activity levels of cortical networks. Vasoactive intestinal polypeptide (VIP) expressing inhibitory neurons have received attention as major integrators of long-range input. They exhibit a laminar bias towards the upper cortical layers. We wanted to investigate if their laminar arrangement is a prerequisite to establishing their long-range connectivity. In reeler mutant mice cortical neurons are misplaced and fail to form a laminar organization. We confirmed that VIP neurons lose their typical distribution and are instead equally distributed throughout the cortical thickness. Using rabies virus tracing, we assessed the long-range input sources of VIP neurons in barrel cortex of wildtype and reeler mice. VIP neurons received input from the same areas in both genotypes. The major input sources were other sensory cortices, motor cortex, posterior parietal association area, and the thalamus. The proportion of subcortical input was preserved in reeler, which indicates that the malpositioning of VIP cells does not hinder their capacity to receive long-range

input per se. However, VIP neurons in reeler mice received a much lower number of ipsilateral cortical inputs and a much higher number of contralateral cortical inputs. We hypothesize that the disorganized arrangement of neurons in reeler compromises the establishment of cell-type specific ipsilateral long-range projections and necessitates compensation by an excess of contralateral inputs. Based on our results we argue that in the absence of a laminar structure, VIP neurons are still maintaining their connectivity with subcortical structures while their cortical connectivity is fundamentally altered.

Title: Structural and functional seasonal plasticity in layer 4 of the adult somatosensory cortex

Authors: *S. RAY[1,2], **M. LI**[3], S. MUELLER[4], P. BOEHM-STURM[4], M. BRECHT[2], R. K. NAUMANN[3];
[1]Weizmann Inst. of Sci., Rehovot, Israel; [2]Humboldt University/BCCN, Berlin, Germany; [3]Chinese Acad. of Sciences, Shenzhen Inst. of Advanced Technol., Guangdong, China; [4]Charité Universitätsmedizin, Berlin, Germany

Abstract: Seasonal cycles govern life on earth, from setting the time for the mating season to influencing migrations and governing extraordinary physiological conditions like hibernation. Brain volume and cortical thickness which change over long time scales are among the most commonly used markers of human structural brain plasticity, but their effects on neuronal activity remain unknown. The study of functional neural plasticity has largely been performed in rodents and been limited to changes in synaptic connections or synaptic weights at very short time scales. Among mammals, shrews are known to show striking seasonal plasticity in skull and brain sizes and thus afford a unique opportunity to identify the functional changes in neuronal activity caused by long term structural brain plasticity. Here we show that the Etruscan shrew, the smallest terrestrial mammal, shows large, correlated seasonal variation in brain structure and function. We find reversible changes in the volume of the cortex, with the volume decreasing

from summer to winter and investigate changes related to the shrew's most important sense - touch - in greater detail. The somatosensory cortex undergoes a layer specific shrinkage during winter that is most pronounced in layer 4, which shrinks by ~30%. This decrease in thickness is linked to a similar reduction in the number of cells in layer 4 of somatosensory cortex. We perform functional two-photon imaging across multiple cortical layers, which revealed a lower number of neurons being suppressed on whisker stimulation during winter. This effect is most prominent in layer 4 of somatosensory cortex with less than half the neurons being suppressed on touch during winter compared to summer. The decrease in the neuronal suppression on touch in winter is accompanied by a reduction in the number of PV+ interneurons and WFA+ perineuronal nets that structure inhibition. The resulting inhibitory tone may adapt the balance for detecting sensory stimuli - and prey - during the cold season, enabling the shrew to be less particular in its choice of food. Informal observations from capture attempts suggest that shrew population density is low in winter and spring and higher in summer and fall, perhaps indicating an annual variation in resource availability and survival. Varying the food resources in the laboratory, also leads to a selective shrinking of the cerebral cortex. Taken together, our findings suggest that Etruscan shrews sacrifice early sensory cortical processing and inhibitory sensory gating in order to survive winter.

Title: The organization of somatosensory cortex in prairie voles (Microtus ochrogaster): Do parental rearing styles impact the functional organization of somatosensory cortex?

Authors: C. R. PINEDA[1,2], M. K. L. BALDWIN[2], ***L. A. KRUBITZER**[1,2];
[1]Psychology, [2]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

Abstract: Early life experience can have a dramatic effect on the functional and architectonic organization of the neocortex. The effects of early sensory input on brain development has been demonstrated by our laboratory in multiple animal models using loss of visual inputs via bilateral enucleation, and differential rearing conditions. We continue to explore how early life experience alters the functional organization of cortical fields in the prairie vole (*Microtus ochrogaster*), taking advantage of their monogamy, biparental nature and their natural variation in rearing

style. Parent-pup interactions include huddling, licking and nuzzling involving prolonged perioral contact. Therefore, we can examine the functional organization of somatosensory cortex in offspring that were exposed to extremes in their tactile interactions with their parents. In several related studies these offspring have been termed high (HC) and low contact (LC). These different parental rearing styles result in behavioral differences in the offspring, independent of genetic inheritance, as shown by cross-fostering studies. Our laboratory has demonstrated that HC and LC offspring have differences in the cortical connections of the perioral representation in the primary somatosensory cortex (S1). Additionally, HC and LC offspring have differences in the relative size of the primary sensory areas in the neocortex. In the current investigation we examine the effect of natural variations in early sensory input delivered to the offspring through their parents (HC vs. LC) on the functional organization of S1. We use previously demonstrated behavioral quantification techniques to produce low contact and high contact prairie voles. Once these animals reach adulthood, we use multiunit electrophysiological recording techniques to characterize the topographical map of S1, with an emphasis on the representations of ethologically important anatomical structures, such as the snout and vibrissae. These data contribute to a growing literature on the mechanisms of intergenerational transmission of behavioral adaptations, independent of genetic inheritance.

Title: Rewarded sensory experience persistently increases excitatory connectivity in superficial layers of somatosensory cortex

Authors: *S. E. MYAL, A. L. BARTH;
Dept. of Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Pyramidal neurons in Layer 2 (L2 Pyr neurons) are well-suited to integrate task-relevant sensory information, as they integrate input from within and outside the cortical column and their connectivity can reflect co-active, feature-specific neural ensembles that can change with imbalanced sensory input. We sought to test whether naturalistic sensory stimulation could induce changes in L2 Pyr-to-Pyr connectivity, and whether these changes could be enhanced

with sensory-reward association training. To compare the effects of uncoupled versus reward-associated sensory stimulation, we used an automated home-cage training system in which mice (C57BL/6, 19-28 days old) nosepoke to receive a water reward accompanied by a gentle air puff onto the right whisker pad. Mice were not water deprived and all trials were self-initiated. After 24 hours of reward-uncoupled whisker stimulation, paired whole-cell recordings of L2 Pyr neurons from contralateral S1 barrel cortex were done to assess changes in synapse function. We found that 24-hour stimulation doubled connectivity rates and increased the number of bidirectional synapses between L2 Pyr neurons. Amplitude, failure rate and paired-pulse ratio were unchanged from baseline, suggesting new synaptic connections were not detected because of enhanced presynaptic release. However, the increase in L2 Pyr connectivity was transient and normalized after 5-day stimulation. We next assessed the effects of sensory-reward association training (SAT, in which whisker stimulation is coupled to water reward). SAT for 24 hours also doubled L2 Pyr connectivity and did not alter presynaptic release properties. In contrast to reward-uncoupled whisker stimulation, Pyr connectivity remained high after 5-day SAT. Thus, we find that L2 Pyr connectivity in S1 can be rapidly altered by naturalistic sensory stimuli, and that L2 circuits differentiate between reward-coupled and reward-neutral sensory inputs. These results challenge the notion that long-lasting, context-dependent plasticity is restricted to higher-order sensory cortical areas and suggest that task-relevant, rewarded sensory information activates distinct cellular and molecular pathways that regulate the persistence of cortical neural ensembles.

Title: Trunk cortex is a sensorimotor amalgam

Authors: ***F. P. PAUZIN**[1], B. NANDAKUMAR[2], G. H. BLUMENTHAL[1], K. A. MOXON[1]; [1]UC Davis, Davis, CA; [2]Univ. Of California Davis, Davis, CA

Abstract: Sensorimotor integration is crucial for perception and volitional movement. Understanding the substrates of sensorimotor integration is important for studies examining learning and recovery after neurological injury or disease, yet little is known about the details of the trunk sensorimotor system. To investigate trunk cortex sensorimotor integration, we used the rat sensorimotor trunk regions of the cortex to address four main goals. First, to identify the

extend of reorganization within trunk cortex, single neuron sensory mapping was used. Second, to similarly identify the extent and internal organization of the trunk motor cortex, intracortical microsimulation (ICMS) was used. Third, to assess sensorimotor integration, sensory evoked potentials were compared across a broad region of sensorimotor cortex. The electrophysiological assessment of the trunk sensorimotor system revealed a surprising amount of somatotopy within the trunk sensory and motor cortices with integration between them. Fourth, high intensity sensory stimuli, which likely activates both proprioceptive and noxious pathways, is highly integrated between hindlimb and trunk sensorimotor cortices but not forelimb. Interestingly, this high intensity stimulation of the hindlimb leads to a stronger response in trunk primary motor cortex (M1-trunk) than the same intensity of stimulation to the trunk itself.
To determine if this cross modality activation to M1-trunk is due to outnumbering projections from primary somatosensory hindlimb cortex (S1-hindlimb) compared to S1-trunk, fluorescent latex microspheres were used as a retrograde neuronal tracer and injected into M1-trunk as determined by the ICMS motor mapping. Interestingly, an equal number of cells from S1-hindlimb and S1-trunk projected to M1-trunk, confirming that M1 trunk is a crossroad in sensorimotor integration. Most of the projecting sensory neurons were found in layer 5 and layer 2/3 of both sensory cortices. However, many cells projecting to M1-trunk were of thalamic origin suggesting that the cross modality activation may have a thalamic provenance. This thalamic projection may be the source of stronger HL activation of M1-trunk compared to trunk activation of M1-trunk. Alternatively, the stronger response in M1-trunk from HL sensory stimulation may be due to a difference in the cortico-cortical projection's strength (analyses are still in preparation). These data fill a gap in our understanding of trunk motor cortex and make clear that its organization supports its functional role.

Title: Responses of neurons in spinal trigeminal nucleus interpolaris (SpVi) to stimulation of the whiskers in different directions and at different speeds

Authors: *T. J. ALSTON[1], C. S. BREESE[2,1], K. J. KLECZKA[1], A. RESULAJ[1], M. J. Z. HARTMANN[1];

Abstract: An important open question in the study of somatosensation is how animals integrate signals from an array of spatially distributed tactile sensors. The present study seeks to address how spatial information is integrated across sensors at the earliest stage of the somatosensory system, using the rat whisker (vibrissal) array as a model. Rats have approximately 30 whiskers on each side of their face arranged in an orderly array of rows and columns. The base of each whisker is embedded within a follicle filled with mechanoreceptors that send signals to primary sensory neurons in the trigeminal ganglion. From there, information is sent to several nuclei in the trigeminal brainstem, including spinal trigeminal nucleus interpolaris (SpVi). Neurons in SpVi have been shown to integrate inputs from multiple whiskers(Furuta 2010). One recent study suggested that SpVi may encode information about the speed and direction of a stimulus moving through the whisker array (Kaloti 2016). However, hardware constraints limited whisker stimulation to the rostral-caudal direction. The present experiments use a novel multi-direction stimulation device to further test the hypothesis that neurons in SpVi encode information about both stimulus direction and speed. We designed and built a stimulator that can mechanically stimulate whiskers in any direction and with a range of speeds mimicking natural tactile interactions. Importantly, we show that the stimulator can also detect whisker contacts as it passes through the array. Using this novel stimulation technique, we performed recordings from a set of SpVi neurons in anesthetized rats. Preliminary data reveal clear differences in spike rates associated with different stimulation speeds and directions, showing tuning of these recorded neurons to object orientation and passing speed through the array. We expect these results to improve our understanding of how spatial information is processed and encoded in more central structures of the somatosensory pathway.

Title: Automated markerless tracking of the vibrissal array and 3D head pose of rodents during a search task

Authors: *K. J. KLECZKA[1,2], A. RESULAJ[3], M. J. Z. HARTMANN[1,2];
[1]Mechanical Engin., [2]Biomed. Engin., [3]Interdepartmental Neurosci. Program, Northwestern Univ., Evanston, IL

Abstract: The rodent vibrissal (whisker) system is a commonly used model in sensorimotor studies, but our ability to fully characterize the way in which rats and mice use their whiskers during natural behaviors is limited. Manual tracking of video data is time consuming, and automated tracking often requires invasive markers to be placed on the animal, or requires the motion or behavior of the animal to be artificially restricted. Using a combination of publicly available tools and custom written code, we developed a method to extract 3D head pose and position of rats and mice, as well as average vibrissal array protraction angle and spread, while animals performed a search task. Three high speed cameras recorded a perched animal searching for a reward in 3D space. A multi-camera calibration was performed, and DeepLabCut (Mathis et al. 2018) was used to track key points on the head and whisker arrays for each camera view to create a 3D representation of the head and whisker arrays. These data can then be compared with a simulated rat head and whisker array to determine the most likely array configuration. The results of the automated tracking were comparable to a small subset of manually tracked video.

Title: Evidence for visual representation of numerosity in natural scenes

Authors: *M. MELL[1], G. ST-YVES[1], E. J. ALLEN[2], Y. WU[3], K. N. KAY[4], T. NASELARIS[1]; [1]Neurosciences, Med. Univ. of South Carolina, Charleston, SC; [2]Psychology, [4]Radiology, [3]Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: In visual cortex of human and non-human primates, high-level visual areas near intraparietal sulcus have been shown to explicitly encode the number of objects in visual displays. To date, evidence for this numerosity code has come from experiments that use simple dot-like visual stimuli, raising the question of whether the numerosity code persists during perception of natural scenes. Here, we assessed evidence for a numerosity code in high-resolution fMRI measurements of responses to thousands of natural scenes in 8 human subjects. To test for numerosity coding we constructed an encoding model that predicted voxelwise

responses as a function of local object counts in each natural scene. We found that a model based upon local object counts was able to accurately predict voxelwise activity in visual cortex. To test if local object counts were acting as a proxy for simple low-level image features, we constructed voxelwise encoding models based on Gabor wavelet filtering of the natural scenes. For voxels in anterior visual cortex, the numerosity encoding model generated more accurate predictions than the Gabor model, indicating that the numerosity code is computationally distinct from low-level visual features. Our results offer evidence for a numerosity code in anterior visual cortex during natural scene stimulation, and suggest that numerosity may be a key higher-order feature that is extracted by the brain during perception of natural scenes. Recent studies have suggested deep convolutional neural networks trained for object classification may include numerosity as an emergent property; further analyses of our data will be directed towards assessing to what extent the computation of numerosity in these networks is similar to that used by the brain.

Title: The natural scenes dataset: Massive, high-quality whole-brain 7T fMRI measurements during visual perception and memory

Authors: *E. J. ALLEN[1], Y. WU[1], J. HUTCHINSON[2], T. NASELARIS[3], K. N. KAY[4]; [1]Univ. of Minnesota, Minneapolis, MN; [2]Dept. of Psychology, Univ. of Oregon, Eugene, OR; [3]Neurosciences, Med. Univ. of South Carolina, Charleston, SC; [4]Radiology, Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: In order to improve models of visual information processing, high-quality datasets are critical. We are conducting a large-scale ultra-high-field fMRI experiment (7T, whole-brain, T2*-weighted gradient-echo EPI, 1.8-mm resolution, 1.6-s TR) in which 8 exemplary human

participants view many thousands of color natural scenes over the course of 40 scan sessions over the span of a year. As subjects fixate a central point, they perform a long-term continuous recognition task in which they judge whether they have seen each image at any time during the experiment, either in the current scan session or any previous scan session. Initial analyses indicate that the data are of exceptional quality, with subjects having nearly perfect response rates, high task performance, low head motion, and spatially stable brain imaging across scan sessions. Further, across repeated trials of the same image, brain activity patterns are highly replicable. High-quality anatomical data including multiple T1s, T2s, diffusion imaging, angiograms, and venograms have also been acquired. Both raw and pre-processed data will be made freely available to the scientific community, and could be used to develop and benchmark computational models as well as help answer a multitude of neuroscientific questions.

Title: Natural scene statistics of depth and motion pertinent to figure-ground segregation

Authors: X. HUANG[1], C. WANG[1], B. ARSENEAU[1], T. E. YERXA[2], *E. A. COOPER[3]; [1]Dept. of Neuroscience, Sch. of Med. and Publ. Hlth., Univ. of Wisconsin – Madison, Madison, WI; [2]Sch. of Optometry, [3]Sch. of Optometry & Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA

Abstract: Segmenting objects from visual scenes, known as figure-ground segregation, is a fundamental function of vision. To examine the neural computations underlying figure-ground segregation, we previously investigated how neurons in the middle-temporal (MT) cortex of macaque monkeys—a cortical area important for motion and depth processing—segregate overlapping visual stimuli. Based on this work, we hypothesized that the properties of MT neurons in response to the binocular disparities and retinal motion of multiple stimuli might reflect a strategy to achieve figure-ground segregation that exploits statistical regularities in these cues during natural vision. To test this hypothesis, it is important to understand the properties of figure and ground during natural vision within spatial regions comparable to the receptive fields (RFs) of cortical neurons. Here, we present the results of a simulation aimed to address this question for foveal and parafoveal MT. First, natural scenes were drawn from an existing dataset

containing both luminance images and high-precision depth measurements (Burge, McCann & Geisler 2016). To label figure and ground regions, human subjects were instructed to identify and trace the boundaries of salient objects in the scenes when they viewed only the luminance images. Next, we placed a simulated observer in each 3D scene. We selected binocular fixation points at random as well as the speed and direction of observer motion, assuming the observer maintains fixation while moving. We then selected a set of random locations for simulated MT RFs (diameter equal to eccentricity) and calculated the distances, binocular disparities, and speeds of points falling within each RF. We found that the average distribution of distances within RFs was bimodal with peaks at near and far depth planes, suggesting that it is common to have multiple surfaces at different depths present within individual neurons' RFs during natural vision. Zeroing in on the RFs falling at the border between figure and ground regions, we found that figure regions tended to be associated with nearer binocular disparities, both in the absolute sense, and relative to the ground regions. Figure and ground regions also tended to differ in speed generated by self-motion, but not as systematically as disparity. However, when isolated objects move in the world, the figure-ground speed difference is likely to be greater. Our results reveal statistical patterns of figure versus ground regions in natural vision, which will guide future studies to determine whether neurons in primate visual cortex exploit these patterns to aid in the segmentation of objects in cluttered natural environments.

Title: Neural representation of obstacles in a scene

Authors: *Y. LEE, S. PARK;
Dept. of Psychology, Yonsei Univ., Seoul, Korea, Republic of

Abstract: Among many interactions we have with objects in the visual world, perceiving and avoiding obstacle objects on our pathway is crucial. What makes an obstacle? An obstacle perception comes from representing spatial relationship of two essential local elements in a scene—an object and a visual path. If a non-portable object (e.g., large furniture) lies in the

middle of the path, it serves as an obstacle, as compared to when it lies clearly out of the path. Previous research using human fMRI has reported that the Parahippocampal Place Area (PPA) is sensitive to subtle changes in the spatial relationship of local elements, while the Occipital Place Area (OPA) is insensitive to such changes and rather represents the number of local elements. Here, we test whether the PPA shows sensitivity to the presence of an obstacle in a scene. Four types of scenes were tested: object only (a large, less portable object in a blank background), path only (a scene with an empty path), object-out-path (a scene with an object located outside of the path), object-in-path (a scene with an object inside the path). Even though the number of local elements are equal between object-out-path and object-in-path conditions, only the latter contains an obstacle. In an event-related design, participants (N = 8) viewed these scenes while performing a color dot matching task on two dots laid over scenes. Using a Representational Similarity Analysis (RSA), we constructed two simple model RDMs: 1) obstacle model (object-in-path vs. others); 2) number of local elements model (one local element (object only; path only) vs. two local elements (object-out-path; object-in-path)). The RSA revealed a significant correlation (Kendall's tau-a) between the neural RDMs for the PPA and the obstacle model, but not local elements model. On the contrary, the neural RDMs for the OPA showed high correlation with both models. These preliminary results indicate that the PPA is sensitive to presence of an obstacle in a scene, created by a meaningful object-path relationship. This suggest that the PPA may play a role in representing the navigational affordance of a scene based on the relationship between object and spatial boundary elements of a scene.

Abstract: Building accurate predictive models of neural activity is a central goal of visual neuroscience. However, creating such models is exceedingly difficult due to the large potential space of inputs and the nonlinear response properties of neurons. In optical physiology, the recorded responses are also often exceptionally sparse, with an average event rate of ~0.2 Hz. To

overcome these obstacles, we seek to observe responses to an extremely large stimulus set dense in natural features and use this data to fit a variety of predictive models. We use optical physiology to record from the visual cortex of mice, aggregating data by matching cells over up to nine recording sessions. Each recording session contains 50 minutes of "training" stimuli consisting of previously unseen natural movie clips, each between 1 and 10 seconds in length, randomly sampled from a variety of sources. Each recording session also contains ~20 minutes of "validation" stimuli. The "validation" stimuli are the same in each recording session and consistent of a fixed sequence repeated 20 times. We fit a variety of models to the "training" data for each neuron, including linear, quadratic, sparse wavelet and convolutional neural network models. Importantly, each of these models is designed to capture the full spatio-temporal receptive field of each neuron, rather than just their spatial tuning properties. We find that of the models, the convolutional neural network model exhibits the best generalization performance. Furthermore, we find that generalization performance is greatly dependent upon the amount of training data available for each neuron. Finally, we use the trained convolutional neural network models to provide visualizations of neural tuning properties throughout mouse visual cortex.

Title: Sulcal depth is a marker for the development and evolution of scene selectivity in high-level visual cortex

Authors: *K. S. WEINER[1], V. S. NATU[2], M. J. ARCARO[3], M. A. BARNETT[4], J. GOMEZ[1], M. S. LIVINGSTONE[3], K. GRILL-SPECTOR[5];

Abstract: Sulcal pits (SPs) are the deepest points along sulci and are genetically and behaviorally relevant. However, the relationship between functional regions and SPs across human development and evolution remains untested. Here, we fill this gap in knowledge by investigating this relationship in a target region that (a) shows selective neural responses for visual presentations of places and scenes and (b) is located deep within sulci in both macaque and human ventral temporal cortex (VTC). Using functional and structural MRI, we identified place-selective regions and sulcal depth maps in 9 macaques, 26 children (5-12 years old, yo), and 28 adults (22-28 yo). Across ages and primate species, we evaluated (a) the anatomical-functional correspondence between place-selectivity and sulcal depth and (b) if cortical surface properties show developmental or evolutionary variations. Our analyses revealed six main findings. First, the topological location of the SPs along the length of the relevant sulcus overlaps with the functional place-selective region, in each species. Second, the place-selective SPs in VTC are ~2.8 times deeper in humans compared to macaques (main effect of species in a 2-way Analysis of variance (ANOVA) with factors species (human/macaque) and hemisphere (left/right): $F_{1,122}$=531.65, p<0.001). Third, place-selective SPs are ~1.1 times deeper in adults than children (main effect of age in a 2-way ANOVA with factors age of subject (child/adult) and hemisphere (left/right): $F_{1,104}$=15.59, p<0.001). Fourth, calculating the correlation between place-selectivity and sulcal depth revealed a significant positive correlation across age groups and species (adults(R±sem):.52±.07; children: 38±.07; macaques: .40±.1). Fifth, this correlation was stronger for human adults than children ($F_{1,104}$=5.12, p<0.05). Sixth, a model of sulcal deepening indicates that differential local properties that are intrinsic to the cortical surface may explain the morphological changes observed in place-selective sulci across species. Together, these findings support a novel hypothesis that the deepening of SPs is an anatomical feature that may reflect the development and evolution of scene-selectivity in high-level visual cortex.

Title: Expanding visual feature spaces towards a general encoding model of scene perception

Authors: A. Y. WANG[1], M. J. TARR[2], L. WEHBE[3];
[1]Ctr. for Neural Basis of Cognition; Machine Learning Dept., [2]Dept. of Psychology, [3]Machine Learning Dept., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Encoding models are widely used in understanding feedforward information processing in human perception. These models have achieved some success in predicting lower-level visual cortex responses in humans and primates using features that were learned via a convolution neural network trained on object recognition. However, higher-level neural responses for scene processing have, as of yet, not been well accounted for by such models. More generally, it is unknown what higher-order features are fundamental for scene perception. In order to exploit the power provided by encoding models to explain basis of scene perception, we created feature spaces that comprehensively captures the kinds of information used in biological scene processing. Feature spaces included activations from pretrained convolutional neural networks, latent feature spaces that are shared by 20 different low and mid level computer vision tasks, such as surface normals and 3d euclidean distances, as well as scene semantics and contextual properties of scenes that are extracted using techniques from language models. BOLD5000, a large-scale fMRI dataset using 5000 images was used to explore the efficacy of these features. During the experiment, four subjects are presented with scene images from standard computer vision datasets (ImageNet, COCO, and SUN) and asked to give a valence judgement. Consistent with previous results, features extracted from convolutional neural network activations of the images explained significant variance of brain responses. Activations from late convolutional layers predicted more anterior parts of the brain including scene regions (PPA, OPA, RSC, etc), while activations from earlier layers predicted early visual cortex. Our results further showed that the computer vision task on which the features are based is critical for predicting brain responses. Features from 3D tasks such as 3D keypoints and 3D edges explained higher variance of the data compared to 2D ones in both regions of interest and voxels from the whole brain. Semantic features of images that are extracted from embedding models of text corpus and image corpus also predicted posterior parts of the cortex. Modern computer vision algorithms thus provide a rich set of tools to represent different types of visual information and enable us to build increasingly general models of scene perception.

Title: How we recognize patterns on crumpled surfaces

Authors: P. GANGOPADHYAY, *S. P. ARUN;
Ctr. for Neurosci., Indian Inst. of Sci., Bangalore, India

Abstract: When we see a crumpled dress with polka dots, we easily infer that the dots are circular. But whether our visual system automatically recovers patterns from crumpled surfaces is unknown. To investigate this possibility, we created stimuli in which patterns are superimposed on surfaces. Critically, the pattern could be either flat or crumpled independently of the surface being flat or crumpled. We hypothesized that the perceived dissimilarity between congruent stimuli (in which both pattern and surface undergo identical distortions) would be smaller than for incongruent stimuli (in which the pattern and surface undergo opposite distortions). Thus, a straight line on a flat surface would appear similar to a bent line on a bent surface. To measure perceived dissimilarity we asked subjects to search for an oddball target among distractors.

We performed three experiments on human subjects to test this hypothesis. In Experiment 1, we sought to characterize how pattern and surface shape combine in perception. To this end, we asked subjects to search for targets that differed from its distractors either by a pattern change, surface change or both. This revealed that the net dissimilarity between two such stimuli was a linear sum of the dissimilarity due to pattern change and due to surface change. However we did not detect any difference between congruent and incongruent pairs.

In Experiment 2, subjects were asked to search for a target among multiple identical distractors, and we asked whether search was easier with congruent or incongruent distractors. This revealed a systematic difference: searching for congruent distractors was significantly faster, suggesting that the two distractors were more similar, confirming our hypothesis. However, this result was based on testing simple patterns (E, H, Y etc) superimposed on simple surface changes related through bending or rotation. In Experiments 3 & 4, we tested the generality of these results. In Experiment 3, we tested simple patterns on complex surfaces such as bumps, saddles, ripples and arbitrary crumpling. In Experiment 4, we tested complex patterns such as object silhouettes on complex surfaces. Across all experiments, congruent stimuli were found to be more similar than incongruent stimuli.

Taken together, our results demonstrate a novel form of invariance in our perception that allows us to recognize patterns on crumpled surfaces.

Title: Real-world physical distance drives human fMRI activation throughout the visual hierarchy

Authors: *M. MALTSEVA[1], D. J. QUINLAN[2], K. M. STUBBS[3], T. A. KONKLE[4], J. C. CULHAM[1];
[1]Dept. of Psychology, [2]Psychology, Huron Col., [3]Western Univ., London, ON, Canada; [4]Psychology Dept, Harvard Univ., Cambridge, MA

Abstract: The brain transforms 2D retinal information into estimates of physical size and distance based on pictorial and binocular cues. Many studies on these factors have relied on images where they must be inferred and have studied factors in isolation. We investigated how brain activation levels (and patterns) in ventral- and dorsal-stream regions depend upon multiple factors that naturally co-occur: retinal size, physical size, familiar size, and distance. Rubik's cubes and dice at their typical sizes (5.7 cm and 1.6 cm) and each other's typical sizes were presented during functional magnetic resonance imaging (fMRI) at two distances (25 cm, within reach, vs 91 cm, out of reach). Objects subtended three retinal angles (in degrees): 1.3 for small, far objects; 15.9 for large, near objects; and 4.7 for both small, near and large, far objects. As predicted, univariate contrasts revealed that the dorsal-stream regions - left superior parietal occipital cortex (SPOC) and bilateral anterior intraparietal sulci (aIPS) - activated more for objects in near (vs. far) space, even when retinal angles were matched, and for physically large (vs. small) objects in near space. Higher-order perceptual visual areas - lateral occipital complex (LOC) and the parahippocampal place area (PPA) - distinguished between object identities, showing higher activation for the Rubik's cube (vs. die), consistent with behavioral data showing that even for size- and distance-matched stimuli, the Rubik's cube is perceived as larger (vs. die). Activation in bilateral V1 and PPA increased with retinal size, confirming predicted retinal size coding. Surprisingly, multivariate pattern analysis (MVPA) revealed that, even when the retinal angles are matched, the physical distance of real objects is coded throughout the hierarchy of visual system in both visual streams. Taken together, these results show that real-world distance is a powerful factor that affects activation throughout the visual hierarchy. Although physical distance has been a previously neglected factor in neuroimaging studies of vision, it appears to be a very important one. Distance may be so important because it is essential for determining an object's physical size for both action and recognition and for drawing attention to behaviorally relevant objects in peripersonal space.

Title: Heterogeneous responses to 3D surface pose in macaque CIP

Authors: *R. DOUDLAH[1], T.-Y. CHANG[1], B. KIM[1], A. SUNKARA[2], A. ROSENBERG[1]; [1]Univ. of Wisconsin-Madison, Madison, WI; [2]Dept. of Surgery, Stanford Univ. Sch. of Med., Stanford, CA

Abstract: A robust three-dimensional (3D) representation of our surroundings, including the pose (orientation and position) of objects, is required to successfully interact with the environment. An unambiguous representation of 3D object pose implies that the shape of 3D orientation tuning curves will be tolerant to the distance at which they are measured. Where and how the visual system achieves a robust 3D visual representation is unclear. Here we evaluate the distance tolerance of 3D orientation tuning in the macaque caudal intraparietal (CIP) area while the monkeys performed an 8-alternative forced choice tilt discrimination task. Planar surfaces were presented at all combinations of tilt (0° to 315° in 45° steps), slant (0° to 60° in 15° steps), and distance (37, 57, 97, and 137 cm). Stimuli were 20° in diameter, defined by random dots (N = 250 dots) with perspective and stereoscopic cues, and presented directly in front of the monkey. We quantified orientation-dependent response modulation at each distance using one-way ANOVAs. Most CIP neurons had significant response modulation at one or more distance (95.3%, 342/359), and 37.3% (134/359) had significant modulation at all four distances, indicating that individual neurons often responded over a broad range of distances. The observed response modulation could reflect selectivity for 3D object pose or local absolute binocular disparities. To dissociate these possibilities, we assessed how much the shape of the orientation tuning curves depended on distance. We defined a distance-orientation tuning invariance (DOTI) index as the mean pairwise correlation between tuning curves measured at different distances with significant modulation. Neurons with disparity selectivity would have low DOTI values, whereas neurons with 3D pose selectivity would have DOTI values closer to 1. A wide range of DOTI values were found (mean = 0.40, SD = 0.28), indicating a continuum of representations ranging from absolute disparity to 3D pose selectivity. High DOTI values were not due to a lack of disparity sensitivity, and therefore indicated tuning for relative disparity gradients. We additionally tested if there is a relationship between CIP activity and the precision of 3D perception by measuring the Fisher Information (FI) carried by each neuron for planar tilt. Across sixteen combinations of slant and distance, the average FI was highly predictive of behavioral sensitivity (Spearman r = 0.96). Together, these results suggest that a more robust 3D visual representation is found in CIP than areas lower in the visual hierarchy, and that the sensitivity of CIP neurons may limit the precision of 3D visual perception.

Title: Clustered micro-organization of direction-selective cells in the primary visual cortex of common marmosets

Authors: H.-H. ZENG[1], ***Z.-M. SHEN**[1], M.-M. POO[2];
[1]Inst. of Neuroscience, SIBS, CAS, Shanghai, China; [2]Inst. of Neuroscience, SIBS, CAS, Shanghai City, China

Abstract: Direction-selective cells have been found in the primary visual cortex (V1) of many species. In cats and ferrets, cells with similar preferred directions are spatially clustered. However, in primates, there have been no convincing evidence for columnar organization of directional selectivity. Here, we simultaneously recorded the activity of large neuronal populations of V1 neurons using *in vivo* two-photon calcium imaging and examined the spatial organization of direction-selective cells in marmoset V1. We found that approximately 1/3 of the neurons are direction-selective, and neurons with similar directional preference are highly clustered in both horizontal and vertical directions. Thus, marmoset V1 direction-selective neurons are distributed in a columnar manner. Such micro-architecture is likely to be important for the organization of direction detection of visual signals in the primate brain.

Title: Heterogeneous responses to 3D surface pose in macaque V3A

Authors: *T.-Y. CHANG[1], R. DOUDLAH[1], B. KIM[1], A. SUNKARA[2], A. ROSENBERG[1]; [1]Univ. of Wisconsin-Madison, Madison, WI; [2]Dept. of Surgery, Stanford Univ. Sch. of Med., Stanford, CA

Abstract: An unambiguous representation of three-dimensional (3D) object pose (orientation and position) is critical for successful interactions with the environment. The neural circuits that create robust 3D visual representations remain unclear. Here we characterized the responses of macaque V3A neurons to 3D surface pose during an 8-alternative forced choice tilt discrimination task. All combinations of tilt (0° to 315° in 45° steps), slant (0° to 60° in 15° steps), and distance (37, 57, 97, and 137 cm) were presented. The stimuli subtended 20° of visual angle, were presented directly in front of the monkey, and were defined by random dot stereograms (N = 250 dots) with perspective and stereoscopic cues. Orientation-dependent response modulation was assessed at each distance using one-way ANOVAs. Most neurons showed significant response modulation at one or more distances (83.5%; 294/352), and 23.3% (82/352) showed significant modulation at all tested distances. Orientation-dependent response modulation could reflect selectivity for 3D pose or local absolute binocular disparities. To dissociate these possibilities, we evaluated if the shape of the orientation tuning curves depended on distance. A distance-orientation tuning invariance (DOTI) index was defined as the mean pairwise correlation between orientation tuning curves with significant modulation at different distances. DOTI values near 1 indicate that the orientating tuning curve shape was invariant to distance (pose tuned). Low DOTI values indicate that the orientation tuning was intolerant to distance (disparity selective). The average DOTI was low (mean = 0.3), indicating that most V3A neurons were not 3D pose tuned. However, the variability in DOTI values was large (SD = 0.31) and some values approached 1, indicating that the orientation tuning of many neurons showed some distance tolerance. This heterogeneity in 3D surface pose responses across neurons suggests a continuum of absolute disparity to 3D pose selectivity. High DOTI values were not due to a lack of disparity sensitivity, indicating that greater pose selectivity reflected tuning for relative disparity gradients. To additionally test for a relationship between V3A activity and 3D perceptual sensitivity, we measured the Fisher Information (FI) carried by each neuron for planar tilt as a function of slant and distance. The average FI of the V3A population was highly predictive of behavioral sensitivity (Spearman r = 0.95). Together, these results suggest that V3A is an intermediate stage in the 2D-to-3D visual transformation, and that the sensitivity of V3A neurons may limit the precision of 3D visual perception.

Title: Transformations of object representations across the human visual processing hierarchy

Authors: *V. MOCZ[1], M. VAZIRI PASHKAM[2], M. M. CHUN[1], Y. XU[1];
[1]Psychology, Yale Univ., New Haven, CT; [2]Lab. of Brain and Cognition, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Previous work has shown that we can derive transformation functions within lateral occipital cortex (LOC) for affine size and viewpoint changes of objects that may generalize across object categories (Ward et al., 2018, *Journal of Neuroscience*). Additionally, we can derive transformation functions between different brain regions across the visual hierarchy for the spatial response profiles of objects in perception and memory (Favila et al., 2018, *Society for Neuroscience Conference*). In the current study, we explore transformations of object representation, rather than spatial representation, between brain regions. We also explore affine transformations within regions along the ventral and parietal areas of the human visual hierarchy. We used an existing fMRI data set consisting of multiple experiments of human participants (n=6-7 each) performing a 1-back task on images of 10 exemplars of 8 categories (Vaziri-Pashkam and Xu, 2018, *Cerebral Cortex*). We analyzed two experiments, where in one, images were shown in two different sizes, and in the other, images were shown either unaltered or equalized in contrast, luminance, and spatial frequency across all categories. We used linear transformation analysis methods across brain regions of interests (ROIs) along the human visual hierarchy. We then derived transformation functions within an object category that link the pattern of activity between two ROIs and those that link the pattern of activity between two formats of the same category within the same ROI. When mapping from one ROI to another, transformations derived from one object category could significantly predict the representation for new instances of the same object category and all other object categories between V1 and ventral occipitotemporal cortex (VOT), between V1 and superior intra-parietal sulcus (IPS), and between VOT and superior IPS. When linking the affine image transformation of an object category within an ROI, transformations derived from one object category could predict the representation for new instances of the same object category, but this did not generalize to all other object categories. This holds for all the ROIs examined, including V1-V4, VOT, lateral occipitotemporal cortex, and superior IPS. These results suggest that while we may derive category-independent transformations between ROIs across the visual hierarchy, we may only

derive largely category-dependent transformations within an ROI for the two affine image transformations tested here.
