Abstract: When using vision to explore the world, a visual scene needs to be segregated into behaviourally relevant blocks: objects. The process of object segregation, despite its complexity, can be performed in a fraction of a second and is seemingly effortless. Previous studies have indicated that neurons in primary visual cortex (V1) show more activity when elicited by figures compared to when elicited by a background. This difference is referred to as figure-ground modulation (FGM). The latency of this modulation suggests that it may be the result of interactions between V1 and higher visual areas. However, recent studies suggest that V1 also influences pop-out effects in superior colliculus, and that superior colliculus can modulate V1 activity via an indirect pathway.
Here, we used multichannel electrophysiological recordings of awake behaving mice to investigate the role of superior colliculus in object segregation. Male C57BL/6J mice were trained to perform a two-alternative forced choice task. In the task, a mouse was shown a figure stimulus embedded in a background that had a different orientation or phase. The mouse would indicate the position of the figure by licking the corresponding side of a lick spout. After training, we recorded electrophysiological signals from superior colliculus during task performance using 16-channel laminar probes.
Multi-unit signals show that both orientation-defined and phase-defined figures elicit FGM in superior colliculus. The onset of FGM is earlier for orientation-defined figures than for phase-defined figures. Further analysis, e.g. comparing FGM onset latency in superior colliculus and V1, investigating the difference in the signal between hits and errors, and analysis of the recorded single units should provide more insight into the role of superior colliculus in object segregation.

Title: Material perception in human and nonhuman primate subjects, compared by the similar discrimination task

Authors: ***M. ITO**, H. TAKEDA, K. FUSHIMI, T. MATSUBARA;
Tokyo Med. and Dent. Univ., Tokyo, Japan

Abstract: Materials on the surface provides a powerful clues to object recognition by perceiving both visual texture information and secondary haptic information, like roughness or hardness. Such material perception is dependent on animal's sensation and experiences. However, the property is not well understood in model animals used for physiological studies. In this study, three monkeys have been trained to perform the material discrimination task, which might be easy for human subjects but very hard for non-human subjects. Then, we examined the relationships between the scores of the material discrimination and the haptic discrimination in both human and non-human subjects for comparison. Thirteen human subjects (6 male and 7 females, age 21-57) conducted two to four daily sessions of the task. In the haptic discrimination task, subjects reported 4 haptic scores (rough/smooth, hard/soft, hot/cold or dry/wet) in 5 steps for each material. In the material discrimination task, subjects reported 5 scores indicating resemblance with 5 reference materials (metal, wood, carpet, gel-sheet, and fur). The task was conducted with or without visual inspection. Order of sample presentation was randomized and each sample was presented once in a daily session. In parallel, three Japanese monkeys (*macaca fuscata*, female, 7.0, 6.8 & 6.9kg) has been trained with the material discrimination paradigm over 35, 29 & 18 months. After pressing a cue-material, they had to touch the same one among 5 reference materials. After the performance has improved above 90%, new object was presented once in a daily session. They have to choose one among 5 reference materials as a response of their categorization. We compared these scores in two dimensional spaces representing haptic and material perception after the modified multi-dimensional scaling procedures. We found that (1) scores of the material and haptic discrimination tended to form compact cluster for each material categories in two dimensional spaces of material and haptic perception, (2) linear regression sufficiently predicted haptic scores from the material scores ($p<0.05$), (3) our material discrimination paradigm was sufficient for direct comparison between human and non-human

primate subjects. In conclusion, material categorization of primate-subjects was largely consistent with human subjects, but showed peculiar differences for some materials, which was dependent on a specific cue-materials as well as a course of training, indicating that they learned properties of materials during the training.

Title: A map of object space in primate inferotemporal cortex

Authors: *P. BAO, L. SHE, M. MCGILL, D. Y. TSAO;
Caltech, Pasadena, CA

Abstract: Object recognition lies at the heart of our ability to make sense of the visual world. Befitting the central importance and computational complexity of object recognition, a large piece of brain, inferotemporal (IT) cortex, is dedicated to solving this challenge. However, how the representation of complex visual objects organized in IT cortex is still not clear. Areas selective for a few categories such as faces, bodies, and scenes have been found, but large parts of IT lack any known specialization, leading to uncertainty over whether any general principle governs IT organization. We recorded fMRI and single-unit responses in IT to a large set of objects, and built a low dimensional object space to describe these objects using a deep convolutional network. We found that single IT cells are projecting incoming objects, formatted as vectors in object space, onto specific preferred axes. Remarkably, cells were anatomically clustered into four networks, according to the first two components of their preferred axes, forming a map of object space. Furthermore, this map was repeated across three hierarchical stages of increasing view invariance, and cells comprising these maps collectively harbored sufficient coding capacity to reconstruct arbitrary general objects. These results provide a unified picture of IT organization in which category-selective regions are part of a topographic map.

Title: Response dynamics in primate V4 are modulated by perceptual dimensions of visual textures

Authors: *T. KIM, W. BAIR, A. K. PASUPATHY;
Biol. Structure, Univ. of Washington, Seattle, WA

Abstract: Past studies have shown that neurons in macaque area V4 play an important role in object recognition by encoding both the geometry of object boundaries and the properties of surfaces, e.g., color, luminance and texture. Recent studies with naturalistic textures suggest that neurons in macaque areas V2 & V4 may process texture information by encoding higher-order image statistics such as the correlations across V1-like filter outputs. Nonetheless, the high dimensionality of such statistics makes interpretation of neural data difficult. Specifically, it is still uncertain how texture encoding in area V4 is associated with human texture perception (e.g., coarseness, regularity, and so on). In this study, our goal was to relate four major dimensions of human texture perception - coarseness, directionality, regularity, and contrast - to the neuronal responses to naturalistic textures. Leveraging methods developed for human psychophysical studies, we first characterized a large database of natural texture images along these four texture dimensions, and then chose a small subset (n = 21) of stimuli that cover a broad range of perceptual qualities of texture. To dissociate the selectivity for a specific orientation (or boundary) within a texture from higher order texture selectivity, each texture image was presented at four orientations (in 45-degree intervals) and at two different sizes (1 x RF, 2 x RF). Overall, we studied the responses of 101 neurons in two awake, fixating monkeys to a set of 168 texture images. We found that approximately 40% of V4 neurons had spiking responses to naturalistic textures that were well explained (i.e., correlation coefficient > 0.5) by a combined selectivity for all four perceptual dimensions. Texture selectivity was highly invariant across different stimulus sizes and orientations. Cluster analyses, used to group texture images based on V4 population activity, resulted in texture groups with clear and interpretable perceptual similarity. Finally, different perceptual dimensions modulated neuronal responses at characteristically different time courses. For example, processing of ‘coarseness’ and/or

‘contrast’ information was significantly faster than that of ‘directionality’ and ‘regularity’. These results indicate that texture selective V4 neurons encode key psychophysical measures of texture by computing simple summary statistics with different temporal dynamics.

Title: Solid shape representation in biological and artificial vision

Authors: *R. SRINATH[1,2], Q. A. WANG[1,2], K. J. NIELSEN[1,2], C. E. CONNOR[1,2];
[1]Neurosci., [2]Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: Vision requires transforming 2D images into knowledge about 3D physical reality. Here, we found that this transformation occurs explicitly in surprisingly early stages of both biological vision (in area V4 of the primate ventral pathway) and artificial vision (convolutional layer 3 of AlexNet, an established model for area V4).
To study the representation of solid versus planar shape, we recorded from single V4 neurons, using the responses to initially random shapes to guide the evolution of subsequent stimulus generations. By comparing responses between shaded solid shapes and planar silhouettes with identical boundaries, we found that a majority of V4 neurons are selectively tuned for solid shape as opposed to planar shape. Solid shape responses were consistent across a variety of 3D shape cues including reflective and refractive material, glossy and matte shading, and binocular disparity. Response-weighted averaging (RWA) analysis in 3D geometric space revealed that V4 neurons are tuned for 3D solid shape fragments defined by the surface and medial axis geometry of shafts, junctions, and terminations. Thus, the ventral pathway quickly shifts from image signals to representations of solid, 3D shape elements.
To investigate whether deep convolutional networks also process 3D shape in intermediate layers, we quantified shape responses of single nodes in the convolutional and fully-connected layers of AlexNet. We used the same stimuli evolved during the neurophysiological experiments and extracted activations of single nodes in AlexNet. For each V4 neuron, we searched for the node in convolutional layer 3 with the most highly correlated responses. We found surprisingly high correlations, with a median of 0.47, and 25% of correlations above 0.55. Strikingly, the 3D selectivity of these nodes was highly correlated with the 3D selectivity of the corresponding V4 neurons (correlation coefficient of 0.64). We also performed the same evolving stimulus

experiment on convolutional layer 3 nodes, characterized their shape tuning with RWA matrices, and observed tuning for 3D shape fragments similar to V4 neurons.
Our results suggest that artificial vision networks succeed in part by implementing an internal representation of 3D physical reality, even though the inputs are 2D images and the outputs are signals for semantic object categories, and thus 3D representations are not externally imposed in any way. In spite of their differences, biological and artificial vision networks find a similar solution, evolving internal representations of the 3D physical elements that make up the real world they interact with.

Title: Short-term memory for border ownership in cortical area V4

Authors: *T. P. FRANKEN, J. H. REYNOLDS;
SNL-R, The Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: A key step in understanding a visual scene is to identify the borders that separate figure from ground and to assign ownership of each border to its figure. Pioneering work conducted by Rudiger von der Heydt and colleagues identified neurons in early visual cortex (mainly in area V2) that respond according to which side of a border belongs to a figure (border ownership sensitive neurons), even if the stimulus information that differentiates figure from ground falls outside of the neuron's classical receptive field (Zhou et al., 2000). Such neurons can display short-term memory for border ownership (O'Herron and von der Heydt, 2009). It has been proposed that neurons in downstream areas may provide feedback signals that help establish border ownership sensitivity in early visual cortex. If this hypothesis is correct, similar short-term memory is expected to be present in these downstream areas. To explore this possibility, we studied the physiology of border ownership in area V4, a major source of feedback to V2. We recorded single- and multi-unit activity in V4 of the awake macaque. We used a pseudorandom sequence of patches with square-wave gratings (8 colors, 6 orientations) to

map each unit's receptive field. We then presented a luminance and color-defined object (square) at different locations on a plain background. To match sensory conditions across figure and ground, the color and luminance of the square and background were reversed on half of all trials. To test for short-term memory for border ownership, we then, after showing figure and ground, removed all stimulus cues to border ownership. We analyzed neuronal responses for object locations for which one of the square's borders overlapped with the receptive field. By comparing spike rates across trials on which the position of that border was identical for different object locations (on opposite sides of the border), we could determine border ownership sensitivity. As has been reported by Zhou et al. (2000), we find that a substantial fraction of V4 units are sensitive to border ownership. In addition, we find that many of these units show persistent border ownership signals after the display was rendered ambiguous. Our findings show that short-term memory for border ownership is not limited to early visual cortex but is also strongly present in V4.

Title: Decoding representations of food images within the ventral visual stream

Authors: *C. CORICELLI[1], K. M. STUBBS[2], R. I. RUMIATI[1,3], J. C. CULHAM[2]; [1]Cognitive Neurosci., Intl. Sch. For Advanced Studies (SISSA), Trieste, Italy; [2]Brain and Mind Institute, Univ. of Western Ontario, London, ON, Canada; [3]ANVUR, Rome, Italy

Abstract: Neuroimaging studies have revealed food-selective activation across a broad network of human brain regions, including areas within the ventral visual stream implicated in visual object recognition. However, the nature of visual food representations is unknown. Moreover, we eat by using hands and utensils to bring food to the mouth, perhaps invoking associations with hand, tool- and mouth-selective regions of the lateral occipitotemporal cortex (LOTC). We used representational similarity analysis (RSA) on data from functional magnetic resonance imaging (fMRI at 3 Tesla) in a selected region of interest (ROI) in left LOTC to investigate whether visual representations of food stimuli are distinct from other visual categories (i.e. other objects). To this end, healthy normal-weight individuals (n=22) performed a one-back task in the scanner

while viewing colored pictures of different object categories (food, body parts, utensils, objects, scrambled food images), matched for retinal size. Consistent with previous literature, univariate contrasts of activation levels (random-effects general linear model; false discovery rate corrected with $p < .01$) revealed food-selective activation (food > other stimuli) within a network of regions, including insula, fusiform gyrus, amygdala, putamen and orbito-frontal cortex. Nevertheless, RSA revealed distinct activation patterns for food stimuli. That is, food representations in left LOTC were highly correlated within-category but distinct from the representations for food-associated items (i.e. tools, hands and mouths, Figure 1). No strong evidence that food representations are more similar to food-associated items compared to unrelated items (i.e. legs) in left LOTC was found. Taken together, these results suggest that although food images evoke activation that overlaps with other visual categories, the neural representation of food is distinct.

Title: Distributed representation of temporally persistent visual categories

Authors: *L. Y. DEOUELL[1], G. VISHNE[2], E. M. GERBER[3], R. T. KNIGHT[4];
[1]The Hebrew Univ. of Jerusalem, Jerusalem, Israel; [3]Edmond and Lily Safra Ctr. for Brain Sci., [2]Hebrew Univ. of Jerusalem, Jerusalem, Israel; [4]Univ. of California Berkeley, Berkeley, CA

Abstract: Research on visual perception has thoroughly characterized the neural activity in response to the appearance of visual stimuli. These responses often reflect the category of the stimuli, but they are transient. In reality, our visual experience is composed of many moments without change, where we still maintain information about our surroundings, yet these periods of sustained viewing have been mostly neglected by past research. We set out to fill this gap and characterize neural tracking of category information beyond the initial moment of change. This was done using intracranial recordings from 10 subjects undergoing surgery for intractable epilepsy (1067 electrodes). Patients viewed images of variable durations (300-1500ms) from several categories, coupled with an identification task to maintain attention. Previously (Gerber et al., 2017), we identified the single electrode correlates of persistent categorical information and found only two electrodes in the posterior fusiform face-selective region that were sensitive to category membership until the end of the stimulus duration. Here, we move to characterize the dynamics of ongoing category selectivity using multi-variate pattern analyses. We trained a classifier (linear discriminant analysis) to distinguish between viewing of objects and faces on a moment by moment basis. Additionally, we used the temporal generalization method (King & Dehaene, 2014), training and testing the classifier on different time-points in order to identify changes in the multi-site pattern. The classification was based on broadband high frequency activity (>30Hz) which was shown to correlate with local neural firing. Sustained selectivity for category information was measured by classifying stimuli of duration ≥900ms. We found sustained categorical selectivity in two subjects. Classifier performance was above chance until the end of the stimuli duration, well after the onset response for category selectivity. Using the temporal generalization method, we show that the pattern of category selectivity remained similar throughout the duration of the stimulus. In both subjects there was a single electrode showing sustained category sensitivity, but importantly, reduced sets of electrodes excluding this

electrode also showed the same pattern of sustained categorical response, meaning that category information might be maintained by more extended regions, even when local categorical information cannot be detected.

Title: Processing of movement-shape associations in inferior temporal cortex

Authors: *D. BURK, D. L. SHEINBERG;
Neurosci., Brown Univ., Providence, RI

Abstract: As we move throughout the world, our brains continuously acquire sensory information and make predictions when visual information is limited. For example, an animal hopping in a foggy park could be perceived as a rabbit or a frog, even when the animal's shape is obscured. How does the hopping movement lead to potential animal identity? More generally, objects often have stereotypical movements, but it remains unknown how movement is used in object recognition. Previous research has shown that the brain associates features (e.g. color, shape, size) to create a unified percept of an object. It remains unknown how visual areas traditionally recognized for processing certain object features, integrate or bind secondary features. Little is known about how motion might affect responses in inferior temporal cortex (area IT) during object recognition. Here we ask whether motion can drive responses in inferior temporal cortex during a task that requires selection of shapes based on motion information. To investigate this, we developed a match-to-sample task for non-human primates that requires subjects to identify moving shapes with variable perceptual noise. Subjects are trained to associate two categories of shapes with category specific motion paths. Behavioral data demonstrates that motion or shape information is used depending on the availability of shape information. We used a pattern classifier to decode motion information from a population of IT neurons recorded during the task and a passive viewing variant. Preliminary data from one animal shows that while motion does not drive IT neurons in the absence of shape information, motion can modulate responses and lead to changes in selectivity. Furthermore, preliminary data suggests that inferior temporal cortex has access to motion information during the active task

where pursuit was allowed, as well as passive viewing where fixation was required. Linear regression analysis showed that local position differences alone could not account for differences in neuronal responses in the active task. Here we aim to demonstrate that learning of associations between movements and shapes can lead to changes in responses in inferior temporal cortex. These findings support a role for integration of motion and shape information in a traditional "shape-processing" area, inferior temporal cortex.

Title: Pattern separation in ventral visual stream

Authors: *K. M. FERKO[1], A. BLUMENTHAL[3], D. PROKLOVA[5], C. B. MARTIN[4], T. BUSSEY[6], L. M. SAKSIDA[1], A. KHAN[2], S. KOHLER[7];
[2]Robarts Res. Inst., [1]Western Univ., London, ON, Canada; [4]Dept. of Psychology, [3]Univ. of Toronto, Toronto, ON, Canada; [5]Psychology, The Brain and Mind Institute, Western Univ., London, ON, Canada; [6]Univ. of Western Ontario, London, ON, Canada; [7]Univ. Western Ontario, London, ON, Canada

Abstract: Pattern separation is a neural computation thought to underlie our ability to form distinct memories of similar events. It involves transforming overlapping inputs into less overlapping outputs. Research on pattern separation has primarily focused on transformations of representations between entorhinal cortex and the dentate gyros of the hippocampus in the context of memory tasks. Pattern separation may, however, also occur in other cortical regions and may not be limited to computations that support memory processing. In the ventral visual stream (VVS) there is considerable evidence for hierarchicaltransformation from feature-based visual representations to conjunctive whole-object representations, with the latter allowing for distinct coding even when objects have significant feature overlap. In the current study, we asked whether this transformation can be understood as pattern separation, and whether pattern separation can be observed even outside the context of classic recognition-memory tasks. To investigate pattern separation in the VVS, we combined fMRI in humans (N=23) with multivariate pattern analyses techniques and compared representations of visual objects in a mid-level visual region, Lateral Occipital Complex (LOC), with those in the region proposed to be at the top of the VVS object processing hierarchy, Perirhinal Cortex (PrC). We presented images of

objects from multiple categories, with differing degrees of visual similarity among exemplars. We administered a variant of a 1-back task with catch trials that required identification of repetition either at the exemplar or category level. For analyses, we grouped exemplars within each category into three levels of perceived visual similarity (low-medium-high) based on participants' own ratings. Behavioural results indicate sensitivity of performance to these varying levels of similarity. Imaging results obtained using Support Vector Machine classification revealed differences in pattern similarity between representations of exemplars in LOC and PrC. Specifically, while patterns in LOC could be distinguished successfully only at the lowest level of visual similarity within categories, patterns in PrC could be distinguished at all levels of similarity. Because patterns at higher levels of visual similarity are overlapping in LOC, but can be differentiated in PrC, these results provide evidence for pattern separation in the VVS.

Title: Activation of high-level visual object representations by spatial frequency magnitude

Authors: *M. ØVERVOLL;
Dept. of Psychology, Uit - The Arctic Univ. of Tromso, Tromso, Norway

Abstract: Structural information is considered to be central for object identification. However, a neural code based on spatial frequency magnitude without structural information may play an independent functional role, for example by supporting efficient within and between category comparisons, and could be sufficient for activating high-level visual object representations. To investigate this possibility, grayscale images of typically red and green objects (e.g., strawberry, broccoli) were phase scrambled, and the resulting images were colored (red or green: congruent/incongruent). Phase scrambling randomizes the structural information in an image while preserving the spatial frequency magnitude. Thus, if spatial frequency magnitude can activate high-level object representations, there should be enhanced processing of phase-scrambled images with congruent colors, as high-level representations can modulate the processing of low-level features, causing stronger responses to features that are typically associated with the object category. In each trial, the stimulus was presented for 1 sec before the color began flickering off/on at a rate of 10 Hz. After 2.5 sec, a circular patch with the same color as the image appeared gradually (opacity 0-100%), with opposite phase, at a random location in the image until response was given or 5 sec had passed. The participants' task was to

press the response key when the color patch was detected. EEG was recorded from 32 locations based on the 10-20 system. Following ocular artifact removal, surface Laplacian was applied to the EEG data using the Perrin algorithm. Occipital (Oz) phase-locked power and inter-trial phase coherence were higher for congruent than incongruent stimuli, and detection threshold was lower for congruent than incongruent stimuli. An analysis of connectivity degree (10 Hz) during the flicker period for both conditions revealed high overall connectivity for prefrontal (Fp1/Fp2) and temporoparietal (P7/P8) regions. Further connectivity analyses (weighted phase lag index) for these regions revealed greater synchronization between Fp1/Fp2 and Oz for congruent stimuli than for incongruent stimuli, indicating enhanced prefrontal-occipital feature maintenance for colors that are associated with the object category. The results suggest that high-level visual object representations can be activated by spatial frequency magnitude, independent of structural information.

Title: Core visual object recognition behavior in common marmosets

Authors: S. L. BOKOR, A. J. E. KELL, Y. JEON, T. TOOSI, *E. B. ISSA;
Neurosci., Columbia Univ., New York, NY

Abstract: Humans and macaques can recognize visual objects in natural scenes at a glance, despite identity-preserving transformations in the view, size, and position of an object. This ability, known as core visual object recognition, reflects a remarkable computational feat that only recently was accomplished at human levels by computer vision systems such as artificial neural networks. Here, we quantify the core object recognition abilities of the common marmoset, among the smallest of the anthropoid primates (monkeys, apes, and humans). Critically, as an anthropoid primate, the marmoset is endowed with a high-acuity fovea at its visual input and an elaborated set of ~150 cortical areas, unlike other small mammalian models such as rodents and tree shrews. It remains unclear, however, whether this small monkey performs invariant object recognition at levels comparable to and with similar behavioral signatures (e.g., image-by-image performance patterns) as larger monkey models in neuroscience such as macaques. To test marmoset visual behavior, we adopted a variant of an operant-conditioned object recognition task previously used in macaques and developed a novel

homecage system for high-throughput behavioral testing in marmosets. We computationally benchmarked our task on a commonly used deep neural network (Alexnet) to assess the difficulty of the visual discrimination component in a visual system without downstream noise or behavioral lapse. The two-object visual discrimination proved computationally challenging: early layers of Alexnet perform near chance levels (50%) whereas higher layers achieve ~80% performance. Our preliminary findings demonstrate that marmosets: (1) complete 500-1500 trials per day (in a 3-hour period); (2) reach performance levels of ~90% on the relatively simple task of pose-tolerant object recognition on blank, gray backgrounds, suggesting low behavioral lapse rates; (3) reach performance levels of >80% on the visually difficult core object recognition task on complex natural backgrounds that was benchmarked on Alexnet; (4) exhibit behavioral signatures (image-by-image performance) that are highly correlated with those of macaques. Taken together, these findings suggest that marmosets and macaques may exhibit similar visual behavior, complementing known similarities at the level of the eye and brain across anthropoid primates. Thus, marmosets may be a valuable, small animal model for neuroscientific studies of high-level visual object recognition.

Title: Disentangling “what” and “where” visual information in neural network vision models

Authors: *E. CHRISTENSEN[1], J. ZYLBERBERG[2];
[1]Physiol. and Biophysics, Univ. of Colorado, Aurora, CO; [2]Physiol. and Biophysics, Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Across a variety of species, the "two-stream" organizational structure of cortical visual processing is highly conserved. A single input source (LGN) is eventually de-mixed into the dorsal (‘where’) stream and the ventral (‘what’) stream. The ‘what’ and ‘where’ in the input space (pixel space) is entangled and represented by an overlapping subset of pixels and must be disentangled to extract this information. How do networks of neurons in the brain disentangle this information from a common source? Where along this pathway is the entangled information split into two outputs? Recent advances in computer vision facilitate answering questions like

these. Training models to concurrently decompose a scene into a multi-faceted representation may confer a generalization advantage. I hypothesize computer vision models that disentangle object identity and location information from scene images will learn more robust visual representations. Vision models that extract multi-faceted information from images will enable more sophisticated and robust autonomous agents capable of visually navigating complex environments the way primates can. Using artificial neural networks (ANN) as a model of visual cortex I trained a simplified vision model to recognize objects while retaining sufficient information to reconstruct the scene. This model is comprised of an encoder, which learns a compressed representation of an image scene and a generator, which attempts to reconstruct the image scene from the representation. Models trained to reconstruct images displayed better generalization and categorization accuracy even when trained with on increasingly unreliable or corrupt data (random labeling of fractions of the data). After training, I examined Shannon mutual information of the output units in the hidden representation. Several model neurons in the scene representation spontaneously learn independent representations of an objects location in the image.

Title: Neural code of face memory in the macaque IT and perirhinal face patches

Authors: *L. SHE[1], M. K. BENNA[2], S. FUSI[2], D. Y. TSAO[1];
[1]Caltech, Pasadena, CA; [2]Neurosci., Columbia Univ., New York, NY

Abstract: The role of face-selective regions ("face patches") in inferior temporal (IT) cortex in face memory remains unclear: how is a new face remembered, and how is this memory re-activated during perception? To address this, we recorded single neurons from two face patches, face patch PR in perirhinal cortex, a region that has been strongly implicated in processes related to visual memory, and face patch AM in anterior IT cortex. We found that PR contains a high concentration of face-selective cells. In both PR and AM, cells are modulated by both face identity and familiarity, and exhibit stronger, prolonged responses to unfamiliar compared to familiar stimuli. Further measurement of neuronal responses to thousands of parametrized unfamiliar faces revealed that for representing unfamiliar faces, a substantial population of PR cells inherit the "axis code" previously found in IT face patches (Chang and Tsao, Cell 2017), which is a low dimensional, linear representation of unfamiliar stimuli. However, for representing familiar faces, PR uses a different code, weakly related to that for unfamiliar faces. A similar deviation from the axis code for familiar faces was observed in AM. Finally, we found a small number of very sparse, 'grandmother cell'-like cells in PR, responding only to a single or a few faces, often personally familiar. These cells might contribute to the memory storage of individual instances of faces. Together these results suggest that PR cells implement a critical stage in face memory storage and retrieval, and may facilitate association between semantic and perceptual memories.

Title: Understanding the brain's code for 3D objects via immersive virtual reality

Authors: *E. KOCH, B. HAGHI, D. Y. TSAO;
Caltech, Pasadena, CA

Abstract: Primate interaction with objects and agents in the visual world requires the brain to construct a 3D model of the environment and the objects within it. For example, even the simple action of grabbing a stick off the cluttered forest floor requires localizing the stick within the scene and with respect to self, and building an internal model of the shape and pose of the stick. Localization of the brain's core geometric engine, and the rules by which the neurons working as part of this module to parse and encode 3D scenes remains unknown. The advances and commercialization of virtual reality headsets provide an exciting tool for probing the brain's code of 3D object representation via immersion into realistic 3D environments, while still preserving the experimental ability to systematically change scene parameters. We have made modifications to the hardware and software of a virtual reality headset with built-in eye tracking (FOVE Inc.) to match a macaque's inter-ocular distance and smaller head. One candidate for the brain's geometric engine is area CIPS (Caudal Intraparietal Sulcus). We localized area CIPS by comparing fMRI activation to disparity-rich stimuli (rippled planes, 3D objects, buildings, and disjoint planes) versus zero disparity stimuli (flat planes) (Tsao et al., 2003). We then targeted CIPS for physiological recordings while immersing the monkeys in a variety of rendered 3D scenes via the modified headset. We tested each CIPS neuron on a large number of 3D stimuli, including flat and curved objects of different sizes, 3D positions, and shapes, to characterize the selectivity of these neurons to a range of geometric parameters. We also analyzed selectivity of units in machine learning algorithms trained on 3D scene reconstruction, and compared the 3D representations in these networks to that in CIPS.

Title: Neural correlates of perceptual switches in binocular rivalry without active report

Authors: *J. K. HESSE[1], V. WADIA[1], U. RUTISHAUSER[2], D. Y. TSAO[1];
[1]Caltech, Pasadena, CA; [2]Dept. of Neurosurg., Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: When two incongruent stimuli are presented to the two eyes, the conscious percept alternates between them, even though the physical input stays constant. This paradigm, also known as binocular rivalry, offers an entry point to study how switches between conscious

interpretations of ambiguous stimuli are represented and broadcasted across the brain. Logothetis et al. (e.g. 1996) measured across different brain regions the extent to which neural activity was modulated by reported switching. However, Fraessle et al. (2014) reported that during active report, modulation by conscious percept is confounded with the act of reporting itself, and that when active report is stopped, modulation vanishes in most parts of the human brain.
We thus set out to study which brain regions show switching behavior during binocular rivalry similar to that during physical switches, and whether this switching requires active report. We performed both single electrode and multi-electrode population recordings in monkeys and humans from a number of areas including amygdala, SMA, and face patches in inferotemporal and prefrontal cortex, while reading out the conscious percept using a novel no-report paradigm. In humans, we also contrasted modulations with active report. Our results allow us to disentangle which neural signatures represent switches of the conscious percept rather than the mere report of it.

Title: Probing the neural substrates of visual imagination in humans

Authors: *V. WADIA[1], J. K. HESSE[1], A. MAMELAK[2], U. RUTISHAUSER[2], D. Y. TSAO[1]; [1]Caltech, Pasadena, CA; [2]Dept. of Neurosurg., Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: Intelligent beings are able to form a coherent model of the world, one that is developed through an active interaction with our environment. The existence of this internal model has several consequences including generating context-appropriate behavior flexibly, efficient planning and one shot learning. It also contributes to the greatly enhanced visual inference capabilities we enjoy relative to machines. Mammalian visual processing has long been thought of as a combination of top down and bottom up processing. An extreme instance of top-down processing occurs in imagination, when a subject can be directed by verbal cues to perceive a stimulus in the absence of any bottom-up input. Animal studies have yielded rich insight into neural mechanisms for bottom-up processing. However, the neural mechanisms for top-down processing have been more elusive, in part due to the impossibility of verbal instruction in animals. Here, we examine the neural mechanisms underlying visual imagination in humans. We performed single-neuron recordings in the medial temporal lobe of epilepsy

patients implanted with depth electrodes with embedded microwires for the purpose of localizing the source of their focal epilepsy. We first map the feature selectivity space of the recorded visually selective cells to a large set of object stimuli and then compare responses of the same cells during a passively viewed vs. imagined setting.

Title: The code for occluded faces in IT cortex

Authors: *Y. SHI, D. Y. TSAO;
Caltech, Pasadena, CA

Abstract: Inferior temporal (IT) cortex is considered the final stage for object recognition in the ventral visual stream. While much progress has been made in IT to understand the code for intact objects, objects in the wild are mostly occluded. How do we recognize occluded objects as easily despite a broad range of information loss? How are occluded objects represented in IT cortex? To address these questions, we performed extracellular recordings in face patch ML of macaque IT cortex. During recording sessions, monkeys passively viewed 13 occluded face sets. Every face set was made from the same 20 intact faces by adding different occlusions. Single-cell responses to occluded faces change dramatically from those to intact faces, both in amplitude and dynamics. Cells showed consistent tuning to occlusion types for every face identity but not vice versa. As a whole, the face cell population encoded different occlusion configurations as separate clusters in the neural space. The distance between representations of occluded and intact faces in the neural space was strongly affected by the side and area of the occluders as well as the information density beneath the occluders. Together, these results argue against amodal completion of occluded face components prior to the middle face patch, and raise the question, how is the brain able to determine facial identity of occluded faces despite such drastic changes in neural responses to occluded compared to intact faces?

Title: Behavioral tools for studying object vision in the northern tree shrew

Authors: *F. LANFRANCHI[1], J. B. WEKSELBLATT[2], F. LUONGO[3], D. Y. TSAO[4];
[1]CALTECH, Pasadena, CA; [2]Biol., Caltech, Pasadena, CA; [3]Caltech, Los Angeles, CA;
[4]Caltech, Pasadena, CA

Abstract: The macaque monkey has classically provided a key model for visual processing, due to its amenability to psychophysical tasks and well-delineated visual hierarchy. More recently, the rodent has emerged as a new model for visual processing, due to the availability of molecular and genetic tools. An ideal model system would satisfy both needs: amenability to complex psychophysical tasks and tractablility for molecularly-based recording and perturbation techniques. Towards this goal, we have embarked on an effort to establish the northern tree shrew as a model organism for study of high-level object vision.
A diurnal animal, the tree shrew has high visual acuity (>10x that of rodents), a cone-dominant retina, and a columnarly-organized visual cortex. Moreover, tree shrew cortex is lissencephalic, enabling increased optical access for imaging neural circuit dynamics compared to the macaque. Due to its small size (~150-200 grams) and relatively short reproductive and developmental cycles (6 weeks gestation, 4-6 months from birth to adulthood, 1-6 offspring per litter), the tree shrew offers experimental and genetic accessibility similar to rodents. We have built a high-throughput, low-cost, automated behavioral apparatus allowing visual behaviors in the tree shrew to be rapidly assayed. We report our initial results training tree shrews on figure-ground and object discrimination tasks. The animals readily learned to self-initiate trials and performed upwards of 1000 trials per day. Initial comparisons demonstrate that tree shrews learned significantly faster than mice or rats on the same tasks. Future work will incorporate head-fixed paradigms, electrophysiological, and optical recordings of neural activity during these tasks.

Inst. of Information and Communications Technology., Osaka, Japan; [6]Tohoku Univ. Grad. Sch. of Information Sci., Sendai, Japan

Abstract: An object can be ideally created from arbitrary materials. A cup can be made of plastic, glass or ice. By means of material or shitsukan perception we can settle to an appropriate choice. It has been shown that the inferior temporal cortex (ITC) plays a pivotal role in both object and material perception. Previous neurophysiological studies about material perception mainly focused on gloss processing in view of the distribution of specular reflection and suggest that gloss strength and sharpnessare encoded by a subpopulation of IT neurons. Gloss is however modulated not only by specular reflection but also by other object properties including the material of which the object is made. To comprehensively understand the role of ITC for material perception, in the present study we conducted the electrocorticography (ECoG) recording from ITC while the monkey engaged in a passive visual fixation task presenting the object images with multidimensional material properties. We specifically rendered three-dimensional computer graphics objects with manipulating five material dimensions of gloss strength, gloss sharpness, translucency, change from metal to glass (metal/glass), change from metal to plastic (metal/plastic). A 128-channel ECoG electrode was placed covering whole ITC area including the lower bank of the superior temporal sulcus. Visual evoked response was recorded and event related spectral perturbation was calculated. The response selectivity in six frequency bands, delta, theta, alpha, beta, low-gamma and high-gamma along the five dimensions was examined. The selectivity for gloss strength was appeared in all frequency bands. Selective electrodes was observed pronouncedly in the anterior part of the ITC for delta, theta, beta and high gamma bands. Selectivity for gloss sharpness was prominent along the whole ITC for beta and low-gamma bands and the middle and the anterior parts of the ITC for

alpha band. Response selectivities for translucency, metal/glass and metal/plastic dimensions were commonly prominent in the posterior part of the ITC but in frequency domain, the metal/ glass and the other two dimensions were separable. Selectivity for the metal/ glass dimension was pronounced only for alpha band, but for the other two dimensions selectivities were pronounced for delta, theta, alpha and low-gamma bands. These results indicate that multiple material properties are represented in the overlapped specific spatial-frequency domains in ITC.

Title: Curvature domains in V4 of macaque monkey

Authors: *J. HU, X. SONG, A. W. ROE;
Zhejiang Univ., Hangzhou, China

Abstract: Previous studies have shown that neurons in V4 are involved in shape encoding, and that some neurons prefer highly curved shape while other neurons prefer straight contours (Carlson et al Curr Biol 2011; Nandy et al., Neuron 2013, 2016). Here, we hypothesize that neurons that prefer curves tend to cluster and to form functional domains, distinguishable from 'orientation domains' which exhibit preference for straight lines. Using intrinsic optical imaging, we imaged V4 in anesthetized macaque monkeys using moving curved gratings at 4 orientations (up, down, left, right), and straight and curved flashing single lines. These maps were compared to maps obtained in response to orientation (standard 'straight contour' moving gratings at 0°, 45°, 90°, 135° orientations), isoluminant color vs achromatic gratings, and high vs low spatial frequency gratings. By statistically comparing and contrasting the different types of maps, we found the presence of domains more responsive to curved than to straight gratings. These domains exhibited significantly stronger response to curvature of a single preferred orientation than to the same curvature at different orientations or to straight lines. As assessed by cross correlation, maps to curvature stimuli of similar orientation were more similar than when compared to those of different orientation or to straight gratings. Spatially, the distribution of these domains were distinct from orientation domains, color preference domains, and high spatial

frequency preference domains. These domains exhibited a degree of spatial invariance consistent with reports from single unit studies.Our data show that there are ‘curvature’ domains within V4 that exhibit preference for curved over straight contour stimuli with preference for a particular curvature orientation. Moreover, these regions form a unique spatial distribution pattern distinguishable from standard functional maps including maps for orientation, color, and spatial frequency. These results are consistent with and extend previous single unit studies of V4. We suggest that, similar to V1 and V2, components of object shape encoding exist in functional domains of V4.

Title: Investigating ventral stream computations in the mesopallium and entopallium of the pigeon brain

Authors: *W. J. CLARK, B. S. PORTER, M. COLOMBO;
Dept. of Psychology, Univ. of Otago, Dunedin, New Zealand

Abstract: The mammalian ventral visual stream exhibits a progressive increase in the complexity of receptive field preferences for categories of visual stimuli along a posterior-anterior axis in primate extrastriate visual cortex, reflecting these neuron’s function in complex pattern recognition. The avian visual nuclei exhibit a feed-forward increase in the complexity of receptive field preferences that recent electrophysiological investigation suggests may emerge with categorical representation of object categories in the anterior mesopallium of the dorsal ventricular ridge (DVR). We performed electrophysiological recordings along a reciprocal pathway between the anterior entopallium and mesopallium in four pigeons while they performed a passive fixation task during which they viewed images belonging to five object categories (human faces, pigeon faces, scrambled face controls, and sine wave gratings). A population of visually responsive neurons in the mesopallium exhibited category-selective responses, with a sub-category firing selectively only to images of pigeon and human faces. The complex preferences of visual neurons in the anterior mesopallium suggests that the avian visual system may recapitulate information using similar mechanisms to those in the primate ventral visual stream. These observations lend support to the view that birds encode sensory representations in parallel processing streams that are homologous with neocortical columns, despite the fact birds group functionally similar cell-classes into dense nuclear clusters that are interconnected, but spatially dispersed in the DVR.

Title: Combined neural responses from different domain-specific regions successfully resolve ambiguous perception

Authors: ***M. ROSENKE**[1], N. DAVIDENKO[2], K. GRILL-SPECTOR[1], K. S. WEINER[3]; [1]Stanford Univ., Stanford, CA; [2]Univ. of California, Santa Cruz, Santa Cruz, CA; [3]Psychology, Univ. of California, Berkeley, Berkeley, CA

Abstract: Humans categorize objects remarkably fast. Prior research shows that neural responses within a single region are correlated with categorical judgments of visual stimuli, which likely contributes to this behavior. However, it is presently unknown if not just one, but several functional regions in cortex may work together to perform categorical judgments. Here, we use regions that subserve face- and body perception in human ventral temporal cortex (VTC) to test if and how responses from both types of regions contribute to categorical judgments of ambiguous stimuli. We generated a novel set of parameterized silhouette stimuli that spanned a continuous morph space between faces and hands, while controlling for low-level image properties. We defined stimuli at 5 morph levels, ranging from fully face-like (level-1) to fully hand-like (level-5), and behaviorally calibrated intermediate (level-3) stimuli to appear equally face-like and hand-like in a large group of participants (N>60). Using these stimuli, we conducted two types of experiments in 14 independent participants: (i) an fMRI block-design experiment during which we measured mean responses in face- and body-selective regions in VTC and (ii) a behavioral experiment in which subjects categorized the morphed stimuli. This approach allowed us to examine the relationship between neural responses and behavioral categorization. We used a linear regression model using mean responses of face- and body-selective regions as inputs to predict behavioral categorization that was measured independently outside the scanner. We report three main findings. First, cortically adjacent face- and body-selective regions in VTC illustrate different response characteristics to face-hand morphs: responses were highest for morphs that were weighted >50% of their preferred categories and steadily declined for morphs that were weighted >50% of their nonpreferred category. Second, a linear model relating perceptual categorization to neural tuning of either a face- or body-selective region explains a significant portion of the variance in categorization performance (R^2: .35 - .54). Third, a linear combination of neural responses of face- (β=.31) and body-selective (β=-0.22)

regions explains significantly more variance (0.83±.04, R^2±SE, Bonferroni corrected $p<0.05$), and is able to predict human categorization judgements (cross-validated R^2= .70±.16) in a left-out subject. Together, these findings support the idea that the combined neural responses of regions selective for different domains more accurately explains human categorical judgements than neural responses from one category-selective region alone.

Title: The role of low-level visual properties in rapid snake detection of human observers

Authors: *T. KIM, D. KWON, H.-K. PARK, D.-J. YI;
Dept. of Psychology, Yonsei Univ., Seoul, Korea, Republic of

Abstract: For primates, the ability to rapidly detect life-threatening stimuli is crucial for survival and reproduction. The presence of threatening stimuli would put evolutionary pressure on primates, leading them to develop a dedicated mechanism for responding to ecological threats. According to the Snake Detection Theory (SDT; Isbell, 2009), because snakes have been prevalent threats to primates, the competition for survival against snakes have inadvertently contributed to the evolution of the visual system of primates. In support of SDT, it has been found that neurons in the pulvinar of monkeys exhibit faster and stronger responses to snake images (Le et al., 2013). In addition, human behavioral studies have also reported that snakes are detected faster and more accurately than non-threatening ones. However, the stimuli (e.g., snakes, fearful faces, and flowers) used in these studies differed in terms of low-level visual properties such as color, brightness, and spatial frequency. In the current study, we investigated the role of low-level visual properties in granting prompt awareness of threatening stimuli. We conducted two behavioral experiments using a continuous flash suppression (CFS) procedure designed to prevent conscious awareness of the target stimuli through dynamic masking. Experiment 1 attempted to replicate the findings of previous studies, measuring how rapidly images of snakes, fearful faces and flowers broke suppression and emerged into awareness. Participants viewed images of the stimuli from each category presented under the CFS and reported the location of the stimuli as soon as they detected the image. Dynamic Mondrian masking stimuli were presented to the participant’s dominant eye, while the target images of

each category were presented to the non-dominant eye. Consistent with previous studies, results showed that the breaking time for detecting snakes and fearful faces were shorter than that for flowers. Experiment 2 then tested the effects of low-level visual properties on breaking time, controlling color, brightness, and spatial frequency of stimuli across all categories. As in Experiment 1, fearful faces were detected faster than flowers. More importantly, however, snakes were no better detected than flowers. The current results suggest that low-level visual properties play an important role in allowing awareness of snakes under CFS. (NRF-2017R1D1A1B03028539)

Title: Evidence that recurrent pathways between the prefrontal and inferior temporal cortex is critical during core object recognition

Authors: *K. KAR[1], J. J. DICARLO[2];
[2]Brain & Cognitive Sci., [1]MIT, Cambridge, MA

Abstract: Recurrent circuits are critical to the primate ventral stream's ability to rapidly categorize objects. Using large-scale neural measurements, we have recently revealed putative recurrent computation dependent signals in the late-phase responses of the inferior temporal (IT) cortex which lies at the apex of the primate ventral stream hierarchy (Kar et al. 2019, *Nature Neuroscience)* . These neural signals are critical for solving the object identities in specific images that are difficult for non-recurrent deep artificial neural networks (ANNs); enabling the primates to outperform various feed-forward ANNs for such images and further suggesting the criticality of recurrent computations during core object recognition. However, we do not yet know which brain circuits are most responsible for these recurrent computations: circuits within the ventral stream? within IT? outside the ventral stream? all of the above? Our recent results provide a targeted disruption strategy for identifying such critical recurrent circuits. Specifically, disruption of the relevant recurrent circuits should prevent the emergence of an accurate representation of the object solutions for the late-solved images in IT. This will in turn result in larger behavioral deficits for the late-solved images (compared to the early-solved images).

In this study, we used this strategy to test one of the circuit hypotheses. Based on the presence of object-category selective neurons, anatomical projections to and from IT, and overall experimental feasibility, we focused our efforts to asses the role of "the ventral PFC to IT recurrence circuit". We pharmacologically silenced (via muscimol) ~10mm^2 of ventral PFC and simultaneously measured IT population activity (with chronically-implanted Utah arrays) in two monkeys, while they performed a battery of core object recognition tasks on our previously bench-marked images. Our results show that muscimol injections (~5 μl) in ventral PFC produced a significant behavioral deficit that is correlated with the object solution times (larger deficits for images with higher solution times). In addition, ventral PFC inactivation also reduced the quality of the late-phase IT population decodes. Interestingly, the late-phase IT neural activity after muscimol injection was better explained by a feed-forward ANN compared to the no-muscimol condition. Taken together, these results imply that PFC is a critical part of the recurrent circuity underlying the production of explicit object representations in IT, used for core object recognition behavior.

Title: Comparing simple invariances in V4 to those in a deep neural network

Authors: *W. BAIR, A. W. BIGELOW, D. V. POPOVKINA, D. A. POSPISIL;
Biol. Structure, Univ. of Washington, Seattle, WA

Abstract: Invariance is a central concept in vision - it describes the ability to maintain a similar representation of an object in spite of large changes in appearance on the retina. Examples of invariance range from simple to complicated-from contrast invariance, to translation and viewpoint invariance for complex objects. Quantifying simple invariances may provide a useful way to compare network representations at a fundamental level, and here we compare units in a deep CNN (AlexNet) to V4 neurons in terms of fill-outline invariance, which we recently tested in vivo (Popovkina et al., 2019, J Neurophysiol), and we examine ON-OFF invariance in the CNN because it is related to fill-outline invariance. Popovkina found that most V4 neurons did not maintain the same shape preferences when simple filled shapes were replaced by outlines of

the same shapes, thus had weak fill-outline invariance (FOI), whereas corresponding HMax models responded similarly to fills and outlines (high FOI). We recently found that AlexNet contains mid-layer units that provide very good models of V4-like translation-invariant shape selectivity (Pospisil et al., 2018, eLife), better than the HMax model, and wanted to test whether a CNN would have high FOI like HMax, or low FOI like V4. We presented the same shapes used to test V4 (Pasupathy & Connor, 2001) to the CNN units in four forms: filled or outline crossed with ON (white on black) or OFF (black on white), testing a wide range of stimulus size and outline thickness. We found most CNN units had strong invariance for shape selectivity across the 4 conditions (fill, outline, ON & OFF), and that these invariances were stronger in a trained network than in an untrained network. However, some units had weak fill-outline invariance, and we used visualization techniques to assess how the selectivity of such outliers differed from the mode. We found that low FOI units in middle layers tended to encode surface features, e.g., color, texture, or smooth gradients, in addition to shape, whereas high invariance units were dominated by shape selectivity. Such joint selectivity for form and texture is consistent with V4 physiology. In deeper layers, strongly outline or fill preferring units subserved specific categories with training examples dominated by outlines or filled forms, e.g., the stethoscope unit preferred outlines and had low FOI. We will report how simple invariances in the CNN depend on layer depth, stimulus size, outline thickness, and training. Our results suggest that CNNs are largely unlike V4 in terms of invariant shape selectivity, yet further analysis of CNN units with low FOI may provide insight into circuits that integrate boundary and surface information.

Title: Visualization of neural representations using generative adversarial networks

Authors: *K. MALAKHOVA;
Pavlov Inst. of Physiol., St. Petersburg, Russian Federation

Abstract: Neurons in the higher-level areas of the visual system respond to complex stimuli, such as faces, body parts, tools. However, the representational space encoded by the cells in the latest stage of visual processing is not clear yet. In this study, we show how deep learning visualization techniques can be applied for the visualization of neurons in the visual system. Using Deep Neural Networks (DNNs), we model a neural response of 140 cortical columns

recorded in the inferior temporal cortex of two macaque monkeys (Sato et al., 2013). The architecture of the model consists of convolutional blocks followed by fully connected layers. The output of the model is a prediction of the response of an individual column for a given visual stimulus. The model has a correlation coefficient of up to 0.86 in predicting the firing rate of certain cortical columns (with a mean of 0.74 for all columns). At the second stage, we visualize the trained model. Representations encoded by the model's neurons are explored using Generative Adversarial Networks (GANs). GANs aim to produce an image which causes a strong activation in a selected neuron. We compare several generative approaches resulting in visualizations of different types: (1) conditioning GANs with prior information to produce natural-looking images (Nguyen et al., 2017), (2) GANs with weak prior or without it, which may output adversarial examples (Olah et al., 2017). The results are compared to a classic approach where images from existing dataset ranked by their evoked response (a tuning curve). We show that the prior distribution obtained during GAN training procedure plays a crucial role in the ability of a generative network to produce images that evoke a high response in the model of the high-level visual areas. We also show how generative techniques can be used in real-time experiments to overcome the constraints introduced by the size of an experimental dataset, which is particularly valuable for the experiments with strictly limited recording time.

Title: Getting to know you - Multivariate pattern decoding of EEG data shows how identity representation is born in the human brain

Authors: G. KOVÁCS[1], G. AMBRUS[1], C. EICK[1], D. KAISER[2];
[1]Dept. Biol. Psychol. Cog. Neurosci, Friedrich-Schiller-University of Jena, Jena, Germany;
[2]Dept. Educ. and Psychol., Freie Univ. Berlin, Berlin, Germany

Abstract: The identification of someone is one of the most important tasks of the ventral visual system. Recently, we have shown that face identity information emerges gradually (between 100 and 400 ms post-stimulus onset) for famous familiar faces with an increasing degree of invariances (Ambrus et al, Cerebral Cortex 2019 Feb 7). Here we describe the results of a series of experiments where we used EEG and multivariate analysis techniques to elucidate the birth of these representations. Human participants viewed a set of highly variable face images of 4

unfamiliar persons before and after (1) a brief perceptual learning task, or (2) an extensive, several-day long personal familiarisation phase. Although face-matching performance was higher for the trained as compared to the novel identities after the perceptual training (1), multivariate representational similarity analysis did not reveal any difference between the learned and novel faces post-learning. The personal familiarisation (2), on the other hand led to a strong signal of familiarity, starting around 200 ms post-stimulus onset and a weaker, later (300 ms) and left lateralised decoding of learned identities. Our results suggest that a far longer and intensiver familiarisation training is necessary to create the robust identity representations, which are typical for the faces of famous persons than previously thought.

Title: Temporal dynamics of dorsal and ventral visual stream interaction during configural face processing

Authors: ***K. D. RANA**[1], A. C. DEL GIACCO[1], V. ZACHARIOU[2], L. G. UNGERLEIDER[1]; [1]Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Cognitive Neurosci. of Aging Lab., Univ. of Kentucky, Lexington, KY

Abstract: Of critical importance to human social interaction is the ability to recognize faces. Classically, facial recognition was considered a task relegated to the ventral visual stream, which contains a network of face-selective regions. Recently, Zachariou and colleagues demonstrated that the dorsal visual stream also contributes to the processing of the configural aspects of faces (Zachariou et al, 2016), which involves perceiving the spatial relationships between facial features. In this study, we used magnetoencephalography (MEG) to quantify when and how the dorsal and ventral streams interact to identify faces with configural differences. Subjects (n=18) viewed sequences of faces organized into 20 blocks of 21 faces each. Their task was to respond via button press if the currently viewed face was different from the face presented immediately before it. The faces could differ in either a configural or featural manner, with the difference type fixed for each block. Within a block, 50% of the trials were difference trials and 50% were not. Difficulty between configural and featural conditions were matched by accuracy separately for each participant. We identified two face-selective regions (lateral occipital cortex (LO) and fusiform gyrus (FG)) and one dorsal-stream region (intraparietal sulcus (IPS)) using functional

localizers in MEG. Dynamic Granger Causality (DGC) analysis revealed a network of communication between LO, FG, and IPS significantly higher than the measured DGC during baseline recordings while correcting for false discovery rate (signed rank test, $z > 2.918$, $p < 0.002$). A feedforward functional connection between 100 to 240 ms from LO to FG was present in both configural and featural trials but was significantly weaker in configural trials (signed rank test, $z = -3.136$, $p < 0.001$). For configural trials only, a bidirectional connection was found between LO and IPS at the same time as the LO to FG connection and a later IPS to FG connection was found between 220 to 310 ms. Our results thus suggest a critical role for IPS in configural face processing, first engaging LO as early as 100 ms and then later engaging FG at 220 ms.

Title: Beyond the uncanny valley: Naturalistic dynamic monkey head avatar elicits behavioral reactions comparable to videos of real monkeys

Authors: *R. SIEBERT[1,3], N. TAUBERT[2,1], S. SPADACENTA[1], P. W. DICKE[1], M. A. GIESE[2,1], P. THIER[1];

Abstract: Natural faces and especially facial expressions provide crucial social information not only for humans, but also for monkeys. Humanoid robots or computer avatars are evaluated as more positive the more human-like they are, but very realistic synthetic agents are perceived as unsettling by humans, a phenomenon known as the “uncanny valley effect”. This uncanny response has been shown to also exist in macaque monkeys. We aimed at generating a standardized monkey head avatar capable of producing natural facial expressions (fear grin, lip smacking, threat and neutral) that does not fall into the uncanny valley. To this end we developed a highly naturalistic moving avatar, animated by motion capture data from monkeys, and, in addition, degraded variants of the avatar of decreasing degrees of realism (furless, grayscale and wireframe avatar heads). We exposed eight adult male rhesus macaques to dynamic and static

clips of all different avatars and to videos of a real monkey and recorded their looking behavior, their facial expressions and various physiological parameters. The monkeys' visual behavior indicates that two of the less realistic avatars, but not the most unrealistic and not the most naturalistic avatar, fall into the uncanny valley. Moreover, the dynamic facial expression of the avatars had a significant effect on the amount of time the monkeys spent looking at the faces, how detailed they explored it and which parts of the faces they focused on. Some monkeys even responded to the avatar videos with reactive facial expressions like lip smacking, fear grinning or signs of agitation. Overall, the results confirm the existence of the uncanny valley phenomenon in monkeys, but show that it can be overcome by using sufficiently naturalistic monkey avatars, which can elicit reactions comparable to videos of real monkeys.

Title: Changes of the variability of neuronal responses in the posterior superior temporal sulcus of monkeys complement rate-based information on social interactions

Authors: *H. RAMEZANPOUR, M. GÖRNER, P. THIER;
Cognitive Neurol., Hertie Inst. for Clin. Brain Research, Univ. of Tübingen, Tübingen, Germany

Abstract: Neural activity in a well-defined patch in the posterior superior temporal sulcus (the "gaze following patch", GFP) of the human and the macaque monkey brain is strongly modulated when the other´s gaze attracts the observer's attention to objects, the other is looking at (Marciniak et al. eLife 2014; Marquardt et al., eNeuro 2017). Our analysis of average discharge rates of neurons in the monkey GFP indicates that they are involved in two distinct computations: the allocation of spatial attention guided by the other´s gaze vector and the suppression of gaze following if inappropriate in a given situation.
Here we asked if the discharge variability of neurons in the GFP could provide complementary information. To this end, we calculated the Fano factor as a measure of trial by trial discharge variability as a function of time. In the analysis we distinguished GFP neurons into task-selective and unselective ones based on their responses in two behavioral paradigms, requiring gaze following or, alternatively, the need to suppress it and to use facial information on the other´s identity to identify distinct spatial locations resorting to learned associations ("identity

mapping"). Selective neurons were activated by only one of the two tasks, whereas unselective ones were driven by both. Our results demonstrate that information on the other´s gaze and the control signals needed to switch between gaze following and identity mapping influence the variability of pSTS neurons independent of type. Whereas erroneous decisions were typically preceded by an increase of discharge variability, correct decisions were associated with low variability, no matter if the neuron was selective or not. Moreover, the strongest drop in variability occurred on average about 20 ms earlier in gaze following trials than in identity mapping trials, in which monkeys had to suppress gaze following in order to use identity cues for the reallocation of spatial attention.
Unselective neurons cannot contribute to the strength of the population signal responsible for the choice of the correct behavior. However, by reducing their discharge variability, unselective neurons improve the signal to noise ratio, thereby helping to increase the assertiveness of the population vote on the correct behavior. The fact that the decision to follow gaze impacts discharge variability considerably earlier than the decision to suppress it in order to map identity is in line with the notion that gaze following is a fast, domain-specific function whose suppression requires extra processing.

Title: The neurons that mistook a hat for a face: Neuronal responses to visual clutter and ambiguity

Authors: *M. J. ARCARO[1,2], C. R. PONCE[3], M. S. LIVINGSTONE[2];
[1]Psychology, Univ. of Pennsylvania, Philadelphia, PA; [2]Harvard Med. Sch., Boston, MA;
[3]Neurosci., Washington Univ. At St. Louis, Saint Louis, MO

Abstract: Inferotemporal cortex (IT) contains neurons that respond selectively to complex visual images such as faces, hands, and bodies. Such neural tuning is typically probed in highly controlled experiments where stimuli are presented in isolation. However, our typical visual experience is more complex. Here, we explored tuning properties of IT neurons under more

naturalistic conditions.
We recorded from microelectrode arrays implanted in the middle and posterior face patches in two adult monkeys. Tuning was first characterized with a rapid serial visual presentation (RSVP) of 3,000 images. Consistent with prior studies, these neurons responded more strongly to human and monkey faces than to any other image category. We then probed tuning to large naturalistic scenes. To identify scene components that modulated these neurons, we presented each image centered at different positions relative to each neuron's receptive field (RF) such that the neuron responded to all parts of each scene across the experiment. Consistent with results from the RSVP task, we found that in naturalistic scenes neurons responded most strongly when faces, and specifically eyes, were centered within their RFs. However, neurons also responded to non-face images, such as cookies, that contained features typical to faces: dark round things in a tan background. These neurons responded to faces even in highly cluttered scenes. The timing of responses and behavioral measures from subsequent free viewing conditions suggest that face-specific activity emerges fast and is driven by bottom-up facilitation prior to awareness. Strikingly, in conditions of visual ambiguity such as occlusion, these neurons also responded to the region of the image where a face ought to be as predicted by context. e.g., neurons did not respond to a picture of a hat held in a person's hand, but did respond when the same hat occluded the face. The timing of responses suggests that occluded-face activity is driven largely by bottom-up facilitation and local recurrent processes.
Together, our results demonstrate that in naturalistic scenes categorical discriminability of face-selective neurons is retinally specific. Further, these neurons are sensitive not only to features common to faces but also to the context of scenes, particularly in cases of visual ambiguity where face-specific visual stimulation is absent. We propose that visual features are the building blocks for face-selective neurons, and context-dependent responses arise from learning regularities in the environment. In support of this, visual features that co-occur with faces, such as bodies, appear to be critical for contextual responses (Cox et al. 2004).

Title: Electrical microstimulation establishes a causal role of the superior temporal gaze-following patch (GFP) in controlling gaze-following and its context dependent modulation

Authors: *I. CHONG, H. RAMEZANPOUR, P. THIER;
Cognitive Neurol., Hertie Inst. for Clin. Brain Res., Tuebingen, Germany

Abstract: In order to identify an object a conspecific is looking at, one must be able to determine his/her eyes and head directions and redirect one's own attention towards said object, thereby establishing joint attention. This process is known as gaze-following, and work in our group has previously shown that a cortical area in the posterior superior temporal sulcus (pSTS), which we have designated the GFP, is recruited for this behavior. Neurons in the GFP provide information on the spatial location of an object of interest under the gaze of another individual, as well as information needed to suppress gaze-following in situations in which it may be inappropriate. In our experiments the need to suppress gaze-following is typically realized by asking the observer to ignore the other´s gaze but to rely on the other´s identity to identify a target, in this case resorting to learned associations between possible targets and identities. To differentiate between the two behaviors, an instruction cue informed the observer whether to follow a conspecific's gaze, or alternatively engage in identity mapping. The target choice was indicated by a saccade to the object selected. Here we report results from experiments in which we deployed electrical microstimulation in the GFP of two male rhesus macaque monkeys to disrupt normal information processing in the patch in order to establish causality. We show that stimulating the GFP disrupted gaze-following if it was instructed, and the stimulation applied in the period in which information on the other's gaze direction and the spatial targets were available. The errors made by the observer were random rather than reflecting a bias for a particular target or a target associated with the seen identity. However, when we shifted the perturbations to the instruction period of the paradigm, the suppression on gaze-following was abolished, and instead identity-mapping became compromised. All in all, our results support a causal role of the GFP in gaze-following. Moreover, they indicate that the GFP is also involved in the executive control of gaze-following, i.e. suppressing gaze-following if inappropriate, by integrating expedient signals contributed by other cortical areas.

Title: Are face processed nonconsciously? Yes, but so are dartboards and alarm clocks: An EEG and b-CFS investigation of nonconscious perception

Authors: H. M. QUILLIAN[1,2], *A. D. ENGELL[1];
[1]Kenyon Col., Gambier, OH; [2]Yale Univ., New Haven, CT

Abstract: The social and evolutionary importance of faces has led to the proposal that they are detected by the visual system even when the viewer is not consciously aware of their presence. Here, we report two experiments that investigate this notion. EXP 1: In this EEG experiment, we used a novel combination of continuous flash suppression (CFS) and steady-state evoked potentials. The former is a well-known paradigm for leveraging interocular rivalry to present stimuli nonconsciously, whereas the latter is an EEG approach that affords greater SNR than prior ERP studies. 23 participants viewed a continuous stream of images, each presented for 167 ms (6 Hz). Within the stream, an "oddball" was presented as every fifth image (1.2 Hz). In our primary experimental condition, "frequent" images were objects and oddball images were faces. In a second condition, frequent images were scrambled objects and oddball images were objects. When stimuli were presented without CFS (i.e., images consciously perceived) we observed significant power at the oddball presentation frequency, 1.2 Hz, and its harmonics. We predicted that when presented with CFS (i.e., images not consciously perceived) we would observe a similar increase in power for face, but not object, oddballs. However, we did not observe any such increase and therefore did not find EEG evidence that faces were being processed outside of awareness. Paradoxically, participants became aware of the stimuli significantly faster in the face oddball condition than in the object oddball condition. Breakthrough time (b-CFS) differences are thought to imply nonconscious processing, but we observed no concomitant face-selective neural signal. EXP 2: One possible reason for the contradictory results would be if the b-CFS difference was due to a low-level visual feature, such as the high curvilinearity of faces, rather than high-level category membership. To test this, we compared the b-CFS for 37 participants who each viewed four different conditions in which the frequent images were always scrambled objects. The oddball images were either faces, objects, highly rectilinear objects (e.g., chess board), or highly curvilinear objects (e.g., dartboard). Consistent with the behavioral results of EXP 1, b-CFS for faces was significantly faster than for objects. Critically, b-CFS for curvilinear objects was also significantly faster than for objects and rectilinear objects, and did not differ from faces. The results of these experiments suggest that any privileged access faces have during nonconscious perception is owed to their relatively high curvilinearity and not to high-level category membership (i.e., the "specialness" of faces).

Title: Visualizing the evolving selectivity in macaque visual cortex using a generative adversarial network

Authors: *P. F. SCHADE[1], W. XIAO[2], T. S. HARTMANN[1], M. S. LIVINGSTONE[1]; [1]Neurobio., Harvard Med. Sch., Boston, MA; [2]Harvard Univ., Boston, MA

Abstract: Neuronal stimulus selectivity arises as a consequence of inputs from other neurons. Short and long-range inputs create complex tuning and dynamic response profiles. From the earliest stages of the macaque visual system, neurons have complex spatiotemporal response patterns, with transient selectivity differing from later sustained selectivity, reflecting the slight delay of lateral and feedback contributions. To investigate the temporal dynamics of responses in macaque visual cortex, we used a genetic algorithm (XDREAM; Ponce, Xiao, Schade et al. 2019), guided by neuronal responses in temporally constrained windows, to search a latent space in a generative adversarial network for images that could drive neuronal responses with predetermined temporal response patterns. The algorithm searched in parallel for images that could cause individual neurons or small populations of neurons in V1, V2, V4, posterior inferotemporal cortex (IT) or central IT to respond selectively with a transient, sustained, or delayed firing pattern. Starting with achromatic textures, complex images and textures evolved that caused neurons to respond maximally within the chosen temporal window. These experiments revealed known temporal dynamic properties of V1, such as delayed surround suppression, thought to arise from local lateral connections and intra-areal recurrent feedback. Similar temporally distinct response profiles were evoked in IT. In classically defined face-patches PL and ML, the algorithm evolved images with features that resembled faces when using the sustained response for the evolution, but those features were only infrequently present when using the transient response. For the algorithm to find images that elicit high firing rates, there must be information in both the high and low firing rate regimes of these neurons. Therefore, even in IT, all gradations in firing rate contain information about the feature selectivity of a neuron. This ‘tuning all the way down’ in feature space argues for a distributed representation over the entire macaque visual system. Since the visual system is a processing hierarchy, and V1 and IT are only stages within the hierarchy, the kinds of computations that take place in these areas are likely not qualitatively different. Given this, we may have a glimpse of how recurrent activity in higher order cortex supports recognition.

Title: The nature of category selectivity in the ventral visual pathway

Authors: B. RITCHIE, J. BOSMANS, S. SUN, K. VERHAEGEN, A. ZEMAN, ***H. P. OP DE BEECK**;
KU Leuven, Leuven, Belgium

Abstract: The end stage of the ventral visual pathway is characterized by a category-based representation of objects. The nature of this category selectivity is ill-understood. Two major factors emerge from the literature. On one hand, the search for category-selective regions with maximal selectivity has shown the presence of a few such regions for a small minority of categories, such as faces and other body parts (Downing et al., 2016). On the other hand, analyses of the distributed pattern of selectivity across occipitotemporal cortex at large have emphasized the dominance of more encompassing dimensions, in particular the animate-inanimate continuum (Connolly et al., 2012; Kriegeskorte et al., 2008; Sha et al. 2015). Here we present an experimental paradigm that is designed to dissociate the two hypotheses. Animate stimuli consisted of a single close-up face and full-body image of 24 animals from different biological classes (48 images total). These were contrasted with images of natural objects. We collected data for behavioral tasks including judgments for pair-wise face and body similarity, and similarity to human faces and bodies. The responses from these tasks were used to construct dissimilarity matrices (DM) to perform representational similarity analysis, and compared with DMs constructed from neural responses from ventral pathway regions selective for objects, faces, and bodies measured with human fMRI (N = 15). We found that while the face-body division dominated the organization of the pathway, a weaker animacy continuum effect was also observed. The animacy continuum effect was also preserved when analyzing face and body responses separately. Overall, categorical object representations are primarily organized in terms of similarity to body part templates, and the apparent organization for animate-inanimate is mostly a secondary consequence.

Title: Anterior face patch neurons display characteristic tuning to specific facial parts

Authors: *E. N. WAIDMANN[1], K. W. KOYANO[1], J. J. HONG[1], B. E. RUSS[2,1], D. A. LEOPOLD[1];
[1]Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Nathan S. Kline Inst. For Psychiatric Res., Orangeburg, NY

Abstract: The macaque inferotemporal cortex contains clusters of neurons that are visually selective for faces. Neurons in anterior medial (AM) and anterior fundus (AF) face patches are both thought to be tuned to particular facial identities, but it has not yet been established which facial parts, if any, are critical for the observed identity selectivity. Using a 'face parts swapping' stimulus paradigm, we asked how information about image components of the face, body, and scene are reflected in the responses of neurons in the AM and AF face patches. We decomposed ten photographs of monkeys into constituent body, outer face, eyes, and mouth parts. We then recombined these parts into photorealistic hybrids of the internal face (eyes + mouth), head (internal face + outer face), monkey (head + body), and whole scene (monkey + background scene) stimuli. Using chronically implanted microwire brush arrays, we recorded the responses of individual cells in response to combination stimuli and isolated component parts (1,350 stimuli total). Many cells demonstrated strong tuning to a select set of individual parts. A subset of cells displayed a preference for only one of the two parts in a category pair during the hybrid stimuli recombination, and these cells did not show major response changes when combined with the non-preferred part. Another subset of neurons, often found in AF patch, showed tuning to both image parts within select swapping categories. For these cells we tested whether the response to hybrid images could be predicted by the summation of responses to parts alone. The neurons tended to show positive correlation between expected (summed responses to isolated parts) and observed response to hybrid stimuli, suggesting additive computation of individual parts. These results suggested that anterior face patch cells are dedicated to only one or two specific features of the face, rather than whole facial identities.

Title: Familiar face recognition as deviations from average faces

Authors: Z. SHEHZAD[1], ***G. MCCARTHY**[2];
[1]Columbia Univ., New York, NY; [2]Yale Univ., New Haven, CT

Abstract: We are highly accurate at recognizing familiar faces even with large variation in visual presentation due to pose, lighting, hairstyle, etc. The neural basis of such within-person face variation has been largely unexplored. Building on prior behavioral work, we hypothesized that learning a person's average face helps link the different instances of that person's face into a coherent identity within face-selective regions within ventral occipitotemporal cortex. To test this hypothesis, we measured brain activity using fMRI for eight well-known celebrities with 18 naturalistic photos per identity. Each photo was mapped into a face-space using a neural network where the Euclidean distance between photos corresponded with face similarity. We confirmed in a behavioral study that photos closer to a person's average face were judged to look more like that person. fMRI results revealed hemispheric differences in identity processing. The right fusiform face area (FFA) encoded face-likeness with brain signal increasing the closer a photo was to the average of all faces (Fig 1a). This suggests that the right FFA matches each face against a template to signal how much the stimulus looks like a face. In contrast, the left FFA and left anterior fusiform gyrus (aFus) encoded person-likeness with brain signal increasing the further a photo was from the person's average face (Fig 1b). This suggests that the left FFA and aFus processes an identity error signal that indicates how much a face looks (un)like that person. Our results encourage a new consideration of the left fusiform in face processing, specifically for within-person processing of face identity.

Title: A relationship between autism quotient score and face viewing behavior in healthy adults

Authors: *K. WEGNER-CLEMENS, J. RENNIG, M. S. BEAUCHAMP;
Neurosurg., Baylor Col. of Med., Houston, TX

Abstract: Humans viewing faces make stereotyped eye movements, with fixations localized to the eye, nose and mouth region of the viewed face. Recently, substantial individual variability in face viewing behavior has been documented: some individuals mainly fixate the eyes while others mainly fixate the mouth (Figure 1A). Inter-individual differences are consistent across stimulus exemplars and testing intervals as long as 18 months but little is known about their origin. Differences in face viewing behavior have previously been linked to clinical diagnoses. In particular, people with autism spectrum disorder (ASD) often avoid fixating the eye region of the face. Based on this observation, we set out to determine whether autistic traits in healthy adults could explain individual differences in face viewing behavior. Autistic traits were measured in 98 healthy adults using the autism-spectrum quotient, a validated 50-statement questionnaire. Face-viewing behavior was measured using two different types of audiovisual movies. Syllable movies had duration 2 seconds and consisted of talkers speaking single syllables ("ba", "ga", or "da") that were identified by the viewer. Sentence movies consisted of talkers speaking complete sentences (mean duration 22 seconds) with no task. For both types of movies, there was a correlation between autism quotient score and percent of time fixating the lower half of the face ($r=0.19$, $p=0.05$ for syllable movies and $r=0.31$, $p=0.008$ for sentence movies). These findings demonstrate that higher levels of autistic traits are linked to avoidance of eye fixations during face viewing in healthy adults.

Title: Whole brain fmri reveals the neural correlates of face pareidolia in monkeys

Authors: *J. TAUBERT[1], S. G. WARDLE[2], S. KUMAR[1], C. T. JAMES[1], E. KOELE[3], A. MESSINGER[4], L. G. UNGERLEIDER[5];
[1]The Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Lab. of Brain & Cognition, [3]NIMH, NIH, Bethesda, MD; [4]Lab. of Brain and Cognition, Natl. Inst. of Mental Hlth., Bethesda, MD; [5]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: The common illusion of faces in inanimate objects, known as face pareidolia, can be considered an error of face detection. Previously we have shown that rhesus macaques (*Macaca mulatta*) perceive illusory faces in the same images (e.g. eggplant, bell pepper, coffee) that humans do (Taubert et al., 2017), demonstrating that the experience of face pareidolia is not unique to humans. Here, we used a functional MRI paradigm previously used in humans (Wardle et al., 2017) to investigate the neural correlates of face pareidolia in the macaque brain. We used contrast agent enhanced functional imaging in awake macaques (Experiment 1, *N*=4; Experiment 2, *N*=2) in a 4.7T Bruker vertical MRI scanner. The on-off block design used the same paired stimuli as the human experiment: examples of face pareidolia and matched objects belonging to the same category. In Experiment 2, we also included real faces as a category of stimuli in the design. Place-selective, object-selective and face-selective voxels in temporal cortex were defined in all 6 subjects based on independent data from a functional localizer experiment. In Experiment 1, we tested subjects previously exposed to the experimental stimuli. The results indicated that object-selective voxels responded less to objects with illusory facial features than to objects with no illusory facial features. In Experiment 2, we tested two new subjects never exposed to examples of face pareidolia. Not only did we replicate the results of Experiment 1, the data further indicated that face-selective voxels in the ventral visual system respond more to illusory faces than to non-face objects; the magnitude of this effect was largest near the face-selective patches on the lateral edge of the superior temporal sulcus. Face-responsive voxels in the amygdala and face-selective voxels in the frontal cortex also responded more to examples of face pareidolia than to non-face objects. It is noteworthy that the pulvinar was engaged more by illusory faces than real faces. These data reveal that an extensive network of brain regions is activated when facial features are falsely detected in the visual environment, even though the visual characteristics of illusory faces differ markedly from those of real faces.

Title: fMRI and MEG reveal the spatial organization and temporal dynamics of illusory face perception in the human brain

Authors: *S. G. WARDLE[1], J. TAUBERT[1], L. TEICHMANN[2], C. I. BAKER[1];
[1]Natl. Inst. of Mental Hlth., NIH, Bethesda, MD; [2]Cognitive Sci., Macquarie Univ., Sydney, Australia

Abstract: The human brain is specialized for face processing, yet we sometimes spontaneously perceive illusory faces in inanimate objects. To understand how the human brain processes illusory faces we used fMRI (N=21) and MEG (N=22) to measure the whole-brain activation patterns in response to human faces, illusory faces, and matched objects without an illusory face in an event-related design. In terms of spatial organization, fMRI cross-decoding analysis revealed that both face-selective FFA and object-selective LO in occipitotemporal cortex were sensitive to the presence of an illusory face, as a classifier trained on the distinction between BOLD activation patterns associated with viewing objects with and without illusory facial features was able to predict the presence of a face in new images. This was not the case for scene-selective PPA, although activity in all three regions could successfully discriminate real human faces from objects regardless of whether they had an illusory face. Examination of the underlying representational structure revealed that illusory faces were represented more similarly to human faces than matched nonface objects were in FFA and LO, but not in PPA. In terms of temporal dynamics, MEG revealed that as quickly as 130ms after stimulus onset the presence of an illusory face in an object could be decoded from MEG activation patterns. Combining fMRI and MEG data showed that the representations of the stimuli measured with MEG from 150-190ms post-stimulus onset correlated with their representations in the FFA measured with fMRI. This suggests the FFA has a role in rapid face detection, even when the facial features are illusory and have visual characteristics markedly different from those defining real faces. Further, MEG revealed that although illusory faces were initially similar to real faces in the brain's representation, by only 260ms following stimulus onset, the illusory faces were treated more like objects than like faces. Overall the results show that illusory faces are processed incredibly rapidly by the human brain. This is consistent with the recruitment of a broadly-tuned template for face detection which privileges sensitivity over selectivity.

Title: Neuronal coding of dynamic partial shape views in the body selective patch of the anterior STS

Authors: *A. BOGNÁR, R. VOGELS;
KU Leuven, Leuven, Belgium

Abstract: Shapes can be perceived as an integrated whole even if their small parts are presented in succession at the same retinal position. Human fMRI studies suggested that these temporally integrated whole shape identities are coded by the lateral occipital complex. To investigate the neuronal mechanisms, we measured single unit responses in the macaque anterior body patch, presenting animal silhouettes moving behind a narrow 0.48° horizontal or vertical slit in both directions.
Responsive neurons were searched with 70 silhouettes. For each neuron, we selected three shapes with different response strengths for further testing. The slit-viewing trials started with the presentation of a fixation spot for 300 ms on top of a noise background, then a vertical or horizontal empty slit inside the noise pattern was presented 1° in the contralateral field, or under the fixation spot, respectively, for 480 ms. The shape moved behind the slit for 773 ms at 6.2°/s. We used two control conditions: a feature-preserved temporal randomized stimulus presentation in which slit-views of 80 ms duration were presented in a randomized order to eliminate the coherent form percept, and one where the 80 ms slit-views were presented in their correct order.
Single neurons showed diverse response patterns during slit viewing. At the population level, firing rates for the slit-views were lower than for the static whole shapes. The shape selectivity of the static stimuli was preserved for the slit-views. We observed a higher firing rate for the slit-views of the original than for their randomized presentation, but the shape selectivity was also preserved for the latter condition.
SVM classification showed reliable decoding of the shapes for the static and slit-viewing conditions. Classifiers trained on the slit-view responses and tested on whole shape responses showed generalization, but not vice versa. Classifying data temporally binned per motion direction showed a high decoding accuracy when the same features were presented, but low accuracy for non-corresponding views. Generalization between orientations was significant but weaker than between motion directions.
Our results suggest that these neurons respond to slit information of their preferred features, but not encode the whole shapes in a slit-invariant way. The differences between the coherent shape and randomized presentation may result from temporal summation of responses to neighbouring views of effective features, which are presented in succession in the original presentation, while these features may be split or surrounded by ineffective body parts, causing masking effects, in the randomized condition.

Title: Effects of tactile stimulation on face and object perception of face transplant patients and controls

Authors: *E. GÜLBETEKIN[1], S. BAYRAKTAR[1], Ö. ÖZKAN[2], Ö. ÖZKAN[2], H. UYSAL[3], A. U. SENOL[4], Ö. COLAK[5], A. SAVKLIYILDIZ[5], D. KANTAR GOK[6];

Faculty, Akdeniz Univ., Akdeniz Univ., Antalya, Turkey

Abstract: The first aim of the study is to understand the effects of tactile stimulation on face perception. The second aim is to find out if there is any difference between facial trauma patients and healthy controls.Two facial trauma patients (a face transplant patient and a patient who has not been operated yet), 10 controls (5female, 5male).The subjects observed faces while a robotic finger was touching on their faces simultaneously. An object perception task was also used as a control task. Forty faces and 40 non-face objects were presented. In the acquisition stage, a fixation point was presented for 3sec, following a black screen for 4sec and a face was presented for 3sec. The robotic finger touched the subject's left cheek for 3sec while he/she was still observing the face. The same procedure was applied for the object task. After each task, the subjects were tested in a face/object recognition test. During the task and test phases, brain signals were recorded via 64 channel Actichamp EEG and subjects' skin conductance responses were recorded via Arduino-based GSR device. Evoked response potentials (ERPs) were averaged from 200 ms before (−200 ms) to 1000 ms after stimulus onset. ERP components were identified and measured with respect to the average baseline voltage over the interval from −200 to 0 ms. The amplitude was measured at occipital and parietal sites (O1, O2, OZ, P3, P4, P7, P8, PO3, PO4, PO7, PO8, TP9, TP10). Results: We found a face-specific P100 response (150-200ms) at the occipital electrode sites (O2, O4, PO4, PO8) and P300 responses over the electrodes OZ, P4,P8, PO3, PO7, PO8 while the subjects were observing the faces. However, the amplitude was higher over the electrodes O1, PO3, PO7, and PO8 during robotic finger stimulation. GSR results showed that the touch of the robotic finger does not have any significant distractive effect ($p>.05$). The subjects' correct response ratios for faces was lower than their correct response ratios for non-face objects $F(1, 11) =44,55$, $p= .001$. Accuracy was .86 for non-

face objects and .65 for faces. The mean accuracy of facial trauma patients is .73 for non-face objects and .50 for faces. The response time (RT) was also different for the two tasks $F(1, 11) = 10,70$, $p = .007$. (1053,81ms and 1462,51ms for non-face objects and faces respectively). The patients' RT was 933,38ms for non-face stimuli and 1340,13ms for faces. It seems that the patients were fast but not correct. The preliminary results indicated that tactile stimulation of one's own face has a significant effect on the perception of other faces. Behavioral and neural data pointed out that there is a difference in face processing of the patients and the controls.

Title: Is the face schema innate? Evidence from learning faces in the congenital blind

Authors: *L. T. L. LIKOVA, M. MEI, K. MINEFF, S. NICHOLAS;
Smith-Kettlewell Eye Res. Inst., San Francisco, CA

Abstract: To address the longstanding questions of whether people blind from birth have an innate face-schema, what plasticity mechanisms underlie non-visual face learning, and whether there are interhemispheric differences in face processing in the blind, we used a unique non-visual drawing-based training in groups of congenitally blind (CB), late-blind (LB), and blindfolded-sighted (BF) adults. This Cognitive-Kinesthetic Drawing approach previously developed by Likova (e.g., 2010, 2012, 2013) enabled us to rapidly train and study training-driven neuroplasticity across a levels of visual deprivation. The five-day 2-hour training taught participants to haptically explore, recognize and memorize raised-line images, and then draw them free-hand from memory, in detail, including the fine facial characteristics of the face stimuli. Such drawings represent an externalization of the formed memory. Functional MRI (Siemens 3T) was run before and after the training. Tactile-face perception activated the occipito-temporal cortex in all groups. However, the training led to a strong, predominantly left-hemispheric reorganization in the two blind groups, in contrast to right-hemispheric in the blindfolded-sighted, i.e., the post-training response-change was stronger in the left hemisphere in

the blind, but in the right in the blindfolded. This is the first study to discover hemispheric lateralization for non-visual face processing. Remarkably, for face perception this learning-based change had a sign inversion: positive in the CB and BF groups, but negative in the LB-group. Both the lateralization and inverse-sign learning effects were specific to face perception, but absent for the control nonface categories of small objects and houses. The unexpected inverse-sign training effect in CB vs LB suggests different stages of brain plasticity in the ventral pathway specific to the face category. The fact that a few days of our training sufficed for the totally-blind-from-birth CB to manifest excellent face perception, and even empathy to the facial expression, implies the presence of a preexisting face schema that can be "unmasked" and reactivated by a proper learning procedure. A rebound learning model and a neuro-Bayesian economy principle are proposed to explain the multidimensional learning effects. The results provide new insights into the Nature-vs-Nurture interplay in rapid brain plasticity and neurorehabilitation.

Title: Intermediate visual features of primes bias trustworthiness ratings of neutral faces

Authors: *A. C. DEL GIACCO, K. D. RANA, X. YUE, M. GHANE, L. G. UNGERLEIDER; Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Recent studies have demonstrated that images of textures comprised of intermediate visual features are sufficient for above chance categorical classification of animacy and elicit a functional effect in the amygdala related to affective content (Long et al. 2018; Zachariou et al. 2018, 2019). Hooker et al. showed that images consisting of threat-related content will color the trustworthiness judgments of subsequently presented neutral faces (Hooker et al, 2011). The present study (n=19) addressed whether intermediate visual features are sufficient to bias trustworthiness judgments of neutral faces. Using an algorithm, adapted from previous studies, we generated textured versions of animal images which removed global shape information but kept intact the original images' varying amounts of curvilinear and rectilinear features (Freeman and Simoncelli, 2011; Zachariou et al. 2018). Subjects were presented a priming paradigm with intact or texturized prime images of animals that varied in: threat content (defined by independent ratings of arousal and valence), and in their intermediate level features

(curvilinearity and rectilinearity). Textures were presented first in the paradigm followed by a high contrast mask and then a neutral face. Participants were asked to rate the trustworthiness of faces on a continuous scale. We used a factorial ANCOVA to measure the effects of the prime image features (valence, arousal, curvilinearity, rectilinearity) and their interaction with the prime type (intact/texturized) on the face trustworthiness judgments. In addition, we performed posthoc correlation tests to assess the direction of bias on the trustworthiness ratings. The results revealed a significant negative bias of trustworthiness rating on the faces when presented primes with low valence, high arousal, and high curvature, but no significant effect of the prime type. This suggests that the texturized prime, with no global shape information, are sufficient to influence trustworthiness judgments of faces.

Title: V4 local field potentials explain shape detection accuracy, precision, and learning

Authors: *E. J. MOORE, K. WEINER, G. GHOSE;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Visual perceptual learning (VPL) is the improvement in the ability to perceive our visual environment, and is essential to how humans and other animals learn to interact with the world. Despite an extensive amount of research, the neural mechanisms responsible for VPL improvements remain controversial. A major challenge has been establishing that physiological correlates of learning is actually responsible for learning, as opposed to merely reflecting changes in the properties or populations responsible. To address this, we employed a perceptual detection task in which neurons in a specific area, V4, have shape driven responses on a scale of tens of milliseconds that are predictive on a trial by trial basis of successful detection. We followed population responses using a chronically implanted electrode while two male subjects (*Macaca mulatta*) learned to detect shapes degraded by noise. Consistent with previous results examining single neurons and neuronal ensembles, we found that, after the course of learning,

variations in the local field potentials of individual electrodes over the course of tens of milliseconds reliably reflected the presentation of degraded shapes and predicted detection decisions made by the animals, and the amplitude of such signals increased after training. Moreover, variations in reliability of shape-related, but not choice-related, signals predicted the significant up-down fluctuations in performance seen over the course of learning in each animal. Together, these results demonstrate that local population signals in area V4 are largely sufficient to explain the timing and reliability of shape detection and how that detection performance increases as a consequence of training.

Title: Sparse deep predictive coding to model visual object recognition

Authors: *V. BOUTIN[1], A. FRANCIOSINI[1], F. RUFFIER[2], L. PERRINET[1];
[1]Inst. Des Neurosciences De La Timone, Marseille, France; [2]Inst. des Sci. du Mouvement, Marseille, France

Abstract: Convolutional Neural Network (CNN) are popular to model object recognition in the brain. They offer a flexible and convenient framework to model the hierarchical stacking of cortical areas that compose the Visual Ventral Stream. However, CNN suffers from major drawbacks in comparison with realistic models of biological vision. First, CNNs are mostly feedforward and cannot account for the recurrent processing that takes place in the visual cortex. Second, the back-propagation rule used to train CNN involves global learning rules unlikely to be implemented in the brain. Third, the representation generated by CNNs are most often dense whereas those generated by the visual cortex are sparse.
To improve biological plausibility, we propose a new model called Sparse Deep Predictive Coding (SDPC). The SDPC framework takes advantage of the Predictive Coding (PC) theory to model the dynamic update scheme observed in the visual cortex. PC suggests, among other scenarios, that feedback connections from a higher cortical area carry neural predictions to the lower cortical area, while the feedforward connections propagate the unpredicted information (or prediction error) to the higher area. As such, the neuronal state of a layer is recursively updated

towards minimized prediction error. Interestingly, PC approximates the CNN back-propagation into a local learning rule that is assimilable to a biologically realistic Hebbian learning rule. Last but not least, PC includes a local competition mechanism between neurons that performs an 'explaining away' strategy with sparse coding. The SDPC offers a hierarchical and convolutional implementation of the PC theory.
We experimentally assess the SDPC model using two different image databases. First, we quantify how well the SDPC is untangling the visual information contained in a handwritten digits database (called MNIST) under normal and noisy condition. To do so, we train a simple linear classifier to recognize SDPC representation, and we assess the classification accuracy with different level of perturbation. Our results show that the SDPC compete with a similar state-of-the-art model in term of classification accuracy and noise robustness. Second, we point out the qualitative similarities between the biological Receptive Fields (RFs) of the early visual cortex and the features learned by the SDPC model on a face database (called AT&T).
As a result, the SDPC model accounts both for high level behavioral observation (recognition under noisy and normal environment) and electrophysiological results as Gabor-like RFs.

Title: Cortical feedback modulation of experience dependent oscillations in mouse primary visual cortex

Authors: *Y. TANG, A. CHUBYKIN;
Dept. of Biol. Sci., Purdue Univ., West Lafayette, IN

Abstract: Experience-dependent plasticity plays an important role in the acquisition of new skills and neural circuit reorganization after injury. Dissecting the circuit mechanisms underlying adult plasticity may help in developing new specific treatments for learning deficits and injury-induced functional impairment. In the mouse primary visual cortex (V1), oscillatory activity emerges after visual perceptual learning, where the mouse passively views a visual stimulus repetitively over days. This oscillation is specific to the spatial frequency of the familiar stimulus and may emerge from the activity of a neuronal ensemble that encodes the spatial frequency of the familiar stimulus. Recent studies have shown that the mouse visual cortex has functionally

specialized regions, among which the lateromedial (LM) visual cortex forms the strongest reciprocal connections with V1. LM feedback connections have been reported to modulate spatial frequency tuning properties of neurons in V1 making them top candidates in modulating the spatial frequency-specific oscillations post-training. To test whether LM modulates experience-induced V1 oscillations, we recorded local field potential (LFP) and single unit activities in V1 with optogenetic inactivation of LM after visual perceptual training. In both LFP and population unit firing, the expression of V1 oscillations was greatly reduced by LM inactivation, with diminished second and third oscillation cycles but almost no change in the visually locked response. LFP frequency band powers were reduced in a wide range of frequencies, which suggests that LM modulates various neural processing pathways that are associated with V1. LM inactivation had broad effects on V1 unit subpopulations, where one subpopulation that fired at multiple cycles had reduced firing at the later cycles of the oscillation and another subpopulation that preferentially fired at the third cycle also showed decreased firing. This preliminary result suggests that LM feedback connections may play a role in familiarity recall in mouse V1.

Title: Representations of image identity and image memorability are shaped by different mechanisms in inferotemporal cortex

Authors: V. MEHRPOUR, T. MEYER, ***N. C. RUST**;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: While we are generally very good at remembering the images that we have seen, we systematically remember some images better than others. The neural correlates of 'image memorability' are thought to reside in high-level visual brain areas such as monkey inferotemporal cortex (IT), where the images that evoke the largest magnitude population responses are remembered best. Remarkably, this same signature is also observed in convolutional neural network models trained to categorize objects, where, like the brain, higher layers of these networks are activated more strongly by some images than others, and the

magnitude of network activation correlates with the images that humans and monkeys find most memorable. Together, these results suggest that the representations of image identity and image memorability are tightly linked. Are they shaped by the same neural mechanisms? To investigate this question, we explored the stimulus-evoked dynamics of IT image identity and image memorability representations in data collected as two rhesus monkeys performed a single-exposure visual memory task. We quantified the dynamics of IT image identity representations as the performance of a multi-way, cross-validated linear classifier at determining image identity based on the IT population response measured at different positions relative to stimulus onset. We quantified the dynamics of image memorability as the strength of the correlation between the magnitude of the IT population response and image memorability scores, also as a function of time relative to stimulus onset. We found that image identity and image memorability representations emerged with different dynamics: identity representations emerged earlier and peaked at 140 ms after stimulus onset, whereas memorability representations emerged later and peaked at 220 ms. These dynamics could be attributed to IT population response vectors that emerged with the distinct patterns indicative of identity representations but with similar magnitudes, and only later reflected the magnitude variation indicative of image memorability. Together, these results suggest that representations of image identity and image memorability are shaped by different mechanisms in IT.

Abstract: While visually exploring the environment, people centralize objects of interest in the fovea. But when the fovea is damaged, as in many Low-Vision (LV) patients, central vision is lost and is no longer useful for seeing. Patients start using systematically one or more peripheral retinal regions called preferred retinal loci (PRL) to perform visual tasks, centralizing objects to this PRL, which is also accompanied by neuroplastic events as changing the retinotopic map in V1 or re-referencing eye movements to this region instead of the fovea. Moreover, their performance using their PRL in some visual tasks that require high visual acuity, like reading, can be improved by training. But ¿Can we exploit these neuroplastic events and train people in their peripheral vision to improve their performance in more complex visual tasks as facial emotion recognition? We explore this question by training peripheral vision of 8 normally sighted subjects for 6 sessions (6 weeks; 1 session/week) in a facial emotion recognition task while their eyes movements are recorded using an eye tracker. The task consisted of 4 blocks of 10 trials each one. In each trial a face was presented with or without emotion, 15º left to a point of fixation. Subjects were encouraged to maintain their vision in the point of fixation and to recognize whether there is an emotional face and which emotion was displayed. At the initial session, subjects were able to correctly recognize the presence of emotion in about 80% of faces, but they correctly identified the emotion in only 60% of cases. Reaction times in this session were about 2.5 sec. After training, subjects were able to correctly identify the emotion in about 75% of emotional faces and the reaction time for recognizing the presence of emotion was reduce by about 30%. We found training normally sighted subjects improves their performance in facial emotion recognition without affecting fixation stability. These results support the idea that peripheral vision can be trained in order to perform a complex visual task as facial emotion recognition and hint to the necessity to further explore the utility of this training protocol in patients with LV caused by retinal diseases that produce central vision loss.

Title: Decoding memory-specific feedback signals from early visual areas

Authors: *J. ORTIZ-TUDELA[1], J. BERGMANN[2], M. BENNETT[3], L. MUCKLI[2], Y. SHING[1];
[1]Goethe Univ., Frankfurt, Germany; [2]Inst. of Neurosci. and Psychology, Col. of Medical, Vet. and Lif, [3]Ctr. for Cognitive Neuroimaging, Univ. of Glasgow, Glasgow, United Kingdom

Abstract: Predictive accounts of the brain rely heavily on the idea that the human brain stores some form of information from which predictions can be drawn. However, the source and nature of this information still remain largely unknown. We propose that episodic memory may be a candidate source for predictions. In order to test this hypothesis, we use a paradigm that has shown to be suited for isolating predictions fed-back to early visual cortex: by physically occluding portions of scenes it is possible to record activity in non-stimulated regions of the early visual cortex. In a first study, participants were trained with cartoon images depicting common real-world locations that included one key object. In a subsequent session 24 hours later, we used high-resolution fMRI to record activity from the voxels in V1 and V2 responding to the retinotopic region corresponding to the object's location while participants performed an object retrieval task. Critically, these images did not include the target objects. We used multivariate pattern analysis to decode scene and object-specific information. The results show that we were able to reliably detect feedback from the scene contexts. However, we could not detect any object-specific information. In a second study, we aimed at strengthening the perceptual features of our participants' memories for the objects by 1) making the objects more distinct in color and shape, 2) increasing the duration of the study session and 3) including a post-study task that required participants to manually draw the objects in their specific location in the original images. Preliminary results show that classification performance for object-specific information is above chance in the occluded sub-regions of both V1 and V2. We also performed cross-classification between different subsets of scenes paired at study with the same objects to assess the generalizability of common information triggered by different cues. Cross-classification was successful in V1 and V2 suggesting precise reinstatement of the objects in memory. As a next step, we will further explore the layer-specific information profile of these feedback signals in the visual cortex and relate them to activity in distant areas that are critical for episodic retrieval (i.e., hippocampus).

Title: Temporal expectation in marmosets

Authors: *T. DRAGOI[1], H. SUGIHARA[1], M. HU[1], J. SHARMA[1], M. SUR[2];
[1]Picower Inst. for Learning and Memory, [2]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: In natural environments, animals continuously use stimuli in specific contexts which help them predict and expect forthcoming events. Expectation is an internally generated state that utilizes prior knowledge of the environment to optimize behavioral responses to changing stimulus contexts. Previous work by our lab and others has shown that humans and macaques utilize prior information such as the probability of an event based on past occurrences, which helps reduce uncertainty and improve performance (Sharma et al. 2003, Summerfield et al. 2006). Expectation in a temporal context has been shown to follow hazard rate measurements of an event's rate of occurrence over time. (Ghose and Maunsell 2003, Janssen and Shadlen 2005). Higher brain areas likely use prior information and feed it back to update motor plans for behavioral adjustments to changing task variables. To uncover if marmosets utilize similar strategies to optimize behavior, we developed an expectation based task in marmosets using an in-home cage training system. Two marmosets were trained to hold off touching a tablet until a visual cue was provided, at which point a touch must be registered. To understand if they used hazard rate to guide expectation in this simple task, we measured reaction times to uniformly varying lengths of time of cue disappearance. Although tested in a less controlled environment, our early results show that marmoset reaction time shortens with longer stimulus duration. The distribution of touches following the disappearance of a cue sharpened over time, with mean latency (0.6s) and full width half maximum (0.021s) decreasing across 3 months of exposure to the task. An uncertainty-based hazard rate model more closely correlated with reaction time when compared to standard hazard rate models indicating that reaction time is sensitive to the uncertainty of upcoming stimulus events. We believe that elapsed time is differentially used to adjust reaction times in response to changing patterns of visual input. Further work will examine the neural underpinnings of stimulus expectation. Specifically, we will use optogenetic and pharmacological manipulations to change balance between cortical excitation and inhibition in local and long range cortical circuits to investigate their role in temporal prediction and expectation. Atypical temporal prediction has been implicated in autism, thus our research has the potential to uncover elements of neural processes in such disorders such as how integration of bottom-up and top down feedback in cortical networks provides contextual processing.

Title: Perceptual scaling improves eyewitness identification

Authors: *S. G. GEPSHTEIN[1], Y. WANG[2], F. HE[2], D. DIEP[1], T. D. ALBRIGHT[1];
[1]The Salk Inst., La Jolla, CA; [2]Div. of Biol. Sci., Univ. of California, San Diego, CA

Abstract: Eyewitness identification has long played a valuable role in criminal investigations and prosecutions. Despite this value, our society has been confronted in recent years with many rank failures of eyewitness testimony. For example, more than 350 people, many serving lengthy prison sentences, have been exonerated in the US because their DNA was found to be incompatible with evidence collected from the crime scene. In approximately 70% of these cases, misidentification by eyewitnesses contributed significantly as evidence for conviction.
It is natural to ask what can be done to improve the "performance" of eyewitnesses, such that they are more likely to identify the culprit and less likely to misidentify an innocent person. A major focus of research on this topic has been the manner in which an eyewitness lineup is presented. The traditional "simultaneous" (SIM) lineup is composed of (typically) six facial photographs shown at the same time. One of the faces is that of the suspect and the others, known as fillers, are of people known to be innocent. The alternative "sequential" (SEQ) lineup involves presenting the photographs one at a time. In both lineup types, witnesses are asked to identify the perpetrator or to reject the lineup if no face matches the memory from the crime scene.
The performance of eyewitnesses under the SIM and SEQ paradigms can be explained as the product of recognition memory, a form of declarative memory retrieval in which a sensory "cue" stimulus elicits the trace of a previous encounter with the stimulus, perhaps in a different form or context. This recognition memory is the internal response of the eyewitness upon which a decision is made. The eyewitness also possesses an internal decision criterion: only signals that meet this criterion lead to identification. Because this recognition process is covert, the overt response ("that's the culprit") confounds the strength of the internal response with the internal decision criterion, leaving the outcome susceptible to unrecognized bias.
We describe a novel lineup procedure that permits estimation of memory strength independent of the decision criterion. This procedure employs a longstanding psychophysical technique called the Method of Paired Comparisons. We find that this approach yields accurate identifications

that are uninfluenced by decision bias. The new procedure reveals structure of eyewitness memory that is inaccessible by traditional lineup procedures, allowing triers of fact to estimate the probative value of testimony proffered by individual eyewitnesses.

Title: Visual perceptual learning in the ferret

Authors: *E. L. DUNN-WEISS[1], J. J. ROSS[2], K. J. NIELSEN[1];
[1]Neurosci., Johns Hopkins Univ., Baltimore, MD; [2]Morgan State Univ., Baltimore, MD

Abstract: Visual perceptual learning has been shown to induce plasticity in adults, and even improve visual acuity in the weak eye of adults with amblyopia. Hence, this plasticity is powerful, and clinically relevant. Previous studies have identified putative neural correlates of learning in visual cortex, using fMRI, EEG, and single-unit recordings. However, how learning affects the joint response properties of groups of neurons in visual cortex has received less attention. To begin to investigate this question, we developed a novel head-fixed behavioral setup for ferrets, designed to test them on two-alternative forced-choice tasks. Ferrets are a useful animal model because their visual cortex shares functional properties with non-human primates, including smooth feature maps in primary visual cortex. At the same time, they are amenable to techniques that allow simultaneous recordings from groups of neurons, such as two-photon imaging or recording with multi-site probes. Here, we used the head-fixed setup to first train ferrets to discriminate between gratings rotated clockwise or counterclockwise relative to an oblique reference. Task difficulty could be manipulated by changing the angular distance between the test gratings and the reference. Ferrets were able to perform this task, demonstrated by low lapse rates on the easiest discriminations, and their performance was fit well by standard psychometric functions. After measuring initial psychometric functions, we trained ferrets to discriminate gratings at threshold. Training systematically improved performance, as indicated by less errors on the trained condition and a change in threshold and slope of the psychometric function. In addition to the orientation discrimination task, we found ferrets to be particularly trainable in direction discrimination and motion integration tasks, and continuous training on the latter also resulted in significant performance gains. These results demonstrate that ferrets exhibit the required behavior to be used in learning studies. We are currently incorporating two-photon calcium imaging and electrophysiological recordings using multi-site probes into these

behavioral experiments. These data will provide important insight into learning-induced plasticity at the network level.

Title: Representations of image memory and image memorability are largely non-overlapping in inferotemporal cortex

Authors: *V. MEHRPOUR[1], E. P. SIMONCELLI[2], N. C. RUST[1];
[1]Psychology, Univ. of Pennsylvania, Philadelphia, PA; [2]New York Univ. / HHMI, New York, NY

Abstract: Humans are generally very good at remembering the images that they have seen, although some images are easier to remember than others. Neural correlates of both 'image memory' and 'image memorability' have been linked to inferotemporal cortex (IT), but current accounts of their representations are in conflict. Considerable evidence suggests that image memory is signaled by a reduction in response for familiar as compared to novel images ('repetition suppression'), and lower firing rates correspond to better behavioral memory performance. In contrast, recent findings demonstrate that more memorable images evoke stronger responses in IT, both when images are novel and when they are repeated as familiar, thereby violating the tenet that lower firing rates map to more robust memory behavior. How can these conflicting accounts of image memory and image memorability representations in IT be resolved? To address this question, we analyzed neural data collected from IT as two rhesus monkeys performed a single-exposure visual memory task in which they viewed images and indicated whether they were novel (never seen before) or familiar (seen exactly once). We compared cross-validated linear decoding performance for memory and/or memorability when applied to the intact data and after removing different types of information from the population. Projecting out total spike count information (i.e., projecting the response vectors onto the subspace orthogonal to the (1, 1, 1, ⋯) vector) had a measurable, albeit small, impact on both memory and memorability decoding performance, suggesting that both signals were partially correlated with the total spike count. However, projecting out the linear axis that best captured

either memory or memorability information had minimal impact on the linear decoding performance for the other signal, beyond that attributed to the total spike count. Together, these results suggest that image memory and image memorability occupy partially but largely non-overlapping linear subspaces in IT.

Title: Primary visual cortex integrates information across a wide range of time scales and can predict conditional and high-order sequential associations

Authors: *S. KNUDSTRUP, C. JENSEN, B. PRICE, J. GAVORNIK, R. SCHECTER; Biol., Boston Univ., Boston, MA

Abstract: Neurons in V1 are tuned to respond to spatial patterns in the visual scene. Receptive fields quantifying this relationship are well characterized and commonly used as a model to understand how the cortex uses feed-forward processing to extract information. One might think this means we can accurately predict firing patterns of V1 neurons based on an analysis of the spatial content of visual stimulation patterns; one would be wrong. Similar spatial patterns drive different responses when they are presented in an isolated "sciencey" context than they do when presented during a "naturalistic" movie and there is no satisfying explanation for why. A variety of recent studies have shown that movement, spatial location, reward expectation, auditory inputs, attention , and visual experience can all modify evoked activity patterns in V1. A possible explanation for the scope of observations is the idea that cortical circuits perform predictive coding. Implied in this notion is a required ability to represent temporal relationships between otherwise discrete elements of a stimulus or memory. Accordingly, we performed a series of experiments to understand how temporal and ordinal context modulates the activity of V1 circuits. We find that V1 can integrate events occurring seconds apart into a predictive representation, suggesting access to some form of memory persisting well beyond the temporal component of classically defined spatiotemporal receptive fields. We also find that V1 activity can encode conditional probability and higher-order sequential relationships. Assuming it has emerged in the months since abstract submissions closed, we will discuss evidence constraining possible mechanisms. Our results support the idea that predictive coding is a canonical function

of cortical circuits that can be observed and dissected in V1, that complex visual processing occurs at a lower-level in the "visual hierarchy" than usually assumed, and suggest a model system to study the mechanistic bases of implicit learning defects associated with various neuropsychiatric disorders.

Title: Unsigned reward prediction error signals in frontal eye field

Authors: *M. R. SHTEYN[1,2], C. R. OLSON[1,2];
[1]Ctr. for the Neural Basis of Cognition, Carnegie Mellon Univ., Pittsburgh, PA; [2]Dept. of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: In classic learning theory, surprise is quantified by unsigned prediction error, which determines how much attention is captured by a particular event. Unlike signed reward prediction error, an unsigned prediction error increases with the improbability of an outcome, regardless of its valence. Neurons in the frontal eye field (FEF) are sensitive to reward amount and are involved in the allocation of attention but it is unknown how they respond to surprising outcomes. To address this issue, we trained macaque monkeys in a Pavlovian paradigm requiring them to maintain central fixation while two visual cues were presented in the neuronal receptive field followed by delivery of a reward. Each cue was presented for 300 ms followed by a 600 ms delay. The leading image, depending on its identity, predicted with high probability ($p = 0.83$) delivery of either a large or a small reward at the end of the trial. The trailing image indicated with certainty that the ensuing reward would be either large or small. The information conveyed by the trailing image usually ($p = 0.83$) confirmed, but occasionally ($p = 0.17$) violated, the prediction conveyed by the leading image. In accordance with previous reports, we found that a leading image indicating a high probability of large reward elicited a strong visual response. Likewise, a trailing image predicting large reward elicited stronger activity than a trailing image predicting small reward. The key question of the study was whether a given trailing image would elicit differential firing depending on whether it confirmed or violated the expectation created by the leading image. We found that the strength of the response to the trailing image indeed was

influenced by surprise. Neurons responded more strongly to a trailing image predicting large reward when the probability of large reward was low (p = 0.17) than when it was high (p = 0.83). Similarly, neurons responded more strongly to a trailing image predicting small reward when the probability of small reward was low (p = 0.17) than when it was high (p = 0.83). With appropriate controls we have established these results depend on information about the impending reward and not on the identity or physical salience of the trailing image. In an additional experiment, we show these results depend on whether informative cues appear inside or opposite the receptive field. These results are consistent with the interpretation that cues signaling surprising outcomes capture spatial attention and, in doing so, recruit excitation of FEF neurons with receptive fields encompassing the cue location.

Title: Determination of correlation between eye movement parameters and academic performance of undergraduate senior students

Authors: H. ARGUNSAH BAYRAM[1], M. SAHINER[2], O. HATIPOGLU[1], *M. B. BAYRAM[1], L. ALTINTAS[2], T. SAHINER[3];
[1]Med. Engin., [2]Med. Sch., Acibadem Mehmet Ali Aydinlar Univ., Istanbul, Turkey; [3]Mem. Hosp., Istanbul, Turkey

Abstract: Objective: It was aimed to investigate the correlation between the neurophysiological parameters of the voluntary eye movements controlled by the brain stem connections of the prefrontal cortex, which have an important role in behavioral and learning physiology, and the correlation between the academic achievements of the undergraduate senior students.
Methods: 35 students (n= 35 participants, 19 males and 16 females aged between 20 and 26 years old (m= 24.77; SD= 3.15)) participated in the study, 6 participants' data has been analyzed. All participants' cumulative academic achievement data (Cumulative GPA) were obtained. Each participant completed a two-stage standard Trial Making Test, one stroop test and one visual attention test while wearing Tobii Pro 2 wearable eye tracker. Eye focus mapping, visual attention points and pupil diameter parameters were collected to obtain information about the cognitive functions of the participants. Fixation index (total gaze point/normalized time on task) was defined and correlated with participants' cumulative GPA (M=3.06 SD=0.31) and Felder-Soloman Index of Learning Styles.
Results: The occurrence rate of micro-saccades, which are the small, involuntary eye movements

observed during attempted fixation moments, and pupil diameter variation indicated that the trail making tests were difficult and distinctive as pupil diameter variation was statistically different during these tasks ($p< 0.05$). Participants' fixation indices indicated significantly higher cognitive load during the difficult Trail Making tasks (m=1.46, sd=0.66) compared with the easy attention tasks (m=1.51 SD=0.33) ($p< 0.001$). Pairwise comparisons showed that the difference between the easy and difficult tasks was statistically significant ($p< 0.05$).
Conclusions: The pupil diameter is an indication of cognitive load. In this study, we offered a fixation index to interpret the cognitive load based on measurement of total gaze points during mental trail making and attention tasks. Gaze analysis of the preliminary results indicated that eye movement strategy and fixation index is correlated with the academic achievements of the senior undergraduate students and the learning style index is a distinctive parameter for interpreting the brain function during cognitive tasks.

Title: Modulation of alpha ERD reflects the acquiring and the emerging structure of novel visual categories

Authors: *J. FISER, S. JELLINEK;
Central European Univ., Budapest, Hungary

Abstract: EEG alpha-band oscillations reflect inhibitory control processes that provide selective access to stored memory, while the onset of alpha event-related desynchronization (ERD) indicates the beginning of recognition/categorization accessing internal conceptual representations. Studies investigating the role of ERD in visual categorization tasks typically use discretely exemplars that are either objects familiar to the observer or have been used in an intensive training into categories prior to the EEG recordings. Thus, it is unclear whether ERD can provide more complex information about the stored representation, such as the dynamics of category formation during learning and the strength of class membership of the given stimulus, beyond simply indicating the onset of the categorization process. We used an altered version of the oddball paradigm typically used for assessing the link between ERD and visual categorization. First, instead of countable individual examples, we used a continuous range of

similar stimuli (human silhouettes) that varied along one parameter, their aspect ratio from thin to fat. Second, we recorded EEG signals throughout the entire learning process, not only after the categories have been formed. Participants' task was to classify the stimulus appearing for 800 ms on the screen as Fat or Thin by pressing a key without receiving any feedback. On each trial, we recorded the participants' choice, RT, and subjective uncertainty as well as their neural responses by a 128-channel high-density EEG setup. Similar to earlier results, we found significant differences in alpha ERD elicited by the frequent and infrequent stimuli [$t(22)=2.88$, $p<.01$]. For stimuli sampled around the category boundary this difference was less articulate early on and became significant only towards the end of the recording sessions. Overall, the amount of ERD was in a remarkably linear agreement with the deviation from the dominant width parameter of the frequent category [$r = -0.98$, $p<.05$]. Thus, alpha-suppression is not only an indicator of the already acquired structure of concepts, but it also allows for reliable tracking the ongoing acquisition of categories, and the strength of the neural response reflects the structure of the internal representation specifying the learned categories.

Title: Single cells in mouse medial prefrontal cortex represent learned rules for categorization

Authors: *S. REINERT, T. BONHOEFFER, M. HÜBENER, P. M. GOLTSTEIN;
Max-Planck-Institute of Neurobio., Martinsried, Germany

Abstract: Categorization is a learning strategy for forming meaningful groups of objects and experiences. Learning a rule to categorize stimuli allows for generalization of existing associations to novel stimuli, thereby aiding adaptive behavioral responses. In order to study representations of learned rules in the brain, we investigated the medial prefrontal cortex (mPFC) of mice engaged in a rule-based, visual category learning paradigm.
Mice (n=11) were trained to attribute visual stimuli (oriented gratings, varying in orientation and spatial frequency) to a rewarded (go) and a non-rewarded (no-go) category. Every mouse learned to discriminate categories of 9 versus 9 stimuli according to a rule, such as grouping stimuli by

their spatial frequency. This required maximally 48 sessions of 150-200 trials each. All animals were able to generalize the learned rule to 18 novel stimuli upon their first presentation. Changing the underlying rule, such as grouping stimuli by their orientation, required the mice to switch their strategy, which took them 6 to 10 training sessions. Both rapid generalization and the ability to switch strategies show that mice, like primates, are able to form rules for categorization.
In order to investigate the underlying neuronal mechanisms, we followed the activity of individual cells throughout the course of learning with two-photon calcium imaging. After learning, a sparse set of L2/3 mPFC neurons responded selectively to stimuli of one of the two categories (i.e. they showed category selectivity). Neurons representing the 'no-go' category evolved category-selectivity later in the learning process than 'go' category-representing cells. After the rule switch, we observed both a shift in cells' responsiveness to follow the new rule, and recruitment of newly category-selective cells. These results suggest an internal, sparse rule representation in mouse mPFC and they highlight its role in behavioral strategy switches.

Title: Learning of visual categories is associated with enhanced feature representations in a subset of mouse visual cortex areas

Authors: *P. M. GOLTSTEIN, S. REINERT, T. BONHOEFFER, M. HÜBENER;
Max Planck Inst. of Neurobio., Martinsried, Germany

Abstract: Associative memories are thought to be stored in a distributed network that can extend across multiple brain regions. However, it is unclear if and how far a high-level neuronal representation of abstract knowledge traces all the way back to early cortical sensory areas. Here we investigate whether perceptual and semantic features of a learned higher-order association (visual categorization) are already represented at the first stages of visual information processing in the mouse neocortex.
We defined two visual stimulus categories by diagonally dividing a two-dimensional stimulus

space consisting of 42 gratings that systematically varied in orientation and spatial frequency. Mice learned discriminating two initial stimuli, one of each category, during five to six daily sessions in a touch-screen behavioral chamber. Over the next six to eight sessions we introduced information-integration categories encompassing all stimuli in a stepwise manner. Mice generalized stimuli within the same category, while stimuli of different categories were discriminated above chance (>70% correct) according to individually learned category boundaries. Categorization was contingent on neuronal activity in visual cortex and depended partly on the retinotopic position of the visual stimulus, suggesting a role for visual areas in representing the learned associations.
Long-term two-photon calcium imaging revealed that after learning, neurons in primary and higher visual areas of the mouse started responding to task components other than the visual stimulus. By fitting an encoding model, we addressed the fine structure of stimulus-specific responses. This revealed that neurons in V1 and higher areas RL, LI and POR showed an overall increase in category selectivity, which depended on changes in both stimulus feature- and category tuning. These results support the view that associative memories percolate throughout the brain, with learning in early stages shaping perceptual representations to support the semantic content.

Title: The interaction of category representation and spatial frequency in the macaque inferotemporal cortex

Authors: *B. KARAMI[1], R. KOUSHKI[1], E. REZAYAT[1], F. SHAKERIAN[2,1], A.-H. VAHABIE[1], M.-R. A. DEHAQANI[3,1];

Abstract: The information carried by different spatial frequency (SF) has long been recognized to represent in a coarse-to-fine sequence. The visual system uses the combination of global and local features, which are carried by low SF (LSF) and high SF (HSF) respectively, to facilitate the processing of the upcoming stimulus. To understand better the mechanistic role of SF processing in temporal dynamics of category representation, we examined neural responses of

the inferior temporal (IT) cortex of macaque monkeys viewing SF filtered face and non-face stimuli with two different exposure times (fast trials: 20ms and slow trials: 200ms). The stimuli were six faces and three inanimate objects and each of which had been filtered in five frequency ranges (band-pass SF filter). In addition, for all the stimuli, corresponding phase-scrambled images were generated. All stimuli were equalized to have same luminance and contrast. We directly addressed spatiotemporal dynamics of object and face representation by investigating how the network of IT neurons processes distinct SF over time. We applied a combination of encoding and decoding methods to the single and population of recoded neural data to explore the role of SF coding properties in IT category representation. Consistent with the coarse-to-fine nature of perception, we found an earlier representation of LSF in IT population compared with HSF. Furthermore, our results showed a systematic category representation difference over SFs in fast and slow trials, while the category information was similar for unfiltered stimuli in both fast and slow trials. These observations suggest a direct link between SF processing and evolution of category information over time. Together, these results provide evidence for the existence of an effective interaction between SF coding and category representation in IT cortex.

Title: Noise correlations facilitate faster and more robust learning

Authors: *M. R. NASSAR;
Brown Univ., Providence, RI

Abstract: The brain represents information in distributed population codes in which particular feature values are encoded by large numbers of neurons. A theoretical advantage of distributed population codes is that a pooled readout across many neurons can effectively reduce the consequences of stimulus-independent variability (noise) in the firing of individual neurons. However, the degree to which this benefit can be employed in practice is limited by noise correlations, or the degree to which stimulus-independent variability is shared, particularly across the subset of neurons that encode a particular stimulus feature (eg. motion direction). In particular, positive noise correlations between neurons that share the same stimulus tuning reduce the amount of decodable information in the neural population. Nonetheless, this type of

noise correlation is reliably observed, particularly between pairs of neurons that provide evidence for the same choice or perceptual categorization, raising the question of why should noise be distributed in this task- and tuning- specific manner. Here I propose that, while potentially constraining the amount of information encoded, such noise correlations reduce the dimensionality of the population response leading to faster and more robust learning. I test this idea with a neural network model of a two alternative forced choice perceptual discrimination task, in which the correlation among similarly tuned neurons can be manipulated independently of the overall population signal to noise ratio. Higher noise correlations led to faster learning of optimal readout and reduced sensitivity to adversarial noise profiles. These results suggest that noise correlations may serve to reduce the dimensionality of learning thereby making it more rapid and robust.

Title: Altered excitatory and suppressive contributions to binocular contrast interactions in visual cortex in amblyopia

Authors: *C. HOU, S. NICHOLAS, P. VERGHESE;
The Smith-Kettlewell Eye Res. Inst., San Francisco, CA

Abstract: Binocular interactions in strabismic amblyopia are typically reported as being absent or greatly reduced due to preferential loss of excitatory inputs from the nonfixating eye (Sengpiel and Blakemore, 1994). Here we studied the neural dynamics of binocular interactions at various visual cortical areas in human amblyopic and normal-vision observers, using source-imaged Steady State Visual Evoked Potentials (SSVEP) over a wide range of relative contrast between the two eyes. A pair of parallel grating stimuli, one in each eye, modulated at distinct temporal frequencies allowed us to quantify spectral components associated with the individual stimuli from each eye (self-terms) and responses due to nonlinear interaction between the inputs from the two eyes (IM terms). Fitting both self and IM terms across different cortical areas simultaneously to a family of divisive gain control models (Tsai et al., 2012) indicated that both forms of binocular interaction shared a common gain control nonlinearity. However, our model fits revealed different contributions from excitatory and suppressive activities across the visual cortical hierarchy in both anisometropic and strabismic amblyopia, compared to normal-vision

observers. Strabismic amblyopes showed extraordinarily strong suppressive activities (high suppressive/excitatory ratio) across various areas including V1, V3a, hV4 and lateral occipital cortex, except for hMT+, compared to normal-vision observers. Anisometropic amblyopes showed a similar pattern of suppressive/excitatory ratio across visual areas, except for hV4, to normal observers. Our findings suggest that in addition to the loss of excitatory inputs from the strabismic eye, suppression in the visual cortex also plays an important role in loss of binocular interactions in strabismic amblyopia.

Title: Quantifying transfer learning in mice across change detection tasks

Authors: *I. MAGRANS DE ABRIL, D. OLLERENSHAW, M. GARRETT, S. R. OLSEN, P. A. GROBLEWSKI, S. MIHALAS;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: Transfer learning can be described as the ability to apply past learning to influence current and future learning. Different degrees of transfer learning can be observed in all animals: It has been shown rodents trained to identify a triangle drawn with a solid line are unable to identify as the same object another triangle drawn with dots, while chimpanzees and humans can do so [Haskell, R. E. Elsevier 2000]. On the other hand, mice are found to be a suitable model to study transfer learning using auditory discrimination experiments [Kurt, S., & Ehret, G. PNAS 2010] or active to passive avoidance [Sprott, R. L., & Stavnes, K. L. Animal Learning & Behavior 1974].
We use data from the Allen Brain Obsevatory – Visual Behavior, standardized *in vivo* survey of physiological activity in the mouse visual cortex while performing a change point detection task. Mice are presented a sequence of images (initial training on gratings with a later transition to grayscale natural images) each for 250 ms. In later training stages, mice are shown a gray scale screen for 500 ms between each image. Animals are trained to respond when the current image is different from the previous image in a go/no-go modality.
Here, we systematically quantify the transfer learning capacity and the speed of transfer in 24 mice at different stages of a visual behavior task. We compare a running d prime for a window of 20 trials between the last session of the previous training phase and the first session of new phase.
The initial change detection training phase took on average 2 days with an average of 300

trials/day. We found the transfer between different stages has distinct time scales as a function of the complexity of the change. A near transfer learning experiment consists of changing the set of natural images presented to the mice. In average, mice adapted within 10 trials. An intermediate TL experiment consists of change from gratings to natural images. In this experiment, mice adapted to an increasing representation complexity (from 2 types of gratings to 8 distinct natural images) in about 40 trials. Finally, we ran a far transfer which consisted of adding 500 ms "grey screen" flashes between every natural image, thus changing the environment dynamics. In average, mice adapted to this experiment in about 100 trials.
This study suggests a fast transfer of learning when compared to initial learning, but multiple time scales for different types of transfer complexities.

Title: Uncovering the mechanisms of short-term memory in a visual change detection task

Authors: *B. HU, J. SHANG, M. GARRETT, M. T. VALLEY, P. A. GROBLEWSKI, D. R. OLLERENSHAW, J. WATERS, C. KOCH, S. R. OLSEN, S. MIHALAS;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: The maintenance of short-term memories is critical for survival in a dynamically changing world. However, the exact form of short-term memory used in neural circuits is unclear. Previous experimental and modeling studies suggest that this memory could either be stored in the form of persistent neural activity or synaptic efficacies via short-term plasticity. Here, we test these two hypotheses in the context of a visual change detection task. Mice were trained to respond to changes in a sequence of natural images while neural activity was recorded using two-photon calcium imaging. We also trained two different models to perform the same visual change detection task. Compared to a recurrent neural network, we find that a feedforward neural network with short-term synaptic depression better captures the asymmetry in responses to image changes in mice and is consistent with the observed adaptation in neural responses across repeated stimuli. Our model also generalizes to novel image sets that it was not trained on, similar to the behavior of mice. A set of optogenetic experiments show that silencing neural activity during an image change impairs behavioral performance, while silencing neural activity prior to the change has no effect. These findings suggest that memory maintenance occurs outside of the visual system, which is consistent with our model as short-term depression is only

incorporated in layers after the encoding of the stimulus. Our results suggest that short-term synaptic depression may serve as an important bottom-up memory signal that can be used by downstream decision-making areas.

Title: Investigating the neural embodiment of prosthetic limbs and tools

Authors: ***H. R. SCHONE**[1,2], R. O. MAIMON MOR[3], C. I. BAKER[1], T. R. MAKIN[2];
[1]Lab. Brain and Cognition, NIH, Bethesda, MD; [2]Inst. of Cognitive Neurosci., Univ. Col. London, London, United Kingdom; [3]Nuffield Dept. of Clin. Neurosciences, Univ. of Oxford, Oxford, United Kingdom

Abstract: Advancements in robotics and information technology have led to the development of highly innovative artificial prosthetic limbs. Despite these advancements, low rates of prosthetic hand usage and even complete device rejection are commonplace amongst amputee populations (Cordella et al. 2016). While significant efforts are being taken to develop technological solutions to combat these issues, little attention is given to potential neurocognitive bottlenecks, such as embodiment (Makin et al. 2017). Recent evidence from our lab has shown that the more amputees use a prosthetic hand, the more the prosthesis is represented as a hand (body-part) (van den Heiligenberg et al. 2018). Thus, amputees that use a prosthesis the most (e.g. in the most hand-like way) should have the greatest propensity to successfully embody the prosthesis. Therefore, we designed a study to investigate the neural representation of prosthetic hands in individuals with the most successful prosthesis usage (e.g. elite prosthesis users, n=4) to determine if a prosthetic hand is represented as either an expert tool or a hand substitute. We included two control groups: able-bodied expert tool users (litter-pickers, n=7) and able-bodied novices (n=15). Using fMRI, we evaluated the representational structure of hands, tools and prostheses, across the body-representation and tool-use networks. To activate these representations, we presented first-person perspective videos depicting actions performed by either a hand, a prosthesis, a litter-picker or an unknown tool. Additionally, using a large battery of behavioural tasks, we investigated other neurocognitive characteristics (e.g. intrinsic

motivation, cognitive load, motor skill) that could promote successful prosthesis/tool usage. Overall, our results help to elucidate the brain's ability to represent and control an artificial device as a body part.

Title: A brief intensive learning intervention affects resting state connectivity and neuropsychological test performance

Authors: *G. M. ROSE[1], A. C. JAGGER-RICKELS[2];
[1]Departments of Anat. and Physiol., Southern Illinois Univ. Sch. of Med., Carbondale, IL; [2]Dept. of Psychology, Southern Illinois Univ., Carbondale, IL

Abstract: Cognitive training can result in complex changes in behavior and potentially beneficial outcomes for many psychological and neurological conditions (e.g., age-related cognitive decline, traumatic brain injury, learning disability). However, at a neurobiological level, the alterations caused by particular training regimens remain largely unexplored. Further, whether the benefits of cognitive exercises are limited to domains specific to the exercises or have broader effects is currently a subject of debate. We have begun to explore these issues by evaluating the effects of a period of intensive training in a single task on the functional connectivity of four resting-state networks and a limited set of cognitive tests from the Woodcock-Johnson IV battery.
The subjects were 29 students, age range 11-19 years, enrolled in the Cognitive Intensive Program at the Arrowsmith School in Toronto, Ontario, Canada. Students practiced the Symbol Relations Task (a computer-based sustained visual-spatial attention task of progressively increasing difficulty) for five hours per day, five days per week, for six weeks. At the beginning and end of the program the students were given a subset of Woodcock-Johnson IV Cognitive tests (Letter Pattern Matching, Numbers Reversed and Pair Cancellation; used to calculate Cognitive Processing Speed and Cognitive Efficiency) and resting-state fMRI images were collected using a Siemens 3T scanner. The CONN toolbox was used to assess changes in four resting-state networks (Default Mode, Dorsal Attention, Salience, and Frontoparietal Control). Students showed variable degrees of improvement in their Symbol Relations performance over

the training period. The connectivity between the Default Mode network and the other three networks displayed significant increases that were proportional to the improvement. The strongest and most common connectivity changes were between regions of the Default Mode and Salience networks. Scores in the Woodcock-Johnson assessments significantly improved except for Numbers Reversed, a measure of short-term working memory. Overall, this study demonstrates that training in the Symbol Relations task strengthens resting-state functional connectivity that may underlie improved cognitive performance.

Title: Causal evidence for expression of perceptual expectations in category-selective extrastriate regions

Authors: M. GANDOLFO, *P. E. DOWNING;
Sch. of Psychology, Bangor Univ., Bangor, United Kingdom

Abstract: Expectations about a visual event strongly shape the way it is perceived**.** Valid cues that predict a target's content or location can improve its detection and discrimination over a range of perceptual tasks. A candidate brain mechanism that supports these cue-driven expectations consists in the prior activation of neural populations that represent the target. Here we provide causal evidence that cue-driven activity in extrastriate category-selective brain regions is directly involved in forming perceptual expectations about the content of a visual target. We tested two visual tasks that demonstrate the effects of verbal cues on the efficiency of perceptual judgments. In a body perception task, valid verbal pre-cues about the sex of a target body image ("m" or "f") improved performance (compared to invalid cues) on binary judgments about the weight of the depicted person. Analogously, in a scene perception task, valid verbal cues about the semantic category of a scene ("kitchen" or "garden") improved performance (compared to invalid cues) on judgments of the target image's orientation, which was either upright or inverted (Fig. 1A). In two further experiments (N=21 each) we used fMRI-guided online transcranial magnetic stimulation (TMS, Fig. 1B) to demonstrate that cue-driven neural activity in category-selective occipitotemporal regions is causally necessary for cueing effects to be expressed in these tasks. TMS was delivered online in each trial, starting at cue onset (4 pulses, 10 Hz) and ending 200 ms before target onset. In the body perception task, TMS delivered over EBA (extrastriate body area) but not over OPA (occipital place area) eliminated

the validity effects of the cues. Likewise, in the scene perception task, stimulation over OPA but not over EBA eliminated the validity effects of the verbal cues (Fig. 1C). In a site and task specific manner, we have established causal evidence that cue-driven brain activity in occipitotemporal category-selective areas, arising before the appearance of a target image, is critical for the expression of perceptual expectations.

Title: Functional changes in areas V1 and V4 during the course of perceptual learning

Authors: *G. L. ASTORGA[1], M. CHEN[1], Y. YAN[2], W. LI[2], C. D. GILBERT[1];
[1]Lab. of Neurobio., The Rockefeller Univ., New York, NY; [2]Lab. of Cognitive Neurosci. and Learning, Beijing Normal University, China, Beijing, China

Abstract: We have previously shown that neurons in visual areas V4 and V1 are adaptive processors, differentially responding to the identical set of stimulus attributes in a task-dependent manner. Neuronal activity is strongly modulated by task-relevant attributes and weakly modulated by irrelevant ones, reflecting top-down influences of expectation and perceptual task. In the current study we took a step further to investigate whether this top-down modulatory mechanism could be modified over the course of perceptual learning. For a monkey previously trained on bisection and vernier discrimination using a set of five-line stimuli, we implanted microelectrode arrays in areas V4 and V1 at locations representing an untrained part of the visual field. The animal was cued to discriminate the positions of the central line in the five-line stimuli, either relative to two parallel flanking lines (the bisection task) or relative to two collinear lines (the vernier task). The animal's discrimination thresholds decreased with training in both tasks. Remarkably, at the early training stages few neurons in V1 but many neurons in V4 showed differential tuning properties between the two tasks performed on the same set of stimuli. After weeks of training, however, most neurons in both areas showed the task dependency. Once present in V1, the manifestation of task-dependent information in V1 precedes that in V4 by 45msec within any given trial. These results suggest a progressive shift of task-dependent top-down influences from higher-tier areas to earlier stages in the cortical hierarchy as animals become proficient in the task.

Title: Grasping in a cluttered environment: Avoiding obstacles under memory guidance

Authors: *H. H. ABBAS, J. J. MAROTTA;
Psychology, Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: We often reach for remembered objects, such as when picking up a coffee cup from behind our morning paper. In cases like this, we rely on visuospatial memory, encoded by the perceptual mechanisms of the ventral visual stream, to guide our actions, rather than on the real-time control of action by the dorsal visual stream (Milner & Goodale, 1995). Further, our motor plans must often accommodate for the messy spaces within which we act, avoiding irrelevant objects in our way. Little research has examined memory-guided grasping during instances of obstacle avoidance, though it is likely that obstacles perceived by the ventral stream as more threatening will produce exacerbated avoidance strategies. This study examined how the availability of visual feedback altered eye-hand coordination in an obstacle avoidance paradigm. Eye and hand movements were monitored as subjects had to reach through a pair of obstacles in order to grasp a 3D target object, under full visual feedback (visually-guided; n = 12), immediately in the absence of visual feedback (memory-guided no-delay; n = 12), or after a 2-s delay in the absence of visual feedback (memory-guided delay; n = 12). The positions and widths of obstacles were manipulated, though their inner edges remained a constant distance apart. We expected the memory-guided delay group to exhibit exaggerated avoidance strategies due to a reliance on the perceptual mechanisms of the ventral steam. Results revealed successful obstacle avoidance and grasps of the target object in all groups, however different avoidance strategies emerged depending on the availability of visual information. The visually-guided and memory-guided no-delay groups used real-time visual information to alter the paths of the index finger and wrist and adjust final index finger positions on the target object, to account for obstacles differentially obstructing the reach path. Still, the no-delay group showed wider index finger paths and a failure to adjust final fixations, resulting from the inability to use visual information for the online control of action. Contrary to expectation, the memory-guided delay group employed a more moderate strategy for avoiding obstacles, with fewer instances of altered index finger and wrist paths or adjusted index finger positions on the target object in response to

positioned obstacles. It seems in the absence of real-time visual information, reaches to remembered objects even after a brief delay follow a “good enough” approach for avoiding obstacles. To conclude, under the perceptual control of the ventral stream, obstacle avoidance behaviour adopts a more moderate, rather than exaggerative, strategy.

Title: Head motion optimizes binocular vision during head-unrestrained reaches

Authors: *H. AL-TAHAN[1,2,3,4,5], J. CRAWFORD[1,2,3,4];
[2]Ctr. for Vision Res., [3]Vision: Sci. to Applications, [4]Departments of Psychology, [5]Dept. of Electrical Engin. and Computer Sci., [1]York Univ., Toronto, ON, Canada

Abstract: Experiments in both monkeys (Arora et al., 2017) and humans (Al-Tahan & Crawford, 2018) have shown that head motion is prolonged and increased when gaze shifts are accompanied by reaches to the same target. This faces the head more toward the target and increase drive to the VOR, resulting in the eyes being more centered in the head during reach. Here, we tested the hypothesis that this motor strategy optimizes depth vision for reach. Specifically, we tested if removing binocular vision reduces reach-related head motion. As in our previous experiment, right eye / hand dominant participants (n=15) were instructed to perform gaze shifts (with or without reach movements) toward visual targets on a 40° x 20° computer screen array placed 60 cm forward from the eye. However, on half of the trials, we masked the non-dominant eye to remove binocular vision. Right eye and hand movements were measured using an *EyeLink II* eye tracker and two *Optotrak* cameras respectively. Preliminary analysis replicated our previous results, i.e., compared to no-reach controls (in the non-masked condition), reach movements were accompanied by larger (M = 3.14º, SD = 1.01º; P =) and faster (M = 8.71º/s, SD = 2.40º/s; P =) head motion, as well as more accurate gaze shifts toward the target (M = 1.92º, SD = 0.42º, P =). However, when the non-dominant eye was masked, head motion was significantly reduced during reaches (M = 2.02º, 0.56º, P = 0.013), but not in the no-reach control task (M = 0.34º, SD = 0.02º; M = 0.30, SD = 0.04º; P = 0.30). Furthermore, head movements were significantly slower (P = 0.048) when the non-dominant eye was masked during reaches (M = 9.21º/s, SD = 1.44º/s; M = 7.34º/s, SD = 1.32º/s), but not in the no-reach control task. Final gaze position showed significantly lower errors when the non-dominant eye

was masked in both reach (M = 1.92º, SD = 0.42º; M = 3.42º, SD = 0.23º; P < 0.001) and control tasks (M = 2.69º, SD = 0.39º; M = 4.51º, SD = 0.27º; P < 0.001) task. These results show that both reaching and binocular vision influence eye-head gaze kinematics and are consistent with the notion that head motion supports binocular vision to optimize accurate reaching in depth.

Title: Effects of initial arm posture on reach endpoint variability

Authors: *P. K. PHATARAPHRUK[1], Q. RAHMAN[3], M. FRUCHTMAN[4], K. LAKSHMINARAYAN[5], C. A. BUNEO[2];
[1]Sch. of Biol. and Hlth. Systems Engin., [2]Arizona State Univ., Tempe, AZ; [3]Univ. of Arizona Col. of Med., Phoenix, AZ; [4]Univ. of Michigan, Ann Arbor, MI; [5]Cleveland Clin. Fndn., Cleveland, OH

Abstract: Reaching movements are corrupted by neural noise that occurs during the planning and execution stages of movement production, contributing to reaching variability (RV). Previous work has shown that when visual feedback is present, RV is dominated by noise associated with arm and target position estimation in visual coordinates. In the absence of vision, variability is more influenced by movement direction, suggesting a stronger role for execution-related noise in muscle coordinates. Based on these findings we hypothesized that RV would depend not only on movement direction but also on initial arm configuration, particularly without vision. This hypothesis was tested using a memory-guided reaching movement task. Human subjects (N=10) performed reaching movements to three virtual frontal plane targets using either adducted or abducted initial right arm postures. On alternate trials, vision of the hand was either continuously present or removed on movement onset. Analysis focused on differences in reach endpoint distributions, which were parametrized by their volume, aspect ratio (distribution shape), and orientation in 3D space. Differences in volume and aspect ratio were

analyzed using a two-way repeated measures ANOVA (factors: visual condition and target location). For orientation a two-way circular ANOVA was used. An alpha of 0.05 was applied for all tests. Results showed endpoint distribution volumes were generally smaller and less variable across subjects when hand vision was available, while aspect ratios tended to be similar for the two visual conditions. For both volume and aspect ratio, little variation with target location was observed. Orientations varied systematically with target location in the vision condition but were highly variable and showed no consistent trends with location when vision was withheld. Regarding the influence of initial arm posture, differences in volume and orientation between postures were found to be larger when vision of the moving hand was withheld. Differences in aspect ratio showed no dependence on the visual conditions and no distribution parameter showed a dependence on target location. In summary, changes in endpoint variability between arm postures were apparent in this study and were larger when visual feedback was absent. This suggests that when vision of the moving hand is removed, endpoint variability is determined largely by execution noise in muscle coordinates.

Title: Brain-computer interface decoding during a sensory-critical task

Authors: *S. SEKHAR[1], E. R. OBY[1], N. T. MCCLAIN[1], A. P. BATISTA[2], P. J. LOUGHLIN[1]; [2]Bioengineering, [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Traditionally, brain-computer interface (BCI) tasks have focused on decoding movement intent during simple goal-directed movements such as center-out reaches. However, in real-world contexts, most of the movements we make require constant sensory feedback. Decoding movement intent in these contexts may provide a challenge in part due to the constantly changing sensory feedback. To help create BCI decoders that can work in realistic behavioral contexts, we adapted the Critical Stability Task (CST) from the human performance literature (Jex et al., 1966). The CST is a prolonged motor control task for which sensory feedback is crucial, wherein subjects interact with an inherently unstable virtual system and must generate continuous sensory-guided actions to balance it at an equilibrium point. The CST

provides a platform where we can design BCI decoders that might provide rich control for feedback-guided movements that are typically sudden and very precise. As a first step toward a real-time BCI algorithm that can execute the CST well, we performed offline BCI reconstructions of hand movements during the CST paradigm. We recorded from motor cortex of two Rhesus monkeys using multielectrode Blackrock arrays. The monkeys performed the CST with their hands, and we reconstructed kinematics from neural activity using BCI decode algorithms. Our accuracy in reconstructing hand kinematics from neural activity was overall quite high, which holds promise for future real-time BCI decoding in the CST paradigm. Additionally, this reassuring outcome provides a testbed for further offline explorations. In particular, we will examine: (1) Can we reconstruct cursor motion as accurately as hand movement from M1? This is possible to ask in the CST, since the two are more dissociated than they are in standard center-out paradigms. (2) Does BCI calibration generalize? That is, if we calibrate a decoder using CST, does it also function well in a center-out paradigm? (3) Do different families of BCI decode algorithm (Kalman filter vs optimal linear estimator, for example) do better at decoding different aspects of the kinematics. (4) Does decode performance change with task difficulty or as sensory feedback becomes more critical for performance?

Title: Hand orientation is influenced by gaze location and saccades in a visual memory-guided alignment task

Authors: *G. N. LUABEYA[1,2,3,4], X. YAN[1,2,3], J. D. CRAWFORD[1,2,3,4,5];
[2]Ctr. for Vision Res., [3]Vision Sci. to Applications (VISTA), [4]Biol., [5]Psychology, [1]York Univ., Toronto, ON, Canada

Abstract: Although visually-guided grasps have been studied extensively, the influence of gaze direction on hand alignment to a seen or remembered object is unclear. Our study uses a memory-guided alignment task to investigate the influence of gaze position and saccades on hand location and orientation. For Experiment 1 (gaze position), participants reached and aligned

an object to a rectangular outline presented on a computer screen in three possible orientations: 0º (horizontal), +45º and -45º. Gaze fixation was central or to the left/right. The target outline was either presented briefly in complete darkness (memory task) or remained illuminated along with visual feedback of the hand (visual task). Comparing the memory task to the visual task, there was a significant main effect of gaze location: participants aimed further to the right of the target when fixating to the left (a 'gaze-dependent overshoot'). There was also an interaction between gaze location and orientation: when looking to the right, participants over-rotated (too CCW for -45º and too CW for +45º), whereas when they looked to the left, they under-rotated (too CW for -45º and too CCW for +45º). There were significant interactions between task, orientation, and gaze position for variable errors. As expected, location was more precise in the visual task, and during central gaze fixation. Likewise, orientation was more precise in the visual task. Fixating a remembered target provided less advantage for orienting precision than for location. Since the difference in orientation was mainly seen in the +45º and -45º orientations, Experiment 2 (saccades) required participants to reach and align the object to either a +45º or a -45º rectangular target. They performed two types of saccades (from central fixation to the left/right gaze fixations or between the peripheral left/right fixation points) during the memory interval. Preliminary results suggest that saccades between the peripheral fixation points produce the classic 'overshoot updating' effect (Henriques et al. J. Neurosci. 1998), but also introduces systematic and variable errors in orientation. Overall, our location results confirm the gaze-dependencies observed in pointing studies, whereas our orientation results reveal several additional interactions between vision, memory, gaze position, and saccades during memory-guided manual alignment.

Title: Synthetic modeling of human visual motion analysis for generating quick ocular and manual responses

Authors: *H. GOMI, D. NAKAMURA;
NTT Communication Sci. Labs, Kanagawa, Japan

Abstract: Human visual motion analysis has crucial roles for quickly adjusting posture, eyes, and limbs in dynamic interaction with environments. It has been revealed that both of ocular and

manual following responses (OFR and MFR) induced by a suddenly applied visual motion are highly sensitive for the visual motion of low-spatial and high-temporal frequency stimulus (under 0.1 cpd and over 10 Hz) [Gomi et al. 2006], whereas those specificities are greatly different from the perceptual sensitivity to visual motion. In addition, OFR and MFR are modulated differently depending on the size and location of visual motion with various spatiotemporal frequencies [Gomi et al. 2013].
Here we examined as to whether these OFR and MFR specificities are acquired by the statistical relationship between the visual motion and self-motion, based on the hypothesis that the function of these rapid responses is to reduce the error (i.e., retinal slip for OFR and reaching error for MFR) caused by self-motion. First, we trained a convolutional network to estimate translational velocities and angular velocities of self-motion from image sequences. The images and self-motion data were recorded by a head-mounted camera during several kinds of daily human movements. High correlation coefficients between the actual and estimated self-motion for the test dataset after learning ($r > 0.8$ for 6-DoF) indicate a successful estimation of self-motion from the time-sequential images although complex computation is required to estimate self-motion from images in the conventional geometry. Interestingly, high estimation performance was preserved for the low-pass (< 0.1 cpd) filtered images while performance was degraded for the high-pass (> 0.4 cpd) filtered images, suggesting that self-motion was dominantly estimated from the low-spatial frequency components. This feature is analogous to the high sensitivity features of OFR and MFR for low spatial frequency stimulus. Additionally, we found some degree of similarity between stimulus-area dependent modulations of the angular component of the modeled network and of OFR and between stimulus-area dependent modulations of the translational component and of MFR. These results would be consistent to the findings in previous experiments that the area MST encodes a self-motion and contributes to generate OFR and MFR, and therefore support the hypothesis that these implicit motor responses have a function to reduce the corresponding errors caused by self-motion.

Title: Enhanced visual detection and visuomotor control in somatosensorily-impaired individuals

Authors: *F. R. SARLEGNA[1], A. RENAULT[2], F. MATONTI[3], J. COLE[4], R. C. MIALL[5]; [1]CNRS and Aix-Marseille Univ., Marseille, France; [2]Aix-Marseille Univ. & CNRS, Marseille,

France; [3]INT, Marseille, France; [4]Poole Hosp., Poole, United Kingdom; [5]Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom

Abstract: Previous research has shown that blind individuals have supranormal abilities in tactile discrimination (van Boven et al. 2000), which is presumably linked to the fact that cortical reorganization in blind leads to the so-called visual cortex to process tactile information (Sadato et al. 1996; Cohen et al. 1997). What would happen to individuals devoid of tactile and proprioceptive information? There is ample evidence that cross-modal plasticity can result in enhanced perceptual abilities in impaired individuals compared to healthy subjects. This idea stems for instance from studies on blind but also deaf individuals, who can have enhanced visual abilities (Bavelier et al. 2006; Lomber et al. 2010). Here we tested the visual perception of two patients with massive yet specific loss of touch and proprioception, using the classic clinical Goldmann's test of kinetic visual field. We found that the visual field is larger in the two chronically deafferented subjects GL (Sarlegna et al. 2010) and IW (Miall and Cole 2007) compared to age-matched controls. More specifically, their detection of visual stimuli was enhanced only in far peripheral vision (>70°), both in monocular and binocular conditions. The superior visual performance may reflect a functional correlate of plasticity of the somatosensory cortices and extend the view of cross-modal plasticity to subjects who suffered acquired deafferentation. To study the impact of the somatosensory loss and the enhanced visual detection on visuomotor function, a prism-adaptation paradigm was tested on healthy-control participants and the two deafferented participants. Results showed that in contrast to controls who were perturbed by the prisms, both deafferented participants rapidly adapted their reaching behavior to the prisms. These findings indicate that visuomotor adaptation is not necessarily driven by a visuo-proprioceptive mismatch. While deafferented participants may be experts at processing of visual information (Blouin et al. 1993; Ghez et al. 1995; Lefumat et al. 2016), our results suggest that visuomotor adaptation is primarily driven by a mismatch between the predicted outcome of the motor commands and visual feedback.

Title: Invariant read-out of eye position from population codes with high-dimensional selectivity

Authors: *J. R. MCFADYEN[1], B. HEIDER[2], A. N. KARKHANIS[2], S. L. CLOHERTY[1], F. A. MUÑOZ[2], R. M. SIEGEL[2], A. P. MORRIS[1];

Abstract: Neural activity encodes information about our intentions and cognitions, and about the external world. In posterior parietal cortex (PPC), for example, single neurons encode the locations of objects, motor plans to reach toward them, and the current posture of the eyes, arms, and body - and often with inseparable joint tuning. A challenge for downstream computation is thus to extract relevant signals from the population activity while ignoring the influence of irrelevant ('nuisance') variables. Here we show that a key spatial variable for vision, gaze direction, can be decoded accurately from population activity in PPC even though the gaze direction tuning of individual neurons changed across sensory and behavioral contexts. We measured extracellular spiking during different stages ('contexts') of a visually-guided reaching task, including a fixation epoch with minimal visual stimulation, a visually-rich delay epoch in which a reach was planned, a "go" epoch, and during the reach. Fixation was maintained throughout the trial at one of nine locations. We found that a decoder trained on activity in the delay context provided accurate estimates of eye position across all other contexts, largely overcoming the non-stationary tuning of single neurons. Where biases did arise, they were substantially improved by a modified decoder that accounted for global differences in responsivity of neurons across contexts. These results reveal a surprisingly invariant population code for eye position that is available via a fixed (i.e. naïve) read-out. Using simulations, we show that such invariance is expected provided that context effects operate along dimensions of the population response that are orthogonal to that of the target latent variable. Our study suggests an efficient strategy for structuring information in multiplexed population codes so that it is selectable for perception (e.g. attention), cognition (e.g. decision variables), and motor control (e.g. action targets) regardless of context.

Title: Prehensile synergies are robust to expectations of rapid upcoming movement changes

Authors: *A. S. NAIK, A. KULKARNI, S. AMBIKE;
Hlth. and Kinesiology, Purdue Univ., West Lafayette, IN

Abstract: Stability is the ability of the motor system to maintain a motor state by rejecting disturbances. Stability of the forces produced by the fingers in an isometric pressing task is reduced prior to self-initiated force changes and when a change in the force is expected, independent of whether the change is executed. Here we explore if similar anticipatory stability changes occur in response to the mere expectation of movement change in an object manipulation task. During the vertical oscillation of an object, the difference in the forces of the thumb and the four fingers combined normal to the oscillation direction (i.e., along the horizontal) are stabilized around zero to minimize unbalanced forces along the horizontal direction. In contrast, non-vertical object movement requires that the normal forces are unbalanced so that the object accelerates along the horizontal direction. Therefore, we hypothesize that the stability of the normal force difference during the vertical oscillation will weaken if the participant expects to change the oscillation direction. Ten healthy participants (24.1 ± 3.9 yrs) performed oscillatory arm movements while holding an object with their digit tips. The amplitude was one-fourth their arm length, and the frequency was 3 Hz. The movement directions were vertical; horizontal (H); top left to bottom right (D1); and top right to bottom left (D2). Participants performed trials with only vertical oscillations and reaction-time trials in which initial vertical oscillations were followed by a change in oscillation direction at a random time in response to an audio-visual cue. Across conditions, the altered direction belonged to the set {H}, {H, D1}, or {H, D1, D2}. A motion capture system measured the object height, and force sensors mounted on the object measured digit tip forces. The forces for the initial vertical oscillation phase for all trials were isolated. The normal force exerted by the thumb and the sum of the normal forces of the four fingers were computed. The forces were time-normalized after aligning the peaks in the object height across multiple oscillation cycles within each experimental condition. The variance across multiple cycles in the thumb and finger normal forces yielded the stability of the normal force difference via the uncontrolled manifold analysis. We found no difference in stability across tasks ($F(4,45) = 0.18$; $p = 0.9$). Therefore, the synergy between the thumb and finger normal forces is robust to expectations of future object manipulation and the number of potential upcoming behaviours. It remains to be seen if these robust synergies influence the efficacy of alterations in object manipulation patterns.

Abstract: Repetitive transcranial magnetic stimulation (rTMS) to a cortical region induces changes in cortical excitability for minutes to hours after the end of intervention. However, it has not been precisely determined to what extent the cortical plasticity prevails spatially in the cortex. Recent studies have shown that rTMS induces changes in “interhemispheric” functional connectivity, the resting-state functional connectivity between the stimulated region and the symmetrically corresponding region in the contralateral hemisphere (Watanabe et al., Hum Brain Mapp, 2014). In the present study, quadripulse stimulation (QPS), a type of rTMS, was applied to the index finger representation in the left primary motor cortex (M1) by using a figure-of-eight coil and four magnetic stimulators (Magstim). The position of the stimulation coil was constantly monitored by an online navigator (Localite). After application of QPS, resting-state functional MRI was administered with a 3-T MRI scanner and 64-channel RF head coil (Siemens Prisma; multi-band GE EPI sequence, TR = 1.0 s, TE = 30 ms, voxel size = 2 × 2 × 2 mm). After a standard preprocessing, functional connectivity was calculated. Then, the interhemispheric functional connectivity after QPS was compared with that before QPS. A cluster of connectivity changes was observed in the stimulated region in the central sulcus. The cluster was spatially restricted to the circle of 20 mm diameter, and was approximately 10 mm long in the depth direction. A localizer scan of the index finger motion confirmed that the cluster of interhemispheric connectivity changes spatially overlapped with the activation related to the index finger motion. These results indicate that the cortical plasticity in M1 induced by rTMS

was relatively restricted in space, and suggest that the interhemispheric functional connectivity can be used to visualize the cortical plasticity induced in the stimulated region.

Title: The stability of the current motor state is influenced by expected movement: Do cognitive events during the inter-stimulus interval of choice reaction-time tasks have a motor counterpart?

Authors: *M. A. TILLMAN[1], S. AMBIKE[2];
[1]Hlth. & Kinesiology, [2]Hlth. and Kinesiology, Purdue Univ., West Lafayette, IN

Abstract: Stability of a motor state is the ability to maintain that state by rejecting disturbances. The stability of a motor state reduces prior to a volitional motor action, or when an action is expected, independent of whether it is executed. It is also known that it takes time to establish the stability of the current motor state when it is preceded by different motor patterns. Therefore, the stability of the current motor state is influenced by prior movements and expected movements. However, the relative contributions of the two sources of destabilization are unknown. Here, we quantify the contribution of each component to the stability of the current state in a finger force production task. Twenty-two participants (age 21.04 ± 0.4 yrs) produced a force with the fingertips by pressing down on sensors. They matched a visually-presented target force in four conditions, with 20 trials per condition. In the first condition the target force was invariant, with no expectation of future movement and consistent movement history. Trials in the second condition began with an invariant target which later moved in a random fashion in the vertical direction. In the invariant-target phase, the history is consistent and there is expectation of movement. Trials in the third condition began with a randomly moving target that then became stationary. In the invariant-target phase, the movement history is variable but there is no expectation of movement. The last condition had an invariant-target phase flanked by variable prior movements and expectation of movement. The targets were color-coded so that the participant knew when to expect movement. Finger force data was analyzed over a one-second window with the target invariant, three seconds after it first became stationary. RMSE was utilized to quantify the stability of performance. Higher RMSE indicates lower stability. A main effect of Condition was discovered ($F(3,21) = 14.02$; $P < 0.01$). The stability of the finger force

was greater when no movement was expected (Conditions 1 and 3) compared to when it was expected (Conditions 2 and 4), irrespective of prior movements. This indicates that the effects of prior actions on the stability of the current state die out, whereas the effects of expected motor actions persist. The invariant-target portion resembles the inter-stimulus interval (ISI) in choice reaction time (CRT) tasks utilized in the cognitive science literature. Data from CRT studies are explained based on cognitive events that occur during the ISI. Since the stability modulation we observe is accomplished via altered muscle activation, our result suggests that the cognitive events during the ISI may be accompanied by motor events.

Title: Stimulus onset synchrony and automatic modulation of motor response induced by a visual distractor

Authors: *Y. ITAGUCHI[1], D. YOSHIOKA[2], M. MIYAZAKI[1];
[1]Dept. of Computer Sci., [2]Grad. Sch. of Sci. and Technol., Shizuoka Univ., Hamamatsu, Japan

Abstract: To explore the mechanism of automatic motor response modulation induced by observed visual motion, we investigated the relation between SOA (stimulus onset asynchrony) and the amplitude of visuomotor congruency effect. Visuomotor congruency effect was induced by a distractor that linearly moved toward one of eight possible directions while participants responded by moving their index finger leftward or rightward based on the presented cue (choice reaction task). A number (1 or 2) was randomly presented on the screen as a response cue. The association of the number and response direction was fixed during the experiment and counter-balanced across participants. The SOA of the distractor presentation (movement onset) and the number cue presentation varied among -50, -33, -17, 0, 17, 33, and 50 ms. Note that in trials with negative SOAs (-50, -33, and -17), the number cue was presented before the onset of distractor movement. Visuomotor congruency was defined based on the directions of finger response and distractor movement, and the congruency effect was calculated by subtracting average RT of congruent trials from that of incongruent trials. The results showed that positive congruency effect was consistently significant in all SOAs, indicating that motor planning is disturbed by visual motion the onset of which is even before (-50 ms SOA) and after (+50 ms SOA) the start of the visual processing for movement planning. This finding suggests that motor planning is not a one-shot processing based on the available information at the start of the planning but one continuously adapting preceding and subsequent environmental changes.

Title: The hand synergies of simple finger and grasping movements are encoded by a common distributed low frequency cortical network

Authors: ***N. NATRAJ**[1], D. B. SILVERSMITH[2], E. F. CHANG[3], K. GANGULY[4]; [1]Neurol., Univ. of California, San Francisco, San Francisco, CA; [2]Bioengineering, Univ. of California San Francisco, San Francisco, CA; [3]Neurosurg., [4]UCSF, San Francisco, CA

Abstract: Prior research has well documented the existence of kinematic synergies, low dimensional building blocks of complex hand movements. However, the neural representation of synergies are still yet to be precisely characterized. To this end, we measured electrocorticographic (ECoG) data over parietal, premotor and sensorimotor areas from 4 patients undergoing clinical monitoring for epilepsy as they performed self-paced grasping and finger movements. The LeapMotion system was used to measure position data from all joints of the hand as the subjects performed the movements. Statistical analysis of the kinematic covariance matrix revealed that like grasp movements, even 'simple' finger movements employed a whole hand control strategy and were characterized on average by three hand synergies. To understand the neural encoding of synergies, raw electrocorticographic data were band-pass filtered, Hilbert transformed and subsequently correlated to the synergies in a multivariate fashion via canonical correlation analyses (CCA). The goal of CCA is to find latent pairs of neural maps (derived from the original ECoG data) and hand configurations (derived from the original synergy data) that in turn produce new pairs of maximally correlated "neurokinematic" synergies. Results revealed that the amplitude of low frequency oscillations (LFO, 0.5-4Hz) produced the most correlated neurokinematic synergies. The LFO neural maps uncovered by CCA encompassed a distributed network over parietal, premotor and sensorimotor regions. Notably, the distributed low frequency network was common to both individual finger as well as grasping movements, highlighting the complexity of individual finger movements. The distributed low frequency network was a robust feature of the data as it underlay both self-paced and cue-initiated movements. Interestingly, high gamma amplitudes sampled at the LFO frequencies outperformed traditional high gamma band-based analysis and were equivalent to LFOs in terms of synergy correlations. Finally, our results revealed that the angle of similarity between the original hand synergies and the neurokinematic synergies were significantly

different from zero (60 degrees on average), implying that the neural encoding of synergies involves a rotation of the synergy space. These results here shed new light on the precise spatiotemporal relationship between a common distributed low frequency cortical network and the previous observed kinematic synergies underlying both simple finger and grasping movements.

Title: Feasibility of a protocol measuring force perception in young children using a play-based assessment in the natural environment

Authors: ***R. M. MOLININI**[1], L. ANDERSON[2], J. LEE[2], K. RAHIMIAN[2], S. C. DUSING[1], V. CHU[2];
[1]Dept. of Physical Therapy, [2]Dept. of Occup. Therapy, Virginia Commonwealth Univ., Richmond, VA

Abstract: A sensitive period in the development of proprioception occurs before four years old. A significant knowledge gap exists regarding the timeline of proprioception development during this critical time. Previous research assessed proprioception indirectly in young children through parent reports or observations. The purpose of this abstract is to describe our initial feasibility assessment of a methodology to objectively assess a young child's development of force perception using a coloring task in their natural environment.
Two typically developing children were assessed: S1 (21 months) and S2 (52 months). Custom made crayons of different material properties and diameters with different breaking strengths were administered systematically to examine the child's force perception. There were 20 possible crayons and up to 5 trials per crayon. Subjects were given the same initial crayon. If the child did not break the crayon they received a crayon with a lower breaking strength. If the child broke the crayon they received a crayon with a higher breaking strength. If the child refused to color a different color crayon with the same breaking strength was provided. Assessments were video-taped and behaviorally coded with Datavyu 1.3.7 to identify the duration of coloring. In future research, the durations of coloring before break will be plotted against the crayon breaking strength to determine force perception thresholds, or the point at which the child can regulate

their force to prevent breakage. Feasibility of data collection was determined by the child's engagement and comprehension of the coloring task. Feasibility of behavioral coding protocol was determined by the ability to complete the full scoring protocol for each child.
S1 spent 25% of the time coloring and 75% holding the crayon. S2 spent 53% of the time coloring. S1 broke crayons on 57% of trials; 75% of breaks occurred while holding the crayon off the paper. S2 broke crayons on 77% of trials; 96% of breaks occurred while coloring. With multiple trials of the same crayon, both subjects increased their duration of coloring before break, S1 increased by a mean of 9.3 sec (SD=5.59); S2 increased by a mean of 7.45 sec (SD=7.07).
Administration of the protocol was feasible. Both subjects engaged in the task and behavioral coding data has the potential to examine force perception thresholds. However, the children's interactions with the crayons were different. The young child predominantly held the crayon, while the older child colored with the crayons. Development of age specific force perception thresholds may be needed given the differences in children's coloring interest and ability across the first 5 years of life.

Title: Hand movements are high dimensional

Authors: *Y. YAN[1], J. M. GOODMAN, JR[1], S. J. BENSMAIA[2];
[2]Dept. of Organismal Biol. and Anat., [1]Univ. of Chicago, Chicago, IL

Abstract: The hand - an extraordinarily sophisticated and versatile organ - is our primary means for interacting with objects. Despite its staggering complexity, hand control is precise and effortless. A compelling hypothesis for how the brain manages to achieve this level of dexterity is that it restricts its control of the hand to a smaller, more manageable subspace than the full range of movements of which the hand is capable. This subspace can be broken down into sets of coordinated movement primitives termed synergies. A relatively small number of synergies can account for much of the variance in hand kinematics, consistent with the interpretation that kinematics are restricted to this subspace. Whether the remaining dimensions of hand movements are structured - and thus under volitional control - has not been investigated. To fill

this gap, we measure - using a camera-based motion tracking system - hand kinematics as human participants perform several manual tasks, namely grasping, typing, and finger spelling in American Sign Language. We then perform a principal components analysis (PCA) on the measured kinematics, as has been previously done, and explore the generalizability of high-variance and low-variance principal components. We also implement machine learning techniques to extract object-specific or sign-specific information from hand postures. First, we find that hand synergies differ across paradigms. Second, lower-variance principal components are systematically structured, suggesting that they are under volitional control rather than reflecting experimental or motor noise. Then, we measure the hand kinematics and neuronal responses evoked in primary motor cortex as two non-human primates perform a grasping task. Again, we find that lower-variance principal components carry object-specific information in both the kinematics and neural data. We conclude that volitional hand movements and their neuronal representation occupy a high-dimensional space.

Title: Walking and texting: Neuromuscular control during smartphone manipulation

Authors: P. K. ACHARYA[1], A. W. VAN GEMMERT[1], ***S. A. WINGES**[2];
[1]Kinesiology, Louisiana State Univ., Baton Rouge, LA; [2]Univ. of Northern Colorado, Greeley, CO

Abstract: Walking while holding a smartphone is one of many everyday tasks requiring predictive control strategies to maintain balance while modifying grip forces to respond to expected inertial forces due to the transport of the object. Additionally, texting on the smartphone while walking adds another layer of complexity because one has to maintain the grasp while allowing the digits to interact with the smartphone. To understand how the motor system solves the challenges posed by the complexity of the task, we investigated whether the neuromuscular control strategies differ between transporting an object and transporting an object while texting. To address whether strategies changed we examined muscle activity during smartphone manipulation while standing and walking, which allowed us to test two specific hypotheses: 1) hand and arm muscle activity will increase during a tapping task regardless of walking condition, and 2) hand and arm muscle activity will increase as walking speed increases. Eight healthy college students participated in the study. Passive markers were used to track whole body motion including specific segments of the right-hand thumb and smartphone.

Surface electromyograms (EMG) were recorded from the right and left trapezius, the three heads of the right deltoid, and nine right upper limb muscles. Subjects executed five different Tasks including one no-tap task and four tapping tasks where they tapped individual letters or a series of letters over the keyboard on the smartphone device using their right thumb. These five tasks were executed during four Movement conditions (MCon) including standing and walking at 80, 100, and 120% of their comfortable walking speed on a treadmill. Repeated measures ANOVAs revealed significant effects of Task for all hand and wrist muscles, biceps and the anterior deltoid muscle ($P < .05$); muscle activity was increased for tapping tasks. Significant effects of MCon were found for all extensors in the forearm, proximal arm muscles, and the first dorsal interosseous ($P < .05$). Standing compared to walking at any speed was associated with smaller amounts of muscle activity. When walking speed increased, muscle activity trended to increase as well, although only in proximal arm and trapezius muscles. MCon did not interact significantly with Task for any measurement. It is concluded that arm muscle activity increases are associated with speed increases while tapping increases all muscle activity of the upper extremities. Furthermore, the increased complexity as result of tapping and walking speed does not change the neuromuscular strategies active for walking and tapping tasks independently.

Title: Response to transport perturbation during reach-to-grasp in virtual environment

Authors: *M. P. FURMANEK[1,2], M. YAROSSI[1], M. MANGALAM[1], S. ANTHONY[1], S. MACIEL[1], L. F. SCHETTINO[3], S. V. ADAMOVICH[4], E. TUNIK[1];

Abstract: In order to successfully reach to and grasp an object, the brain must control both transport of the hand to the object and preshaping of the fingers to grip the object. Classical theory suggests these two components are coordinated in parallel via two independent visuomotor channels. However, there is recent empirical evidence that motor control for reach

and grasp may be coupled. Here, we investigated how a mechanical perturbation of reach influenced preshaping of grip aperture. We hypothesized that if indeed reach and grasp are independent this mechanical perturbation would have no influence on the preshaping of grasp aperture as hand approaches the object. Using a custom virtual environment, five subjects (28.3 ±9.01 years) reached to grasp a virtual object. All subjects participated following IRB approved informed consent. On 25% of trials, resistive or assistive force (200 ms duration, 2, 4, 6N magnitude) was applied to the wrist 200 ms following movement onset using a robotic manipulandum. Mechanical perturbation of transport increased or decreased peak transport velocity during when applied in an assistive and resistive way, respectively. Critically, aperture scaled with changes transport velocity in direction and magnitude dependent manner. Following the perturbation response, the aperture trajectory returned to the unperturbed pathway. These preliminary results indicate a relationship in the coordination underlying the transport and grasping components of a reach-to-grasp movement. Understanding the relationship between reaching and grasping will provide useful insight for robotic/prosthetic applications to optimize efficiency in object grasping.

Title: Finger force perception during pressing tasks, Comparison of force matching and psychophysical reports

Authors: *C. J. CUADRA[1], M. L. LATASH[2];
[1]Kinesiology, Pennsylvania State Univ., State College, PA; [2]Dept. of Kinesiology, Pennsylvania State Univ., University Park, PA

Abstract: We explored a recently introduced scheme of perception based on the concept of iso-perceptual manifold (IPM) in the combined afferent-efferent space of neural signals. Within this scheme, we assume that afferent (sensory) signals from multiple sources are estimated within a frame of reference provided by the multiple ongoing efferent processes that can be adequately described as time-varying spatial reference coordinates. An IPM is equivalent to stable perception of a physical variable. We used force-matching tasks between the two hands, and verbal reports, to explore finger force perception in a two-finger pressing task. The main

hypothesis was that accuracy would be lower and variability higher during individual finger force matching in a two-finger task compared to one-finger tasks. The subjects produced accurate force levels under visual feedback by pressing with either two fingers or one of the fingers of a hand (task-hand). They tried to match the total two-finger force or individual finger forces by pressing with the other hand (match-hand, no visual feedback). Also, we used verbal report within a psychophysical scale on the level of force that the task-hand was producing. The match-hand showed higher inter-trial force variability during single-finger matching when the task-hand performed the two-finger task compared to trials when the task-hand performed single-finger tasks. The match-hand overestimated the force of the task-hand at low forces and underestimated it at high force. The verbal report consistently overestimated the task-hand force, with larger errors for higher forces. These findings confirm our main hypothesis by showing that perception of individual finger forces can vary in multi-finger tasks within a space (IPM) corresponding to veridical perception of total force. Matching hypothetical commands to fingers, rather than finger forces, could be responsible for the force overshoots.

Title: Skill learning with the left non-dominant hand is predicted by interhemispheric connections to right superior parietal lobule

Authors: *B. A. PHILIP[1], M. P. MCAVOY[2], S. H. FREY[3];
[1]Occup. Therapy, Washington Univ. Sch. of Med., St. Louis, MO; [2]Radiology, Washington Univ. Sch. of Med., Saint Louis, MO; [3]Psychological Sci., Univ. of Missouri, Columbia, MO

Abstract: Movement of the left non-dominant hand is primarily driven by the right (contralateral) motor cortex, but previous studies have shown an increased role of the left (ipsilateral) hemisphere during skill learning and execution of demanding tasks. However, the mechanism and role of left hemisphere influence on right hemisphere remains unknown. Here, 22 healthy right-handed adults (15 female, age 29 ± 11) underwent resting state functional connectivity (FC) magnetic resonance imaging before 10 days of training on a left hand precision drawing task. We explored our data to identify pre-training interhemispheric FC that predicted subsequent post-training left hand performance. 86% of participants successfully improved their

left hand movement smoothness across training. These training-related increases in movement smoothness were predicted by pre-training FC between left primary motor cortex normative hand area (M1-hand) and right superior parietal lobule (SPL), and between left intraparietal sulcus (IPS) and right SPL. These two right SPL targets were restricted in size (0.66 cm^3 connected with left M1-hand, 1.46 cm^3 connected with left IPS), but still overlapped: shared voxels comprised 46% and 22% of the volumes, respectively. Therefore, the acquisition of precision skill with the non-dominant left hand seems to involve FC between a specific area in the right SPL, and left hemisphere areas involved in precision movement (left M1) and hand choice (left IPS). If confirmed, this pathway may reflect a key neural mechanism supporting skilled movement with the left non-dominant hand: specifically, a transcallosal route by which the right hemisphere capitalizes on left hemisphere specializations. These findings present a first step toward identifying new rehabilitation opportunities for patients with persistent impairment of their right dominant hand.

Title: Moving objects upside-down: The robustness of dexterous manipulation

Authors: *L. OPSOMER[1], F. CREVECOEUR[1], J.-L. THONNARD[1], J. MCINTYRE[2], P. LEFEVRE[1];
[1]Univ. Catholique de Louvain, Louvain-la-Neuve, Belgium; [2]Univ. Paris Descartes, Paris, France

Abstract: In 1987, during a live performance in Tacoma, Mötley Crüe's drummer amazed the audience by having his entire kit revolve to play his solo upside-down, thereby proving theatrically that motor adaptation to reversed gravity is possible. Performing skilled movements in an upside-down position requires not only a reprogramming of the motor patterns to perform the same task as in upright position; it also involves an update of the forward model that predicts the changes in load at the fingertip resulting from arm motor commands. Previous studies suggest that the effects of gravity are taken into account to optimize motor behavior and are estimated anticipatively with the use of an internal model. Due to the permanent and ubiquitous nature of gravity on Earth, the prior on gravity direction is very strong. We then wondered how fast the kinematics and dynamics of arm movements can adapt when the orientation of the body with respect to gravity is reversed relatively to the usual upright position and if that adaptation

leads to after-effects. We approached these questions in the context of finger-arm coordination during object manipulation. Eighteen subjects participated in the experiment, which consisted of rhythmic arm movements performed along the feet-to-head axis and with a manipulandum held in precision grip. All participants performed 6 blocks of 20 arm oscillations in the *Upright* (head up) position, followed by 16 blocks in the *Upside-down* (feet up) position and finally 10 blocks back in the *Upright* position. Grip dynamics was assessed by means of the offset, gain, correlation and lag of the grip force (GF) - load force (LF) relationship. Our results show a great robustness of the grip-load force correlation and synchronization in the face of a reversal of body orientation. More specifically, from the first block in *Upside-down* position the gain of GF modulation was similar to the one in the *Upright* position and the lag between GF and LF remained close to zero. Moreover, no after-effect was observed following the 16 blocks performed in the *Upside-down* condition. Subjects coped with being upside-down by increasing the mean level of GF. Overall, this robustness of the grip-load force coordination shows that the orientation of the body with respect to gravity is taken into account to properly estimate future changes in LF during GF planning. Notwithstanding, grip dynamics were progressively tuned more finely with practice in the *Upside-down* position, as evidenced by an increasing correlation between GF and LF and a decrease in the mean level of GF during the five first blocks.

Title: Artificial proximity sensation using transcutaneous electrical stimulation improves force control at telerobotic operations

Authors: Z. ZHAO[1], *M. YEO[1], S. RYU[2], H. PARK[1];
[1]Dept. of Electrical and Computer Engin., [2]J. Mike Walker '66 Dept. of Mechanical Engineering, Texas A&M Univ., Texas A&M Univ., College Station, TX

Abstract: Sensory feedback plays a pivotal role in enhancing the control accuracy of teleoperation by providing information about the object under manipulation and its environmental interaction. In robotic surgery, to improve the control accuracy of surgical robotic arms, visual feedback of the operation site is provided with a magnified high-definition 3D camera. However, such visual feedback has a line-of-sight problem, and further, the processing of rich visual information can add cognitive loads to surgeons. For these reasons, visual feedback might not be optimal, especially when the surgery involves delicate organs with the intricate

vessel or nerve arrangements. To regulate force accurately at contact, additional sensory information on the distance between the end effectors and organs is necessary. To address the unmet need to deliver distance information to surgeons, we incorporate an artificial proximity sensation to the teleoperation system. We hypothesize that the proximity sensation enhances the accuracy, reduces the initial force level, and shortens the time for handling sensitive objects. To test the hypothesis, we employed a robotic gripper and a wooden board with two force sensors to mimic the pinch operation in robotic surgeries and a sensitive object, respectively. During the test, we asked subjects to telerobotically pinch the object located along the line of sight, with minimum force on both fingertips. The distance information, between each side of the gripper and the object, is delivered to the operator's fingertip by a pulsing sensation with a frequency proportional to the distance. After the contact, we discretely increase the stimulation frequency to the level for subjects to feel as constant tingly sensation instead of pulsing sensation. Three types of sensory feedback were tested and compared: only visual feedback, visual feedback with numbers indicating the distance, and visual feedback with artificial proximity sensation. Experimental results demonstrate that subjects can pinch the board with the smallest force on each fingertip when the artificial proximity sensation is provided. This result suggests that adding artificial proximity sensation can improve force-control performance during robotic surgery.

Title: Sensorimotor rhythms during action observation are sensitive to experience but are not associated with skilled performance

Authors: *K. A. FERCHO[1,3], T. J. BOSCH[1], R. M. HANNA[2], L. A. BAUGH[1];
[1]Basic Biomed. Sci., [2]Ctr. for Brain and Behavior Res., Univ. of South Dakota, Vermillion, SD;
[3]FAA Civil Aerospace Med. Inst., Oklahoma City, OK

Abstract: Neural activity over sensorimotor brain regions within the alpha (8-13 Hz) and beta bands (14-22 Hz) is modulated when an observer views actions. This activity is dependent on the observer’s experience with the action being observed, as well as recent experience with the observed object. However, little is known about the functional significance of this activity for skilled motor performance and the relationship between the object type and sensorimotor activity. This study used EEG to answer the following: 1) Do different types and amounts of sensorimotor experience with objects differentially alter alpha and beta band event-related

desynchronization (ERD) during observation 2) Do differences in alpha or beta activity correlate with skilled motor performance? Participants (N = 140) watched a short video showing an actor lifting objects with which they had varying levels of experience: a toothpaste tube (Common), a brass block (Familiar), or a yellow plastic block of unusual density (Novel). Next, participants gained experience by performing 300 lifts with the same objects (Extensive) or two lifts with the same object and 298 lifts of distractor objects (Brief). Participants then viewed the same short video. Thus, participants were assigned to 1 of 6 groups: 1) Common Extensive; 2) Common Brief; 3) Familiar Extensive; 4) Familiar Brief; 5) Novel Extensive; or 6) Novel Brief. Alpha and beta activity over C3 was analyzed for baseline and post-lifting action observation. Motor performance was assessed through an analysis of load phase duration. At baseline, there was greater beta suppression for the Common object when compared to the Novel object. Post-task, an Object x Experience interaction was found; for those in the Extensive experience group, there was more beta suppression for the Common object compared to the Novel object. However, recent experience only affected beta suppression for those in the Novel object condition, with increased beta suppression for Brief compared to Extensive groups. There was no significant effect of object or experience on alpha activity. Lifting kinematics revealed the most efficient lifts were observed for Common objects, followed by Familiar, and then Novel objects. Post-task beta band suppression was correlated with load phase duration for the Novel Extensive group, indicating increased beta suppression was associated with less efficient lifts. Therefore, increased beta suppression does not correspond with skilled motor performance. Beta activity may reflect a particular sensitivity and attentional bias to the somatosensory aspects of novel objects in an object lifting task, in addition to neuronal processing efficacy.

Title: Teleoperated robotic hand can tell size and softness of the object without vision, if force feedback from finger joints and tactile feedback from the fingertips are provided

Authors: *S. MANOHARAN, H. PARK;
Electrical and Computer Engin., Texas A&M Univ., College Station, TX

Abstract: Technology has been steadily increasing in complexity over the past few decades. Tools become to have more features and more degrees of control that increases the learning time for the operators. By repetitive usage, operators acquire intuitiveness in controlling the complex tools. However, at the initial stage of learning, high cognitive load should be involved. We

hypothesize that the initial learning process can be accelerated by multisensory feedback provided from the tools to the body. Earlier studies like the rubber hand and robotic hand experiments showed that multisensory feedback, composed of visual and tactile feedback, could establish a sense of ownership of a rubber glove. To test the hypothesis, we employed a robotic hand having independently-controllable 5-digits, and a glove with built-in electrodes that provides multisensory feedback to the tip of each finger. The robotic hand is controlled by subject's finger movements, as a master-slave control. The multisensory feedback is composed of visual feedback, tactile feedback, and force feedback. We added force feedback as the robotic hand can experience resistance when it grabs an object. For the visual feedback, the operator sees the real-time motion of the robotic hand as a low-latency mapping of their finger movements. For the second feedback, 5-tactor system is incorporated for tactile feedback using electrical stimulation. For the third feedback, force feedback system is incorporated for each of subject's fingers using an exoskeleton, in order to emulate the force experienced by the robotic hand. We tested the basic operation of the control of robotic hand along with the multisensory feedback capability. Subjects were asked to distinguish the four objects, as wooden/foam spheres and wooden/foam cubes. With both force feedback from finger joints and tactile feedback from the fingertips, teleoperated robotic hand can tell the size and softness of the object without vision, while it cannot without either force or tactile feedback.

Title: That's not my hand: Attributing errors to external sources dampens predictive but not proprioceptive changes in hand position estimates

Authors: *R. Q. GASTROCK[1,2], S. MODCHALINGAM[3,2], C. M. VACHON[1,2], B. M. 'T HART[2], D. Y. HENRIQUES[3,2];
[1]Psychology, [2]Ctr. for Vision Res., [3]Kinesiology & Hlth., York Univ., Toronto, ON, Canada

Abstract: People account for the source of motor errors when adapting to dynamic conditions within the environment or their own body. Adapting reaches to altered visual feedback of the hand involves updating hand position estimates based on changes in proprioception and efferent-based predicted sensory consequences, where predictions are computed by internal forward models based on the outgoing motor command. Our recent work showed that shifts in hand

position estimates persist, despite knowledge of the external nature of the perturbation. However, such explicit knowledge should allow for the brain to attribute the source of errors externally and not shift hand position estimates. Here, we manipulated the extent of external error attribution in four ways while participants trained with a 30 degree rotated hand-cursor: the 1) “non-instructed” control group received neither instructions nor different visual stimuli, 2) “instructed” group received a counter strategy for the rotation, 3) “cursor jump” group saw the cursor misalignment mid-reach on every trial, 4) “hand view” group saw both their actual hand and misaligned cursor on every trial. During training the instructed group immediately countered the rotation, while other groups showed typical learning rates. During reaches without visual feedback of the cursor, participants either included or excluded any strategy developed to counter the rotation. Only the non-instructed group could not do so at will, suggesting a lack of explicit awareness of the perturbation. Moreover, reach aftereffects for the hand view group were lower compared to the other groups. Participants also estimated the location of their unseen hand before and after training. They either generated their own movement, allowing for hand localization with both proprioception and predictions, or the robot moved their hand, leaving only proprioception. We found that shifts in predicted sensory consequences were dampened for the hand view group, but proprioceptive recalibration persisted in all groups. Furthermore, we found that proprioceptive shifts correlated with reach aftereffects. Thus, although groups differed with error attribution to the cursor, we speculate that proprioceptive recalibration is not based on the hand but on the cursor.

Title: Implicit components of learning and the two-rate model

Authors: *J. E. RUTTLE[1,4], B. M. 'T HART[2,5], D. Y. HENRIQUES[3,4];
[1]Psychology, York Univ., North York, ON, Canada; [2]Ctr. for Vision Res., York Univ., Toronto, ON, Canada; [3]Dept Kinesiol & Hlth. Sci., York Univ., North York, ON, Canada; [4]Ctr. for Vision Res., North York, ON, Canada; [5]Ctr. for Vision Res., North york, ON, Canada

Abstract: People are very good at correcting their reaching movements based on error feedback. It is believed that there are at least two processes that are involved in this error-based learning. Some processes of adaptation have been well explained by a two-rate model proposed by Smith et al., 2006, which includes a fast and slow process, that respond differently to errors, and combine to change motor output, including those changes seen during rotated visual feedback training (McDougle et al., 2016). This model is specifically able to explain a rebound to a previous performance when error feedback is removed. Unfortunately, this model does not acknowledge the two other changes that occur either as a product of motor learning or as a driving force of motor learning; changes in hand estimates and reach aftereffects. These two changes are thought to be implicit as they persist even when the perturbation is removed, participants have no visual feedback, or they are told to ignore the perturbation. Here, we tested how vision during training plays a role in changes in hand estimates and compared the time course of reach aftereffects to the slow process. First, it appears that continuous feedback of the cursor and thus increased exposure to the visual-proprioceptive mismatch between the hand and cursor leads to larger changes in hand estimates than when exposed to impoverished visual feedback during rotated cursor training. Second, the participants show less of a rebound and do not seem to retain their previously learned states for as long. Finally, regardless of the instructions given to participants about how to execute reaches, reach aftereffects do not seem to match the time course of the slow process. In summary, the two-rate model cannot account for the commonly seen outcomes associated with motor learning and additional models may be required.

Title: Proprioceptive recalibration generalizes relative to hand position

Authors: *B. M. 'T HART, J. E. RUTTLE, D. Y. HENRIQUES;
York Univ., Toronto, ON, Canada

Abstract: People can quickly adapt their movements to various circumstances. When feedback on hand position is rotated around the start position, motor adaptation to this change is generalized to nearby reach directions, but peaks at the visual position of the trained target. In addition, our feeling of hand position is also recalibrated by altered visual feedback on hand position (proprioceptive recalibration). However, little is known about how these changes in felt

hand position generalize. In previous work with adaptation to a visuomotor rotation, proprioceptive generalization showed several distinct patterns. We observed 1) nearly uniform generalization, 2) generalization peaking around the direction of the visual training target and 3) generalization peaking closer to the trained movement direction (rotated relative to the visual target). What are the underlying causes of the differences in the generalization patterns? Those studies used different training and testing tasks. Interestingly, training paradigms or tests that were targeted at evoking or measuring recalibrated proprioception, seem more likely to result in a peak at the trained reach direction, as opposed to at the direction of the visual target. It is possible that the experienced proprioceptive signal is recalibrated, and the experienced signal should be close to the reach direction, not the visual target. This would predict that the direction of the rotation determines where generalization of recalibrated proprioception peaks. With a clockwise and counterclockwise 45 degree rotation, we find this is the case. The data on generalization of proprioceptive recalibration suggest that the training signals (sensory prediction error, motor or task error and visuo-proprioceptive discrepancy) have different effects on reach adaptation and proprioceptive recalibration, and these effects may be combined in distinct ways in different training and testing paradigms.

Title: Unbounded implicit motor adaptation

Authors: *S. MODCHALINGAM[1,2], M. CICCONE[1], B. M. 'T HART[2], D. Y. P. HENRIQUES[1,2];

Abstract: When our intended movements have unintended outcomes, the human motor system can quickly adapt future movements. Motor output is modified in a way such that motor errors, that is, the difference between the expected and the perceived consequences of any motor output, are reduced. Both implicit and explicit components play key roles in adaptation. Explicit components, such as the use of conscious strategies to counter a perturbation, can be quickly employed and allow for flexibility in rapidly changing conditions. Implicit components on the

other hand, such as the unconscious updating of internal models, arise slowly and allow for reliable, persistent changes in the motor system. When adapting reaching movements, implicit components of adaptation have been demonstrated to have an upper boundary in the amount by which they alter future movements, regardless of the size of the experienced perturbation (Bond & Taylor, 2015); that is, they are thought to be limited in scope. Here, we reduce the motor errors experienced by participants when adapting their reaches to a visuomotor rotation, which increases in small steps. Consequently, we show that the recently proposed upper boundary on implicit adaptation can be overcome. This suggests that while implicit adaptation is difficult to achieve during tasks with large, salient errors, necessitating explicit strategies, in most natural situations implicit adaptation is sufficient and leaves costly cognitive resources free for other tasks. Bond, K. M., & Taylor, J. A. (2015). Flexible explicit but rigid implicit learning in a visuomotor adaptation task. *Journal of Neurophysiology*. https://doi.org/10.1152/jn.00009.2015

Title: Network effects of cerebellar non-invasive stimulation: An MEG study on dystonic patients and healthy controls

Authors: *S. C. FICARELLA[1], A. RICHARD[2], Q. WELNIARZ[1], C. GALLEA[1,3,2,4], S. MEUNIER[2], E. ROZE[1,3,5], M. VIDAILHET[1,3,2,4,5];

Abstract: Dystonia is a movement disorder characterized by abnormal muscular contractions and motor planning (Gallea et al., 2016). The cerebellum plays a critical role in dystonia (Lehéricy et al., 2013; Gallea et al., 2015) representing a potential therapeutic target (Tewari et al., 2017). However, the role of the cerebellum within the neuronal networks involved in movement planning is unclear. This study aims at investigating the network effects of cerebellar non-invasive stimulation during motor preparation. To this aim, 16 focal hand dystonia patients (FHD) and 19 healthy volunteers (HV) were included in the study with sham and cerebellar stimulation (transcranial magnetic for HV and transcranial alternating current stimulation for FHD). Participants performed a visuo-motor adaptation (VMA) task triggering cerebellar activity, before and after stimulation, while brain activity was recorded with

magnetoencephalography. Participants moved a joystick to reach a target with a cursor presented on a screen, under two different conditions. In the control condition, joystick's movements and visual feedback were related directly to the cursor's motions. In the deviation condition, visual feedback was rotated inducing trajectory error (curved), which participants had to correct to produce trajectories as straight as possible. While both sham and cerebellar stimulation significantly reduced errors in both groups, cerebellar stimulation significantly improved, compared to sham stimulation, the trajectory-correction learning rate in patients. Coherence measures between cerebellum and motor cortex for the beta frequency band correlate negatively with the learning rate. While the amplitude of trajectory errors was comparable between groups, HV adjusted their motor trajectories faster than patients and this learning rate was boosted by cerebellar stimulation compared to sham stimulation, more efficiently than in patients. This effect is likely due to a modulation of the coherence between the cerebellum and the motor cortex, in the beta frequency band. Cerebellar stimulation improved participants' learning rate, which depends on cerebellum-motor cortex communication. Title: The effect of error-sensitivity and perturbation schedules on the slow and fast processes in reach adaptation

Authors: *A. T. BANSAL[1], B. M. 'T HART[2], D. Y. HENRIQUES[1];
[1]Kinesiology & Hlth. Studies, [2]Ctr. for Vision Res., York Univ., Toronto, ON, Canada

Abstract: Adapting movements to our ever-changing environment likely involves many neural processes, and the two-rate model (Smith et al., 2006) nicely demonstrates that at least two processes are at work, called the “fast” and “slow” process. It explains a rebound phenomena, where people revert to reaching as if they were still adapted to the initially learned rotation, when doing error-clamped trials after a short reversal of the adapted perturbation. Later work has mapped the fast and slow processes onto explicit and implicit learning, respectively. To test this link between the model processes and actual learning processes, we used a within-subjects

design where all participants (N=29) adapted to the same rotation introduced both gradually and abruptly (apropriately counterbalanced to prevent carry-over effects). Gradual rotations should rely on implicit learning more than abrupt rotations and lead to larger rebounds. However, we found no effect on either the size of the rebound or the fitted model's parameter values, suggesting that the two model processes may not directly reflect implicit and explicit learning. In a second experiment, all participants (N=35) did two of four conditions with abrupt rotation only (counterbalanced as before) where we varied both the duration of the reversal period (4 or 12 trials) and the amplitude of the rotation (aligned or reversed). Crucially, the initial learning phase is exactly equal, and should involve actual learning processes (both fast and slow) equally. We see no effect of the duration of the reversal period, but model parameters and rebounds change with the amplitude of the rotation in the reversal period. Consequently, the model predicts that the two processes are not equally involved in early learning, despite equal training. This further suggests that the applicability of the model is limited, as is fully in line with the conclusions of Smith et al. (2006). Furthermore, the first experiment was done with a stylus on a tablet in a laboratory setting and the second experiment using a regular mouse in a large computer room. Each experiment had one identical condition, to allow testing if two-rate paradigms may be done on regular PC's, and we found no decrease in performance.

Title: A supination task to assess corticospinal function in mice

Authors: ***S. F. AGGER**[1], N. SERRADJ[1], E. C. MEYERS[2], A. M. SLOAN[3], E. R. HOLLIS[1]; [1]Burke Neurolog. Inst., White Plains, NY; [2]Texas Biomed. Devices Ctr., Univ. of Texas at Dallas, Richardson, TX; [3]Vulintus, Inc., Louisville, CO

Abstract: In order to fully understand corticospinal circuit function in the learning and execution of skilled movements we have been working in concert with Vulintus, Inc. in order to develop a forelimb supination module for the MotoTrack mouse behavioral system. This task allows for repeatable, objective quantification of a stereotyped supination movement in an unbiased manner. Supination, the ability to turn the paw/hand from palm down to palm up, is critical for dexterity and is one component of the skilled reach behavior, a complex motor task used to

assess learning and recovery of skilled motor function.
Skilled motor control is affected by spinal cord injury and impairments of supination are characteristic of damage to the corticospinal tract, the direct output from neocortex to the spinal cord.
C57BL/6J mice, both male and female, had aluminum head plates attached at six weeks of age. Mice were water restricted and began training by eight weeks of age. Once mice learned how to turn a small knob with the assistance of the investigator, they began training daily using a stepped protocol with increased levels of difficulty. The degree of difficulty was determined by the counter weight and minimum turn angle. By the end of training mice were able to turn above a 10° threshold with a counter weight of 1g for at least 50 trials within a 15 minute session. Following completion of training, mice underwent unilateral transection of the left medullary pyramid (pyramidotomy). Testing was resumed one week post-pyramidotomy and continued twice weekly through eight weeks.

Title: Action discovery and refinement through reinforcement in the mouse corticostriatal network

Authors: *A. C. MOSBERGER, L. J. SIBENER, V. ATHALYE, H. F. M. RODRIGUES, R. M. COSTA;
Columbia Univ., New York, NY

Abstract: In novel action discovery, when an exploratory action leads to reward, credit is assigned to certain dimensions of the action, which are repeated, leading to refinement of the action over time. We are investigating how this mechanism unfolds in the corticostriatal network. Two distinct neuronal classes project from cortex to striatum, intratelencephalic (IT) and pyramidal tract (PT) neurons. Here we show that for the mouse forelimb circuitry, IT and PT cells are distributed across widespread cortical areas with specific distinctions in their locations.

These sensorimotor glutamatergic inputs from cortex to striatum are hypothesized to provide an efference copy of the planned and/or ongoing action, allowing the assignment of credit to the relevant action dimensions at corticostriatal synapses - a process that allows learning through reinforcement. To study this, we developed a novel joystick task, in which head-fixed mice can move a joystick in any direction on a 2D plane using their forelimb. Mice are trained to move the joystick from a predefined initial position to a target area in an uncued and self-paced manner. The training requires no external guidance except delivery of a reinforcer upon entering the target area and automatic returning of the joystick to the start position. After initial exploration within the 2D action space, mice gradually increase their accuracy and achieve high hit rates of 80% within 2 weeks. With learning, joystick trajectories become less tortuous, and more similar to each other, unveiling unprecedented forelimb control. Flow field analysis of the trajectories reveals a decrease in directional variability and a shrinkage of the used action space over time further indicating refinement of the action. To allow the repeated investigation of action learning, we change the location of the target area, requiring mice to discover the new target, and refine a new action through reinforcement. Using 2-photon imaging of anatomically distinct corticostriatal circuits of the mouse forelimb in combination with this joystick task we are currently identifying IT and PT neuronal dynamics of action discovery, credit assignment, and action refinement through reinforcement.

Title: Thalamostriatal circuits in flexible and automatized motor skill execution

Authors: *L. J. SIBENER, A. C. MOSBERGER, H. RODRIGUES, V. ATHALYE, R. M. COSTA;
Columbia Univ., New York, NY

Abstract: Over the course of our lives, we learn to perform a variety of actions, which require exact motor control to be successful. Learning to perform a novel action starts with it being behaviorally flexible, and eventually transitions to automatized execution. We are investigating how this transition unfolds in the thalamostriatal network.

It has been shown that plasticity of glutamatergic inputs to the striatum are critical for motor learning. Previous investigations into striatal information integration have focused on glutamatergic cortical projections to dorsal striatum (DS), while largely ignoring glutamatergic input from the thalamus. The densest thalamostriatal projection come from the parafasicular nucleus (Pf), which projects widely to DS. Lesions of Pf produce deficits in goal-directed learning and reward devaluation. We hypothesize that Pf input into DS mediates flexible performance of motor skills.
To study the role of Pf during flexible motor skill execution, we developed a novel head-fixed joystick task, in which mice move an unrestricted joystick in a 2D plane. Mice learn to move the joystick from a set start position to one of two rewarded target areas. Over several sessions, mice increase their accuracy, and individual trajectories become shorter, less tortuous, and more similar, showing expert forelimb control. After ~2 weeks of training, we change the target location, requiring mice to switch from automatized executions to behaviorally flexible movements. Intra-session vector field analysis reveals an increase in variability and exploration within the action space shortly after the target switch. Then trajectories show the same refinement with the new target. We are now using 2-photon imaging of thalamostriatal circuitry to identify dynamics of this behavioral flexibility and refinement. These experiments are the first to dissect the role of thalamostriatal circuits in emergence of highly skilled forelimb control in mice.

Title: Reinforcement learning of continuous movements in the basal ganglia

Authors: *J. M. MURRAY, S. ESCOLA;
Columbia Univ., New York, NY

Abstract: --While the basal ganglia (BG) circuit has long been known to be involved in the learning and execution of voluntary movements, recent experiments involving multicellular recordings and optogenetic perturbations have made it possible to test at a more detailed level traditional assumptions about its role in action selection and sequencing and in the control of

movement vigor.
--To address the neural representations in BG underlying learned motor behaviors, we constructed a computational model of the BG circuit to implement reinforcement learning for a skilled reaching task. Unlike existing models of BG, the model operates in continuous space and time, without requiring that neurons exhibit pure selectivity for particular actions or that descending pathways through the BG are strictly parallel and action-specific.
--We then analyzed the neural representations that emerged in the trained network, including their relation to behavior and evolution during task learning. We found from this analysis that many of the prominent features of BG activity from recently published experiments could be recovered, including coactivation of direct- and indirect-pathway neurons at movement onset, positive correlation of both of these populations with movement vigor, and the evolution of transient dopamine signals as the task is learned. These modeling results provide a framework for interpreting existing experimental data and for generating predictions to be tested in future experiments.

Title: Corticospinal neuron function during skilled and unskilled forelimb training

Authors: *F. MARINO[1], N. SERRADJ[1], A. M. SLOAN[2], E. R. HOLLIS[1];
[1]Burke Neurolog. Inst., White Plains, NY; [2]Vulintus, Inc., Louisville, CO

Abstract: The corticospinal tract is the principal mediator of skilled motor control. Cortical motor representations (motor maps) depend on the underlying output of corticospinal and other corticofugal neurons. These maps are plastic and reorganize in response to skilled, but not unskilled, motor training. Modern optogenetic tools allow us to evaluate these networks by imaging endogenous activity of defined neurons over longitudinal studies. We used multiphoton imaging in concert with the MotoTrak isometric pull module (Vulintus, Inc.) to record the effects of skilled and unskilled training on corticospinal function. Mice 6 to 8 weeks old were injected with AAV2retro-GCaMP7f at cervical level 7 for retrograde transduction of corticospinal neurons with the genetically encoded calcium indicator GCaMP7f. Following transduction, mice received a cranial window implantation over exposed motor cortex and an affixed rectangular

aluminum head bar. Corticospinal neurons transduced with GCaMP7f were imaged using 2-photon microscopy during learning of our head-fixed skilled or unskilled forelimb behavior. Water restricted mice were trained daily on the isometric pull system. Training of our skilled task began with two weeks of behavioral shaping during which the target range for isometric pull was narrowed from 5-20 grams to 15-18 grams. After shaping, mice were trained for another two weeks to a minimum of 60% proficiency. Our unskilled isometric pull mice are trained over two weeks with an adaptive threshold which is calculated as the 50^{th} percentile of the previous 10 trials starting at a lower boundary of 5 grams. During training, neural activity was recorded to assess changes in motor networks during skilled or unskilled motor learning. After completing training, mice underwent bilateral transection of the medullary pyramids (pyramidotomy). Corticospinal neurons in the motor cortex were recorded twice weekly during testing post-injury to determine injury-induced changes in cell activity and motor networks. Images from recording sessions were preprocessed in FIJI to remove noise and further processed in MATLAB using constrained nonnegative matrix factorization (CNMF). This method consists of non-rigid motion correction followed by CNMF to select neurons and extract their fluorescent traces for analysis. These data are synchronized with output from our MotoTrak system to extract frames when the animal is actively pulling the lever. Normalized $\Delta F/F_0$ for each neuron is segmented by movement and identified as a successful or unsuccessful pull. Average corticospinal activity was compared between skilled vs unskilled movement both during training and post-injury.

Title: Learning adapted feedback responses to unpredictable force fields during reaching

Authors: *F. CREVECOEUR, J. MATHEW, P. LEFEVRE;
Univ. of Louvain, Louvain-la-Neuve, Belgium

Abstract: Motor adaptation results from the acquisition of novel representations in the nervous system allowing improvements of performance across a broad range of tasks. To date, there has been much emphasis on the acquisition of such patterns for predictable disturbances, and previous work highlighted that both prior and feedback control mechanisms share knowledge

about limb and environmental dynamics. Here we investigated whether healthy adults could learn to produce adapted feedback responses to unpredictable force field disturbances applied during reaching to address whether sensory feedback during movement could be used to adjust movement control. We instructed 18 healthy adults to perform reaching movements towards a visual target with a robotic handle (KINARM). On a random subset of trials (probability 1/3), we applied either an orthogonal field (lateral force proportional to forward velocity), or a curl field (force proportional and orthogonal to hand speed), both of clockwise or counter-clockwise directions, randomly interspersed with unperturbed trials. We found a reduction in path length across force field trials for both perturbations and directions, indicative of better compensation for the applied disturbance. An analysis of average surface activity from the main muscles involved in lateral corrections indicated that there was no systematic increase in co-activation, and highlighted a down-regulation of perturbation-related responses within 240ms of reach onset, which accounted for the improvement in online correction. Furthermore, the measured force at the handle became gradually better correlated with the commanded force, re-calculated offline based on the velocity profile of each trial. This increase in correlation was also observed in a standard adaptation paradigm performed as a control experiment (n = 8 participants), which confirms that it is a metric sensitive to adaptation. Together these observations indicate that feedback responses to unpredictable disturbances were tuned to the specific force profile experienced within each perturbation trial, and displayed similar improvements as in standard adaptation to predictable disturbances. These observations highlight that the nervous system adapts feedback control strategies within a trial to the experienced disturbances, and are consistent with the hypothesis of online adaptation during reaching.

Title: Single-pulse transcranial magnetic stimulation over the parietal cortex does not impair implicit visuomotor adaptation

Authors: ***F.-A. SAVOIE**[1], L. DALLAIRE-JEAN[2], F. THÉNAULT[2], K. WHITTINGSTALL[1], P.-M. BERNIER[2];
[1]Dept. de Médecine Nucléaire et Radiobiologie, [2]Dept. de Kinanthropologie, Univ. de Sherbrooke, Sherbrooke, QC, Canada

Abstract: Whether the parietal cortex contributes to the adaptation and maintenance of internal models (*i.e.* implicit adaptation) remains unclear. In a recent electroencephalogram study, Savoie et al. (2018) observed increased parietal activity in response to visuomotor sensory prediction errors in the hemisphere contralateral to the perturbed visual feedback, raising the possibility that the parietal cortex could sub-serve implicit adaptation. The goal of the present study was to causally test whether the phasic parietal responses reported by Savoie et al., which occurred 140 - 260 ms after the provision of visual feedback and peaked at location P4 of the 10-20 electrode system, were related to implicit adaptation. Participants reached toward one of two visual targets located on either side of a fixation point, while being pseudo-randomly submitted to a 45 degree visuomotor rotation. For left target trials, the rotation was clockwise so that the cursor feedback fell into the right visual hemifield, whereas the opposite was true for right target trials. On half of all rotation trials, single-pulse transcranial magnetic stimulation (TMS) was applied over either the right (P4, N = 14) or left (P3, N = 14) parietal cortex 150 ms after movement onset (*i.e.* the approximate moment of parietal response onset reported by Savoie et al.). To determine whether TMS influenced implicit adaptation, hand drift was compared on t trials that followed rotation with (RS+1) and without (R+1) TMS. It was hypothesized that interfering with parietal activity would reduce hand drift. Results revealed potent hand drift on post-rotation trials as compared to both rotation and null rotation trials (left target: p less than 0.002; right target: p less than 0.002, Bonferroni corrected), indicating that visuomotor rotation resulted in robust trial-by-trial behavioral updating, a reflection of implicit adaptation. Contrary to our hypothesis, however, neither left nor right parietal stimulation significantly impacted post-rotation hand drift for either target (left target: $p = 1.00$; right target: $p = 1.00$, Bonferroni corrected). These data suggest that parietal areas located under P3 and P4 are not critical for implicit adaptation. However, they may be important for other processes at play during sensorimotor adaptation, such as explicit adaptation, retention of motor memories, online control or proprioceptive recalibration.

Title: Prior history of learning saturates the brain's capacities to form motor memories

Authors: *R. HAMEL[1,2], J.-F. LEPAGE[2], P.-M. BERNIER[3];
[1]Kinanthropologie, [2]Pediatrics, Univ. de Sherbrooke, Sherbrooke, QC, Canada;
[3]Kinanthropologie, Univ. De Sherbrooke, Sherbrooke, QC, Canada

Abstract: Learning rarely occurs in isolation from previous experiences. In fact, the brain's response to an ongoing event depends on its previous history of activity. Namely, a growing body neurobiological evidence now indicates that previous learning, by disrupting the brain's homeostatic state, can transiently saturate its capacity to undergo further neuroplastic changes. One ensuing possibility is that previous history of learning could ultimately impair retention of ongoing events. The objective of the present study was to test this possibility. For that purpose, three groups adapted twice to the same gradually introduced 21° visuomotor rotation, which occurred over two separate sessions. Given that prior learning-induced saturation was expected to be transient in time, the inter-session interval (ISI) was manipulated to either last 2min (n = 20), 1h (n = 20) or 24h (n = 20). For both sessions, retention was assessed immediately after adaptation through the persistence of biases in reaching behaviors during No Vision (i.e., vision of the cursor was occluded) and Washout phases (i.e., veridical vision of the cursor was provided). The main dependent variable was Hand Direction at PV (°). The hypothesis was that an ISI of 2min, as compared to a 24h ISI, would impair retention of the second as compared to the first session. Results indicated a three-way interaction that confirmed this hypothesis by ultimately revealing that retention was selectively impaired in the 2min ISI condition during the second as compared to the first session ($p = 0.013$; Cohen's dz = 0.652), while this effect was absent in both the 1h ($p = 0.940$; Cohen's dz = 0.017) and 24h ISI conditions ($p = 0.717$; Cohen's dz = 0.082). A control experiment (n = 20) and additional analyses further revealed that results could neither be accounted for by differing levels of adaptation prior to the assessment of retention nor, crucially, by physical fatigue. Verbal reports confirmed that the rotation remained unperceived for both sessions and for all groups. Globally, the present results suggest that the brain's capacity to form motor memories can be impaired by the previous history of learning, an effect that falls in line with the homeostatic constraints known to tightly regulate neuroplastic changes.

Title: Intensive motor learning induces EEG and behavioral changes that are reversed by a nap

Authors: *M. F. GHILARDI[1], **E. GIRAU**[2], S. RICCI[3], E. TATTI[4], C. CHAN[2], C. CIRELLI[5], G. TONONI[6];
[1]CUNY, New York, Italy; [2]CUNY, New York, NY; [3]Dept. Physiology, Pharmacol. & Neurosci., CUNY Med. Sch., New York, NY; [4]CUNY Sch. of Med., New York, NY; [5]Univ. of Wisconsin Madison Dept. of Psychiatry, Madison, WI; [6]Univ. of Wisconsin Madison, Madison, WI

Abstract: We investigated whether intense training in a motor adaptation task to rotated visual display induces neuronal fatigue in well-rested subjects and if a nap or quiet rest reverses such changes. 36 young healthy subjects performed 3 one-hour blocks of a reaching task with visuomotor learning (ROT), followed by a two-minute recording of sEEG with eyes open and by *mem* and *mov* tests, the former with working memory characteristics, the latter with motor features of ROT but without the learning component. At the end of the morning 20 subjects took a 90-minute nap, while 16 quietly rested for the same time. Similarly, 9 subjects underwent three blocks of simple reaching task (MOT). We found that intensive learning to adapt movements to new visuo-motor correspondences induced local power increases during spontaneous EEG over the cortical areas engaged by the task. After two one-hour ROT blocks power increased in the α range over a left fronto-central area and in the β range over a left centro-parietal cluster (mean±SE: 19±4%). A further block of ROT produced increases over a centro-frontal area (41±11%) in the θ range, in two symmetrical centro-parietal areas (left: 49±14%, right: 45±12%) in the α range, and over a cluster of electrodes in a centro-parietal area on the left (27±7%) in the β range. Also, in the frontal cluster, α and β power changes during the task positively correlated with θ power increases in sEEG3, suggesting that low frequency increases in sEEGs is related to learning activity. Such EEG changes were accompanied by an increasing number of errors when subjects performed *mov (*$p<0.001$), while performance in *mem* did not significantly change ($p=0.160$). Interestingly, MOT did not affect performance in *mem* ($p=0.787$) and only slightly improved *mov* ($p=0.020$), suggesting that the EEG effects of neuronal fatigue are related to learning. Local EEG changes, test performance and learning ability were renormalized by an afternoon nap but not an equivalent period of quiet wake. The frontal region, with the greatest increase after ROT, showed a significant power decrease in the 1-8 Hz frequency range only after the nap ($p=0.036$) but not after quiet wake ($p=0.540$). Additionally, *mov* performance improved only after a nap ($p=0.002$), while performance in *mem* did not change in either group. Finally, post-sleep improvements in *mov* were related to the nap δ; activity during N3 sleep ($r=0.82$, $p=0.002$). These findings suggest that specific neural circuits become fatigued with intense learning even without sleep deprivation. Restoration occurs only after a nap but after quiet rest of the same duration.

Title: Practice in a motor learning task increases movement-related beta modulation depth over frontal and ipsilateral parietal areas in a subsequent motor test

Authors: *E. TATTI[1], S. RICCI[2], R. MEHRARAM[3], N. LIN[4], S. GEORGE[4], M. F. GHILARDI[4];
[1]CUNY Sch. of Med., New York, NY; [2]Dept. Physiology, Pharmacol. & Neurosci., CUNY Med. Sch., New York, NY; [3]Newcastle Univ., Newcastle upon Tyne, United Kingdom; [4]CUNY, New York, NY

Abstract: Modulation of beta oscillations (15-30 Hz) is a prominent phenomenon characterized by event-related desynchronization (ERD) during movement execution followed by a post-movement rebound (event-related synchronization, ERS) after the movement end. We previously found that beta modulation depth (ERS-ERD) increases with practice in an arm-reaching task. Such increases are likely to represent plasticity-related changes.
Here we investigated whether the magnitude of beta peak ERD, ERS and modulation depth is affected by previous practice with a visuomotor learning task. Subjects performed three 40-minute blocks with ROT (8 targets, 4 cm distance), a visuomotor adaptation task (28 subjects, age: 24±4) or MOT, a similar motor task without the learning adaptation component (14 subjects, 25±5). Before and after each block, both groups completed *mov*, a 5-minute reaching test with targets at 3 distances and 8 directions, without the adaptation component. High density EEG was recorded throughout the experiment. Mixed model repeated measures ANOVAs were run to test whether peak beta ERS, ERD and modulation depth over three regions of interest (ROIs, frontal, left and right parietal) differed across blocks and between task conditions. After both ROT and MOT, *mov* showed the greatest magnitude of beta modulation depth over the left parietal ROI, followed by the frontal and right parietal ROIs. Further, for all the ROIs, we found a progressive increase of beta modulation depth across the four blocks of *mov*, mostly over the left parietal ROI. Comparison between task conditions revealed that *mov* in the ROT condition was characterized by a steady, significant increase across blocks of beta modulation depth over the right and frontal ROIs, an effect that was not present during the MOT control condition. In general, the magnitude of beta modulation depth increased after the first block of MOT, but showed little change after the subsequent MOT blocks. Importantly, these effects were not accompanied by significant changes of motor performance indices during *mov*. Beta modulation

depth increase across blocks was mostly accounted for by changes in the ERS magnitude. In summary, increases of beta modulation across *mov* tests were more prominent after visuo-motor learning than after a simple motor task, especially over the right and frontal ROIs, areas that are involved in the learning task.
Since beta modulation might represent plasticity-related phenomena, these findings suggest that learning-related effects of prolonged practice in an implicit visuomotor adaptation task are carried over to subsequent motor tests in areas that are mostly involved in the specific learning.

Title: Consolidation of motor memory induced by instance-reliant learning

Authors: *M. JAVIDI, G. TAYS, S. BAO, *J. WANG;
Univ. of Wisconsin, Milwaukee, WI

Abstract: Motor adaptation, a type of motor learning, is thought to involve two distinct processes: algorithmic (or error-based) learning and instance-reliant (or use-dependent) learning. instance-reliant learning is a mechanism in which repeated performances of a motor task results in the accrual of motor instances that contribute to fast, automatized performances of the same task later. It has been shown that instances can be accrued not only during active performances of a motor task, but also during passive performances, which then can also be used to facilitate subsequent learning of a similar motor task that has not been experienced previously. While instance-reliant learning has implications for neurorehabilitation, it is unknown whether the effects of instance-reliant learning can persist over long periods of time. The objective of this study, thus, was to determine whether the facilitative effect of instance-reliant learning on visuomotor adaptation will last over several time delays (i.e., 5 minutes, 1 hour, 24 hours). The working hypothesis was that motor memory obtained as a result of instance-reliant learning will be consolidated to have a lasting effect for up to 24 hours. Neurotypical, right-handed young adults experienced four experimental sessions: baseline, passive training, time delay, and testing. All subjects became familiarized with a general targeted reaching task during the baseline session. In the passive training session, they received passive proprioceptive training of their dominant arm that was moved passively by an exoskeletal robot in a “desired” target direction (i.e., the direction to be learned later during the testing session) repeatedly. Following that, the subjects were randomly assigned into 3 groups: each experiencing a different time delay of either

5 minutes, 1 hour or 24 hours. In the testing session, the subjects performed reaching movements under a novel visuomotor condition, in which the visual display was rotated 30 degrees counterclockwise about the start circle. A group of control subjects were also tested, who experienced the baseline, 5-minute time delay, and testing sessions. Results indicate that all three experimental groups adapted to the rotation substantially better and faster than the controls. This demonstrates that motor memory obtained as a result of instance-reliant learning can be consolidated to have a lasting effect for at least 24 hours, which in turn suggests that an intervention protocol based on the idea of instance-reliant learning may be a viable option for improving arm motor function in stroke survivors, especially those with moderate-to-severe hemiparesis.

Title: The nature of savings associated with a visuomotor adaptation task that involves either one arm or both arms

Authors: ***R. JAMES**, S. BAO, J. WANG;
Univ. of Wisconsin, Milwaukee, WI

Abstract: Visuomotor adaptation is a gradual process in which the nervous system adjusts the sensorimotor mappings in response to the changes in sensory inputs or environmental characteristics. Visuomotor adaptation usually results in savings, which refers to the phenomenon of faster relearning when exposed to a previously experienced condition later. The nature of savings is typically studied using a paradigm in which the same arm experiences multiple conditions related to savings (adaptation, deadaptation, readaptation). It has seldom been studied, however, using a paradigm that involves both arms. This is important, given that savings is observed not only when adaptation and readaptation occur with the same arm, but also when they involve both arms. Here, we investigated the nature of savings by examining how deadaptation with one arm, with or without visual Feedback (VFB), would influence the pattern of savings observed during readaptation with the same or the other arm. Neurologically intact young adults first performed targeted reaching movements under a 30-degree visuomotor rotation condition with the left arm. Following that, they were divided into six subject groups, who experienced additional conditions differently as follows: 1) deadaptation with the left arm (with VFB), then readaptation with the right arm; (2) deadaptation with the right arm (with VFB), then readaptation with the left arm; (3) deadaptation with the left arm (without VFB), then

readaptation with the right arm; (4) deadaptation with the right arm (without VFB), then readaptation with the left arm; 5) deadaptation with the left arm (with VFB), then readaptation with the left arm; (6) readaptation with the right arm (control condition). We hypothesized that if savings was associated with an internal representation that is effector independent, the pattern of savings observed during readaptation would be similar regardless of which arm was used during the deadaptation and readaptation sessions. Results showed that the amount of savings varied depending on which arm was used during the deadaptation session, and that the pattern of savings was not affected by the presence or absence of the visual feedback. Our findings suggest that internal representations developed following visuomotor adaptation involve some aspects that are effector independent (model-based, error-based or algorithmic learning) and other aspects that are effector dependent (model-free, use-dependent or instance-reliant learning); and they further suggest that the nature, or the amount, of savings can vary depending on whether it involves a single (e.g., one arm) or multiple (e.g., both arms) motor effectors.

Title: Cognitive and sensorimotor contributions to the nine-hole peg test: A functional near-infrared spectroscopy study

Authors: *L. BONZANO[1], L. PEDULLÀ[1], G. BRICHETTO[2], M. BOVE[1];
[1]Univ. of Genoa, Genoa, Italy; [2]Multiple Sclerosis Italian Fndn., Genoa, Italy

Abstract: The Nine-Hole Peg Test (9-HPT) is used to measure finger dexterity in various neurological diagnoses, e.g., stroke, brain injury, Parkinson's disease and multiple sclerosis (MS). In this test, the subjects have to take the pegs from a container one by one and place them into the nine holes on the board, then to remove the pegs one by one and replace them back into the container.
The 9-HPT is usually considered as related to muscle strength and tactile sensitivity of the thumb, and proposed as gold standard measure of manual dexterity in MS research and clinical practice. However, it can involve cognitive aspects due to the "strategy" adopted to fill and empty the holes as fast as possible.
The aim of this work was to measure the 9-HPT performance in healthy subjects, while investigating task-related activity of prefrontal and sensorimotor cortical areas by functional near-infrared spectroscopy (fNIRS).
Twenty healthy volunteers were asked to perform the 9-HPT with their right (dominant) hand,

while recording changes in cortical oxy-hemoglobin concentration. The control condition (1-HPT) was defined by applying a paper mask, of the same color as the board, covering eight holes and leaving only the central hole visible: the subject had to take the pegs one by one, place them into the only hole on the board as fast as possible, and put them into a container close to the board.
We measured the time needed to complete the 9-HPT and the 1-HPT, and video-recorded the movements.
A block design was adopted, with three alternating task and rest periods for each condition (i.e., 9-HPT or 1-HPT).
The fNIRS study was conducted with two 8x8 channel-systems in tandem configuration (40 channels; source wavelengths 760nm and 850nm). The optodes were positioned over a cap based on the 10/20 EEG reference to cover cortical areas with a role in cognitive and sensorimotor functions, including Brodmann's areas 9, 10, 11, 3, 4, 6, 45, 44 and 40.
All participants completed the 9-HPT and the 1-HPT in less than 20 s.
On average, cortical activation was higher during the 9-HPT than the 1-HPT performance; the contrast analysis (9-HPT>1-HPT) revealed higher activation of bilateral prefrontal and left sensorimotor cortical areas during the 9-HPT.
Individually, the subjects following a regular pattern in filling and emptying the holes showed less activation; subjects adopting different strategies showed higher activation mainly located in the prefrontal areas.
In conclusion, the 9-HPT is commonly proposed as measure of hand dexterity but it involves complex functions. We suggest taking this into account when analyzing 9-HPT scores, especially in people with MS who can report cognitive and attentional deficits.

Title: Functional connectivity between thalamus, primary motor cortex, and primary sensory cortex in humans with essential tremor

Authors: *B. PARKS[1], E. OPRI[2], S. CERNERA[1], A. GUNDUZ[2];
[2]Biomed. Engin., [1]Univ. of Florida, Gainesville, FL

Abstract: Essential tremor (ET) is a hyperkinetic disorder that affects 0.9% of the population worldwide, and presents primarily as intention tremor of the bilateral upper limbs. Deep brain stimulation (DBS) has been shown to be clinically effective in reducing this tremor, but its mechanisms are poorly understood, necessitating studies that investigate functional connectivity between pertinent brain structures. The ventral intermediate nucleus of the thalamus (Vim) is a common target for DBS. During DBS surgery, we temporarily placed an electrocorticographic (ECoG) strip to record from the primary motor and primary sensory cortex, in addition to the Vim. We ran a simple cued motor task, which consisted of three states: rest, cue, and go. Separating out each trial into its respective condition, we calculated connectivity between the discrete structures described utilizing directed transfer function (DTF). To determine validity of connectivity values produced, surrogate analysis was performed. Average DTF values for connections between structures was then calculated, and connectivity values between conditions were compared for all structures using t-tests with p-values modified for multiple comparisons via false discovery rate (FDR). We discovered that connectivity between the Vim and the primary motor cortex differs in the strength of the connection between conditions. The difference in connectivity between conditions could lead to a more complete understanding of the motor system. Quantifying the functional connections that exist between deep brain structures and the cortex is fundamental for understanding the underlying mechanisms of DBS, together with improving the understanding of physiological movement.

Title: The effect of acute aerobic exercise on the consolidation of motor memories

Authors: *S. R. HOLMAN, W. R. STAINES;
Kinesiology, Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Previous research has shown that acute aerobic exercise performed prior to motor training can assist with motor skill acquisition through enhancement of motor cortical plasticity. Recently, studies using high intensity interval training performed post-motor training have found improvements in the retention of the motor skill. This suggests that the timing of exercise relative to motor training is important to enhance motor memory consolidation, although the mechanisms are unclear. We hypothesized that acute moderate intensity exercise performed post-

motor training would also assist with motor skill retention and that this behavioural change would be positively correlated with neural markers of cortical plasticity post-exercise. Thirty three participants were randomly assigned to one of two groups: exercise (EXE) or control (CON). During the first visit, participants completed a motor training session of a bimanual wrist flexion task using left/right wrist movements to control the vertical/horizontal cursor position on a computer screen. Targets appeared in the upper left of the screen and the cursor appeared in the bottom right after 2 s to cue movement and generate a cortical movement-related potential (MRP). After motor training, participants in EXE performed a session of moderate intensity exercise on a recumbent bike for 20 minutes (70% of heart rate reserve). Participants in CON read for the same amount of time. Both groups completed two post-training tests after the exercise or rest: one 10 minutes after the exercise/rest session (Post 1), and one once heart rate returned to resting level in EXE (Post 2) or 30 minutes after rest in CON. Participants returned to the lab 1 day and 7 days later to complete retention and transfer tests of the task. MRPs were measured using electroencephalography (EEG) to investigate cortical plasticity related to motor performance and exercise during the first visit. Behavioural measures of speed and accuracy were collected at all timepoints as response time and root mean square of the difference in the actual from the ideal trajectory of the cursor. Preliminary analysis of behavioural data suggests that participants in EXE were able to retain the skill better than participants in CON. The EEG data demonstrates markers of cortical plasticity as an increase in the MRP amplitude from early to late training, which is consistent with previous motor training studies. The relationship of the changes observed over motor training to the adaptations post-exercise are being explored. These results may inform motor learning paradigms and future studies with other populations including older adults and neurorehabilitation patients.

Title: The influence of the subjective estimation of force production on motor-related cortical potentials

Authors: *T. MIYAMOTO, T. KIZUKA, S. ONO;
Hlth. and Sport Sci., Univ. of Tsukuba, Ibaraki, Japan

Abstract: When the force was adjusted to a certain target level, the amplitude of the force is estimated by one’s sense of effort. It has been demonstrated that the subjective estimation of force (planned force) doesn’t always match to actual force when the visual feedback was not

available. Previous EEG studies have reported that the amplitude of motor-related cortical potentials (MRCP) increase in proportion to the magnitude of the force and the rate of force development. Those studies have given subjects the online visual feedback of a target level to produce a force, which indicates that the actual force is related to MRCP while the relationship between “the planned force” and MRCP is still uncertain. Since the motor imaginary evokes MRCP without overt movement, MRCP might be influenced by not only the actual force but also the cognitive process associated with force production. Therefore, in this study, the EEG was recorded under two conditions (blind and visual conditions) and two target levels (20 and 60% of maximal voluntary contraction [MVC]) to clarify the influence of the planned force on MRCP on the force production. Healthy males who are right hand dominant participated in this study. The isometric elbow flexion force was measured at 90° flexion. The force was produced as fast as possible (ballistic contraction). Under the blind condition, the force was produced at each target level (20 and 60%MVC) based on their subjective estimation without external feedback. Under the visual condition, the force was produced at each target level to the visual target line on oscilloscope screen. The blind condition was performed first, then the visual condition was performed to avoid the effects of visual feedback. The target levels were random order consisting of 50 trials per condition. The EEG was recorded from 20 electrodes according to the 10-20 positions. EEG signals were time-locked to the onset of agonist EMG. The results showed that there was a significant correlation between the actual force and the MRCP amplitude from the EMG onset to offset at frontal-central electrodes. In contrast, the MRCP amplitude prior to the EMG onset, which is related to motor preparation, showed no or slight significant correlation at same electrodes. These results suggest that cortical activities related to motor preparation could be influence by the planned force, which are not always associated with the actual force.

Title: Developmental aspects of predictive motor abilities

Authors: ***S.-W. PARK**[1], A. CARDINAUX[2], D. GUO[1], P. SINHA[2], D. STERNAD[1];
[1]Northeastern Univ., Boston, MA; [2]MIT, Cambridge, MA

Abstract: In motor control prediction is required for humans to interact with objects in the environment such as intercepting a ball, because signal transmission is too slow for feedback-based control. Although prediction is widely acknowledged as fundamental in computational models in human motor control, its developmental aspects have not yet been studied. This study devised a suite of interceptive tasks implemented in a virtual environment to examine predictive abilities of children and adults. Five virtual interception tasks were designed to examine different aspects of prediction with different degrees of challenge. In two tasks subjects moved a paddle to catch a virtual ball with the ball trajectory partially occluded, and to intercept to bounce the ball to hit a target. To reduce demands on motor coordination, two additional tasks used button pressing to test temporal and spatial prediction. In one control task subjects lifted the paddle to a static target as fast as possible (reaction time). The experiments were conducted in a research laboratory with thirty 7 to 12-year-old children and 14 young adults. In addition, the same experiments were stationed at the Museum of Science in Boston, where over 400 museum visitors across ages 5 to 92 performed the tasks. The task scores were analyzed in their development across age; the specific question was at what age the performance became indistinguishable from adults. Results showed that the catching ability improved with age and reached the level of adults at age 12. Children's performance differed depending on the degree of ball occlusion, but this sensitivity disappeared at age 10. The bouncing performance, which required control of impact position and velocity, reached adult level slightly earlier at age 10. Similar to the catching task, the performance of the two spatial and temporal prediction tasks became indistinguishable from adults at age 12. In contrast, the reaction time of the children participants continued to develop beyond age 12. The results at the museum were largely consistent with the in-lab results validating the robustness of the test paradigms. Taken together, the results identified developmental aspects of the ability to execute sensorimotor functions that involve prediction. The results also provide normative data to study predictive motor impairment in children with developmental disorders, such as autism spectrum disorder.

Title: Extrinsic noise benefits skill acquisition and timing accuracy

Authors: *A. CAHILL, Z. ZHANG, S.-W. PARK, D. STERNAD;
Northeastern Univ., Boston, MA

Abstract: When executing actions requiring accuracy such as target-oriented throwing, improvements with practice are typically characterized by decreases in error and variability or noise. However, advances in the physical sciences have demonstrated noise can also be beneficial, specifically by stabilizing, destabilizing, or masking undesired properties of a complex nonlinear system. This study examined the effects of adding noise to performance feedback in a motor task with the hypothesis that noisy feedback may exert "pressure" on the performer to suppress their intrinsic noise. Using skittles, a virtual target-oriented throwing task, subjects threw a virtual ball by rotating a lever arm and released the ball by lifting the hand from a force sensor to measure the time of release. In the virtual workspace, the ball was tethered to a vertical post and moved around the post with an elliptical trajectory determined by the angle and velocity of the ball at release. Error was defined as the minimum distance between the target and the ball trajectory. Mathematical analyses of the modeled task show redundancy, as an infinite number of angle-velocity combinations at release resulted in successful target hits, defining a solution manifold. Previous research showed that the arm trajectory can align with the solution manifold, creating a "timing window," reducing the demands on accurate timing of ball release. Additionally, "timing error" quantified the difference between the actual time of ball release and the time of release that would have achieved minimum error for each throw. By adding noise to the timing of ball release, we expected subjects to decrease their intrinsic noise and channel it into task-irrelevant dimensions.

Two groups of 10 subjects practiced skittles for 11 daily sessions. On days 3-8 the ball trajectory of the noise group was calculated from release parameters that were randomly selected from a range 10ms earlier or later than the veridical ball release time, modifying the ball trajectory displayed on-screen. Results showed that noise subjects performed significantly better than controls (using veridical release times for calculations). This success was primarily due to a decrease in timing error. Timing window did not increase, likely due to the specific geometry of the solution manifold. Importantly, they maintained this improved timing error on days 9-11 after the noise was withdrawn. These findings demonstrate that humans are capable of increasing their precision when extrinsic noise is present. Ongoing studies investigate the same noise manipulation in the task of bouncing a ball to examine how these beneficial effects of noise may depend on the task.

Title: A cortico-basal ganglia model for choosing an optimal rehabilitation strategy for hemiparetic stroke

Authors: *S. ELANGO[1], S. V. CHAKRAVARTHY[1], S. JAYAKUMAR[1], R. NARAYANAMURTHY[1], V. MURALIDHARAN[2];
[1]Dept. of Biotech., Indian Inst. of Technol. Madras, Chennai, India; [2]Dept. of Psychology, Univ. of California San Diego, La Jolla, CA

Abstract: The major difficulty in designing an optimal motor rehabilitation strategy for stroke patients is the inherent contradictions that prevail in the existing intervention techniques (Hatem, Saussez et al 2016). To address this issue, we employ a cortico- basal ganglia model that can perform simple bimanual reaching tasks. The model consists of two components for each arm (right and left), comprising of an outer sensory-cortical loop and an inner basal ganglia loop that drives a simple 2-arm kinetic model to reach its respective target. These components are coupled at the level of their motor cortices by a coupling factor **ε**, thus facilitating bimanual arm movements. The reaching characteristics observed in the equidistant bimanual reaching study conducted by Rose and Winstein (Rose and Winstein 2004) have previously been captured by our model (Narayanamurthy et al, Bernstein Conference 2017). This model has now been extended to capture two other experimental paradigms from the same study namely congruent and incongruent aiming tasks. As observed in the experiment, the incongruent task setup under bimanual conditions showed an increase in the peak resultant velocity of the affected arm as opposed to the congruent task setup. This effect is attributed to the increased complexity and bimanual nature of the task setup. We also perform a comparative study between Constraint Induced Movement Therapy (CIMT), bimanual and unimanual reaching tasks and quantify their effect in terms of reaching error of the paretic arm as a function of distance (closest the arm can reach to the target) under two conditions of stroke: acute and chronic. It is observed that for lesions of smaller size, bimanual paradigm and for lesions of bigger size, both CIMT and unimanual paradigms prove to be more effective respectively. This effect is especially pronounced in chronic stroke condition. Thus, the model functions as a prototype test-bench for choosing a patient-specific rehabilitation strategy.

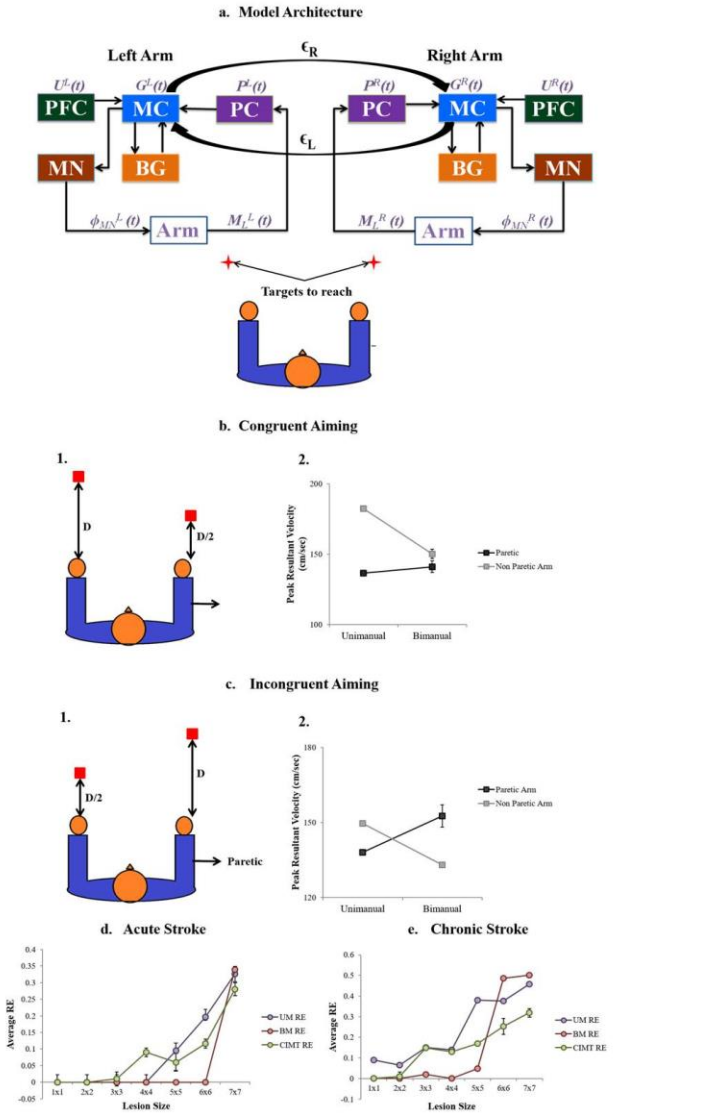

Figure: *A. Proposed Cortico-Basal Ganglia model architecture.* ***B. Congruent Aiming -*** *1. The task setup is shown. In this paradigm, the paretic arm has an easier (closer) target. 2. Peak Reaching Velocity (PRV) for both the arms are shown in unimanual and bimanual condition. In both cases, the non-paretic arm has higher PRV. C.* ***Incongruent Aiming -*** *1. The task setup is shown. In this paradigm, the paretic arm has a more complex (farther) target. 2. PRV is higher for the paretic arm under bimanual condition in this task setup. D. Lesion size vs reaching error in the case of acute stroke. E. Lesion size vs reaching error in the case of chronic stroke.*

Univ. of Physical Educ. and Sports of Ukraine, Kyiv, Ukraine; [2]Lab. on Theory and Methodic of Sport Preparation and Reserve Capabilities of Athletes, Natl. Univ. of Physical Educ. and Spor, Kyiv, Ukraine

Abstract: Competitive anxiety is related to athletes' performance. Due to this, it is important to maintain it on an optimal level. While anxiety has a well-studied gender difference that is related to the opposite patterns of activity in left parietal and temporal lobes, dorsomedial prefrontal cortex, cerebellum, and occipital gyrus, gender differences in competitive anxiety and its factors are not fully investigated. Coping strategies contribute to the decrease of psychiatric symptoms like depression and anxiety that supports an assumption of its importance for performance regulation. Exploratory research of competitive anxiety and coping strategies in Ukrainian junior handball national team was conducted. Participants of the study are 35 adolescences with mean age 15.63 (SD = 0.49). 13 participants were male, while 22 participants were female. Participants completed Ways of Coping Questionnaire (WCQ), which was developed by Folkman & Lazarus in 1988 and adopted by Bityutskaya in 2015, and Sport Competition Anxiety Test (SCAT), which was developed by Martens in 1977 and adopted by Hanin in 1982. Mean scores were: 8.74 (SD = 2.50) for Confrontive Coping, 8.22 (SD = 2.98) for Distancing, 13.63 (SD = 2.67) for Self-Controlling, 11.23 (SD = 3.22) for Seeking Social Support, 7.94 (SD = 1.93) for Accepting Responsibility, 9.86 (SD = 3.52) for Escape-Avoidance, 12.49 (SD = 2.97) Planful Problem-Solving, 13.49 (SD = 3.15) for Positive Reappraisal, and 19.02 (SD = 4.20) for SCAT. Female athletes scored 20.55 with SD = 3.63 on SCAT and 8.6 with SD = 1.92 on Accepting Responsibility scale. Male athletes received mean score 16.46 with SD = 3.95 on SCAT and 6.8 with SD = 1.36 on Accepting Responsibility scale. Female athletes have significantly higher scores on both SCAT and Accepting Responsibility scale of WCQ with $p=0.007$ and $p=0.006$ respectively. Cohen’s d was 0.47 for both tests. Spearman correlation test revealed moderate between SCAT scores and Accepting responsibility coping correlation $r = 0.39$ with $p = 0.02$ for the whole sample. Thus, accepting responsibility coping strategy is associated with increased competition anxiety in Ukrainian athletes. Both accepting responsibilities coping and competitive anxiety level are gender biased and are higher in female athletes but these gender differences have a moderate size effect.

Title: Perceptual modulation of the somatosensory system during planning

Authors: *A. DALIRI[1], B. MCGUFFIN[2];
[1]Col. of Hlth. Solutions, [2]Arizona State Univ., Tempe, AZ

Abstract: When we plan for movements, we also predict sensory consequences of our own movements; we use our predictions to prepare task-relevant sensory systems for their potential roles in sensory processing (Blakemore et al. 1998, 2000; Shergill 2003; Wolpert and Flanagan 2001). In the speech domain, we have shown that the speech motor system uses a similar mechanism to prepare the auditory system during speech planning (Daliri and Max 2018; Merrikhi et al. 2018). Such results are consistent with the fact that the speech motor system strongly relies on the auditory feedback (Guenther 2016). However, it is unclear whether the speech motor system also uses similar mechanisms to prepare the somatosensory system during speech planning.

In the present study (n=20), we developed a novel behavioral paradigm to investigate the modulation of the somatosensory system during speech planning. We measured the responsiveness of the somatosensory system at various time points during speech planning by delivering electrical stimuli to the lower lip. In two conditions (speaking and reading), participants were asked to judge whether they felt the near-threshold electrical stimuli (participant-specific intensity, 85% detection ratio at rest). In the speaking condition, participants overtly produced target words shown on a computer monitor. In the reading condition, participants read target words silently without any movement. We found that the detection ratio was attenuated during the speaking condition whereas it remained unchanged during the silent reading condition. This perceptual modulation gradually increased at time points closer to the onset of speech and was the largest during speech production.

Overall, our results suggest that the speech motor system prepares the somatosensory system during speech planning. These results are consistent with results of previous studies that have examined auditory modulation during speech planning (Daliri and Max 2018; Merrikhi et al. 2018; Mock et al. 2015), suggesting that the speech motor system may use similar mechanisms to prepare different sensory modalities.

Title: Visuospatial attention modulates motor cortex excitability

Authors: *S. BANDA, A. ANAND, S. CONVENTO, J. M. YAU;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Sensory processing guides our motor behaviors. To facilitate reflexive behaviors or to prime actions, visuospatial attention may automatically engage with the motor cortical system. Here we characterized the effects of visuospatial attention on motor cortex excitability. In two experiments, we delivered transcranial magnetic stimulation (TMS) over left motor cortex (M1) while measuring motor evoked potentials (MEPs) from participants' right hand. We manipulated participants' visuospatial attention using a challenging visual detection task performed on visual targets positioned near the left and right hands. In Experiment 1, we found that directing spatial attention near participants' right hand, even in the absence of visual cues, resulted in increased left M1 excitability. This result reveals the effects of endogenous visuospatial attention on M1 excitability. In Experiment 2, we qualitatively replicated the effects of endogenous visuospatial attention and characterized the effects of exogenous visuospatial attention and the temporal profile of acute visual influences on motor excitability. Our results imply that visuospatial attention automatically modulates motor cortex excitability. The automatic engagement of the motor system by visuospatial attention circuits conceivably results in faster and more precise motor behaviors.

Title: Neural correlates of error-prediction in the course of motor learning

Authors: *M. JOCH[1,2], L. K. MAURER[1,2], M. HEGELE[1,2], H. MAURER[1], H. MÜLLER[1,2]; [1]Justus Liebig Univ., Giessen, Germany; [2]Ctr. for Mind, Brain and Behavior - CMBB, Marburg and Giessen, Germany

Abstract: A forward model is a neural process that generates predictions based on sensory and efferent (e.g. information about motor commands in form of an efference copy) information. It is also assumed that forward model predictions are used for sensorimotor learning. However, we do not know how the forward model itself develops during learning. In the following experiment, we investigated the development of the forward model while learning a novel motor task using neurophysiological measures in the electroencephalogram (EEG).
Six participants trained on a semi-virtual goal-directed throwing task for 23 sessions with 400 trials each. To quantify the development of the forward model we recorded a neural potential located in mid-frontal brain regions, called error-related negativity (ERN, e.g. Falkenstein et al., 1991). The EEG was recorded in sessions 1, 5, 10, and 23. In addition, we analyzed the feedback-related negativity (FRN), which reflects processing of the terminal result feedback (i.e. hit or miss the target) and should behave complementarily to the ERN. The following results were calculated from a partial dataset. A complete dataset will be presented at the conference.
The behavioral results show a clear increase in task performance measured by the target hit rate (*S1*: 25%; *S5*: 48%; *S10*: 52%; *S23*: 62%). With respect to the neural correlates, we find an increase of the ERN mean amplitude over the sessions (*S1*: -.06μV; *S5*: -.07μV; *S10*: -.10μV; *S23*: -.32μV). Simultaneously, the FRN mean amplitude decreased (*S1*: -4.50μV; *S5*: -2.34μV; *S10*: -.75μV; *S23*: 1.17μV).
The development of the ERN and FRN mean amplitudes while learning a novel motor task suggest a shift error processing mechanisms. More specifically, early in learning, the control system relies more on information coming from external sensory feedback (larger FRN amplitude). With the increase of task performance, the forward model is able to generate more accurate outcome predictions. Thus, early information of outcome predictions is increasingly being used for error processing (larger ERN in late sessions). This points out that processing error information based on external feedback of the movement outcome is especially relevant when the movement outcome prediction is inaccurate and vice versa.

Title: Interfering with potentiated actions produced by near-hand targets using rTMS

Authors: *A. PAOLETTI, M. SKELLEKIE, L. BROWN;
Psychology, Trent Univ., Peterborough, ON, Canada

Abstract: People display enhanced perception of visual targets when they are presented near hand. Research suggests that the near-hand effect relies on the same mechanisms that process visual information for action. According to the theory of affordances all objects afford a specific action, and there is evidence that simply viewing an object leads to the automatic generation of an associated potential motor response. It is possible that the generation of potential actions is enhanced when targets are located near one's hands. To investigate whether action potentiation drives the near-hand effect, participants were asked to respond to a target presented either near or far from a hand placed in the display. Participants completed this task both under normal conditions and under the influence of 1 Hz rTMS applied to the left motor cortex for 15 minutes, which should suppress actions potentiated by targets near the right hand. We found a significant right near-hand effect in both the control and rTMS conditions. For the left hand we found a significant near-hand effect in the control condition, but surprisingly it was reversed in the rTMS condition. We consider the possibility that right-hemisphere motor cortex activity - released from interhemispheric inhibition after rTMS suppression of the left motor cortex - may interfere with the near-hand effect. The action potentiation hypothesis is reconsidered within the context of these findings.

Title: A cortical command circuit coordinates food handling and manipulation

Authors: *X. AN, H. MOHAN, K. MATHO, A. KEPECS, J. HUANG;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: In rodents and primates, food handling and manipulation using synergistic hand-mouth maneuvering is necessary for feeding and requires online sensorimotor coordination as well as dexterous motor control; the underlying neural circuits are not understood. We carried out a systematic optogenetic screen of pyramidal neuron (PyN) projection types and cortical areas that induce forelimb and orofacial movements in the mouse. We define a rostral forelimb orofacial area (RFO; centered around anterior 1.7mm and lateral 2.3mm), where activation of Fezf2 corticofugal PyNs (PyN^{Fezf2}) and PlexinD1cortico-striatal PyNs (PyN^{PlexD1}) induce highly coordinated forelimb and orofacial movements resembling feeding. We further reveal a caudal forelimb orofacial area (CFO; centered around anterior 0.3mm and lateral 3mm), where activation of Tle4 cortico-thalamic PyNs (PyN^{Tle4}) induce similar action, an effect dependent on functional RFO. Antero- and retro-grade tracing from these PyN types in RFO and CFO depict a highly connected cortical network involving primary and secondary sensory and motor areas of the forelimb and orofacial regions. This cortical network is embedded in the cortico-striatal-thalamic system, with outputs to numerous subcortical targets from midbrain, hypothalamus, to pons and spinal cord. Chemo- and opto-genetic inactivation of RFO and/or CFO PyNs impairs hand maneuvering and hand-mouth synergy during food handing, manipulation, and eating in head-fixed and free-moving mice. These results begin to implicate specific neuron types, cortical circuits and brain systems in sensorimotor coordination for object manipulation.

Title: Effect of chronic low back pain on movement inhibition using a Go/No-Go paradigm

Authors: *R. L. JUDY[1], W.-E. WANG[1], J. ALDERUCCIO[1], M. KLEIN[1], G. BRODY-HEIM[1], A. ANTONY[2], J. S. THOMAS[3], S. COOMBES[1];
[1]Applied Physiol. and Kinesiology, [2]Anesthesiol., Univ. of Florida, Gainesville, FL; [3]Virginia Commonwealth Univ., Richmond, VA

Abstract: Acute pain is a potent sensory signal that notifies the human body of immediate danger which can prime the motor system for action. For individuals with chronic low back pain (cLBP) movements often become slow, methodical, and rigid; typically displaying less variability in trunk-pelvis coordination, difficulty adapting to gait perturbations, less lumbar flexion, and freezing-like behaviors. Thus it is plausible that individuals with cLBP who experience movement evoked pain (MEP) would be better at inhibiting movement, but this hypothesis has not been directly tested. The purpose of this study was to investigate muscle activity during a Go/No-Go full-body reaching task in individuals with cLBP who do (cLBP-MEP) and do not (cLBP-noMEP) experience movement-evoked pain. Data was also collected from a pain-free control group (HC). We hypothesized that the cLBP-MEP group would be better able to inhibit movement and therefore make fewer errors during a Go/No-Go reaching task. Muscle activity was collected from the right deltoid as well as bilaterally from the thoracic longissimus, multifidus, and tibialis anterior during each trial. Participants wore a HTC Vive virtual reality (VR) headset where virtual targets were displayed. The task began with the appearance of a blue cube to cue subjects to get ready. If the target turned green, subjects had 750 msec to reach and touch the cube. If the target turned red, subjects had to inhibit movement. Location of the virtual targets were normalized to subject anthropometric characteristics to necessitate approximately 60 degrees of trunk flexion. A custom MATLAB program was used to identify errors during No-Go trials based on an increase in EMG activity above an individually determined threshold. A one-way between groups ANOVA found significantly fewer No-Go errors in the cLBP-MEP group compared to each of the other groups based on EMG activity in the right multifidus (RM) and the left tibialis anterior (LTA) muscles. Our observations suggest that movement-evoked pain is associated with better performance on a Go/No-Go reaching task, consistent with previous literature which links chronic pain with the inhibition of movement.

Title: Noisier muscle activation exacerbates dysmetria in Friedrich’s ataxia relative to Spinocerebellar ataxia 6

Authors: *S. L. BRACKSIECK[1], A. CASAMENTO-MORAN[1], N. L. CLARK[1], B. YACOUBI KEYHANI[1], S. H. SUBRAMONY[2], D. E. VAILLANCOURT[1], M. CORTI[3], E. A.

CHRISTOU[1];

Abstract: Dysmetria is a common symptom for Spinocerebellar ataxia type 6 (SCA6) and Friedrich's ataxia (FA). However, it remains unknown whether greater degeneration of the central nervous system in FA results in greater dysmetria than SCA6. Our purpose was to compare dysmetria in the two ataxias and determine whether increased CNS noise is a contributor to dysmetria differences. In addition, we determined the relationship between dysmetria and functional capacity of FA. Thirteen individuals with SCA6 and ten individuals with FA performed 50 trials of goal-directed contractions with ankle dorsiflexion while we recorded the EMG activity of the primary agonist (Tibialis Anterior; TA) muscle. We quantified the following: 1) dysmetria as the endpoint error during the goal-directed task; 2) CNS noise as the endpoint variability and the variability in the activation of the TA muscle; and 3) FA functional capacity as the score from the modified FARS clinical assessment. We found that FA exhibited greater dysmetria than SCA6 ($P < 0.01$) which was related to greater time endpoint variability ($R^2 = 0.47$). Greater time endpoint variability was associated with a more variable activation of the agonist muscle ($R^2 = 0.47$). Finally, greater dysmetria in FA correlated with their modified FARS score ($R^2 = 0.40$). Therefore, we provide novel evidence that the additional degeneration of FA relative to SCA6 results in a noisier activation of the agonist muscle, which impairs time control that leads to increased dysmetria and impaired functional capacity.

Title: Frontal cortical control of brainstem inhibitory neurons projecting to the intralaminar thalamic nuclei

Authors: *E. BOSZ[1,2], V. M. PLATTNER[1], M. A. DIANA[3], L. ACSADY[1];
[1]Inst. Exp. Med. Hung Acad Sci., Budapest, Hungary; [2]Semmelweis Univ., Budapest, Hungary; [3]Pierre at Marie Curie Univ., Paris, France

Abstract: Our previous data demonstrated that glycine transporter2 (GlyT2) positive neurons of the pontine reticular formation (PRF) inhibit the intralaminar thalamic nuclei (IL). Selective photoactivation of PRF-IL fibers evoked behavioural arrest for the duration of the stimulation. The strong motor response was surprising as PRF has been implicated in arousal but not in motor control. In the recent study, we aimed to examine the inputs of the PRF inhibitory cells probably carrying motor signals and the impact of these inputs on the activity of PRF inhibitory neurons. Retrograde tracer injected into the PRF labelled L5 pyramidal cells located in the cingulate and M2 cortices and neurons in the deep cerebellar nuclei. This connectivity is consistent with a possible motor functions but inconsistent with the presumed role in arousal. Injections of AAV-ChR2 into the frontal cortex of RBP4-Cre/Glyt2-eGFP double transgenic mice revealed that the entire PRF receives L5 inputs. Cortical afferents contacted mostly thick calibre dendrites of the GlyT2+ cells in the PRF. Juxtacellular recording and labelling in the PRF under ketamine/xylazine anaesthesia demonstrated that rhythmic activity of Glyt2+ cells was tightly linked to the slow cortical oscillation and was disrupted upon its spontaneous desynchronization. Pharmacological inactivation of the cortex led to decreased irregular firing of the GlyT2+ neurons. Photoactivation of M2 L5 cells evoked short latency action potentials with high probability in the PRF. These experiments indicate strong motor cortical control over the PRF-GlyT2 cells. In *in vitro* preparation optogenetic activation of M2 fibers reliably produced purely glutamatergic synaptic responses on PRF-GlyT2 cells. Both AMPA and NMDA receptors were functional at these synapses, which showed little short term depression during stimulation trains. Photoactivation of PRF-GlyT2 cells led to significant decrease in the firing rate of IL cells *in vivo*, suggesting that cortical activity may lead to decreased IL output in a selected cell population. To decide if the evoked behavior effect is purely motor related or has cognitive components as well we are doing *5 choice serial reaction time task*. If we activate the PRF-IL pathway we can examine if the cognitive abilities of the animal are impaired or the effect is purely motor related. Our results indicate that synchronous higher order motor (M2) cortical activity can reliably activate inhibitory neurons of the PRF, thus likely send a behavioural signal computed by frontal motor cortical regions. PRF GlyT2 cells in turn transfer this signal to the IL thalamus affecting thalamocortical and thalamostriatal activity.

Title: Visual and proprioceptive cuing differentially evoke two distinct routes for imitation

Authors: *M. W. ISAACS, L. J. BUXBAUM, A. L. WONG;
Moss Rehabil. Res. Inst., Elkins Park, PA

Abstract: Imitation is an efficient means of rapidly learning new movements such as novel motor skills. This ability is often lost after a left-hemisphere stroke (apraxia), and deficits in imitation may be observed even in the ipsilesional (non-paretic) side. Such impairments may limit the ability to teach these patients new movement patterns during rehabilitation; hence patients with apraxia are among the poorest to recover following a stroke. What exactly is disrupted in these patients with imitation impairments remains unclear. One current hypothesis is that imitation involves the ability to reproduce desired body configurations; such representations are informed and updated by integrating visual and proprioceptive feedback of the limb. It is thought that the ability to plan body-configuration representations becomes disrupted by lesions to the inferior parietal lobule (IPL). In contrast, we have recently demonstrated the existence of an alternative route to imitation that specifies instead only the trajectory of the end effector; deficits in trajectory-planning have been associated with lesions to dorsal premotor cortex. Thus we hypothesize that patients may be impaired along either of these two routes, depending on the site of their lesion. To test this, we recruited a group of patients with left-hemisphere strokes and age-matched controls. Participants were asked to reproduce novel, meaningless gestures with their left (non-paretic, non-dominant) arm. Gestures were cued either visually by viewing the motion of a cursor to encourage trajectory-based planning, or proprioceptively without vision of the arm to encourage body-configuration-based planning. Participants also completed background tests to control for general proprioceptive, visual, or working memory deficits. We found that patients could be separated into two groups based on behavior: one group was moderately impaired at imitating both visually and proprioceptively cued movements relative to controls, while the other group was disproportionately worse at imitating proprioceptively cued movements. We observed that lesions associated with disproportionately poor proprioceptive imitation localized to the IPL, whereas patients that performed comparably in the two cuing conditions had more dorsal and frontal lesions, consistent with our hypothesis. This suggests that damage to the IPL results in an impaired ability to use proprioceptive information to plan body configurations during imitation.

Title: Why don't humans always respond to a stimulus?

Authors: *L. MOHEIMANIAN[1,2], S. PARASKEVOPOULOU[1], P. BRUNNER[1,3], G. SCHALK[1,2,3];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Ctr., New York State Dept. of Hlth., Albany, NY; [2]Dept. of Biomed. Sci., State Univ. of New York at Albany, Albany, NY; [3]Dept. of Neurol., Albany Med. Col., Albany, NY

Abstract: The perceptual threshold is defined as the intensity of a stimulus that results in a response 50% of the time. Many previous studies have used stimuli around perceptual threshold to study different aspects of perception, but they have made little progress in understanding why people respond to stimulation in some trials but not others. Our work addresses this important neuroscientific question by recording electrocorticographic (ECoG) signals fromsensory and motor corticesin 6 human subjects that performed an auditory reaction time task. In this task, the subjects were asked to rapidly respond with a button press to a beep sound that was presented near perceptual threshold. As expected, the subjects responded to ~50% of all sounds. We set out to determine the specific neural mechanisms that could account for this variability in responses. We hypothesized that: 1) the transmission of sensory activity from sensory cortex to motor cortex is disrupted in trials in which no response occurred; and 2) variations in cortical excitability can explain these variations in transmission. To test our first hypothesis, we determined the cortical locations at which broadband gamma activity (a widely recognized marker of population-level cortical activity) significantly increased in response to stimulus onset. We then detected the onset of such broadband gamma activity in individual locations and trials, and quantified the fraction of all trials that had a detection at a particular location.Our results demonstrate that in trials that did not result in behavior, the number of detections decreases along the trajectory from auditory to motor cortex ($r = -0.56$, $p<0.001$). This decrease is not present in trials in which the subject responded ($r = -0.08$, $p>0.05$). To test our second hypothesis, we quantified cortical excitability (by measuring the instantaneous amplitude of low-frequency oscillations) at the time of broadband gamma onset, and did so separately for responded and missed trials. Our results show that cortical excitability is lower in trials that did versus did not result in behavior (38% increase, $p<0.01$). In summary, our study shows that when humans are presented with an auditory stimulus that is close to perceptual threshold, moment-by-moment fluctuations in cortical excitability determine whether population-level cortical responses to sensory stimulation are transmitted to motor cortex to produce a behavioral response.

Title: Temporal sequencing in the human auditory system

Authors: *J. R. SWIFT[1,2], G. SCHALK[1,3,2];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Ctr., New York State Dept. of Hlth., Albany, NY; [2]Dept. of Biomed. Sci., State Univ. of New York, Albany, NY; [3]Dept. of Neurol., Albany Med. Col., Albany, NY

Abstract: A number of recent studies have identified cortical areas within the human auditory system that are specialized for processing very specific types of sounds such as speech, language, or music. However, the specific temporal sequencing of processing in these areas is currently unknown, primarily due to technical limitations of the most prevalent imaging and analytic methods. Functional magnetic resonance imaging (fMRI) cannot resolve brain activity at the requisite temporal resolution (< 100 ms), and electro/magnetoencephalography do not have enough spatial resolution. A number of studies have demonstrated that recordings directly from the surface of the brain (electrocorticography (ECoG)) has both high spatial and temporal resolution, and have shown that ECoG is useful for neuroscientific investigations of the auditory system. Furthermore, practically all previous studies relied on cross-trial averaging of responses at individual locations, but this form of averaging blurs specific temporal sequencing due to the known temporal variance in responses. In our ongoing study, we are evaluating ECoG responses to auditory stimulation using a new method developed in our laboratory. This method can detect the onset of population-level cortical activity in individual trials, and facilitates highly accurate temporal localization of responses to auditory stimuli at individual locations. To date, we presented auditory stimuli to 15 epilepsy patients with implanted ECoG grids (76-250 channels), and applied single-trial onset detection to each location that responded to the auditory stimuli. In each location, we calculated this location's onset time as the median onset time across all trials. As expected, preliminary results localize auditory responses primarily to superior temporal

gyrus. The earliest cortical responses occurred around 130 ms after stimulus onset. Most importantly, preliminary results show a clear temporal progression from posterior to anterior parts of superior temporal gyrus. Current efforts seek to determine the specific temporal sequencing of cortical responses across different functionally distinct areas within auditory cortex.

Title: Kinematic changes in the uninjured limb after unilateral brachial plexus injury

Authors: L. SOUZA[1,2], G. FREIRE[1,2], J. MARTINS[3], L. LUSTOSA[1,2], T. POZZO[4], ***C. D. VARGAS**[1,2];
[1]Inst. of Biophysics Carlos Chagas Filho, Rio de Janeiro, Brazil; [2]Inst. of Neurol. Deolindo Couto, Rio de janeiro, Brazil; [3]Inst. of Neurol. Deolindo Couto, Rio de Janeiro, Brazil; [4]IIT@UniFe Ctr. for Translational Neurophysiol., Ferrara, Italy

Abstract: When reaching or moving an object from a standing position the brain has the challenge of stabilising upper limb movements while conserving postural balance. This complex task is done through the recruitment of motor synergies allowing to control our actions through the functional coupling of muscle groups. Traumatic brachial plexus injury (TBPI) causes important sensory and motor impairment of the affected limb. The objective of this study was to investigate if TBPI affects trunk/upper limb synergies through the kinematic recording of the uninjured limb. Eight volunteers with a severe unilateral traumatic BPI and nine age-paired healthy volunteers were invited to perform two different tasks while index finger kinematic parameters were measured. The first task consisted in, from a standing position, perform a series of reaching movements towards a homogenous surface located at a distance shoulder-surface of 120% of the arm's length upon which no specific endpoint was drawn. Results collected for the uninjured limb showed lower values for time to peak velocity (0.39%, SD 0.04 vs 0.47%, SD 0.04) and longer movement duration (1.71s SD 0.35 vs 1.48s SD 0.36s) in TBPI individuals

compared to healthy participants for the uninjured limb's index finger marker ($p < 0.01$), suggesting a higher cost for motor planning and execution after a TBPI unilateral lesion in this task. Furthermore, TBPI individuals presented lower index finger displacement (mean 68.39 cm SD 6.23) compared to those of healthy volunteers (70.98 cm SD 7.37, $p < 0.01$), which may indicate a strategy of minimising the upper limb movement amplitude to prioritise the conservation of balance. In a second task, the volunteers were asked to perform an elbow flexion/bringing a cup to the mouth movement in the upright position. Results showed lower values for time to peak velocity (Mean 0.37% SD 0.04 vs 0.40% SD 0.04, $p< 0.05$) in seven TBPI compared to eight healthy subjects for the uninjured limb's index finger marker, confirming that a unilateral TBPI lesion leads to higher cost in performing movements with the unaffected limb even when no explicit trunk movement is required. In conclusion, this study shows that severe unilateral TBPI affects the kinematics of the contralateral, unlesioned limb. These results point towards a higher cost in controlling trunk/upper limb movements in TBPI individuals compared to healthy individuals. In addition, it serves as a warning for the clinical community about the need of individualised therapeutic practices in TBPI to help reverse trunk and contralateral limb adaptations caused by the lesion.

Title: How does the brain produce behavior? Advances in understanding of large-scale cortical physiology

Authors: *G. SCHALK;
Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Ctr, NYSDOH, Albany, NY

Abstract: Previous research has produced ample evidence that specific areas in the brain are remarkably functionally specialized, and that flexible behaviors are supported by coordinated dynamic interaction of these areas. At the same time, it is unclear whether these interactions follow fundamental principles that generalize across brain areas and different dynamic behaviors. We propose that, despite the known diversity in function and anatomy of different brain areas, many characteristics of dynamic behaviors (such as reaction time) can be explained by the moment-by-moment variations in cortical excitability and cortical excitation, and by five surprisingly simple principles that govern them. In my talk, I will describe these principles and will show results of modeling and experimental studies supporting them. Using modeling studies, I show how these five principles can explain: 1) the relationship between broadband gamma and oscillatory power and phase; 2) the relationship between oscillatory power/phase and response rate; 3) alpha frequency-dependent changes in reaction time; 4) the relationship between stimulus intensity and reaction time/response rate; 5) the differences in reaction time/response rate for unisensory vs. multi sensory stimulation; and 6) the differences in reaction time/response rate for congruent vs. incongruent stimulus presentation. Using experimental studies, I demonstrate that these principles can explain up to 41% of the single-trial variance in reaction time in a reaction-time task, and show that they can describe why people respond or do not respond to a stimulus presented at perceptual threshold.
In summary, there is increasing evidence that many human behaviors or experimental findings can be explained by surprisingly simple principles that appear to generalize to different behaviors and brain regions.

Title: A novel take on zona incerta efferent connections from axonal tracing mapped with PHA-L in the rat

Authors: *D. S. ZAHM[1], M. T. DESTA[1], S. SUBRAMANIAN[1], Y. TAN[2], K. P. PARSLEY[1]; [1]Pharmacol. and Physiol., [2]Surgery, St. Louis Univ. Sch. of Med., Saint Louis, MO

Abstract: Aside from Ricardo's classic autoradiographic study (Brain Res 214:43-60, 1981) and some subsequent regionally circumscribed descriptions, current understanding of the outputs from the zona incerta (ZI) is based mainly on retrograde labeling. Here, we report some

previously unappreciated features of ZI output organization revealed by mapping from focal injection sites with the sensitive anterograde tracer PHA-L. We find that ZI efferents arising from rostromedial (rm) clusters of A13 dopaminergic and melanin-concentrating hormone neurons (that we think were correctly regarded as aligning with the medial hypothalamus system - Sita et al., Neurosci 148:949-69, 2007) project successively less densely to the same structures from progressively more caudolateral (cl) ZI sites that lack A13 and MCH neurons, suggesting a rm-cl gradient. The vicinity of the A13 neurons is densely and preferentially targeted by projections arising more laterally in the ZI. Labeled fibers in neocortex (Lin et al., Science 248(4962):1553-6) are generally very sparse, although stronger after medial injections, and often ramify in cortical superficial lamina 1, consistent with origins as displaced lateral hypothalamic and/or ventromedial thalamus (VM) neurons. In the lateral habenula, mainly the caudal oval nucleus gets labeled input that is very dense after rm injections, but spare to negligible after more cl injections. Thalamic projections are patchy in intralaminar, LD, LP and PO nuclei and involve the whole of none of them in any given section. Dense ZI outputs to the superior colliculus (SC), labeled by injections into all but one ZI site, are diffuse in the rostral SC, but more caudally form discrete, wedge-shaped sectors with distinct densely labeled tri-partite bands over intermediate and deep SC cell laminae together with a deepest patch centered on the boundary between the periaqueductal gray and adjacent tegmentum. The exception was an injection into the boundary between the ZI and VM that labeled amongst the most numerous descending axons seen in the study, but virtually none in the SC, indicating either that output from the VM is not purely ascending, or ZI at the VM boundary region lacks a projection to the SC. Otherwise, all of our PHA-L injections into the ZI labeled projections that descend both to the SC and caudal brainstem, which challenges consensus that projections to the SC and brainstem arise preferentially, respectively, in ZI dorsal and ventral tiers. Together, these insights suggest a rm-cl differentiation of ZI and add new, functionally significant perspective to our understanding of ZI outputs that would have been unavailable other than with the aid of PHA-L.

Title: Spatial-temporal tuning properties of the rodent frontal orienting field neurons

Authors: *L. LI[1], Y. CHEN[1], H. CHEN[2], J. LI[1], C. MA[1], J. C. ERLICH[3];
[1]NYU-ECNU Inst. of Brain and Cognitive Sci. at NYU Shanghai, Shanghai, China; [2]Dartmouth College, Psychological and Brain Sci., Hanover, NH; [3]NYU Shanghai, Shanghai, China

Abstract: Overt attention, indicated by orienting sensors on the head towards the direction of interest in the environment, is critical for the animal's survival and success. Orienting has been extensively studied with sophisticated behavioral paradigms in primates. However, researches in rodents are mainly carried out with two-alternative forced choice(2AFC) tasks. Here we developed a novel multidirectional orienting task in rodents inspired by classic primate saccadic eye movement paradigms. In this task, the rat orients its head to various directions by nose-poking into one of the 7 ports on a vertical 2-D wall. The direction of a single or a sequence of orienting movements are guided by visual cues. Previous studies with 2AFC tasks have implicated the rodent frontal orienting field (FOF) as a key circuit element for spatial cognition. Here we recorded from the right FOF of a rat during the visually-guided orienting movements with 64-channel silicon probes. Over 30% of all identified neurons displayed directional selectivity between the visual cue onset and the movement, and the preferred directions of FOF neurons spanned across all 6 tested orienting directions. Direction selectivity of these neurons were either transient or lasting, and better aligned to either the visual cue or the movement. In some neurons, directional selectivity emerged around 70 ms after the visual cue onset, comparable to early visual response in primate FEF. We observed a subset of neurons tuned to orienting directions in an egocentric reference frame, yet there were also neurons whose firing rate were influenced by the task context of the movement. These results indicate that FOF is a critical node for the planning and execution of orienting movements, and will promote research in the neural basis of spatial cognition in the rodent model system.

Title: Real-time burst detection of neural oscillations allows behaviourally relevant neurofeedback

Authors: *G. KARVAT, A. SCHNEIDER, M. ALYAHYAEY, F. STEENBERGEN, I. DIESTER;
Freiburg Univ., Freiburg im Breisgau, Germany

Abstract: Neural oscillations as important information carrier in the brain, are increasingly interpreted as transient bursts rather than as sustained oscillations. Short (<150 ms) bursts of beta-waves (15-30 Hz) have been documented in humans, monkeys, and mice. These events were correlated with memory, movement and perception, and were even suggested as the primary ingredient of all beta-band activity. However, a method to measure these short-lived events in real-time and to investigate their causal impact on behaviour and overall oscillatory power is missing. Here we present a real-time data analysis system, capable to detect short and narrowband bursts. The system is associated with an operant conditioning apparatus for rodents, thus enabling closing the loop between oscillatory events and behaviour (neurofeedback). We successfully trained 3 rats to increase the beta event rate in motor cortex, and indeed observed an overall increase in beta-power, supporting the critical role of events on beta-band activity. The increase in beta could be linked to behaviour, as a machine learning algorithm could reliably predict occurrences of beta events based on the rats' movements. Our results demonstrate the potency and flexibility of the real-time neurofeedback system in freely moving rodents as well as the impact of transient bursts on global oscillatory power. Our approach can be a starting point for a plethora of studies targeted at understanding the causal role of oscillatory bursts. For example, instead of artificial external stimuli, real-time burst-triggered stimulus presentations could be combined with behavioural and electrophysiological measurements, thereby allowing to probe the intrinsic function of oscillatory bursts. Furthermore, neurofeedback has been clinically used for decades without a clear understanding of the underlying neural mechanisms. As our tool is ideally suited for rodents, it can be combined with additional invasive or non-invasive treatments and post-mortem histology, thereby providing a new testbed with high relevance for future clinical developments.

Title: Marker free 3D tracking reveals insights into the role of the motor cortex in movement planning and execution in freely moving rodents

Authors: *A. SCHNEIDER[1], C. ZIMMERMANN[2], T. BROX[2], I. DIESTER[1,3,4];
[1]Optophysiology Lab., [2]Computer Vision Group, [3]BrainLinks-BrainTools, [4]Bcf, Univ. of Freiburg, Freiburg, Germany

Abstract: To study the role of motor cortex in movement preparation and execution in rodents, precise information about the executed movements is required. Previous approaches relied onto restricting the animal movements to a simplified, highly trained behavior or required the use of markers to track the unrestrained movements of the animal (Mimica et al. 2018). Key point detection via deep learning so far only allow 2D estimations of key point positions (Mathis et al. 2018). Here we introduce a network that is based on a multi-view approach via 7 cameras for the prediction of 3D positions of defined body parts. Predicting points in 3D removes the depth ambiguity and allows for experiments with unrestrained animals while minimizing self-occlusion of body parts. We manually annotated 12 key points (tail, nose, eyes, ears, front/hind paws) for training the model. Our network can be adapted to various behavioral tasks and subjects requiring only minimal human input by leveraging active learning. In order to precisely synchronize behavioral data with electrophysiological recordings we implemented hardware-triggered cameras (30 fps). With this combined approach, we recorded 3 rats (female, 1 Sprague Dawley and 2 Long Evans) with chronically implanted laminar 32 channel probes in motor cortex (front paw area, AP: 1.2/3.9 mm, ML: 2.3-2.4 mm) freely foraging in a transparent box. On average, we recorded 35 single units per session (total 317). 141 (44.5%) neurons were significantly modulated with movement (Welch t-test, Bonferroni corrected). Motor cortex contained information about several body posture variables, e.g. body pitch and head angle (linear regression: 47% and 9% explained variance, respectively). Interestingly, shifting the neural data relative to the behavior revealed that some variables were represented at different time lags. While body-pitch was best predicted at zero lag, front paw speed was best predicted with ~100 ms lag suggesting a planning role of the motor cortex. Our multi-view body pose estimation approach contains the unique combination of marker-free whole body movement estimation as well as precise movement tracking of individual body parts (e.g. front paws) in freely moving rodents in 3D. Thereby, the marker free 3D tracking method allows assessing the involvement of the motor cortex in movement planning and execution in unprecedented detail.

Title: Long-range connectivity does not predict functional response types in mouse anterior lateral motor cortex

Authors: *W. YANG, Z. DING, N. LI;
Baylor Col. of Med., Houston, TX

Abstract: Intermingled neurons in frontal cortex exhibit selectivity for sensory, motor, and cognitive variables. We examined behavior-related activity in mouse anterior lateral motor cortex (ALM) in relation to the structure of the underlying neural circuits. Mice performed a tactile decision-making task in which they used their whiskers to discriminate object locations and reported their choice using directional licking. We analyzed the spiking activity from over 6,000 ALM neurons. ALM neurons exhibited heterogeneous activity that correlated with the tactile stimulus, future movement, and other behavioral variables. Subsets of ALM neurons exhibited highly similar activity profiles over time. Based on the shape of the peristimulus time histogram, ALM neurons could be clustered into over 30 functionally distinct sub-populations. ALM could not maintain activity in isolation, rather, behavior-related activity is mediated by multi-regional interactions between ALM and connected brain regions (Svoboda & Li, *CONB* 2018). We examined the possibility that distinct ALM functional cell types are differentially driven by distinct long-range inputs. We related ALM functional cell types to long-range inputs from three brain regions that form multi-regional circuits with ALM - contralateral ALM (cALM), secondary somatosensory cortex (S2), and ventral-medial thalamus (VM). Silencing these brain regions produced qualitatively distinct effects on ALM activity: silencing VM abolished ALM activity in most neurons; silencing S2 silenced ALM activity mostly in the superficial layers; silencing cALM produced little change in ALM activity. These observations suggest that each long-range input has unique roles in mediating ALM dynamics.
To measure long-range connectivity, we modified ChR2-assisted circuit mapping (Petreanu et al,

Nat Neurosci 2007) and applied it *in vivo* to identify ALM neurons receiving direct inputs from each of the three brain regions. These postsynaptic ALM neurons were further analyzed in terms of their intrinsic and synaptic properties as well as their responses during the task. We found that long-range inputs indiscriminately targeted ALM neurons with respect to their functional cell types. ALM neurons coupled with each brain region were equally diverse as other non-coupled ALM neurons. Furthermore, we did not find any relationship between intrinsic properties nor synaptic properties of ALM neurons and functional response types during behavior.
These results suggest that the structure of long-range inputs is not sufficient to explain response types in frontal cortex.

Title: The corticospinal tract is involved in sensory filtering but not motor command in the lumbar cord of rodents

Authors: *C. BICHARA[1,2], Y. MORENO-LOPEZ[1], M. CORDERO-ERAUSQUIN[1];
[1]INCI - CNRS, Strasbourg, France; [2]Univ. of Strasbourg, Strasbourg, France

Abstract: A well-coordinated movement relies on a properly planned motor command and the consideration of incoming sensory information: the “expected” inputs (when they are linked to the motor command itself) and the more relevant “unexpected” ones (that require correcting the ongoing movement). The cortex is involved in the control of both of these motor and sensory functions, and it has been recently hypothesized that it does so through a common pathway: the corticospinal tract (CST). The goal of this study is to unravel how the cortical filtering of sensory inputs hinges on the cortical motor command to produce well-coordinated voluntary motor behaviors. As serious motor afflictions can result from dysfunction of these circuits, their better characterization could unveil potential therapeutic targets.
First, we mapped the regions of the cortex that elicit muscle contractions and sensory filtering using photostimulation. Then, in the identified area, we injected a virus encoding for the trans-synaptic tracer wheat Germ agglutinin (WGA) fused to a cre-Recombinase along with a spinal cord injection of a virus encoding for Cre-dependent form of ChannelRhodopsin2. This allowed us to identify CST’s postsynaptic neurons in the spinal cord, to analyze their localization and nature, and to test the effect of their specific activation in vivo.
We first demonstrate that the same area of sensorimotor cortex evokes both muscular contraction and primary afferent depolarization (PAD), i.e. sensory filtering. We show that CST neurons

located in the area in charge of top down sensory-motor control project in the spinal cord onto interneurons located in the deep dorsal horn (lamina IV to VII). Importantly, their selective activation leads exclusively to PAD, but no muscle contraction.
This result suggests that while sensory filtering through PAD and muscular contractions originate from the same region of the sensory-motor cortex, they diverge in their pathways and reach different populations of neurons in the spinal cord. PAD is controlled by the CST whereas the motor command is indirect and convey its message through subcortical structures.

Title: Value information that affects decision making is transmitted from the thalamus to the motor cortex

Authors: E. YOSHIDA[1], K. NAKAE[2], K. KOBAYASHI[3], S. ISHII[2], *M. MATSUZAKI[1]; [1]Grad. Sch. of Med., The Univ. of Tokyo, Tokyo, Japan; [2]Grad. Sch. of Informatics, Kyoto Univ., Kyoto, Japan; [3]Natl. Inst. for Physiological Sci., Okazaki, Japan

Abstract: We can estimate the values of presented cues and decide whether to act after each cue presentation through operant conditioning. It is thought that the striatum is a critical region to estimate such cue values and that the motor cortex generates the motor command for the appropriate action. However, it is unknown whether and how cue value information estimated in the striatum is transmitted to the motor cortex, including the secondary and primary motor cortical areas (M2 and M1). Anatomically, the motor thalamus receives the projection descending from the striatum and sends axons to M2 and M1. We recently reported movement-related activity in thalamocortical (TC) axons projecting from the motor thalamus to M1 in mice performing a self-initiated lever-pull task (Tanaka et al., 2018). Here, we developed a new reward-based lever-pull task. In this task, one of two cues with different sound frequencies (cues A and B) was randomly presented in each trial. After a cue period, the mice chose whether to pull the lever with their right forelimb. When the mice pulled the lever, a water reward was delivered at a high probability in the cue A trial and a low probability in the cue B trial. After

training for this task, the mice pulled the lever more frequently in the cue A trial than in the cue B trial. During the task, we conducted two-photon calcium imaging of TC axons in the left M2 and M1. Activity of a subset of TC axonal boutons increased after cue A onset, while few boutons exhibited increased activity after cue B onset. Linear discriminant analysis revealed that the emergence of cue information transmitted by M2-projecting TC axonal boutons preceded that of cue information transmitted by M1-projecting ones. Channelrhodopsin-2 stimulation of M2-projecting TC axons during the cue period increased the frequency with which the mice pulled the lever in the cue B trial. These results suggest that M2-projecting axons of the motor thalamus transmit cue value information that can affect subsequent decision making.

Title: Intracortical microstimulation of sensorimotor cortex in short-tailed opossum (Monodelphis domestica): New insights into the evolution of motor cortex in mammals

Authors: *A. C. HALLEY[1], M. K. BALDWIN[1], M. ENGLUND[2], A. SANCHEZ[1], L. A. KRUBITZER[1,2];
[1]Ctr. for Neurosci., [2]Psychology, Univ. of California, Davis, Davis, CA

Abstract: The organization of the neocortex in some marsupials, such as the short-tailed opossum (*Monodelphis domestica*), is thought to reflect that of the earliest mammals. Early studies that utilized electrophysiological recording and cortical stimulation found that marsupials such as the Virginia opossum (*Didelphis virginiana*) appeared to have a single region of neocortex which contained both a sensory map of the face and body as well as motor map of the face and body. More modern studies using short-train intracortical microstimulation (ST-ICMS) in the short-tailed opossum found that only movements of the vibrissae and jaw could be elicited from a relatively small region of the somatosensory cortex that responds to cutaneous stimulation of the face (Frost et al., 2000). The absence of a separate motor area rostral to S1 in marsupials led to the hypothesis that early mammals exhibited a sensorimotor “amalgam” which is retained in living marsupials, but which was differentiated over eutherian evolution into separate M1 and

S1 fields (Lende, 1963). However, recent work in our laboratory has shown that long-train intracortical microstimulation (LT-ICMS) elicits movements from somatosensory cortex (not only from motor cortex and premotor cortex) in most eutherian mammals including primates, tree shrews and rodents. In this study, we utilized LT-ICMS to reinvestigate the types of movement that can be evoked from the neocortex of the short-tailed opossum. We found that movements could be elicited from a much larger region of cortex than in previous studies, and that movements included body regions other than the vibrissae and jaw, such as the hindlimb and forelimb. We also found evidence for an additional motor representation of the vibrissae that is rostral and medial to the classical area of sensorimotor overlap. These two vibrissae representations were separated by motor representations of the forelimb and hindlimb. Our results indicate that, as in other marsupials and eutherian mammals, S1 contains a complete motor representation of the body overlapping with the somatosensory cutaneous representation. Our finding of a separate rostromedial vibrissal motor region suggests there are at least two separate fields within cortex from which movements could be evoked, one corresponding with S1, and one in a rostral field, which could correspond to a primitive M1. Given the motor functions of S1 in eutherian mammals, we propose that early mammals exhibited S1 (rather than an undifferentiated "amalgam") and that a separate motor cortex was elaborated over the course of eutherian evolution.

Abstract: The activity of motor cortex is closely related to strides and is necessary for accurate stepping on a complex terrain. How this activity is generated remains unclear. This is largely because we still do not know much about information motor cortex receives during locomotion and how it contributes to the formation of cortico-spinal commands. The ventro-lateral nucleus

of thalamus (VL) is the main source of the ascending projection from the thalamus to motor cortex, and its signals may be particularly important for shaping the cortico-spinal commands. The goal of this study was to clarify the contribution of signals from the VL to the formation of locomotion-related activity of motor cortex. In two chronically instrumented cats (a male and a female) we recorded the activity of neurons in layer V of motor cortex as cats walked on a flat surface and horizontal ladder. We first reversibly inactivated approximately10% of the VL unilaterally with a glutamatergic transmission antagonist CNQX and analyzed how the VL inactivation affected activity of neuronal subpopulations in motor cortex. We focused on neurons that contribute axons to the pyramidal tract (pyramidal tract projecting neurons, PTNs) or project to the red nucleus. We also studied subpopulations of neurons that have somatosensory receptive fields on different segments of the forelimb. In one of the cats we later lesioned 50-75% of the VL bilaterally with a neurotoxin kainic acid and recorded the activity of motor cortex over the next month. We found that contribution of the VL to the locomotion-related activity of motor cortex neurons is chiefly excitatory, fluctuates over the step cycle, and depends on the locomotor task. We further found that the VL contribution is larger to the activity of PTNs with slow- than fast-conducting axons, particularly during the complex task of ladder locomotion, when it accounts for nearly 100% of the slow-conducting PTNs' activity. We also found that during both simple locomotion on the flat surface and complex visually-guided stepping on the ladder, the VL contribution to activity of motor cortex neurons is limb segment-specific. The contribution is large to the activity of neurons related to the shoulder and elbow, and small for the wrist and paw-related cells. To the activity of the shoulder-related group, the VL contributes most during the transition from the stance to swing phase, and most heavily influences the elbow-related group during the transition from the swing to stance. The experiment with kainic acid lesions showed that these VL contributions are only partially replaced even when movements recover after the lesions.

Title: Modularity produces a robust neural code for motor planning

Authors: *G. CHEN[1], B. KANG[2], J. W. LINDSEY[2], S. DRUCKMANN[2], N. LI[1];
[1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Stanford Univ., Stanford, CA

Abstract: Resilience to perturbations is a fundamental property of biological systems. We previously found that activity in the mouse premotor cortex during motor planning is remarkably robust to large-scale perturbations. Each hemisphere of cortex could independently maintain preparatory activity and support behavior. When one suffered a perturbation, signals from the other hemisphere helped restore correct activity. This previous work suggests a modular organization for robustness across the two hemispheres. However, it is unclear how the two hemispheres coordinate their dynamics and if modularity produces a more robust neural code during normal motor planning. Here, we directly measured interhemispheric interactions using bilateral silicon probe recording in premotor cortex during motor planning. Preparatory activity in each hemisphere was highly independent of the other in some mice. Despite this modularity, preparatory activity was coordinated across hemispheres on single trials, where activity on both hemispheres consistently predicted mice's future movements. This suggests the two hemispheres are weakly coupled. Other mice exhibited lesser degree of modularity, where one hemisphere drove preparatory activity in the other. We found that mice exhibiting modularity were more robust under external unilateral optogenetic perturbations than mice that do not. Remarkably, the degree of modularity also predicted performance variations among individual mice in unperturbed trials. Weakly-coupled modules may enable self-corrections that allow individual modules to overcome internal noise and reduce the probability of making a mistake. Thus, high degree of modularity produced a more robust neural code that enables mice to plan movement accurately under normal and challenged circumstances.

Title: Modulation of superior colliculus biases cortical action representations and behavior

Authors: *A. M. THOMAS, N. LI;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Volitional behaviors require planning prior to execution. Neurons in frontal cortex dynamically encode action plans long before movement onset, yet it remains unclear how these motor representations emerge. Outside of cortex, this preparatory activity has also been detected in motor structures like the superior colliculus. Though evidence implicates both regions in action selection and movement initiation, the nature of their interaction remains poorly understood. We examined cortico-collicular interactions using a delayed response task in mice. Animals used their whiskers to discriminate the position of an object during a sample period. After a delay period (1.3 s), the animals reported their choice via directional licking (left or right). Previous research indicates that the anterior lateral region of motor cortex (ALM) is required to perform the task. Within each hemisphere of ALM, intermingled neurons exhibit preparatory activity that is selective for either contra- or ipsilateral motor responses. A lateral region of the superior colliculus (lSC) has also been suggested to control licking movements (Rossi et al, Nat Neurosci 2016). We found that unilateral activation of lSC evoked contralateral licking, and bilateral inactivation blocked licking altogether. Anatomical tracing experiments revealed that the lSC receives direct input from ipsilateral ALM and projects back to ALM through medio-dorsal and ventral-medial thalamus, forming a loop. Next, the lSC was optogenetically manipulated during different epochs of the delayed-response task. Unilateral inactivation of the lSC during both the delay and response periods (but not the sample period) produced ipsilateral choice biases. Even transient inactivation of lSC during the early delay was sufficient to bias upcoming behavior, with an 800 ms window between the photostimulus offset and go cue, suggesting that the lSC participates in the selection of future movements. Electrophysiological recordings during behavior revealed that the majority of SC neurons showed preparatory and movement-related activity. We next measured the influence of lSC over cortical function by manipulating lSC and recording ALM activity during behavior. Unilateral SC inactivation during the delay period specifically abolished contra-selective representations in ALM, but ipsi-selective representations remained intact, thereby biasing preparatory activity and behavior towards ipsilateral actions. In summary, these results suggest that the SC contributes to the emergence of cortical action representations during motor planning and participates in volitional behavioral control.

Title: Cortical features predict movement dynamics during emergence from anesthesia

Authors: *S. GAO[1,2], V. KRISHNAMURTHY[2], D. P. CALDERON[1];
[1]Anesthesiol., Weill Cornell Med., New York City, NY; [2]Electrical and Computer Engin., Cornell Tech, Cornell Univ., New York City, NY

Abstract: The electroencephalogram (EEG) is a technique often used to determine the depth of anesthesia. However, the variety of cortical patterns in the EEG associated with the type of anesthetic and concentration have made difficult the implementation of a precise tracking method of depth of anesthesia. Moreover, arousal behavior has been poorly examined during emergence. As a result, current biomarkers lack specificity. We hypothesize that restoring movement during emergence from anesthesia is a dynamic process closely link to changes in cortical activity.
To test this hypothesis, *we* ramped down anesthetic while simultaneously recording local field potentials (LFPs) and movement in mice. We applied a Bayesian Gaussian Mixture model to cortical LFPs and conducted a cross mutual information analysis to predict motor behavior using the clustered cortical states in isoflurane, sevoflurane and a pharmacologically induced arousal model.
The application of cluster analysis to cortical LFPs derived defined cortical states while rodents emerge from the anesthetics. These states served as predictors of intervals in which there is lack of movement, slight movement and generalized movement. The analysis was unable to predict righting reflex, a behavior often used to detect awakening suggesting that cortical involvement is absent in this behavior. Restoring motor behavior is a dynamic process that begins tens of minutes earlier than the righting reflex. Defined cortical states predicted motor behavior in two mechanistically different anesthetics and a pharmacologically induced-arousal model. Understanding the cortical features associated with the dynamics of motor behavior unveils novel biomarkers to accurately track emergence from general anesthesia in rodents and other species.

Title: Distinct activity of pyramidal and fast-spiking neurons in the mouse premotor cortex during a voluntary movement

Authors: *N. C. GIORDANO[1], C. ALIA[2], L. FRUZZETTI[3], A. CATTANEO[4], L. BONINI[5], M. CALEO[6];

Abstract: The premotor cortex is necessary for motor planning. In mice, a putative premotor area controlling voluntary licking has been identified and physiologically mapped in the anterior-lateral motor cortex (ALM). However, the role of distinct physiologically identified ALM neuronal classes in voluntary movement planning and execution is still unknown. To address this issue, we used head-restrained mice trained to lick a reward delivered at random intervals. Mice spontaneously performed either single isolated licks or a burst of consecutive licking events (6-8 Hz), which we categorized, *a posteriori,* into two classes: single (=1 lick) and multiple licks (≥3 consecutive licks). During the task, we extracellularly recorded single unit activity from the ALM using a 16-channels single shank silicon probe. We identified putative pyramidal (PNs) and fast-spiking neurons (FSNs) based on well-established physiological features of their spike waveforms, and then we investigated their functional properties during the licking task. We found that most of the neurons' activity anticipated the licking onset by 100-200 ms. This is consistent with an involvement of the ALM in lick planning. Most of the neurons (about 90%) increased their firing frequency in correspondence with the movement, but suppressive modulations were also observed in a subset of units. For both PNs and FSNs, we found significantly greater discharge during multiple than single licks. Notably, FSNs modulated their activity about 100 ms earlier than the PNs. During multiple vs single licking events, the peak discharge was significantly delayed for both PNs and FSNs. Furthermore, almost all FSNs showed a peak in their response before the beginning of the sequence of licks. The differential timing of activation of PNs and FSNs suggests that inhibitory activity may be relevant for voluntary movement initiation, and FSNs appears to be more directly related to the planning of an entire motor sequence.

Abstract: Motor thalamus serves as a gateway to the cortex, relaying sensorimotor information from subcortical structures to motor-related areas of the cerebral cortex. The cerebellar-recipient region of motor thalamus (MTh_{CB}) is thought to convey the “go” signal for movement execution, yet the underlying neural mechanisms that lead to goal-directed movement initiation remain unresolved. To generate a causal-mechanistic understanding of how movement emerges from the interaction between MTh_{CB} and M1, we trained mice to engage in a goal-directed forelimb manipulandum task. Initial pharmacological inactivation experiments in trained mice revealed forelimb M1 ($M1_{FL}$) output to be essential for limb coordination and task engagement, while MTh_{CB} conveys information necessary for cue-evoked, goal-directed movement initiation. By employing Gradient-index (GRIN) lens-mediated 2-photon population calcium imaging we show that MTh_{CB} output is dominated by a coordinated increase in activity immediately prior to movement initiation. This population-wide neural signature was reliable from trial-to-trial and temporally uncorrelated with respect to cue presentation, consistent with a feedforward movement initiation signal. To investigate how MTh_{CB} input shapes cortical output, we performed whole-cell patch-clamp recordings from L5B projection neurons in $M1_{FL}$. Individual L5B neurons exhibited consistent membrane potential trajectory changes across trials spanning a continuum from hyperpolarised to depolarised, with the onset dynamics of these subthreshold signatures reliably following that of the recorded MTh population. To provide a causal link between MTh activity, motor cortical output and movement initiation, we employed a dual optogenetic stimulation strategy employing either direct stimulation of motor thalamic neurons or motor thalamocortical axon terminals in $M1_{FL}$ in the absence of an auditory cue. Both manipulation strategies resulted in recapitulated forelimb push movements in 30 - 50% of trials,

driven by L5B pyramidal neuron V_m trajectories similar in magnitude and direction to cue-evoked trials. Importantly, light-evoked forelimb push movements were context-dependent. Together, our findings provide the first causal-mechanistic description of how MTh_{CB} interacts with primary motor cortex to initiate goal-directed forelimb movements.

Title: Synaptic and cellular basis for prefrontal anticipation of motor behavior

Authors: C. ZHANG, M. ALLEGRA, F. KOUKOULI, U. MASKOS, J.-P. CHANGEUX, *C. SCHMIDT-HIEBER;
Inst. Pasteur, Paris, France

Abstract: Neuronal activity in the prefrontal cortex (PFC) in rodents is associated with voluntary motor behavior. To drive motor action, PFC neurons need to integrate information about the external world and internal states. However, how synaptic inputs to these neurons are integrated and modulated during anticipation of voluntary movement remains unclear. Here we address this question by performing *in vivo* whole-cell patch-clamp recordings and 2-photon imaging from PFC neurons in awake mice during resting and voluntary movement on a treadmill. We find that PFC principal neurons show large membrane potential fluctuations during resting periods (variance 28 ± 3 mV^2, n=26) that decrease in amplitude before and during spontaneous running periods (variance 16 ± 4 mV^2, n=26). In addition, action potential firing frequency increases before the onset of spontaneous running in most PFC neurons, but then remains low (0.3 ± 0.2 Hz, n=26) throughout the running period. *In vivo* two-photon Ca^{2+} imaging from superficial layers of PFC confirms this anticipatory activity signature for a subpopulation of PFC principal neurons. Both pharmacological blockade of nicotinic acetylcholine receptors and chemogenetic inhibition of parvalbumin-positive GABAergic interneurons can affect membrane potential dynamics and spike firing before and during voluntary movement. Together, our results provide insight into how cholinergic modulation of GABAergic inputs to the PFC exerts a critical influence on neuronal activity during anticipation

of motor behavior, suggesting that it may play a role in decision making during anticipation of movement.

Title: A motivation signal in motor cortex for high-stake actions

Authors: *M. ELBAZ, S. SUBRAMANIAM, Q. LEJEUNE, C. ETHIER;
CERVO - Laval Univ., Quebec City, QC, Canada

Abstract: In both rodents and primates, the motor cortex is involved in controlling the execution of skilled movements. Yet, during skilled movements, movement-related activity in motor cortex does not fully account for trial-to-trial neuronal variability. Both upstream (e.g., cognitive) and downstream (e.g., feedback) components may thus modulate motor cortical activity during skilled execution.
Motivation might be one of the cognitive components modulating motor cortical activity. Indeed, skilled movements require attention, a cognitive effort. As the stake of the action increases, a greater effort to maintain an optimal attention may be engaged, resulting in a greater need for motivation. In this scenario, skilled movements' proper execution would rely on finely adjusted motivation and depend on the anticipated stake of the action.
To test whether the motor cortex encodes motivation during skilled movements, we designed a behavioral task in which rats are trained to pull on a lever and maintain a pulling force above a specified target level, for a predetermined duration, in order to obtain either zero, one, or five food pellets. One of three tones, indicating to the animals the amount of reward to expect, is played at the onset of each trial when the rats make initial contact with the lever.
Remarkably, up to 500ms before rats initiate a trial, i.e. before they know the stake of the upcoming trial, motor cortical preparatory activity already contains information about their motivation. Indeed, a particular preparatory activity is required for the rats to succeed in high-stake trials, although the required motor action to successfully complete a trial is the same, whatever its stake.
Our results provide two novel observations: 1- motor cortical activity is modulated by expected

reward value during movement, and 2- the importance of an adequate preparatory state for the success of a skilled motor action varies with respect to its expected reward value.

Title: Causal dissection of cortical-striatal interactions governing the neural circuit control of reaching

Authors: ***M. A. NICHOLAS**, P. BELSEY, E. A. YTTRI;
Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Motor cortex and the basal ganglia work together to plan movements, potentially through the generation of motor plans and control of kinematic parameters respectively. This hypothesis, as well as other contrasting notions, have clear and testable predictions about the contribution of motor cortex to striatal dynamics and animal behavior. However little is known of basal ganglia dynamics and goal-oriented behavior change in the absence of input of motor commands from motor cortex during recovery from surgical ablation.
First we sought to study movement kinetics during goal directed behavior before and immediately after ablation of the caudal forelimb area (CFA). Age and sex-matched adult mice (n=6) were trained to perform a self-paced bimanual forelimb movement task to gain a fluid reward and upon reaching expert performance, mice received bilateral aspiration lesions of CFA. The first task implemented non-dexterous reaching and did not require fine-movement control or timing, but rather the joystick movement beyond an amplitude threshold. Directly following recovery from anesthesia, mice were run on the above task and continuously each day following lesion until recovery. We found that movement kinetics are severely impaired immediately following ablation and begin to recover towards baseline performance following 6-8 days.
A second cohort of mice were trained in a reaction time task, wherein the reach was required to wait for a go-cue occurring at a random point in time. Following lesion, again we found a severe impairment of movement kinetics that returned over time. Reaction time was found to drastically increase and then return to pre-ablation levels. Population activity within the striatum demonstrated a similar trend of decreasing and returning to pre-ablation levels comparable to the movement kinetics recovery time. However, neural tuning to movement onset and kinematics

was permanently lost.
Finally, the locomotor abilities of all mice were evaluated before lesion and every day following to study potential effects of surgical ablation of motor cortex. We found the locomotion was largely intact, but that the when faced with a decision the animal paused in place for tens of seconds.
Results of the above studies help to understand how the brain can control for movement dynamics during goal directed behaviors as well as during recovery from cortical damage. Decisions related to movement initiation and control arise from multiple brain areas and this study aims to use highly quantifiable movement kinetics, neural activity and non-dexterous behavioral tasks to elucidate the roles of crucial nodes of this networks both before and following surgical ablation.

Title: Flexible routing of bimanual forelimb movements by dual descending pathways of the motor cortex

Authors: *J. PARK, J. W. PHILLIPS, A. HANTMAN, J. T. DUDMAN;
HHMI Janelia Res. Campus, Ashburn, VA

Abstract: An action is defined by the outcome achieved rather than specific movements executed. Actions can maintain a robust independence relative to specific effectors. This implies that actions comprise both abstract representations and flexible realizations thereof as concrete movements. One common example of this flexibility is the ability to make coordinated movements of one or both limbs. Such flexibility is thought to be mediated by descending neocortical control. In line with this, sustained activation of motor cortical regions can produce both uni- and bimanual movements. Moreover, a putative cortical substrate for bilaterally coordinated control and unilateral control are the intratelencephalic (IT) and pyramidal tract (PT) classes of deep layer projection neurons. However, little is known about the cortical control of bimanual actions. The majority of work has focused on single limb movements of reaching to a target, grabbing and manipulating an object. In general, these studies found modest differences between IT and PT neural correlates of movement. To address these issues, we trained mice to make bimanual movements of a joystick past varying thresholds - a quantitative, goal-directed task that is sensitive to acute inactivation of motor cortex. Harnessing dense sampling across depths with Neuropixels recordings we found that movement-related activity dimensions were

not evenly weighted across depths. Optotagging suggested that this depth difference indeed reflected a difference in cell-types. This observation was confirmed with cell-type specific calcium imaging. In sum, we discovered a clear dissociation between IT and PT neural correlates during bimanual forelimb movements. IT neurons exhibited dramatically stronger modulation than PT neurons. However, the relative magnitude of IT or PT activity modulation was not perfectly aligned to a key movement-related dimension of population activity suggesting that neither population alone was obligate for motor execution. In line with this, cell-type specific perturbation produced large, distributed changes in neural activity. Surprisingly, despite these changes in many individual neurons, some modes of population dynamics remained unaltered consistent with little change in movement quality. Thus, large mean changes in the activity of IT and PT neurons were primarily confined to a 'movement-null' dimension of motor cortical population activity. Taken together, these provide a compelling model for the flexible routing of cortical output activity with conserved motor kinematics. We suggest that this may be a key element to the flexible, effector independent, control of purposive action.

Title: Calcium imaging reveals neurons with complex activity patterns in mouse motor cortex during a reach-to-water task

Authors: *H. A. GRIER, M. T. KAUFMAN;
Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: Electrophysiology in non-human primates has shown that motor cortex generates complex, time-varying activity patterns during reaching and grasping. We wish to understand whether motor cortex dynamics are similar in the mouse. Two-photon calcium imaging has enabled recording the activity of large numbers of neurons in head-fixed mice performing well-controlled forelimb motor tasks. Examining neural activity during reaching in mice provides the possibility of comparing cortical dynamics during these behaviors across species, identifying interspecies commonalities and differences. Using a simplified version of an established reach-to-water task with two targets (Galinanes et al. 2018), we simultaneously recorded activity of 1189-1492 neurons in layer 2/3 of the caudal forelimb area (CFA) in transgenic GCaMP6s and

virus-injected GCaMP6f mice as they performed reaches cued by sound. Preliminary data show that a substantial fraction of neurons are significantly modulated by this task; 56-78% of cells were significantly modulated over time or across condition. Interestingly, many of these modulated neurons nonetheless had low estimated firing rates: ~50% of modulated neurons showed firing rates <1.5 events/s over the full course of the reaching behavior. With sufficient trial counts, a subset of neurons were identified displaying complex time-varying patterns beyond the featureless "bump" of activity often reported in mouse motor behaviors. In both GCaMP6s and GCaMP6f animals, fine temporal features were present in ~10% of cells, including those with low firing rates. This was corroborated by cross-validated Principal Component Analysis across neurons which revealed a dimensionality in the range of 2-5. The presence of complex single-neuron firing rate patterns even in low-firing-rate cells suggests that cortical dynamics during mouse reaching behaviors may be more distributed than previously thought, with pattern generation involving even low-firing neurons that are often ignored.

Title: Role of rat secondary motor cortex in complex movements and decision making

Authors: *A. BURMAN[1,2], E. M. VAZEY[3], D. E. MOORMAN[1];
[1]Psychological and Brain Sci., Univ. of Massachusetts Amherst, Amherst, MA; [2]Inst. of Biomed. Engin., Univ. of Buenos Aires, Buenos Aires, Argentina; [3]Dept. of Biol., Univ. of Massachusetts, Amherst, MA

Abstract: Modern Brain Machine Interfaces (BMIs) use increasingly more recording channels to facilitate the simultaneous access to large numbers of neurons. These systems require heavy computational resources and offline signal processing. In order to develop a portable and autonomous BMI, suitable for brain controlled robotic prosthesis, it is necessary to reduce the computational requirements of these systems. One way to address this issue is to investigate motor coding in different brain areas, in which neuronal populations use different strategies to encode or drive actions. The secondary motor cortex has been found to be involved in several cognitive / high-order functions, although it is not clear how neural representations of these higher-order functions are related to the details of complex movement encoding. One possible

route to developing optimized, efficient BMI decoding strategies is to focus on this area. Thus the goal of the current project is to determine the extent to which neuron ensemble activity in rodent secondary motor cortex encodes high-level goals and decisions vs. specific mechanics of motor commands.
To address this issue, we trained 4 male fluid-restricted Long-Evans rats to perform a 2-alternative forced choice (2AFC) task on an automated T-maze. During the task, animals were presented with two different cues (1 and 8 kHz tones) which specified the need to choose either the left or right side (counterbalanced across animals) to receive reward (20 ul water). Following correct or incorrect choices, rats are required to return to the starting point (through returning arms) to start a new trial. Sessions consisted in between 150 and 350 trials. All animals reached 80% correct trials after 5-10 sessions.
After the criterion was met, rats were implanted with a custom 16 tetrode chronic drive in secondary motor cortex (AP +2 to +3, ML +0.5 to 1.5). Tetrodes were initially implanted at 0.5 mm ventral from the surface of the brain and driven down to 2.5 mm in 80 um steps after each recording session. Single neuron and local field activity is currently being recorded using the Open-Ephys acquisition system and Intan headstages.
During task performance, rats are filmed with two cameras mounted on the ceiling, and detailed behavior tracking is performed offline with DeepLabCut software. To date we have recorded a small number of neurons in secondary motor cortex during these behaviors and have demonstrated the ability of DeepLabCut to track rat behavior on our task. These preliminary results support feasibility of our ongoing studies in which neural correlates of 2AFC decisions will be contrasted with the specific motor plans required to enact these decisions.

Abstract: Previous work has shown that the neural adaptation facilitates the consolidation of skillful neuroprosthetic control. Meanwhile, closed-loop decoder adaptation (CLDA) algorithms can reliably improve macaque monkeys' initial behavioral performance without hindering the beneficial neural adaptation, such as the formation of a stable neuroprosthetic tuning map. However, it is not fully understood how the formation of these maps and the consolidation of neural activity patterns are affected by different initial levels of decoder adaptation. Here we investigated how neural patterns changed while macaque monkeys learned to control a brain-machine interface (BMI), via chronically implanted electrode arrays in motor cortex, using decoders with varying levels of initial adaptation. Our results show that the rate of improvement in BMI control is invariant to the initial levels of decoder adaptation. Furthermore, this behavioral improvement is highly correlated with the formation of the ensemble activity pattern. This suggests neural mechanisms underlying neuroprosthetic learning that are independent of decoder adaptation levels.

Title: Closed loop BCI decoder optimization in a tetraplegic subject with a chronic ECoG implant

Authors: *D. B. SILVERSMITH[1], R. ABIRI[1], N. HARDY[1], E. F. CHANG[2], K. GANGULY[1]; [1]Neurol., [2]Neurosurg., UCSF, San Francisco, CA

Abstract: Brain-Computer Interfaces (BCIs) promise to assist individuals with severe motor impairments. A great deal of progress in decoder optimization and rapid calibration for BCIs has been made over the last decade; in particular, closed loop decoder adaptation (CLDA) algorithms are commonly used to achieve quality BCI performance with minimal training data. However, these algorithms have primarily been developed and tested using spike-based neural features from monkeys with intact motor systems. Comparable performance in human assistive BCIs has remained elusive.
Here, we tested the capacity for chronic electrocorticography (ECoG) implants to support BCI

control. Generally, ECoG implants have been proposed as a compromise with high enough spatial resolution while causing less tissue damage than more invasive, spike-based implants. Recent work by Wang and colleagues has demonstrated the potential for short-term ECoG implants (i.e. < 30 days) to support BCI control in human subjects with motor impairments. We tested and further developed CLDA algorithms in a human tetraplegic subject with a chronic ECoG interface. More specifically, we implanted a 128-channel ECoG grid over the left motor and somatosensory cortices of a subject with bilateral pontine strokes resulting in tetraplegia. We then developed a real-time system to acquire signals, process and detect neural features, and decode motor intention using a Velocity Kalman Filter decoder. We then calibrated our decoders for each experiment using CLDA algorithms to achieve fast, stable control and evaluated decoder performance on a Center-Out task. We have specifically tested ECoG BCI performance while systemically varying neural features and varying system parameters, e.g. changing decoding timescales and incorporating methods to compensate for signal non-stationarities. Preliminary results suggest that incorporating a range of low to high frequency neural features, longer decoding timescales and enabling continuous CLDA led to the best performance. Our results provide further support for the possible use of an ECoG-based implant for neuroprosthetic control.

Title: Use of optical brain-computer interface to identify neural strategies underlying new skill acquisition and performance following extended practice

Authors: *B. B. JEON[1], S. M. CHASE[1], S. J. KUHLMAN[2];
[1]Biomed. Engin. and Carnegie Mellon Neurosci. Inst., [2]Biol. Sci. and Carnegie Mellon Neurosci. Inst., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: The circuit basis by which new skills are acquired and executed is ill-defined. This is in part because learning is a complex, distributed process involving neurons from multiple brain areas, as well as multiple cortical cell types. Brain computer interfaces (BCI) can circumvent this issue by creating a causal relationship between the activity of a defined set of neurons and a

rewarded outcome. We developed hardware to read out the real-time neural activity of ensembles of individual neurons in awake, behaving mice using 2-photon calcium imaging. We then used this system to address the question: once adopted, is a successful strategy recalled repeatedly in subsequent sessions? Four mice were successfully trained to control a BCI device, using the same ensemble of six cortical excitatory neurons from layer 2/3 over the course of multiple imaging sessions lasting approximately one to two weeks. In this task, the summed activity of three randomly selected neurons, referred to as 'direct positive' neurons, is used to drive an auditory cursor to a target threshold; an additional 3 'direct negative' neurons are randomly selected and their combined activity is subtracted from the drive to threshold to prevent the subject from simply increasing the activity of all neurons within the local circuit. When the target is reached, a water reward is available for the mouse to collect. Mice performed up to 600 trials per session, and we quantified performance as the percentage of trials in which the target was successfully reached within the session. A trial is scored as unsuccessful if the target is not reached within 10 seconds of the trial start. There are three broad categories of strategy by which subjects could gain control of the device. First, they could increase the frequency by which the three 'direct positive' neurons coordinate their activity to reach the target. Second, they could decrease the activity of 'direct negative' neurons. Third, they could drive one of the 'direct positive' neurons to cross the target threshold.
In all cases (each of the 4 mice), subjects incorporated the strategy of increasing the drive of one 'direct positive' neuron to cross the target threshold. Further analysis revealed that within a given session all mice used multiple strategies, and once a strategy was adopted, it was not necessarily repeated in subsequent sessions. These results indicate that during practice of a newly acquired skill, neural circuits exhibit volitional flexibility.

Title: Dynamical influence of premotor and primary motor cortex during movement

Authors: *R. A. D'ALEO[1], A. G. ROUSE[2], M. H. SCHIEBER[3], S. V. SARMA[4];
[1]Johns Hopkins Sch. of Med., Baltimore, MD; [2]Neuroscience, Del Monte Inst. for Neurosci., [3]Neurol. and Neurosci., Univ. of Rochester, Rochester, NY; [4]Biomed. Engin., Johns Hopkins, Baltimore, MD

Abstract: Investigating what neurons in different motor regions encode during movement provides insight into the complex sensorimotor control system. While there are anatomical distinctions between premotor cortex (PM) and primary motor cortex (M1) attributed to their upstream and downstream pathways and cytoarchitecture, their functional distinction within the motor pathway is less clear as they have largely been studied independently using static correlations between kinematics and neural activity. To disentangle PM and M1 during movement, experimental paradigms have relied on delay tasks which have led to the interpretation that PM is involved in preparation of movement and M1 is involved in execution of movement. However, these analysis methods and experimental paradigms have limited ability to interpret dynamical interactions and influence across cortical regions. A recent approach to studying neuronal activity during movement is to construct a dynamical systems model (DSM), wherein cortical activity is perceived as a trajectory through a neural state-space, which in turn generates a movement in physical space. This approach allows for the populations to influence each other in a dynamical manner, which in turn generate movement. To date, applications of DSM have relied on delay paradigms in which the movement is decomposed into preparation and execution, characterizing activity in single regions and over brief time periods during which no abrupt events (e.g. movement onset) or stimuli (e.g. visual cue) occur. To capture long time periods, a different DSM is constructed in each time period that modulate with different external events. Here, we expand the DSM framework to allow for a *single* model to characterize neural dynamics (i) over the entire non-delay movement task (ii) during which multiple events occur and (iii) between multiple brain regions. The events are modeled as exogenous inputs driving the activity in PM and M1, whose firing rates are in general coupled and evolve dynamically to generate kinematic output. We apply our general DSM approach to neuronal data captured in two nonhuman primates executing a reach-to-grasp task and demonstrate the model's ability to reconstruct population activity in *both* PM and M1 simultaneously in addition to kinematic trajectories. Evaluation of the DSM solution allows us to uncover functional distinctions between PM and M1 through the influence of each cortical population on the neural and kinematic state throughout an arm reaching movement.

Title: Awakening proprioception in neuroprostheses: Modeling of muscle spindles transducers

Authors: *A. CIMOLATO[1,2,3], M. LAFFRANCHI[2], E. DE MOMI[1], S. RASPOPOVIC[3]; [1]Dept. of Electronics, Information Sci. and Bioengineering, Politecnico Di Milano, Milano, Italy; [2]Rehab Technologies, Inst. Italiano di Tecnologia, Genova, Italy; [3]Dept. of Hlth. Sci. and Technol., ETH Zürich, Zuerich Eth-Zentrum, Switzerland

Abstract: Proprioception, in specific kinesthesia sensation is essential in legged motor control since it provides kinematic information about the state of the body segments. Muscle spindles receptors along intrafusal muscles translate their stretch into nervous activity through two distinct type of afferent fibers. Human modelization and validation has always been a major issue due to the impossibility of simultaneous fiber elongation and microneurography recordings. Objective of this work is to propose a computational model able to predict neural firing activity from muscle spindles afferent fibers during human legged locomotion. Musculoskeletal modeling is used in order to simulate in silico the lower limb motion and estimate the interested muscles' kinematics. This particular step allows investigation on human data of previously proposed muscle spindle transducer model, validated only on animals' recordings. Microneurography of muscle spindles afferent fibers and task related joint trajectories from previous studies on humans are used for model reparametrization and validation. Sequential combination of musculoskeletal modeling and the proposed muscle spindles transducer model are planned to be employed in the designing of a bidirectional lower limb neuroprosthesis. Predicted activity will be used through invasive neural stimulation to restore real-time proprioceptive feedback during voluntary prosthetic joint movements.

Title: Multiphoton imaging in alert mouse visual cortex reveals sparse, distributed activation of neurons by electrical stimulation

Authors: *M. C. DADARLAT[1], Y. J. SUN[2], M. P. STRYKER[3];
[1]Univ. of California, San Francisco, San Francisco, CA; [2]UCSF, San Francisco, CA; [3]Ctr. for Integrative Neurosci, Dept Physiol, Univ. California Med. Sch., San Francisco, CA

Abstract: Electrical stimulation is a highly-effective, temporally-precise technique to evoke neural activity in the brain, and is critically important in research and for clinical applications. Understanding the strength, time-course, and spatial spread of neural activation elicited by electrical stimulation in awake, behaving animals is therefore of great interest. To do so, we imaged visual cortex of chronically-implanted transgenic mice using 2-photon fluorescence calcium imaging to measure responses of inhibitory and excitatory neurons evoked by electrical stimulation. GAD-CRE Ai14 mice, which labeled inhibitory neurons with tdTomato, were injected with an AAV 2/1 GCaMP6s virus. A plate for head fixation and a single stimulating microelectrode were implanted and covered by a three mm glass cranial window centered over the electrode tip. After allowing three to four weeks for viral expression, the mouse head was fixed while it stood or ran on a styrofoam ball floating on air. Electrical stimuli consisted of a train of twenty-five biphasic pulses delivered at 250 Hz with a range current amplitudes (1, 5, 10, 15, 20, 25, 30, 40, and 50 microamps). Ten repetitions of each stimulus were presented at each current amplitude, delivered in pseudo-random order once every ten seconds. The number of neurons significantly activated by stimulation grew with the amplitude of stimulation current; however, recruitment of neurons was sparse and distributed across the imaging field — many neurons close to the electrode tip were never activated, even at the highest stimulation amplitudes. Nevertheless, the fraction of neurons activated by stimulation fell with distance from the electrode tip, as did the magnitude of evoked responses. Finally, we found that the pattern of activation evoked by electrical stimulation was similar for excitatory and inhibitory neurons, and was stable over the change in cortical state induced by locomotion.

Title: Midbrain nucleus in pigeon generates locomotion elicited by electrical stimulation

Authors: *J. JANG[1], Y. JUNG[1], C. BAEK[2], S. PARK[3], S. SHIM[2], K. SEO[3], J.-M. SEO[2], S. KIM[2], Y.-K. SONG[1];

Abstract: The research topic of controlling animal behavior through the locomotion system is a fundamental study for the field of robo-animals. Among them, the pigeons have the advantage of having a wide field of view that cannot be seen by people and flying away extremely long distances without being disturbed. However, brain-machine- interface(BMI) technology that implements the aviation capability of the bird still at an elementary level, the need for research related functional aviation brain mapping is increasing. Although the anatomy of the central nervous system of the pigeon has been well-established, it remains unknown about the correlation of what extent structure with function of the flight-related motor nucleus in the brain. In particular, the avian study for functional brain mapping is much uncertain compared to primates, the fundamental study on the motor mechanism of the avian flight is essential. Therefore, in this study, we explore the specific motor areas of the pigeon brain, electrically stimulate to elicit motor or flight behavioral responses and visually evaluate by using movement tracking.
Stereotactic insertion of four monopolar depth electrode(0.203mm) were targeted to pigeon(*Columba livia*, n=9) midbrain. Three locomotion-associated midbrain nuclei containing FRM(Formatio reticularis medialis mesencephalic), ICo(Ventral part of Nucleus intercollicularis), and PAG(Periaqueductal gray) were investigated to elicit flying and walking behaviors. We found that pigeon's body movement including turning, flapping flight, and walking was successfully generated while FRM, ICo, and PAG were electrically stimulated, respectively. The overall electrical current to stimulate these nuclei was of 1mA intensity and 200μs duration.
In this study, we have investigated the behavioral function of particular midbrain nuclei and demonstrated intended motor actions of axial turning, flapping flight and walking. We also have established techniques to implant electrodes into the pigeon brain more accurately and consistently via a stereotaxic frame with a bird-specific adapter. Although our research executed with a wired stimulator in a closed space, future studies using the wireless system could provide more meaningful results if flight experiments are conducted in an open-field. In addition, we expect to induce natural movement of takeoff, landing and flight through simultaneous stimulation of multiple nuclei.

Title: Behavioral assessment of sensory percepts induced by dorsal thoracic epidural spinal cord stimulation in primates

Authors: *A. P. YADAV[1], M. O. KRUCOFF[1], M. A. LEBEDEV[1], M. ABD-EL-BARR[2], M. A. NICOLELIS[1];
[2]Neurosurg., [1]Duke Univ., Durham, NC

Abstract: Lack of somatosensory feedback is a major obstacle to optimally integrating neural prostheses into an individual's body schema. Electrical stimulation of the somatosensory cortex and thalamic nuclei have been proposed to generate sensory percepts in individuals with loss of sensorimotor function; however, these targets require open intradural cranial surgery and accurate targeting of tiny brain structures. It is plausible that alternative target structures along the somatosensory pathway might be capable of encoding meaningful sensory percepts induced by electrical stimulation in a less invasive and more readily clinically translatable fashion. Previously, our group demonstrated that stimulation of the dorsal surface of the spinal cord in rats can be used to transmit sensory information to the brain, and that rats learn to discriminate temporally varying patterns of dorsal column stimulation. In the present study, we generated sensory percepts using percutaneous leads implanted on the dorsal surface of the spinal cord in 3 rhesus macaques, using a routine procedure that is performed in over 50,000 human patients annually and is FDA-approved for certain pain-control indications. Three monkeys were trained to move a joystick-controlled cursor into one of two visual targets. After basic training on the joystick task, they were implanted with epidural percutaneous leads on the dorsal surface of the spinal cord, and externalized leads connected to a custom external pulse generator. Monkeys had to hold a cursor inside a center target during a brief preparatory period while electrical stimulation was presented. Using a two-alternative forced choice task, monkeys were trained to detect artificial stimuli generated by electrical signals delivered at the lead contacts in a charge-balanced bipolar biphasic manner. Using psychometric analysis, we then studied the behavioral sensitivity to detection of sensory percepts at various stimulation parameters such as frequency, pulse width, and duration. We observed that the current threshold for detection of sensory percepts significantly decreased with an increase in frequency, or pulse-width, or duration of stimulation. We also showed that monkeys were able to discriminate between two stimuli that

varied in stimulation frequency as well as those that varied in spatial location. Our results suggest that thoracic epidural spinal cord stimulation can be used to provide valuable information from a prosthetic device back to the central nervous system through a non-visual route, and that the relationship between sensory percepts and stimulation parameters can be explored to create discriminable percepts.

Title: Population level analysis of the correlations between spinal interneuron and motoneuron firing during reflexive motor activity in the spinalized and spinal intact decerebrate cat

Authors: *M. A. LEMAY[1], M. A. GALLO[1], S. SHANKAR[1], A. J. KRUPKA[3], C. K. THOMPSON[2];
[1]Bioengineering, [2]Spinal Neuromotor Lab., Temple Univ., Philadelphia, PA; [3]Natural Sci., DeSales Univ., Center Valley, PA

Abstract: Spinal alpha motoneurons receive most of their synaptic input through spinal interneurons, yet population level patterns of activity between spinal interneurons and motoneurons have not been widely investigated. We present an approach to record large numbers (>30-50 per trial) of spinal interneurons and motor units in order to better quantify how interneurons influence the firing of motoneurons. The experiments were performed on spinalized or spinal intact decerebrate cats. Lumbar spinal cord recording sites were exposed via laminectomy. The right hind limb was secured to a frame and two ankle extensors (soleus and medial gastrocnemius (MG)) were exposed and their tendons separated. In the spinal intact cats, cuff electrodes were placed on the ipsilateral sural nerve and contralateral common peroneal (CP) and tibial nerves. Two 64-channel microelectrode arrays were inserted into the L3 and L6/L7 spinal segments just medial to the ipsilateral dorsal root entry zone to record throughout the intermediate zone of the spinal gray. 64-channel electrode arrays were placed onto the muscle belly of the right MG and/or soleus. Reflexive motor activity was evoked through tendon vibration (~100Hz) or stimulation of the CP, tibial or sural nerves. Neural and EMG units were decomposed and the spike times of both types of units correlated using generalized-linear-model (GLM) analysis methods. Motor units were generally quiescent at rest but showed a robust

increased discharge rate in response to vibratory or nerve stimuli. In contrast, a number of interneurons were active at rest with some demonstrating significant increases in average discharge rate in response to vibratory or nerve stimuli. For vibratory stimuli, motoneurons demonstrated interspike intervals (ISI) tied to the fundamental or harmonics of the vibration frequency, while this was not observed for most interneurons. This differing pattern of activation is consistent with the direct monosynaptic projections from the muscle spindle onto the homonymous motor pool; highly punctuated ISI histograms are frequently observed at the level of the motoneurons, but relatively infrequently across spinal interneurons. GLM analysis showed a number of significant interactions between interneurons and individual motor units that were not observed in some of our prior work looking at interneuronal firing and intramuscular EMGs. The ability to collect these spike train data simultaneously and in large numbers is necessary to better quantify the synaptic input from spinal interneurons to spinal alpha motoneurons under a variety of reflexive, pharmacological, and surgical conditions.

Title: The motor command to a single motor pool during different modes of activation

Authors: *C. TAYLOR[1], T. KMIEC[2], F. NEGRO[3], C. K. THOMPSON[2];
[1]Kinesiology, [2]Physical Therapy, Temple Univ., Philadelphia, PA; [3]Univ. degli Studi di Brescia, Dept. of Clin. and Exptl. Sci., Brescia, Italy

Abstract: Muscle force and movement are generated through the graded activation of spinal motoneurons. It remains unclear how the CNS regulates the activation of spinal motoneurons. There are two commonly debated theories; the motor command encodes for kinematics or kinetics. Here, we record the discharge of single motor units from the biceps during two isometric tasks, elbow flexion and forearm supination, at similar levels of intensity to quantify the synaptic input to and intrinsic excitability of human spinal motoneurons during these modes of activation. High-density surface electromyography of the short head of the biceps brachii was recorded from 11 neurologically intact participants while they performed low-level, isometric, flexion or supination contractions. These contractions were guided with visual feedback and consisted of either steady holds or time-varying efforts. These data were decomposed into their

underlying motor unit action potentials using a well-validated algorithm. The synaptic input to the motoneuron was estimated using intramuscular coherence whereas the excitability of spinal motoneurons was quantified using hysteresis between appropriate motor unit pairs (delta-f). Intramuscular coherence in the 7-12 Hz band was greater in 10/11 individuals during supination than in flexion. No differences were observed in other frequency bands. No difference was observed in the excitability of spinal MNs between modes of activation. These data suggest the synaptic drive to biceps motoneurons may be different during different modes of activation, while the excitability of the motor pool remains invariant. These alterations in common synaptic drive suggest the motor command to the biceps motor pool contains information regarding the limb movement.

Title: Motor unit activation underlying upper limb reflexes to a mechanical displacement

Authors: *I. KURTZER[1], F. NEGRO[2], C. K. THOMPSON[3];
[1]Biomed. Sci., New York Inst. of Technol. Col. of Osteo. Med., Old Westbury, NY; [2]Univ. degli Studi di Brescia, Dept. of Clin. and Exptl. Sci., Brescia, Italy; [3]Spinal Neuromotor Lab., Temple Univ., Philadelphia, PA

Abstract: Over fifty years of research has examined feedback corrections to unexpected perturbations to our limbs or body. A common limitation of this work is examining the compound electrical activity (net EMG) rather than the underlying action potentials of isolated motor units. A handful of studies obtained this information through the time-consuming approach of indwelling electrodes. Here we describe preliminary data using high-density surface EMG electrodes to non-invasively identify dozens of concurrently active motor units. Six healthy individuals (23-47 yr) were seated with their right arm encased by a robotic exoskeleton while a high-density array electrodes was placed over their elbow flexor (brachioradialis) and elbow extensor (triceps lateral). For partial validation, fine-wire electrodes were sometimes inserted into the target muscle. Subjects performed a simple postural task: maintaining their hand within a 1 cm target against a constant flexion or extension torque at the elbow followed by a randomly timed pulse of elbow torque (100ms) which stretched or shortened the contracting muscle. Six blocks of 20 trials were collected. The resulting surface signal was decomposed into corresponding motor unit discharge times using an automated decomposition algorithm, whereas intramuscular EMG was decomposed using a semi-automated tool. Muscle activity and motor

unit discharge was assessed with the conventional approach of peristimulus time histograms (PSTHs). This yielded a high rate of agreement between the array and fine wire decomposition. PSTHs on net EMG and motor unit discharge also demonstrated a high correspondence in the series of bursts termed the short-latency (20-50ms) and long-latency (50-100 ms) reflex. Peristimulus frequencygrams (PSFs) were also constructed from motor unit discharge times and demonstrate high levels of consistency across muscles, perturbations, and subjects. Moreover, there was a notable difference in the PSFs during the short- and long-latency epochs: motor unit activity in the short-latency epoch expressed little change in firing frequency whereas motor unit activity in the long-latency epoch expressed a large sustained increase in firing frequency. Our preliminary results demonstrate the ability to decompose multiple motor units in upper limb muscles during mechanical perturbations and reveal patterns that could not be observed in the net EMG. Different PSFs between the short and long latency reflex epoch likely reflects different their afferent signals and central circuits and will require realistic sensori-motor models for their proper interpretation.

Title: Distinct contributions of mesencephalic locomotor regions in locomotion control

Authors: *Y. HUANG[1,2], Z. WANG[1,2];
[1]Inst. of Neuroscience, State Key Lab. of Neuroscience, CAS Ctr. for Excellence in Brain Sci. & Intelligence Technology, Chinese Acad. of Sci., Shanghai, China; [2]Univ. of Chinese Acad. of Sci., Beijing, China

Abstract: Movement control is important for animals to survive in the changing world. Based on the internal and external needs, the individual should respond to initiate, maintain, or terminate its locomotion. Long before in 1970s, the mesencephalic locomotion region (MLR) has been identified as a key region to modulate locomotion by electric stimuli, eliciting locomotion in the dorsal region and stopping locomotion in the ventral part. Recently, with optogenetics methods and transgene mice, researcher have figured out distinct contributions of MLR to locomotion at cell-type-specific level. The general idea is that vGluT2 neurons initiate and speed up locomotion, whereas GABA neurons slow down and terminate locomotion. However, there are

still more questions on how different inputs of MLR precisely modulate locomotion, and how the sub-populations of MLR execute our behavior. In the present study, by using rats in our studies, we tried to make more subdivision of MLR and examined the fucnction of those sub-regions on locomotion. In our preliminary results, we found that rats' locomotion was halted or speeded up by photostimulation activation of neurons from rostral to caudal of MLR, respectively. By tracing the sources of neural inputs into each sub-region by CTB-647, we found that the rostral of MLR receives more projections from Central of Amygdala (CeA) and Substantia nigra pars reticulata (SNr), while the caudal of MLR more from superior colliculus (SC) and Periaqueductal gray (PAG). In our future work, we will try to figure out how those sub-population neurons receiving different inputs regulate locomotion in MLR. Since locomotion disorder is associated with some disease, such as Parkinson's Disease and Huntington's disease, the results of our studies will be helpful to understanding mechanism of those disorders and the invention of new treatments.

Title: Characteristics of the pubococcygeus muscle motoneurons reflex activity in the male rat

Authors: *O. LARA-GARCIA[1], Y. MAR DE LEÓN[1], M. LARA-GARCIA[2], P. PACHECO[3], L. NICOLAS-TOLEDO[1];
[1]Ctr. Tlaxcala de Biologia de la Conducta, Univ. Autónoma de Tlaxcala, Tlaxcala, Mexico; [2]Univ. Veracruzana, Xalapa, Mexico; [3]Inst. de Investigaciones Biomédicas, Univ. Nacional Autonoma de México, Mexico, Mexico

Abstract: In females, pubococcygeus muscle (Pcm) is multifunctional due to its participation in micturition, defecation, dorsiflexion (lordosis) evoked by male stimulation during copulation. Pcm also increases intravaginal pressure, and participates in tail deviation to facilitate penile intromission. Moreover, it has been described that Pcm is reflexively activated by stimulation of perigenital skin, distal vagina, and clitoris from which is known that at least 3 spinal interneurons participate in its activation. In males, Pcm participates in micturition and ejaculation. However, it is unknown which perineal areas participates in Pcm reflex activity (if any) and if this reflex activity is conditioned by gonadal hormones as in females. Thus, we explored Pcm reflex activity by mechanical stimulation of perigenital areas such as scrotum, perineal skin, and glans penis of intact and castrated animals. Results: In males Pcm reflex activity is also present and is characterized by discharges with different amplitudes and frequencies. In intact rats, perineal

skin brushing, pressure to scrotum and/or to glands penis produced tonic *"on"* and *"off"* (after-discharges) responses; while, phasic *"on"* and *"off"* responses were obtained only during pressure of scrotum and/or glans penis. Surprisingly, in castrated rats we found that Pcm reflex activity is highly sensitized i.e. perineal skin brushing, and pressure to scrotum produced tonic *"on"* and *"off"* responses with higher frequencies and longer duration than intact rats. Meanwhile, phasic "on" and "off" responses were present in perineal skin, and pressure to scrotum and/or glans penis. Discussion: In female, estradiol is acting as a neuromodulator on this reflex activity, as long-lasting after-discharges of Pcm motoneurons are noticed in proestrous or estradiol-treated rats. Surprisingly, castration promotes the onset of this reflex activity sensitization in males. Therefore, other gonadal hormones namely testosterone and/or dihydrotestosterone are involved in Pcm reflex activity modulation, which is important for processes such as ejaculation or micturition.

Title: Strategy of motor unit activation during eccentric and concentric dynamic contractions

Authors: J. LETIZI, B. SHIWANI, J. C. KLINE, S. ROY, G. DE LUCA, *P. CONTESSA; Delsys & Altec Inc., Natick, MA

Abstract: Distinct neural control strategies have been postulated during the execution of eccentric vs. concentric muscle contractions [1]. However, since traditional methods for investigating motor unit behavior are limited to isometric conditions, the strategies employed by the nervous system to regulate different types of dynamic activities remain unknown. We used a non-invasive system of wearable sensors and automated motor unit extraction algorithms to reveal the neural strategy that regulates concentric vs. eccentric contractions in the Biceps Brachii. N=5 healthy subjects (3 male, 2 female, 23-31 years old) were asked to perform repeated elbow flexion/extension curls while holding a 10 lbs weight. Elbow joint angle was monitored using an electrogoniometer (Biometrics, UK). A surface array sensor placed on the skin over the Biceps Brachii recorded four concurrent electromyographic (sEMG) signals,

filtered between 20-450 Hz and sampled at 2 kHz (NeuroMap™ System, Delsys, MA). The sEMG signals were decomposed into the constituent motor unit action potential (MUAP) shapes and firing instances using novel decomposition algorithms designed to identify and track MUAPs throughout dynamic movements [2]. Consistent with previous findings, the size principle of motor unit recruitment was maintained in both concentric and eccentric contractions [3]. We also make a novel observation that, even though motor units displayed higher firing rates during the concentric phase, the firing rate vs. MUAP amplitude relation showed consistent adaptations during both phases, indicating that the firing rate organization of the motor unit pool is invariant to the task. This finding supports the existence of a unique neural strategy that regulates motor unit behavior during concentric vs. eccentric tasks in which motor unit firing modulation is driven by the varying mechanical demands of the tasks.

Title: Differential adjustments to low and high threshold motor units during experimental muscle pain

Authors: *E. MARTINEZ-VALDES[1], F. NEGRO[2], D. FARINA[3], D. FALLA[1];
[1]Sch. of Sport, Exercise and Rehabil. Sci., Univ. of Birmingham, Birmingham, United Kingdom; [2]Univ. degli Studi di Brescia, Dept. of Clin. and Exptl. Sci., Brescia, Italy; [3]Dept. of Bioengineering, Imperial Col. London, London, United Kingdom

Abstract: Most of the knowledge about motor unit control strategies during painful conditions comes from research performed during low-force sustained contractions. These previous studies have recognized that discharge rate decreases when nociceptive substances are infused into the muscle [1]. Despite this consistent observation, it is not currently known how the central nervous system controls motor unit behavior during painful muscle conditions at higher levels of excitation [i.e. forces closer to the maximum voluntary contraction (MVC)]. In this study, we aimed to compare the behavior of tibialis anterior motor unit firing properties during low (20% MC) and high-force (70% MVC) contractions in four conditions: baseline (no pain), isotonic (injection of control non-painful solution to the muscle), pain (injection of hypertonic saline solution) and post-pain. Surface EMG signals were recorded from 15 participants (26 (3) years, 6 females) using a matrix of 64 electrodes while performing ankle-isometric dorsiflexion. Signals from the four different conditions were decomposed and the same motor units were tracked across conditions [2, 3]. The amount of neural drive received by the motor unit pool at each force level was estimated by calculating the difference in discharge rate from recruitment to target torque [4]. At 20% MVC, motor unit discharge rate and estimated neural drive decreased significantly during pain (baseline vs. pain: 12.7 (1.1) Hz to 11.5 (0.9) Hz, $p<0.001$), without observing any other adjustment to motor unit properties. In contrast, at 70% MVC, discharge rate and estimated neural drive increased significantly during the painful condition (baseline vs. pain: 19.7 (2.8) Hz to 21.3 (3.5) Hz, $p=0.029$). These changes were also accompanied by a decrease in recruitment threshold (baseline vs. pain: 59.0 (3.9) %MVC to 55.9 (3.2) %MVC, $p=0.02$). Results from this study show that there is a differential adjustment among low and high-threshold motor units during painful conditions. Increases in synaptic input to high threshold motor units might be likely required to engage fast muscle fibers in order to move away from the painful stimuli, and thus prevent further damage to muscle tissue.

Title: Factors influencing estimation of motoneuron excitability using analysis of motor unit populations

Authors: *L. M. MCPHERSON[1,2], A. S. HASSAN[3], F. NEGRO[6], M. CUMMINGS[4], R. K. POWERS[7], J. P. DEWALD[4], C. HECKMAN[5], C. K. THOMPSON[8];

Sci., Brescia, Italy; [7]Dept Physiol & Biophysics, Univ. Washington, Seattle, WA; [8]Spinal Neuromotor Lab., Temple Univ., Philadelphia, PA

Abstract: Neuromodulatory synaptic inputs to motoneurons (via 5-HT and NE) have a dramatic influence on motoneuron excitability, in part because they facilitate induction of persistent inward currents (PICs). PICs lead to amplified and prolonged motoneuron output in response to excitatory synaptic inputs, which appropriately scales motoneuron output according to task demands. This ability is an essential component of neural control of movement, and its disruption has been implicated in motor deficits in populations with neurological injury.
The standard method for estimation of neuromodulatory synaptic input and PIC amplitude is to quantify recruitment/de-recruitment hysteresis during slow linear “triangle” contractions through a paired motor unit analysis (F).
The F technique requires that motor units pairs must meet certain criteria based on assumptions related to the underlying physiology, e.g., motor unit pairs must have sufficient correlation of their firing rates, as the firing rate trajectory of the lower threshold (control) unit is used as an approximation of the ionotropic excitatory synaptic input to the higher threshold (test) unit. The difference in recruitment time between the control and test units must be long enough to ensure the PIC of the control unit is fully active before test unit recruitment. Firing rate saturation in the control unit may also bias the F calculation and is often controlled for. Despite these standard criteria, the specific threshold values for each criterion vary across studies, as do computational factors such the type of firing rate smoothing filter and the accuracy of motor unit spike times. The purpose of this study is to determine the sensitivity of F to differences in the factors discussed above. To estimate motoneuron firing rates in humans, we used a high-density surface EMG decomposition to obtain motor unit spike times, in combination with a custom semi-automatic editing tool to improve accuracy. This approach provides spike times from large populations of motor units, which enables a robust, systematic analysis of factors influencing the estimation of PICs in humans. Here we present findings of this systematic analysis applied to data from the triceps of 10 healthy participants during isometric triangle contractions.

Title: The need of accurate decomposition methods for the precise estimation of the neural drive to muscle

Authors: *F. NEGRO[1], E. MARTINEZ-VALDES[2], L. M. MCPHERSON[3], C. K. THOMPSON[4], A. CUDICIO[1], U. YAVUZ[5];

Univ., Miami, FL; [4]Spinal Neuromotor Lab., Temple Univ., Philadelphia, PA; [5]Biomed. Signals and Systems, Univ. Twente, Enschede, Netherlands

Abstract: Decomposition of the electromyographic (EMG) signals can provide essential information about central and peripheral properties of motor units (MUs). Recently, high-density (HD) multi-channel electrode systems have been developed for surface EMG detection. HD-EMG overcomes the classical bipolar detection and provides detailed spatial information of the electrical activity over a large portion of the muscle. When tens of EMG channels are available, convolutive blind source separation can be used for the automatic decomposition. The “blind” separation of concurrently active MUs is based on the statistical properties of sources, not on expected discharge patterns of motor unit. Becaue of this, the extracted solutions do not always correspond to physiological MU firing patterns. For this reason, measures of reliability have been developed (e.g. Silhouette (SIL) [1]) as a surrogate measure of decomposition accuracy and automated exclusion of non-physiological MUs. However, even using high values (e.g. SIL=0.85-0.90), a number of firings may be still erroneous. In these cases, visual inspection from an expert operator may be used to supplement the capability of the automatic algorithm to resolve erroneous firings. In this study, we aimed to compare the decompositions extracted from the fully automatic method [1] with the ones subsequently edited by an expert operator (semi-automatic). The semi-automatic method provides the possibility to update the automatic decomposition results by iterative visual editing of the individual discharge times and the verification of the improvement in the estimation of the sources. Results are reported for four subjects in the Vastus Lateralis muscle over a wide range of contraction intensities. Average discharge rates of the extracted MUs were similar between the automatic and semi-automatic methods (11±2 vs 11±2 pps). On the other hand, Coefficient of Variation (19±3 vs 15±2%) and Force Recruitment Threshold (35±2 vs 32±3%) were significantly lower in the semi-automatic method ($P<0.05$). Similarly, the correlation between neural drive and force well as the coherence between spike trains were significantly higher in the semi-automatic case. These data

demonstrate some motor unit parameters are particularly sensitive to the erroneous identification of discharges by automatic decomposition methods and, therefore, the results of these methods should always be processed by accurate techniques and verified by visual inspection. Title: Within and across day repeatability of estimates of human spinal motoneuron excitability

Authors: *C. K. THOMPSON[1], T. KMIEC[1], P. KUMAR[2], L. M. MCPHERSON[3], F. NEGRO[4];
[1]Physical Therapy, [2]Kinesiology, Temple Univ., Philadelphia, PA; [3]Florida Intl. Univ., Miami, FL; [4]Univ. degli Studi di Brescia, Dept. of Clin. and Exptl. Sci., Brescia, Italy

Abstract: The discharge of a spinal motoneurons and the contraction of its associated muscle fibers represents the smallest quanta of motor output. The discharge of a spinal motoneuron is regulated not only by its synaptic input, but also by its intrinsic excitability. Though we are not yet able to directly measure the excitability of human spinal motoneurons, approaches have been developed to estimate the synaptic input to human spinal motoneurons by substituting the current injected by an invasive microelectrode with the discharge of a low threshold motor unit during time varying volitional contractions. Using pairs of motor unit discharge receiving similar synaptic input, the excitability of a spinal motoneuron can be assessed by quantifying the difference in frequency of a low threshold unit at the recruitment and derecruitment of this higher threshold motor unit (delta-f). Understanding the excitability of human spinal motoneurons is of interest in a number of aspects of motor control, however the repeatability of this measure is unknown. Here twelve individuals completed three sets of three dorsiflexion contractions over three nonconsecutive days. Surface electromyographic signals are collected from the tibialis anterior using a 64-channel electrode matrix. Offline, signals were decomposed into their corresponding motor unit action potential spike trains using a well-validated convolutive blind source separation approach; each unit was visually inspected for accuracy. Within each of these 324 contractions, an average of 21±8 motor units were decomposed resulting in 171±135 delta-f comparisons per contraction. No differences in delta-f estimates

were observed across contractions, sets, or days. Intraclass correlation coefficient analyses (2,1) demonstrates the average delta-f measure has poor test-retest reliability across three consecutive contractions, whereas moderate reliability is observed across sets and days. When motor units are tracked across contraction and only the same motor unit pairs are assessed across trials, repeatability values were even lower than when using the population data. These data demonstrate the delta-f measure is variable across repeated contractions, though this variability decreases with increased number of observations. Further, these data point to the utility of population data for this approach. It remains unclear if this variability is due to error of measurement or if this variability reflects the underlying physiological processes.

Title: Striatopallidal pathway modulates neuroprosthetic learning by volitional control of calcium signals in the cortex & globus pallidus

Authors: *J.-F. CHEN[1], L. ZHANG[1], Y. ZHOU[1], C. LIU[1], W. ZHENG[1], Z. YAO[1], Q. WANG[1], Y. JIN[2], S. ZHANG[2], W. CHEN[2];
[1]Wenzhou Med. Univ., Wenzhou, China; [2]Zhejiang Univ., Hangzhou, China

Abstract: Brain-machine interfaces (BMI) hold promise for restoring motor function for disabled patients and providing a novel approach to sensorimotor learning. At the core of BMI adaptation is neuroprosthetic learning by volitional control *(independent of movement)*, but their neural circuit and neuromodulator bases are largely unexplored. To better define the volitional control mechanisms at the cellular level, we have developed a calcium-based neuroprosthetic task in which mice were conditioned to volitionally increase calcium signals above the specified threshold for the reward independent of movement. Using calcium activity as a volitional controller, we revealed, with the neural activity-behavior causality, the distinct neuroplasticity changes during neuroprosthetic learning and in response to the decoder changes. Importantly, we have demonstrated, for the first time, that the calcium signal in the globus pallidal neurons (the striatopallidal output nucleus) acted as a volitional controller signal to support the development

of neuroprosthetic learning. Furthermore, we demonstrated that pharmacological blockade adenosine A_{2A} receptors (highly enriched in the striatopallidal pathway) facilitated neuroprosthetic learning and converted an ineffective conditioning protocol to the effective for neuroprosthetic learning. Collectively, these findings define striatopallidal pathway control of neuroprosthetic learning and suggest a novel neurorehabilitation strategy to improve neuroprosthetic learning by pharmacological targeting the striatopallidal A_{2A} receptor.

Title: Adaptation of neural activity in parietal cortex of rhesus monkey during control of 3D reaches in a brain-computer interface

Authors: ***E. FERREA**[1], P. MOREL[1], A. GAIL[1,2,3];
[1]Cognitive Neurosci. Lab-Sensorimotor Group, German Primate Ctr., Goettingen, Germany; [2]Univ. of Goettingen, Goettingen, Germany; [3]Bernstein Ctr. for Computat. Neurosci., Goettingen, Germany

Abstract: Posterior parietal cortex (PPC) is known to integrate visual and proprioceptive sensory information, e.g. about the position of the own hand during reaching. In a joystick task with curved trajectories, activity in PPC was previously shown to correlate better with the immediate (zero time-lag) cursor direction than with its previous positions (Mulliken et al. 2008), arguing against mere sensory encoding. Such findings support the idea that PPC contributes to internal forward model computations and real-time state estimation for online motor control: it could combine expected with actual sensory feedback to form an inner belief of how motor commands affect the state of the body. From previous studies it is unclear if neural encoding is more compatible with the idea of an efference copy, the predicted sensory feedback (visual or proprioceptive) or a state estimation, since in manual task these parameters are typically confounded. We here used a brain-computer interface (BCI) to study motor control with the cursor motion (the motor command) being fully experimentally controlled and proprioceptive feedback being held constant. In different sessions, a BCI decoder was linked to different populations of neurons, i.e., subsets of primary motor (M1) and dorsal premotor cortex (PMd)

units. The complementary subset of M1 and PMd neurons, and all PPC units, were not linked to motor output controlled by the decoder. We applied a visuomotor rotation paradigm to dissociate visual feedback from motor representation.
Results show that over the course of adaptation to the perturbation, neurons in all three brain areas coherently shifted their tuning to counteract the applied visuo-motor rotation, irrespective of being part of the BCI decoding units or not. PPC units thereby better predicted the direction from the immediate cursor position towards the static goal rather than the actual cursor movement direction, inconsistent with the idea of an efference copy signal. To test if visual or motor-related encoding determined this PPC activity, we trained an offline decoder based on PPC activity during unperturbed baseline trials and applied it to perturbed rotation trials. PPC population activity consistently encoded adaptive changes that did not reflect changes in the visual input but matched the changing motor output. Trial-to-trial updating of the decoded cursor trajectories from PPC correlated with the acquired behavioral improvements. In conclusion, our findings support the hypothesis that PPC reflects a real-time state estimation of immediate cursor-to-target direction in a motor reference frame suited for online control and error correction of movements.

Title: Effects of inter-stimulus interval duration and predictability on sensorimotor beta

Authors: *R. B. LERICHE, N. JACKSON, K. PETERSON, Z. ASPANDIAR, V. HUFNAGEL, N. C. SWANN;
Human Physiol., Univ. of Oregon, Eugene, OR

Abstract: Introduction: In motor tasks, the inter-stimulus interval (ISI) between the fixation-cue and go-cue can have a varied, jittered, or fixed duration. This period is often used as a baseline period for electroencephalography (EEG) studies as a comparison for subsequent motor-related activity. Choosing how the ISI is set may unpredictably impact subsequent motor responses as both motor preparation and execution involve modulation in the beta frequency range (13-30 Hz). Moreover, purely visual processing is also associated with beta modulation in several areas including the sensorimotor cortex. Our observations affirm how beta activity during preparatory intervals may influence neural processing during motor responses.
Methods: We conducted a delayed-go task with blocks of fixed or varied ISIs (block-order randomized). The task began with a fixation cue, followed by an arrow (go cue) pointing left or

right. Participants responded via button presses using their right hand. The ISI for fixed blocks was 500ms and for varied blocks, the ISI was randomly selected per trial to be 300, 400, 500, 600, or 700ms. Healthy participants aged 18-30 (n=14) completed both blocks with concurrent scalp EEG. We focused our analysis on data from the electrode over left sensorimotor cortex (C3), contralateral to the responding hand. We calculated beta power using the pwelch function in MATLAB for the ISI epoch of each trial and then averaged across trials.
Results: Between all fixed and varied ISI conditions the average beta power from electrode C3 was significantly lower in the fixed versus varied ISI condition (Wilcoxon's signed rank test, p= 0.0064). The average beta power from electrode C3 was significantly lower in the fixed blocks versus varied trials of 500ms duration (Wilcoxon's signed rank test, p= 0.0070). There were no differences across the varied ISI duration (i.e. comparing 300, 400, 500, 600, and 700ms ISI varied trials, Kruskal-Wallis test, p= 0.979).
Discussion: These results suggest that predictability of the timing of forthcoming motor responses is associated with reduced beta. Since beta power decreases are associated with motor preparation and execution we suspect that this reduced beta power may be a manifestation of motor preparation with known go cue timing. These preliminary results suggest a need to further examine the relationship between peri-movement beta modulations and the need for careful consideration of the ISI in task design.

Title: A neuromechanical model of continuous wrist motion

Authors: *L. ZIEGELMAN[1], R. SUN[1,2], Y. HU[1], W. A. DELGADO[1], M. E. HERNANDEZ[1]; [1]Univ. of Illinois At Urbana-Champaign, Urbana, IL; [2]Sch. of Med., Case Western Reserve Univ., Cleveland, OH

Abstract: This study aimed to create a neuromechanical simulation of wrist motion in six degrees of freedom. This is done by adapting a previously proposed neuromechanical model of hand pronation and supination to also model hand flexion, extension, radial deviation, and ulnar deviation. This model explores the effectiveness of adapting a Matsuoka Oscillator to account for continuous wrist motion and is personalized to account for physiological changes to the

neuromechanical system due to aging. Both healthy young and older adults (HYA, HOA) performed three trials of continuous wrist motion in all six degrees of freedom for 20 seconds while wearing a research grade IMU (InertiaCube BT) to validate the kinematics of the theoretical model. The proposed model is shown to be flexible to modeling multiple modalities of wrist motion and is validated using experimental data.

Title: Transient behavior and predictability in manipulating complex objects

Authors: *R. T. NAYEEM[1], S. BAZZI[1], N. HOGAN[2], D. STERNAD[3];
[1]Northeastern Univ., Boston, MA; [2]MIT, Cambridge, MA; [3]Departments of Biology, Electrical & Computer Engineering, and Physics, Northeastern Univ. Dept. of Biol., Boston, MA

Abstract: Humans dexterously manipulate a wide variety of complex objects. A mundane example is transporting a cup of coffee: the hand applies a force to the cup, and also indirectly to the liquid, which in turn acts back on the hand. Previous work in our lab investigated how humans tune into resonant frequencies when rhythmically moving a dynamic object. Unlike in free movements, subjects did not minimize effort but adopted strategies that rendered interactions predictable. In those studies subjects started from rest, always at the same initial conditions; the transient was excluded from analysis, focusing on steady state behavior. As transients can be complex, depending on initial conditions, this study examined whether humans choose initial conditions to reduce transient duration prior to reaching steady state. We hypothesized that subjects find initial conditions that minimize the transient duration and settle to steady state behavior that renders object dynamics predictable.
The experimental task consisted of interacting with an object simulated by a robot with haptic feedback. The cup of coffee was simplified to a cart-and-pendulum system moving on a horizontal line; the subject moved the cart, while the pendulum only moved indirectly. The cart-pendulum system was visually presented as a ball rolling in a cup. Importantly, movements of the cup also accelerated the ball, which in turn acted back on the hand. Participants moved the cup back and forth rhythmically between two targets paced by a metronome at 0.6Hz without losing the ball. They were instructed to explore their initial conditions within a start box before initiating the rhythmic movement by exiting the start box when they were ready. Participants performed 120 trials, each 15s excluding pre-trial exploration. Dynamic simulations were performed to understand the effect of initial conditions. To calculate transient duration, steady state started at the time when relative phase between ball and cup was close to zero. Mutual information between applied force and cup motion evaluated predictability of the steady state behavior.
Preliminary results showed that subjects converged to a small set of initial conditions, they decreased the transient duration with practice and established a steady state defined by relative phase between cup and ball; mutual information increased with practice. Simulations confirmed that these initial conditions corresponded to shorter transients. These results present first support for our hypothesis that humans can identify initial conditions that minimize transients and favor steady state behavior that enhances predictability.

Title: Foraging as an evidence accumulation process

Authors: *J. DAVIDSON[1], A. EL HADY[2];
[1]Collective Behavior, Max Planck Inst. for Ornithology, Konstanz, Germany; [2]Princeton Neurosci. Inst., Princeton, NJ

Abstract: The patch-leaving problem is a canonical foraging task, in which a forager must decide to leave a current resource in search for another. As a decision task, patch-foraging is a behavior that can be directly linked to fitness; theory and experiments have derived optimal strategies and tested for conditions where animals do or do not follow them. Although a mechanistic decision model is needed to interpret experimental studies regarding the neural mechanisms behind foraging decisions, current models of patch-leaving decisions do not consider the imperfect and noisy sampling process through which an animal gathers information. In this work we formulate a mechanistic model of patch-leaving decisions by linking ecological models of the patch-leaving task with models of evidence accumulation that are used in systems neuroscience. We solve the model for conditions where foraging decisions are optimal and equivalent to the marginal value theorem, and perform simulations to analyze deviations from optimal when these conditions are not met. By adjusting the drift rate and decision threshold, the model can represent different strategies, for example an incremental, decremental, or counting strategy. These strategies yield identical decisions in the limiting case but differ in how patch residence times adapt when the foraging environment is uncertain. To describe sub-optimal decisions, we introduce an energy-dependent marginal utility function that predicts longer than optimal patch residence times when food is plentiful. Our model opens up a space to study naturalistic decision making in a quantitative manner. We discuss the model in the context of readily existing data sets, as well as how it can be used to plan future experiments which seek to identify neural circuits underlying patch-leaving decisions.

Title: A computational model of mixed pattern generation for forward locomotion in *C. elegans*

Authors: *E. J. IZQUIERDO[1], E. O. OLIVARES[2];
[1]Cognitive Sci. Program, Indiana Univ., Bloomington, IN; [2]Cognitive Sci. Program, Indiana Univ., Bloomington, IN

Abstract: *C. elegans* locomotes in an undulatory fashion, generating thrust by propagating dorsoventral rhythmic bends along its body. As in many other organisms, there are likely multiple mechanisms, internal and external, contributing to the generation, propagation, and coordination of these rhythmic patterns. Experimental and theoretical work has provided support for the role of both stretch-receptor feedback (SRF) and central pattern generators (CPGs). However, current work leaves a number of major questions unanswered: (1) Can multiple CPGs coordinate their activity to produce the traveling wave necessary for locomotion, in the absence of SRF? (2) Can SRF alone drive locomotion, in the absence of CPGs? and (3) How can SRF and CPGs work together to increase the robustness of the locomotory behavior? In current work, we integrate a neuromuscular model of the ventral nerve cord with a biomechanical model of the worm's body. We then use an evolutionary algorithm to determine unknown physiological parameters of the model so that the complete system reproduce the kinematics of forward locomotion. We performed experiments under three conditions: SRF was never available during evolution; SRF was always available; and SRF was intermittently available. We then analyzed the ensemble of solutions as a way to explore theoretical possibilities to the motivating questions. Under all conditions, the model worms reproduced the speed of the worm and were consistent with key kinematic features of locomotion, including frequency, wavelength and amplitude of bending. From the first condition, we determined that a chain of CPGs, without SRF, can drive forward locomotion on agar. We demonstrate this is feasible through pacemaker neurons as well as intrinsic network oscillations. Analysis of the solutions reveal that motoneuron gap-junctions alone can coordinate anterior-posterior oscillations. In the second condition, when SRF was available, the neural controller takes advantage of this information to both generate and propagate the rhythmic pattern without the need for CPGs. Although other computational models of reflex pattern generation have been published to date, this is the first to account for the size and directionality of the anatomical processes postulated to sense stretch in the worm. Finally, in the third condition, model worms utilize mixed pattern generators: a combination of multiple CPGs that use SRF to fine-tune, coordinate and modulate the motor patterns. We analyze representative solutions from this group in detail to reveal principles underlying the coordination of internal and external mechanisms that generate robust and flexible locomotion in the worm.

Title: Chewing drives stepping rates regardless of chewing initiation timing suggesting top-down control of coupled oscillators

Authors: *B. SAMULSKI, J. PREBOR, S. MORRISON;
Kinesiology and Rehabil., Old Dominion Univ., Norfolk, VA

Abstract: Chewing plays a vital role in daily life by facilitating nourishment. Walking functions as a primary way to explore and interact with the environment. These two seemingly unrelated tasks appear to share a coupling mechanism when performed together. The directionality of this relationship has not been well studied, so little is known about the nature of how these coupled oscillators coordinate. Previous research has initiated chewing prior to performing the secondary task and consistently sets the rate of performance of the coordinated action. Previous research suggests a top-down control model, whereby chewing entrains stepping. An alternative theory that the movement performed first, temporally, could set the coupling pattern between actions remains plausible. The aim of this study was to investigate whether initiating chewing before or during gait affects walking patterns. Fifteen healthy young (18-40) and fifteen older adults (age 60-75) participated in the study. Individuals were asked to chew at three different speeds: 1. preferred, 2. self-selected slow, and 3. self-selected fast. Chewing rates were recorded using surface EMG recordings from the masseter muscles. This was performed while the person stood (baseline) and when walking over a pressure sensitive walkway. For the gait tasks, chewing was introduced either prior to the beginning of the walk or mid-way through the walking trial. Participants self-selected the walking speed for all trials. A baseline assessment of each person's gait was performed with no concurrent chewing. Gait parameters such as step/ stride length, gait velocity, step cadence, and step time were measured. Fast chewing and slow chewing were associated with changes in step cadence. Overall, the results indicate that the timing of when chewing began did not alter how stepping rates were influenced. When chewing was performed prior to walking, the step rate coupled in a 1:1 manner to the chewing rate across all chewing speed conditions. When chewing began during gait, the step rate coupled to the chewing rate in a 1:1 ratio for each of the trials. Coupling of the two continuous motor tasks may indicate that neural mechanisms which dictate timing of tasks, such as central pattern generators for the mouth and limbs, may be interconnected. The relationship describing the interplay between neural oscillators during performance of simultaneous tasks is not clear. The bilateral innervation of chewing musculature, as well as the proximity of chewing control centers in the midbrain, support a hierarchical influence of chewing rates on gait.

Title: A hybrid modeling framework for the comparison of motor and sensory peripheral nerve fiber recruitment during stimulation

Authors: *S. ROMENI[1], G. VALLE[1,2], A. MAZZONI[1], S. MICERA[1,2];
[1]Translational Neuroengineering Lab., The Biorobotics Institute, Scuola Superiore Sant'Anna, Pontedera, Italy; [2]Ctr. for Neuroprosthetics and Inst. of Bioengineering, École Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland

Abstract: The importance of modeling in the field of neuroprosthetics is hardly overestimated: invasive implants are expensive and require the joint efforts and interplay of teams of experts from several different backgrounds. Modelling could concurrently enhance both the effectiveness and the efficiency of neuroprostheses accompanying the whole process from experimental planning to the interpretation of the obtained results. Moreover, the comparison of alternative models for a given phenomenon could contribute and shed some light on the underlying processes providing an invaluable tool for progressive scientific research.
We employed the framework of hybrid modeling, a computational model based on the separation of the two problems of (1) volume conduction in naturalistic structures of the charge injected by an electrode and (2) determining the consequent response of the targeted nerve fibers.
Different levels of approximation were defined for the geometries of mammal spinal nerves, and the geometries of an intraneural (TIME) and an extraneural (FINE) electrodes were defined parametrically. Such nerves were populated with naturalistic fiber samples both in terms of diameter distributions which were efficiently packed in the physiological structures. The problem of the determination of the most adequate family for the fiber diameter distribution was studied, leading to the choice of adequate beta mixture distributions.
The recruitment properties of motor and sensory nerve fibers in terms of recruitment curves and global and local selectivities were compared through the implementation of computational models found in literature, which were previously extensively characterized for the current use through the simulation of their stimulation with a point electrode in a homogeneous medium.
Then two realistic stimulation settings (corresponding to intraneural and extraneural stimulation experiments) were studied, in which it appeared clearly how the different physiology of motor and sensory fibers - embodied in the employed models as different Hodgkin-Huxley parameters for the ion channel equation corresponding to Ranvier nodes - had drastic consequences on the recruitment of the two modeled fiber types.
The present work could be generalized through reciprocity arguments to neural signal recording simulation as well, thus providing a tool for the complete characterization of bidirectional prostheses. The intrinsic conceptual modularity of the modeling flow could moreover allow the inclusion of more fiber types for the simulation of a great variety of applications and implants.

Title: Decoding motor tasks through supervised subspace alignment

Authors: *I. PENIDO[1,2], J. B. HYNES[3], J. P. DONOGHUE[4], C. E. VARGAS-IRWIN[1];
[1]Neurosci., Brown Univ., Providence, RI; [2]Carney Inst. for Brain Sci., Providence, RI;
[3]Neurosci., Brown, Providence, RI; [4]Wyss Ctr. For Bio and Neuro Engin., Geneva, Switzerland

Abstract: Within a species, the brains of different individuals are laid out according to general stereotyped patterns. However, the precise microstructure of each resulting brain network is unique. For vertebrates, there is not a one-to-one correspondence between the neurons in one subject and those in another, so it is not possible to directly map activity patterns across different brains. However, when individuals from the same species perform a given behavioral task, it is reasonable to assume that their brains are performing equivalent computations: although the precise activity patterns may differ, the relationship between the sets of patterns observed in each brain is likely to be similar. Neural computation occurs in subject-specific high dimensional substrates. However, the activity patterns recorded for a given behavioral task tend to be concentrated in relatively low dimensional sub spaces (commonly referred to as neural 'manifolds', although they do not necessarily conform to the formal mathematical definition). We propose that brains performing equivalent computations will operate on manifolds with similar topological structure. Building on this basic idea, we present a computationally accessible method that uses similarity-based clustering (Vargas-Irwin, 2015), followed by an optimized linear transform to align neural data from different brains into a common unified state space (USS) representation.
We examined the potential for universal decoding models applicable across different subjects and sessions using M1 cortical data from three macaque monkeys performing two different tasks: a center-out radial reaching task (including 8 different reach directions), and a grasping task (including 3 different grips).
Our results show that small samples of data (approximately 5 exemplars for each movement category) are sufficient to find the projection matrix into an existing USS. In this way, the amount of data available to train classifiers can be greatly increased, significantly improving discrete movement classification accuracy (for either reach direction or grip type). Our results support the idea that the structure of task-related manifolds tends to be preserved across subjects

and sessions, and suggest that decoding models applicable across different brains at the level of single units are viable.

Abstract: The basal ganglia are an evolutionary conserved subcortical nuclei involved in action selection and learning. Their importance is highlighted by the severity of the diseases affecting it, such as Parkinson's and Huntington's, and a variety of psychiatric diseases. The striatum, the largest structure of the basal ganglia, is the main input stage. For the striatal projection neurons (direct and indirect type), fast spiking interneurons, cholinergic interneurons and low threshold spiking interneurons there exist detailed information about electrophysiology, but only sparse data of the neuronal connectivity.
We present a large scale in-silico reconstruction of the mouse striatum micro-circuitry, based on somato-dendritic-axonal morphologies and detailed compartmental models of each neuron subtype optimised using BluePyOpt to match experimental elecrophysiological recordings. The striatal neurons are randomly placed within a 3D volume corresponding to the striatal structure (mesh downloaded from Allen Institute for Brain Science), with densities of the different types of neurons matching that seen in experiments. Putative synapses are detected using a touch detection algorithm, which is he pruned by a set of rules based on connectivity data, giving the

final set of synapses.
The striatal microcircuit model is simulated using Parallel Neuron on a Cray XC40 machine. The striatal network is driven by simulated cortical and thalamic input. Using this network model we can investigate the role of the principal neutrons as well as their interactions with the subgroups of interneurons in the circuit.
This study is funded by: Horizon2020 grant agreement 720270 and 785907 (Human Brain Project, SGA1 and SGA2); The Swedish Research Council; Swedish e-Science Research Center. The network model is simulated on a Cray supercomputer provided by the Swedish National Infrastructure for Computing (SNIC) at PDC KTH.

Title: A modeling and optimization framework for understanding the role of reflexes in the feline hindlimb in promoting proportional coordination of the joints during yield

Authors: *T. GOVINDARAJ[1], D. R. HOWLAND[4], G. SAWICKI[2], T. R. NICHOLS[3];
[1]Sch. of Mechanical Engin., [2]Sch. of Mechanical Engineering, Sch. of Biol. Sci., [3]Sch. of Biol. Sci., Georgia Inst. of Technol., Atlanta, GA; [4]Kentucky Spinal Cord Injury Res. Center, Depts of Neurolog. Surgery, Anat, Univ. of Louisville, Louisville, KY

Abstract: Proprioceptive pathways arise from a variety of receptors, including muscle spindles and Golgi tendon organs. Muscle spindles measure changes in length and velocity, while tendon organs measure active contractile force. Force feedback is more widely distributed than length-dependent feedback pathways, so force-dependent pathways are likely to regulate inter-segmental coordination. During the yield, or weight acceptance phase of locomotion, the knee and ankle obey proportional coordination [1], or equal joint angle excursions. To understand how force feedback can help promote proportional coordination, we are developing a three segment model of a feline hindlimb in Simulink, with realistic lengths and masses and a rotational spring and damper at each joint to represent the intrinsic properties of muscle with integral stretch reflexes. Based on the known distribution of muscular mass, joint impedance decreases from hip to ankle. In this initial version of the model, there is no provision for biarticular muscles. Force

feedback is represented by a matrix multiplying the joint torques. To simulate the limb's behavior during yield, the initial configuration is set as the beginning of the weight acceptance phase (E2), and a force equivalent to the maximum ground reaction force experienced during yield in level walking is applied over 50 ms. We are using a proportionality index to investigate whether this coordination is accomplished by intrinsic neuromechanical properties alone or whether intermuscular reflexes are necessary. As expected from the non-uniform distribution of impedance, the magnitude of joint flexion due to the perturbation decreases from ankle to hip with no interjoint force feedback, and the measure of proportional coordination is 1.05*10^6. We are currently evaluating the effects of interjoint feedback according to patterns observed experimentally. These patterns include gradients of feedback from proximal to distal, distal to proximal, or focused on the ankle musculature. Initial trials with uniform magnitudes of interjoint force feedback resulted in a proportionality index of 1.28*10^6, which is 21.4% greater than the index of the intrinsic neuromechanical properties alone. Therefore, this result supports our hypothesis that proportional coordination is accomplished by interjoint force feedback. Future versions of the model will include coupling terms to represent biarticular muscles, and the use of an optimization approach to determine what patterns of feedback would result in proportional coordination. Title: Resting state auditory motor functional connectivity and dopaminergic responses during rhythmic auditory motor entrainment: A [11C]-(+)-PHNO PETand fMRI study

Authors: *Y. KOSHIMORI[1,2], A. P. STRAFELLA[2], M. VALLI[2], V. SHARMA[1], P. RUSJAN[2], S. HOULE[2], M. H. THAUT[1,2];
[1]Music and Hlth. Sci. Res. Collaboratory, Univ. of Toronto, Toronto, ON, Canada; [2]Res. Imaging Ctr., CAMH, Toronto, ON, Canada

Abstract: Auditory-motor entrainment using rhythmic auditory stimulation (RAS) has been shown to improve motor control in healthy persons and persons with neurological motor disorders such as Parkinson's disease and stroke. Neuroimaging studies have shown the modulated activity in the areas of corticostriatal and corticocerebellar circuits in response to RAS. Our previous study showed that the presence of RAS significantly improved the finger

tapping performance measured using absolute tapping period error and its variability and resulted in less dopamine (DA) response in the left ventral striatum (VS) in eight young healthy adults (Koshimori et al., 2019). However, we did not find any correlations between the behavioral and neuroimaging data. This may be because the motor improvement is more associated with brain function on a circuit level. As resting-state functional connectivity (rs-FC) predicts task performance, we sought to investigate the relationships between rs-FC, and DA and behavioral changes between task conditions (i.e., finger tapping performance with and without RAS) in these participants. The resting-state functional MRI data were preprocessed and analyzed using CONN functional toolbox. The seed ROIs included bilateral auditory areas. We found several auditory motor pathways that showed significant correlations with changes in the behavioral measures. Among them, rs-FC between left Planum Polare and left SMA also showed a significant correlation with the DA changes in the left VS ($p = .006$). We also investigated the relationship between the DA changes in left VS and auditory limbic pathways and found significant correlations between the DA changes and (1) rs-FC between the right posterior SFG and left hippocampus ($p = .01$) and (2) rs-FC between right Planum Polare and left amygdala ($p = .02$). However, these pathways did not correlate with the behavioral measures. Our findings suggest that auditory motor pathways may modulate motor performance and mediate the DA responses in the striatum during rhythmic auditory motor synchronization.

Title: Diversity of dopaminergic and glutamatergic marker expression in the meso-diencephalic dopaminergic nuclei in mice

Authors: *M. FOUGÈRE, D. RYCZKO;
Univ. De Sherbrooke, Sherbrooke, QC, Canada

Abstract: Dopaminergic (DA) neurons are known to use glutamate as a co-transmitter. However, whether this occurs in all meso-diencephalic DA nuclei is not fully resolved. Here, we compared the expression of DA and glutamatergic markers in A8, A9, A11 and A13 in 6 to 18 weeks old male mice. First, we carefully identified the location of A8, A9, A11 and A13 nuclei in 40 µm coronal sections of wild type mice (n = 5 mice) using immunofluorescence experiments against the tyrosine hydroxylase (TH) or the dopamine active transporter (DAT). Then, we performed the same experiments in transgenic mice expressing a fluorescent protein (ZsGreen) in neurons expressing the vesicular glutamate transporter 2 (VGluT2) (VGluT2-ZsGreen mice). For each DA nucleus, we chose a representative section and counted bilaterally the neurons positive for TH, DAT or VGluT2. Results are expressed as mean ± sem. In A8 (n = 2 mice), we found 46 ± 17 TH-positive, 43 ± 24 DAT-positive and 149 ± 35 VGluT2-positive neurons. In A9, we found 77 ± 3 TH-positive (n = 4 mice), 31 ± 20 DAT-positive (n = 3 mice) and 188 ± 24 VGluT2-positive neurons (n = 4 mice). In A11, we found 32 ± 5 TH-positive (n = 4 mice), 0 ± 0 DAT-positive (n = 2 mice) and 218 ± 14 VGluT2-positive neurons (n = 4 mice). In A13, we found 105 ± 9 TH-positive (n = 3 mice), 0 DAT-positive (n = 1 mouse) and 83 ± 17 VGluT2-positive neurons (n = 3 mice). The percentage of TH-positive cells that were also positive for VGluT2 was 99 ± 1 % in A8, 99 ± 1 % in A9, 90 ± 5 % in A11, and decreased to 1 ± 1 % in A13. Conversely, the percentage of VGluT2 cells that were also positive for TH was 30 ± 4 % in A8, 42 ± 5 % in A9, 13 ± 2 % in A11 and 2 ± 1% in A13. Our results confirm that DAT is not present in A11 and A13, whereas TH is present in the four nuclei under study. More interestingly, whereas almost no DA neuron was positive for VGluT2 in A13, almost all DA neurons in A9 were also positive for VGluT2. This suggests that meso-diencephalic DA nuclei display a clear diversity in terms of co-transmitter content, with a gradient of co-expression of dopamine and glutamate that increases from rostral to caudal DA nuclei. Whether such diversity plays a role in the variety of behaviors that DA neurons control remains to be explored.

Title: Stimulation of the ventral roots activates regions of the dorsal horn that are necessary to trigger locomotor-like activity in the neonatal mouse spinal cord

Authors: *M. FALGAIROLLE, M. J. O'DONOVAN;
NINDS, NIH, Bethesda, MD

Abstract: Motoneurons can trigger locomotor-like activity and regulate the frequency of the ongoing rhythm in the isolated spinal cord of the neonatal mouse. They were believed to project to only inhibitory Renshaw cells, but they have recently been shown to also target a subset of excitatory, V3 interneurons. To visualize the interneurons activated by ventral root (VR) stimulation we expressed Gcamp6f (a genetically encoded calcium indicator) into excitatory (VGLUT2-cre), inhibitory (VGAT-cre) and cholinergic (ChAT-cre) neurons, thereby encompassing the three major interneuronal classes of the neonatal mouse spinal cord (P0-P4). We focused on the caudal lumbar segments (L5-L6) whose ventral roots, when stimulated, trigger locomotor-like activity more often than the other lumbar ventral roots. We used epifluorescence to image the lateral and dorsal aspects of the cord, as well as the medial aspect of the hemisected cord and the cut transverse face (after removing the caudal or the rostral segments). Following VR-stimulation, we found that glutamatergic and inhibitory neurons were activated in the lateral deep dorsal horn, the superficial dorsal horn and along the central canal. These interneurons were tonically activated by both dorsal and VR-stimulation, were depressed in the presence of dopamine or AMPA-receptor blockade, but remained active in cholinergic antagonists. In the presence of high divalent concentrations in the extracellular solution, the VR-evoked calcium signals were enhanced even though polysynaptic components of the dorsal root-evoked responses were depressed. No calcium signals were detected in these areas when VR-stimulation failed to evoke electrical activity in other ventral roots. Partial removal of the dorsal horn in the segment of the stimulated VR, blocked activation of these regions and the locomotor rhythm. However, in these preparations, stimulation of sacral afferents could still evoke tonic calcium signals and the locomotor rhythm indicating that the locomotor circuitry was intact. Labelling and electrophysiological recordings from these neurons will be performed to determine their inputs and outputs to determine the identity of the activated cells. These results suggest that although the dorsal horn is not required for the locomotor-like rhythm, activity in dorsal interneurons appears to mediate the effects of ventral root stimulation either by amplifying the excitability of the cord or by transforming the properties of the locomotor network. Title: Convergence and divergence of the excitatory drive to motoneurons within the spinal escape circuit in adult zebrafish

Authors: *I. PALLUCCHI[1], M. BERTUZZI[2], A. EL MANIRA[3];
[1]Karolinska Institutet, Stockholm, Sweden; [2]Neurosci., Karolinska Institutet, Solna, Sweden; [3]Karolinska Inst., Stockholm, Sweden

Abstract: Animals perform diverse motor actions to successfully navigate their environment. Swimming and escape are two locomotor behaviors that, in adult zebrafish, are mediated by distinct circuits. The swimming circuit comprises three speed modules, allowing a broad modulation of this behavior, making it possible to generate the locomotor rhythm and the smooth transitions in the locomotor speed. The escape circuit instead faces the necessity of ensuring a fast, strong and highly coordinated movement to avoid threats, and is mediated by activation of the fast primary motoneurons (pMNs). How the excitatory drive to the pMNs is organized within the spinal cord is still unclear. Using dual whole-cell patch-clamp recordings in the *ex-vivo* preparation of the adult zebrafish, we reveal a highly divergent connectivity pattern from a subset of dorsal V2a interneurons to pMNs. Indeed, a single escape V2a interneuron makes synaptic contact with all pMNs across several segments (up to 11 pMNs tested with a single V2a interneuron). The escape V2a interneurons are bidirectional, with a descending and an ascending axonal projection, and make synaptic connections with pMNs located both caudally and rostrally to their somata, showing a one-to-many broadcast of the synchronizing excitatory drive. The drive from a single escape V2a interneuron is shared among pMNs innervating the dorsal or ventral myotomes. Conversely, we reveal a high degree of convergence onto pMNs, with several escape V2a interneurons connected to the same pMN. These connections are mediated by mixed chemical and electrical synapses through which the state of the pMN can influence synaptic transmission. In addition, pMNs are also coupled via gap junctions, which seem to guarantee synchronization of the firing for a reliable execution of the fast and strong movement underlying escape. In conclusion, we reveal a novel circuit in the spinal cord, which contributes to the generation of the escape behavior through the excitatory drive provided by escape V2a interneurons to pMNs. Our results reveal that convergence and divergence of excitation within the spinal escape circuit ensures a powerful, synchronized output that engages fast motoneurons along the body to produce escape behavior.

Title: Brainstem command neurons that specify locomotor direction

Authors: *J. M. CREGG, R. LEIRAS, O. KIEHN;
Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Descending command neurons instruct spinal networks to execute basic locomotor functions, such as which gait and what speed. The command functions for gait and speed are symmetric, implying that a separate unknown system with asymmetry instructs locomotor direction—left or right? Here we report the discovery that *Chx10*-lineage reticulospinal neurons act to specify the direction of mammalian locomotor movements. *Chx10* neurons exhibit exclusive ipsilateral projection, and can arrest or decrease locomotor activity ipsilaterally without affecting the opposite side. This circuit mechanism acts as the basis for left or right locomotor movements in freely moving animals: selective unilateral activation of *Chx10* neurons causes ipsilateral movements whereas inhibition causes contralateral movements. Spontaneous forward locomotion can thus be transformed into an ipsilateral movement by initiating a brake on the ipsilateral side. We identify the contralateral superior colliculus as a principal input, and show that the superior colliculus imparts directional commands via *Chx10* reticulospinal neurons. Together these data describe the only known descending system with the capacity for directing left/right locomotor asymmetries.

Title: The role of dopaminergic transmission in olfactomotor processing in lampreys

Authors: *P.-A. BEAUSÉJOUR[1,2], J.-C. VEILLEUX[2], F. AUCLAIR[1], S. CONDAMINE[1], G. DAGHFOUS[1], C. NGOVANDAN[1], D. VEILLEUX[1], B. ZIELINSKI[3], R. DUBUC[1,2];

Abstract: Animals rely on chemical cues to guide locomotion towards olfactory targets such as preys and sexual partners. In the sea lamprey (*Petromyzon marinus*), a basal vertebrate, we have previously characterized a neural pathway responsible for olfactory-evoked locomotion (Derjean *et al.* 2010; PloS Biol 8(12): e10000567). The information travels from olfactory sensory neurons to a single glomerulus located in the medial part of the OB (medOB) from which projection neurons directly contact the posterior tuberculum (PT), a dopaminergic nucleus corresponding to the mammalian SNc/VTA. The PT then activates brainstem motor centers such as the mesencephalic locomotor region (MLR) and reticulospinal cells to activate spinal locomotor networks. The mechanisms by which the PT converts olfactory information from the medOB into a motor response remain undetermined.
In this study, we aimed to describe the connectivity from the medOB to the PT, notably to: (1) locate and identify the phenotype of PT neurons receiving medOB inputs, (2) describe neuronal activity generated in the PT following olfactory stimulation, and (3) investigate possible feedback mechanisms allowing the PT to modulate medOB transmission.
First, tracer injections and immunofluorescence revealed that the medOB sends abundant fibers to the PT and axons are seen close to dopaminergic, glutamatergic and GABAergic neurons co-labeled by a biocytin injection in the MLR. Moreover, multi-unit recordings revealed that several PT neurons are activated following electrical stimulation of the olfactory nerve or the medOB. Calcium imaging of PT neurons labeled with Calcium Green dextran injected in the MLR revealed different response patterns to olfactory stimulation.
We also found that dopaminergic (DA) neurons in the PT project to the medOB in addition to an intrinsic DA innervation. Intracellular recordings of reticulospinal cells displayed reduced responses to electrical stimulation of the olfactory nerve when DA was microinjected in the medOB, suggesting that DA neurons in the PT can also control the olfactory inputs they receive by modulating upstream medOB activity. Further experiments revealed that D2 and probably D1 receptors located in the medOB are involved in this modulation.
Altogether, these observations suggest that medOB projection neurons directly contact different cell populations within the PT, which then project to the MLR to drive locomotion. Moreover, DA neurons in the PT project back to the medOB providing a mechanism to gate olfactory inputs to the motor command system.

Title: Multi-faced functions of the reticulospinal systems involved in muscle tone regulation with respect to the modulation of neurotransmitters within the brainstem

Authors: *K. TAKAKUSAKI, M. TAKAHASHI, T. NAKAJIMA, R. CHIBA;
Asahikawa Med. Univ., Asahikawa, Japan

Abstract: The reticulospinal system is involved in state-dependent motor functions. Specifically, medullary reticulospinal neurons (RSNs), which are directly or via pontine reticular formation (PRF) neurons excited by cholinergic neurons in the pedunculopontine tegmental nucleus (PPN) are considered to induce muscular atonia during rapid eye movement (REM) sleep, while those excited by non-cholinergic neurons in the mesencephalic locomotor region (MLR) which corresponded to the dorsal part of the PPN and cuneiform nucleus are responsible for execution of locomotion during wakefulness. While not yet established, it has been hypothesized that the reticulospinal system is composed of a mixture of heterogeneous populations of RSNs having different functions, and the appropriate group of the RSNs could be selected to achieve state-dependent functions (Chase 1980). Because the PPN/MLR as well as the PRF are major targets of GABAergic, monoaminergic (noradrenergic and serotonergic), orexinergic and cholinergic systems that exhibit state-dependent alteration, here we examined how these neurotransmitter systems acting on the PPN/MLR and PRF altered the excitabilities of medullary RSNs, spinal interneurons and motoneurons innervating hindlimb muscles, resulting in modification of postural muscle tone in decerebrate cats. We observed that an activation of cholinergic PPN neurons sequentially activated cholinoceptive PRF neurons, RSNs in the dorsomedial part of the medullary reticular formation (MRF) and lumbar interneurons in the ventromedial part of the grey matter (inhibitory system) so that muscle tone was abolished. On the other hand, serotonergic projections to the PRF not only reduced the activity of the inhibitory system but excited ventromedial medullary RSNs and lumbar interneurons in the intermediate region (excitatory system), resulting in increasing the level of muscle tone. Moreover, GABAergic, monoaminergic and orexinergic projections to the PPN reduced the activity of the inhibitory system instead of increasing the activity of the excitatory system. These results suggest the presence of, at least, two sets reticulospinal-interneuronal systems with respect to the control of postural muscle tone, and either one is selected to develop state-dependent motor functions by

these neurotransmitter actions. The present findings may provide insights into the pathophysiological mechanisms of neurological disorders which associated with sleep-related motor disturbances such as narcolepsy and REM-sleep behavioral disorders.

Title: Endoscopic calcium imaging of brainstem V2a stop neurons

Authors: *J. SCHWENKGRUB, E. GATIER, J. BOUVIER, B. BATHELLIER;
Paris-Saclay Inst. of Neurosci. (NeuroPSI), Gif-sur-Yvette, France

Abstract: Medullary V2a "stop neurons" are a genetically-defined class of brainstem reticulospinal (RS) neurons, known to regulate the episodic nature of locomotion: their controlled activation arrests locomotion by depressing rhythm-generating circuits in the spinal cord. Yet, their endogenous activity during spontaneous initiation or arrest transitions of locomotor activity has not been described. In particular, whether V2a stop neurons are transiently recruited at or prior to locomotor offset, or instead constitutively activated when animals do not walk is an important piece of information for our understanding of the neuronal coding of locomotive state.
Despite methodological advances for *in vivo* brain imaging in mice, imaging the activity of select reticulospinal circuits in freely behaving mice has remained a technical challenge owing to the deep location of neuronal somata, and the intermingling of multiple cell types in the same area. To overcome this, we first explored the efficiency of various viral vectors (different AAV constructs, HSV) to express the fluorescent calcium sensor GCaMP6 selectively in subgroups of V2a neurons defined genetically (Chx10-expressing), spatially (somatic residence) and by their projection pattern (projection to the spinal cord). We found that the most robust labelling was achieved using a Cre-dependent AAV1 injected into the medullary reticular formation of Chx10-Cre animals. Following viral injections, a gradient index (GRIN) lens was implanted above the reticular formation to enable optical access to changes of fluorescence of individual V2a neurons by epifluorescence microendoscopy. PCA-ICA algorithms as well as manual ROI selection were

applied to allow accurate cell activity detection. We identified V2a neurons whose activity was correlated with halts in locomotion and found that their mean activity is increased during non-locomotive episodes compared to ongoing locomotion, but not constitutively. With the help of machine learning, we also found that the activity of V2a RS neurons can be a reliable predictor of the transitions to locomotor arrest.
To our knowledge, no other reports have successfully targeted V2a neurons for *in vivo* imaging of reticulospinal circuit activity. Our labelling and microendoscopy methodology coupled with behavioral monitoring helps to establish a better understanding of the contributions of subcortical pathways to motor processing.

Title: Complex locomotor sequences encoded by different command neurons in adult zebrafish

Authors: *E. M. BERG, L. MROWKA, A. EL MANIRA;
Karolinska Inst., Stockholm, Sweden

Abstract: The brain is spontaneously active even in the absence of sensory inputs. Such spontaneous activity was originally thought to play a role only during early development, whereas in adults it was regarded as “noise” that needs to be overcome to allow for a meaningful information transfer. Recently, however, an emerging concept regards this activity as biologically meaningful. Here, we extend this concept to motor behavior to determine if brainstem-spinal cord circuits in adult zebrafish can generate spontaneous, versatile motor sequences in the absence of any sensory inputs. We show that the isolated CNS of adult zebrafish produces spontaneous sequences of swimming with varying vigor, i.e. fluctuations in speed and amplitude. This coordinated locomotor activity represents an internally generated correlate of spontaneous behavior in the absence of any sensory inputs. These spontaneous sequences can be of slow, less vigorous swimming activity mainly engaging slow motor units or they can spontaneously develop into motor sequences that, after a slow, less vigorous start,

switch to a fast, more vigorous activity engaging large muscle units. The onset, duration and vigor of these spontaneous swimming sequences appear to be encoded by the activity of the nucleus of the medial longitudinal fasciculus (nMLF), which is known to drive locomotion in larval zebrafish. Using patch-clamp recordings, we reveal two distinct subtypes of neurons in the nMLF that selectively encode the different aspects of the spontaneous swimming sequences. The first subtype, which is located medially in the nMLF, encodes the onset and duration of the swim sequence and is active during slow, less vigorous swimming. The second subtype, located laterally, encodes the increase of vigor and becomes active during the transition to faster and stronger swimming of a spontaneous sequence. These two subtypes of nMLF neurons are spatially segregated and appear to receive inputs from different brain areas. In summary, we show that complex motor sequences are generated intrinsically in the absence of any sensory input and their onset, duration and vigor are encoded by specific midbrain command neurons.

Abstract: Different effects of $5HT_7$ receptor blockade on limb coordination in the neonatal and adult rats suggests that there may be major developmental changes in the influence of 5-HT on locomotion. Previous research has determined that electrically stimulating the parapyramidal region (PPR) in neonatal rats can initiate locomotor-like activity and the presumed mechanism of action is serotonergic (5-HT) as using a $5\text{-}HT_7$ receptor antagonist applied on the surface of the lumbar cord blocked the evoked locomotor-like activity. Similarly, the blockade of the $5HT_7$ receptors in adult rats can also halt fictive locomotion, but not over ground locomotion.

The aims of this study were to determine the changes during development of spinal 5-HT_7 receptors and the contribution of serotonergic neurons to the initiation or the facilitation of locomotion in adult rodents. The protein expression levels of 5-HT_7R were detected in different spinal segments in 3, 6,15 day old rats and adults (n=4-5/group) using Western Blot. For the selective excitation of 5-HT neurons, excitatory Designer Receptors Exclusively Activated by Designer Drugs (DREADDs, n=9) were stereotaxically injected into the PPR using adeno-associated viral vectors (AAV8-hSyn-DIO-hM3Dq) in adult female rats with Cre-recombinase in 5-HT neurons. After a recovery period experiments were performed in decerebrated (un-anesthetized) rats while recording lumbar ENG activity and arterial blood pressure. Mesencephalic locomotor region stimulation was used to induce fictive locomotor activity in order to assess changes after applying the DREADD actuator clozapine-N-oxide (CNO) via intracerebral (i.c.) injections. The injection site was verified post-hoc with frozen-sectioned tissue by mapping the DREADD fluorescent reporter protein. Aged matched, non-injected female rats were a used as controls (n=8). We examined changes in fictive locomotor output and BP responses. We found changes in $5HT_7$ receptor expression levels in multiple spinal regions over the age groups tested, with the lumbar cord showing a highly significant downregulation in adults when compared to younger rats. Our previous research (Armstrong et al., SFN 2017) used systemic injections of CNO, but it is now known that CNO metabolizes to clozapine, and clozapine can negatively influence the locomotor networks. By using i.c. injections, we have found that potential for back metabolism is reduced and we have more robust changes to both fictive locomotion and blood pressure after i.c. application of CNO. The i.c. injections of saline had no effect on the amplitude or frequency of BP or ENG output.

Title: Neuronal age-related recruitment and coordination among reticulospinal neurons control stimulus-dependent variability of escape behavior in larval zebrafish

Authors: M. TANIMOTO[1], *A. PUJALA[2], R. LU[3], N. JI[4], M. KOYAMA[1];
[1]HHMI Janelia Res. Campus, Ashburn, VA; [2]Neurosci., [3]Janelia Res. Campus, Ashburn, VA; [4]Univ. of California Berkeley, Berkeley, CA

Abstract: Reticulospinal (RS) neurons control various aspects of locomotion such as its initiation, duration, and termination. However, we understand little of how the activity is coordinated among RS neurons to produce a flexible locomotor repertoire. We chose to address this question in the context of escape behavior in larval zebrafish. During escape, a zebrafish transitions from fast whole-body movements to slower movements of the caudal part of the tail. As both the fast and slow phases display inherent and stimulus-dependent variability (Liu and Fetcho, 1999; Pujala and Koyama, 2019), escape provides an opportunity to examine the coordination of RS neurons and its role in behavior. We first examined Ca^{2+} responses of RS neurons with 2-photon Bessel beam imaging while delivering electrical stimuli either to the head or tail to induce variable escape responses. Behavior was monitored either with video monitoring of tail movements in head-fixed preparations or with EMG recordings of axial muscles in genetically paralyzed fish. This revealed distinct recruitment of RS neurons based on their differentiation time similar to hindbrain V2a neurons (Pujala and Koyama, 2019). Short-latency response was almost always accompanied by activation of the Mauthner cell, which is the earliest born neuron within the RS group. The activity of several other early-born neurons was modulated based on the strength of the fast phase of escape response. On the other hand, the activity of later-born neurons was dependent on the duration of the slow phase of escape. Loose-patch recordings further revealed that many neurons within the early-born group exhibit transient spiking only when fish exhibit strong movements during the fast phase of escape, whereas the later-born group exhibits spiking that is sustained until the end of the slow phase. Femtosecond laser ablations of each of these groups revealed their causal contributions towards a specific phase of the escape response: the early-born group contributes to the fast phase while the later-born group contributes to the slow phase. Preliminary single-cell labeling and paired recordings of RS neurons revealed spinal connectivity patterns consistent with a phase-specific role for each age group. Taken together, these analyses revealed temporally coordinated recruitment of distinct age groups of RS neurons, each of which contributes to flexibility within a particular phase of escape behavior. Moreover, these results opened a way to study the detailed circuit mechanisms of how neurons born at different times are coordinated together to produce coherent behaviors.

Title: Exploring inhibitory neuronal connectivity in the mouse locomotor circuit

Authors: *S. DI COSTANZO[1,2], G. GATTO[1], F. STAM[1], M. GOULDING[1];
[1]The Salk Inst. for Biol. Studies, La Jolla, CA; [2]Biol. Sci., Univ. of California San Diego, La Jolla, CA

Abstract: Terrestrial vertebrate animals generate a wide array of locomotor behaviors that rely on the timely coordination of flexor-extensor muscle activity across several joints to generate limb movement. This coordination is finely regulated by a core network of spinal cord interneurons (INs) defined as the locomotor central pattern generator (CPG). Previous studies from our laboratory found that two inhibitory IN populations within the CPG network, defined as V1 and V2b INs based on their developmental origin, regulate flexor-extensor motor activity during different phases of the walking step cycle. V1 INs control locomotor speed and suppress flexor activity during extension in the stance phase of walking, whereas V2b INs suppress extensor activity during the swing phase of walking. This evidence led us to ask whether this differential contribution to locomotion is determined by a distinct recruitment of these two classes of INs during walking. Thus, we decided to investigate the spinal and peripheral monosynaptic inputs onto V1 and V2b INs. We have used a combination of mouse genetics and viral rabies-based tools to perform an accurate anatomical analysis of their respective connectivity patterns. This involved the generation of a double stop mouse line to restrict the TVA receptor and the G protein expression to neurons expressing both *Cre* and *FlpO* recombinases. Using specific intersectional genetic tools, we were able to selectively infect V1 and V2b INs with an EnvA pseudotyped rabies virus. Interestingly, our results indicate that these two IN populations receive partially differential inputs from the local spinal circuit and from DRG afferents. So far, our data confirms the hypothesis that, while these two inhibitory IN populations encompass partially overlapping functional cell types, their differential connectivity to the spinal cord/DRG microcircuitry suggests they might be differentially recruited during the step cycle. By studying the anatomical connectivity of V1 and V2b neuronal circuits, we aim to clarify how the activity of individual inhibitory population help shape movement and how CPG INs integrate external cues from the environment, which is still largely unknown.

Title: Spinal V3 Interneuron subpopulations diversify along temporally ordered developmental pathways

Authors: *D. A. DESKA-GAUTHIER[1], J. BOROWSKA-FIELDING[1], H. ZHANG[1], J. B. BIKOFF[3], Y. ZHANG[2];
[2]Med. Neurosci., [1]Dalhousie Univ., Halifax, NS, Canada; [3]Dept. of Developmental Neurobio., St. Jude Children's Res. Hosp., Memphis, TN

Abstract: Animals exhibit a wide range of locomotor behaviours empowering their navigation through dynamic environments across land, sea and air. Spinal interneurons (INs) form the basic sensorimotor circuits that ensure coordinated spatiotemporal muscle contractions from leisurely walking, to high-speed running, to swimming. However, the functional architecture and heterogeneity of spinal IN circuits underlying their control of task-dependent locomotor outputs remains largely elusive. In the current work, through investigation of the cardinal V3 IN population, we reveal that molecularly discrete V3 subpopulations diversify along temporally-ordered early embryonic timelines forming heterogeneous laminar clusters, axon projection profiles, sensory innervations, and intrinsic electrophysiological and morphological properties. Furthermore, through an investigation of task-specific c-fos expression, we revealed that molecularly discrete dorsal V3 subpopulations are differentially recruited across distinct speed- and weight bearing-dependent sensorimotor behaviours. Thus, our current work indicates that developmentally and genetically discrete IN subpopulations are the building blocks of topographically clustered spinal circuits engaged across different locomotor tasks.

Title: Distinct neuronal drives from central locomotor circuits modulate breathing during exercise

Authors: *C. HÉRENT, S. DIEM, G. FORTIN, J. BOUVIER;
Paris-Saclay Inst. for Neurosci., CNRS, Gif-sur-Yvette, France

Abstract: When animals run, respiration increases to match the augmented energetic demand. Yet the neuronal bases of this homeostatic adjustment are poorly documented. Here we investigated, in mice, i) the nature of respiratory changes during acute locomotor exercise, ii) the possibility that central locomotor circuits directly modulate breathing, and iii) the identities of putative respiratory neuronal targets.
First, we combined chronic electromyographic recordings of the diaphragm with limb video-tracking in mice running on a treadmill and show that the breathing frequency increases immediately at the onset of locomotion. This operates without temporal coupling of the locomotor and respiratory rhythms, regardless of the locomotor speed and gait. We next addressed the possibility that the mesencephalic locomotor region (MLR), enabling locomotor initiation, may in addition modulate breathing. We show that photo-activation of glutamatergic MLR neurons can reset the respiratory rhythm and upregulates breathing frequency prior to locomotor movements. Since the respiratory frequency then further increases upon locomotor engagement, we also investigated a possible direct influence of the spinal locomotor central pattern generator (CPG) on respiratory activity using *ex-vivo* brainstem/spinal-cord preparations from neonatal mice. We find that activating the locomotor CPG increases the frequency of inspiratory-like activity.
Viral tracings indicate that the MLR sends collateral projections to the preBötzinger complex (preBötC), the main inspiratory rhythm-generator, while the locomotor CPG does not but rather targets the Retro-Trapezoid Nucleus (RTN), another essential population of respiratory neurons. Accordingly, genetic-deletion or chemical-silencing of RTN neurons, respectively *ex-vivo* and *in-vivo*, reduces the locomotion-induced respiratory increase.
Altogether, our work indicates that central locomotor circuits provide distinct drives to respiratory centers: 1) a descending feedforward drive from the MLR to the preBötC that may prime respiration in anticipation of exercise and 2) an ascending drive from the locomotor CPG to the RTN that increases respiratory frequencies during ongoing locomotion.

Abstract: In vertebrates including humans, the basic pattern of locomotor movements is generated by a neuronal network residing in the spinal cord (the spinal locomotor network, SLN), while the descending commands from the brain turn SLN on and off, control the vigor of locomotion, modify the basic pattern for steering, obstacle avoidance, etc. Forward locomotion can be evoked and its vigor can be controlled in the decerebrate preparation by stimulation of the mesencephalic locomotor region (MLR) of the brainstem. This experimental paradigm has been extensively used for investigation of SLN. However, due to technical difficulties related to recording of spinal interneurons during real locomotor movements, the experimental data related to operation of SLR during real locomotion with normal sensory feedback are extremely limited, and the majority of data were obtained during fictive locomotion in the paralyzed animals. In the present work, we managed to overcome technical problems and to record activity of putative spinal interneurons from L4-L6 during real MLR-evoked treadmill locomotion with normal sensory feedback in the decerebrate cat preparation. We analyzed their activity phases by taking into account the previously ignored information about stability of neuronal modulation in the sequential locomotor cycles. First, data with smaller variability are more reliable statistically per se. Second, one can suppose that interneurons constituting the SLN core, have more stable activity than those receiving locomotion-related input but not critically important for generation of locomotor movements. Our analysis allowed to reveal functional neuronal groups presumably generating the vertical and horizontal components of the step, and to characterize their location in the spinal cord. Based on analysis of the relationship between activity phases of the groups, we suggest functional connections between them and propose a novel model for generation of locomotion that combines the reciprocally active half-centers with the generating ring.

Abstract: In order to test the feasibility of self-organization in the spinal cord based on musculoskeletal mechanics and behavioral experience, we have designed a model creature with the simplest musculoskeletal system and sensor population that we thought might exhibit an interesting range of behaviors. The nervous system is composed of simplified, non-spiking neurons with linear transfer function and implementing a variant of Hebbian learning. We describe how randomly activated movement patterns such as generated in early development could give rise to naturally occurring connectivity patterns between sensors and spinal neurons. These are the first steps toward identifying how the CNS could potentially discover and utilize such adaptive mechanisms to help shape spinal circuits that ultimately facilitate the learning and performance of voluntary behaviors.

Title: Analysis of the transverse distribution of the locomotor CPG during different speeds of fictive locomotion

Authors: V. RANCIC, K. BALLANYI, *S. GOSGNACH;
Dept of Physiol., Univ. of Alberta, Edmonton, AB, Canada

Abstract: The basic rhythmic activity that underlies stepping is generated by a neural network, situated in the spinal cord, known as the locomotor central pattern generator (CPG). While a series of lesion experiments has demonstrated that the mammalian locomotor CPG is distributed throughout the lower thoracic and lumbar spinal cord, the specific transverse distribution of the component interneurons that comprise this neural network is unclear. Here we use an isolated, upright spinal cord preparation and evoke fictive locomotor activity of various frequencies either by electrical stimulation of the brainstem, or by the application of a series of pharmacological cocktails. This preparation enables us to identify locomotor-related neurons across the transverse plane of the spinal cord by discerning all those neurons that exhibit rhythmic Ca^{2+} oscillations which have the same frequency as electroneurogram activity recorded from the hindlimb ventral roots. Analysis of preliminary data indicates that locomotor-related interneurons are distributed throughout the ventral spinal cord with the majority located ventromedially. Interestingly, the specific neurons that are rhythmically active, and the overall pattern of activity observed, changes when the speed of fictive locomotion is altered. These findings are consistent with data indicating that there is a speed dependent recruitment of interneuronal populations during locomotion, and suggests that the locomotor CPG is not a static network, but rather the specific neurons recruited vary extensively based on demand.

Title: Cats stepping on a split belt treadmill reveal a functional organization of commissural interactions within the spinal locomotor circuits

Authors: E. M. LATASH[1], W. H. BARNETT[1], R. A. CAPPS[2], S. M. DANNER[4], A. FRIGON[5], I. A. RYBAK[4], *Y. I. MOLKOV[3];

Abstract: Rhythmic limb movements during locomotion are controlled by oscillatory neural networks/central pattern generators (CPGs) located in the spinal cord. It is considered that a separate CPG controls each limb. Dynamic interactions between CPG networks coordinate left and right limbs during locomotion. These interactions have been experimentally investigated using spinalized cats stepping on a split-belt treadmill. The speed of each belt was varied in a tied-belt or split-belt fashion while recording continuous gait transformations. In tied-belt experiments with increasing belt speed, swing phase duration remained relatively constant, whereas stance phase duration decreased. In this case, the gait represented a symmetric antiphase pattern, in which the swing phases of left and right legs were separated by intervals of dual support when both limbs were on the ground. In split-belt experiments, the locomotor pattern was perturbed asymmetrically. At low ratios of belt speeds, stance duration on the fast side decreased but cycle duration remained the same bilaterally. At high ratios of belt speeds, the cats produced multiple steps on the fast side for each step on the slow side. Split-belt experiments also revealed an asymmetric mode of synchronization in which stance on the slow side was initiated when stance on the fast side ended. Thus, the swing phase on the fast side immediately succeeded swing on the slow side without an interceding interval of dual support.We adopted these experimental results to elucidate potential neuronal mechanisms of interlimb coordination using a tractable mathematical model describing two interacting locomotor CPGs controlling left and right limb oscillations. Each CPG contained two neuronal populations mutually inhibiting each other representing flexor and extensor CPG half-centers. A slowly inactivating persistent sodium current governed dynamics of rhythmic activity in both neuron populations and neuronal synchronization within each population. An excitatory drive to the flexor population defined the oscillation frequency of each CPG and each flexor population received commissural inhibitory inputs from the contralateral flexor and extensor populations. We simulated split-belt locomotion by setting different oscillation frequencies in left and right CPGs. By analyzing model behavior under different conditions, we identified dynamic properties of the CPGs and organization of commissural interactions between them, allowing the model to reproduce experimental data on tied-belt and split-belt locomotion. Our results reveal an organization of commissural interactions within spinal locomotor circuits.

Title: Role of spinal V3 interneurons in left-right coordination of locomotor activity

Authors: N. A. SHEVTSOVA[1], H. ZHANG[2], S. DANNER[1], I. RYBAK[1], Y. ZHANG[2];
[1]Drexel Univ. Col. of Med., Philadelphia, PA; [2]Med. Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: Left-right coordination during mammalian locomotion is provided by several types of commissural interneurons (CINs) that mediate interactions between rhythm generating circuits located on each side of the spinal cord. It has been shown that alternation of left and right rhythmic activity in the cord involves V0 CINs. While V3 CINs have been implicated in left-right coordination, the mechanisms by which they interact with the spinal rhythm generators and regulate the locomotor activity remain elusive. To address this issue, we combined experimental studies with computational modeling. Fictive locomotor activity was evoked by NMDA/5-HT mixture in the isolated neonatal spinal cord of *Sim1*$^{Cre/+}$*; Rosa 26*$^{ChR2(H134R)-EYFP}$ mice, in which V3 interneurons could be photo-activated. Flexor and extensor activities were recorded from left and right L2 and L5 ventral roots, respectively. Bilateral photoactivation of V3 neurons slowed down the ongoing rhythm, prolonged extensor phase durations, increased the extensor burst amplitude, and, at high light intensities, could stop rhythmic activity. When photostimulation of V3 neurons was applied to one side of the cord, the locomotor cycle period and extensor burst durations on both sides were increased, but the degree of changes on the contralateral side was more significant than on the ipsilateral side. Further increase of the stimulation could eventually suppress the contralateral oscillations with a sustained extensor activity, while the ipsilateral rhythmic activity remained. To further delineate the V3 function, we developed a computational model of the spinal circuits consisting of two (left and right) rhythm generators (RGs) interacting via $V0_V$, $V0_D$ and V3 CINs. With the suggestion that V3 CINs provide mutual excitation between the left and right RG's extensor centers, the model was able to reproduce our experimental data described above. Additionally, the model was consistent with the well-established function of V0 CINs as the regulators of left-right alternation during locomotion,

which further validated our model. Based on the combined experimental and modeling studies, we suggest that V3 CINs provide mutual excitation between the left and right extensor centers.

Title: Correlating neural and behavioral responses in an insect model

Authors: *B. A. NAVIA, B. SHIN;
Andrews Univ., Berrien Springs, MI

Abstract: Phonotaxis in female cricket *Acheta domesticus* can be selective or unselective in response to model calls with varying syllable periods. Discrimination of and movement towards a model call implies that networks of neurons are activated when the call is recognized as attractive. Several approaches to demonstrate the influential role of auditory neurons in phonotaxis have been used with different levels of success. One such approach (current study) seeks to evaluate the behavioral and neuronal responses in the same animal, using identical auditory stimuli. This approach allows us to establish a correlation between the neuronal and behavioral responses, as well as to predict the behavior of the animal based on the response of an auditory neuron. A number of auditory neurons (in the brain and prothoracic ganglion) in this model have been identified and proposed to play a role in the control of phonotaxis. The L3 prothoracic auditory neuron has been suggested to influence syllable period selective phonotaxis in this species. In response to calls with attractive syllable periods, the L3 produces a burst of action potentials, which diminish in response to consecutive syllables. Such a decrease in the number of action potentials calculated as percentage is called decrement. Preliminary results indicate that syllable periods which produce positive phonotaxis, also elicit higher decrement values in the neuronal response of the same animal. In the lab, young (5-10 days), virgin females are more likely to respond phonotactically to calls with syllable period ranging between 50 and 70 ms. Older, virgin females (> 20 days), exhibit more variability in the range and number of syllable periods they respond to, which may or may not overlap with the range indicated for young ones. Implications of these findings are discussed.

Title: Testosterone levels regulate dopamine innervation in the inner ear of a seasonally breeding vocal fish

Authors: *J. PERELMUTER[1], L. DEMIS[2], R. A. MOHR[3], J. A. SISNEROS[4], P. M. FORLANO[5];

Abstract: Seasonally breeding vertebrates often undergo dramatic changes to sensory systems, facilitating the detection and evaluation of mates during courtship, however the mechanisms regulating these changes are not well understood. The plainfin midshipman (Porichthys notatus) is a marine teleost that migrates from deep water winter habitats to coastal breeding sites in the summer. Courting males use acoustic signals to attract females to their nests. Coincident with the transition from nonreproductive to reproductive state, females undergo both an increase in peripheral auditory sensitivity and a decrease in dopaminergic efferent innervation of the inner ear. Previous work has linked changes in gonadal hormone levels, including testosterone, to peripheral auditory plasticity. Furthermore, we have recently demonstrated that the summer reduction of dopamine in the inner ear results in a release of inhibition, contributing to the adaptive increase in auditory sensitivity. To determine if testosterone regulates dopamine, we ovariectomized nonreproductive, winter females and treated them with either testosterone or control elastomer implants and, after a 30-day period, assessed both circulating testosterone levels and dopamine innervation in the inner ear via immunohistochemical labeling with tyrosine hydroxylase (TH) antibodies. In the experimental group, testosterone levels were elevated and negatively correlated with the number of TH puncta (putative release sites of dopamine). These data support the hypothesis that a pre-migration increase in testosterone initiates the seasonal change to dopamine input to the inner ear, which directly alters peripheral auditory sensitivity. Androgenic regulation of dopamine may be a mechanism by which other seasonally breeding vertebrates synchronize reproductive readiness and nervous system plasticity.

Title: Molecular characterization of vocal neurons in Xenopus laevis

Authors: R. T. INAGAKI[1], S. RAGHURAMAN[1], L. LEAVITT[1], K. CHASE[1], T. STEEL[2], E. ZORNIK[2], B. M. OLIVERA[1], ***A. YAMAGUCHI**[1];
[1]Sch. of Biol. Sci., Univ. of Utah, Salt Lake City, UT; [2]Biol., Reed Col., Portland, OR

Abstract: A major goal of neuroscience is to understand the neural mechanisms of behavior. We have focused on the central vocal pathways of African clawed frogs (Xenopus laevis) to address this question because of the simplicity of its sound generating mechanism and the availability of fictive vocalizations that allow us to study the neuronal activity underlying behavior *in vitro*. Previously, we have identified a type of premotor neuron called Fast Trill Neurons (FTNs) in the central vocal pathways of the X. laevis, that are critical for vocal production in males. Previous electrophysiological studies showed that the FTNs express NMDA receptors and GABA/Glycine receptors. Molecular characterization of different types of neurons provide a foundation for discovering the functional role of each cell type in the circuit. In this study, we further explored additional molecules that are expressed by the FTNs in order to better predict the functional properties of the neurons. To this end, we used constellation pharmacology and single-cell RNA sequencing to characterize FTNs. Constellation pharmacology is a cell-based high-throughput phenotype-screening method that utilizes pharmacological agents to illuminate the cell-specific combination (constellation) of key proteins such as ion channels and receptors that define specific cell types. The technique involves imaging intracellular Ca^{2+} levels in >500 neurons in primary cell culture and monitoring neuronal response to a battery of ligands. Thus, the Ca^{2+} response profile generated by every neuron allows the identification of unique combinations of receptors and ion channels expressed by different neuronal cell types. Using this technique, we identified four classes of putative FTNs. In addition to their sensitivity to NMDA and GABA/glycine, these four classes of neurons showed sensitivity to substance P and/or ACh. Intracellular recordings obtained from FTNs using a whole-brain preparation verified that the neurons depolarize in response to substance P and/or ACh. In addition to these receptors, we have carried out single-cell RNA sequencing following the constellation pharmacology to

identify transcripts expressed by the FTNs. The identification of key proteins expressed by FTNs allows us to deduce the function of the neuron.

Title: Syntax information maximization: Optimizing classification of mouse ultrasonic vocalizations

Authors: ***S. HERTZ**, B. WEINER, N. PERETS, M. LONDON;
The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Vocal communication in animals is a prevalent behavior with practical implications for understanding the neural control of speech. Rodents are an attractive animal model for this purpose, but understanding their ultrasonic vocalizations (USV) is limited because we do not know the basic building blocks and their rules of assembly. Many algorithms for classifying USVs into syllables based on their individual acoustic features are constantly being developed, but there is currently no objective criterion to evaluate the quality of their results.
Here, we developed a statistical framework based on information theory (named Syntax Information Score, SIS) that allows comparison and ranking of arbitrary classification algorithms of sequential data. We further designed and tested a novel algorithm (Syntax Information Maximization, SIM) that showed that the SIS can be used to optimize the classification of USVs. To support the statistical framework, we composed a dataset by recording USVs during male-female interaction sessions (460,000 USVs grouped into 44,000 sequences). We used this dataset to compare the classifications of three popular algorithms. The statistical comparison showed that the classifications were fundamentally different and nonhomologous. In addition, Markov model analysis of the labeled USV sequences revealed high-order structures (i.e., syntax), with the label of a USV dependent on the labels of preceding USVs. As the Markov models differed between the algorithms, we developed the Syntax Information Score (SIS) that provides a quantitative comparison of classifications based on their predictive power. The SIS was used to measure the capabilities of the three algorithms to find regularities in the data. Finally, we designed and tested the Syntax Information Maximization (SIM) algorithm. The SIM

incorporates optimization of the predictive power as an integral driving force of a classification algorithm. We applied the SIM on a training-set of USV sequences, and showed that it was able to generalize to data that had not been considered before (the test-set), resulting with an improved classification of USVs.
Improvement in USV classification is crucial for interpreting social interactions, and for understanding neural control of vocalization. Our results demonstrate that USV syntax holds valuable information for achieving this goal.

Title: Using a sound source localization system to determine the function of mouse vocal signals during naturalistic group interaction

Authors: *M. R. WARREN, R. S. CLEIN, J. P. NEUNUEBEL;
Univ. of Delaware, Newark, DE

Abstract: Across the animal kingdom, acoustic communication is vital for transferring information between animals, conveying social status, reproductive interest, and kinship [Bradbury and Vehrencamp, 2011; Matsumoto et al., 2016; Moles et al., 2007]. Similar to other animals, mice vocalize in a myriad of social contexts [Kazdoba et al., 2016] and have therefore become a valuable model to study vocal communication [Burke et al., 2018]. There is, however, a lack of detailed knowledge about the information communicated between mice and how vocal signals shape social behavior. This is due to difficulties in identifying the vocal activity of specific individuals within social groups. We overcame this difficulty by employing an eight-channel microphone array system to track the vocal activity of individual mice within groups [Warren et al., 2018]. We discovered that mice emit specific types of vocal signals based upon their role in a social encounter: males acting aggressively typically emit signals that decrease in frequency, while males acting submissively emit signals that increase in frequency. While the results indicate that mice emit behaviorally-dependent vocalizations, we have been unable to determine the role these signals may play in shaping social behavior Therefore, to identify the function of signal emission, we used a conditional mouse model of deafness (B6.Pou4f3tm1.1; [Tong et al., 2011]) to selectively ablate hearing in adults (8-12 weeks) and, consequently, sever the flow of auditory information between animals. Genotype-matched groups of four mice (two males and two females), either hearing (WT; n = 6 groups) or conditionally deafened (Het; n = 6 groups), were allowed to freely interact over 5 hours. We found that hearing and deafened mice

engaged in similar numbers of social behaviors, including males following other males (Mann-Whitney; $Z = -0.75$, $p = 0.45$), males following females ($Z = 0.85$, $p = 0.58$), and males fleeing from other males ($Z = 0.66$, $p = 0.51$). When assessing context-dependent vocal emission, hearing mice replicated our previous findings, altering their vocal repertoire based upon behavioral context. Strikingly, deafened males also emitted context-dependent vocal signals. This novel finding, in conjunction with our ability to track the instantaneous behavior of multiple mice simultaneously, will allow us to determine the immediate behavioral response to these signals as a function of hearing ability. This will provide vital information about the role vocal signals play in mouse communication as well as the extent to which these signals communicate social information.

Title: Quantifying dynamic social and vocal behavior of freely interacting mice using a sound source localization system

Authors: *R. S. CLEIN[1], D. T. SANGIAMO[1], M. R. WARREN[1], J. P. NEUNUEBEL[2]; [2]Psychological and Brain Sci., [1]Univ. of Delaware, Newark, DE

Abstract: Across the animal kingdom, social status affects access to the resources necessary for survival and reproductive success. Social status is determined by the outcome of agonistic behaviors and stabilizes over time (Williamson et al., 2017). In mice, most studies examining social dominance focus on interactions that occur when hierarchical relationships are stable. However, a detailed understanding about the development of hierarchical relationships is lacking. We recorded unrestricted social interaction in mixed-sex (2 males and 2 females) groups ($n = 11$) of adult mice (B6.CAST-Cdh23Ahl+/Kjn, 13-21 weeks old). Interactions were recorded for 5 hours using a sound source localization system (Warren et al., 2018), and then courtship and agonistic behaviors were automatically extracted with a machine based learning system (Kabra et al., 2013). To quantify social status, we calculated a step function based on when male-male agonistic behaviors occurred. Each function allowed us to define discrete behavioral states where one male was engaging in all of the agonistic or submissive behaviors. Using these functions, we quantified the number of times that the aggressor changed (state changes), and the magnitude of the overall difference in social status. Across experiments, the number of state changes (14-125) and the overall difference in status (absolute values: 0.02-0.97) were negatively correlated ($r = -0.68$, $p = 0.02$). When examining how social status affected the

interactions between a male and female, we found that the male's overall status was not predictive of the number of courtship displays ($p = 0.10$) or propensity to interact with females immediately following an aggressive behavior ($p = 0.65$). Interestingly, a male's current behavioral state influenced his courtship displays. Males in an aggressive state engaged in more courtship chases than males in a submissive state ($p = 0.03$). Males in a submissive state, however, had a greater propensity to immediately interact with females following agonistic behaviors than their aggressive counterparts ($p < 0.01$). Additionally, submissive males vocalized more than aggressive males during the social interactions with females ($p = 0.02$). Taken together, these results suggest that a male's particular role in a recent agonistic experience impacts subsequent interactions with a female.

Title: Mechanisms of ultrasonic vocalization production in excised rat larynges

Authors: *J. HÅKANSSON[1], A. AGARWAL[2], C. P. ELEMANS[1];
[1]Univ. of Southern Denmark, Odense M, Denmark; [2]Dept. of Engin., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Murine rodents produce ultrasonic vocalizations (USVs; pitch ranging from 30 to 100 kHz) that play important social roles, such as mating and territorial defense. Furthermore, pup USVs are crucial to induce maternal search and retrieval behavior, while visual or olfactory cues are less relevant. Because USVs in rodents do not appear to be learned, they have become a vital and rapidly increasingly used translational tool for linking gene mutations to behavior in mouse and rat models of neurodevelopmental, communication, and autism spectrum disorders. These genetic models demonstrate significant acoustic changes that resemble the atypical vocalizations seen in human disorders. However, we cannot meaningfully relate acoustic features to experimental treatments or rodent models, because we have a critical lack of insight into which physical and physiological mechanisms of USVs are produced and controlled by the brain and which result from potential changes to the larynx physiology. To test the current outstanding hypotheses on how laryngeal morphology contributes to USV production in rats, we combined *in vitro* excised larynx experiments with computational flow models. USVs were produced only

when the arytenoids and vocal folds were opposed, leaving only a small opening at the dorsal region of the vocal folds, close to the arytenoid cartilages, which is consistent with *in vivo* endoscopic observations. Additionally, larynges were fixed in specific USV producing configurations and their 3D geometries were quantified from microCT scans. We then simulated fluid flow though the 3D geometries to estimate crucial control parameters of whistle frequencies. Furthermore, we tested the importance of the ventral pouch on rat USV production by experimental manipulations and showed larynges capable of producing USVs without air flow jet hitting the alar edge and resonating the ventral pouch.

Title: Take a deep breath: Sighing and vocal motor control in SD-rats

Authors: *T. RIEDE;
Midwestern Univ., Glendale, AZ

Abstract: Augmented breathing or sighing is a characteristic breathing pattern in rodents generated by dedicated midbrain neuron populations. Its main function is to prevent alveolar collapse, but in some species, most prominently in humans, augmented breaths are incorporated into vocal behavior. A role of augmented breathing for vocal production in other mammals is unknown. Here we utilize subglottal pressure recording in awake spontaneously behaving male Sprague Dawley rats to elucidate the role of augmented breaths in ultrasonic vocalization. Overall breathing rate is dependent on social context or motor activity. We found that sighing rate did not change in different contexts. Furthermore, rats place vocalizations into more than one fifth of their augmented breaths ("vocal sighing") during social interactions. Different call types and sometimes multiple calls were placed into the exhalation phase following an augmented inhalation. The exhalation phase changed in a call type specific manner. We also found differences in the shape of the augmented inhalation pressure signal preceding a vocal sigh. We conclude that vocal motor control is integrated with sighing behavior.

Title: Using degus to studying relationship formation between adult females

Authors: A. L. THATCHER, S. COOKE, K. WEBB, K. BUTLER, *N. INSEL;
Univ. of Montana, Missoula, MT

Abstract: Many animals form long-term social bonds that allow them to coordinate and cooperate with one another. In mammals, cooperative and affiliative behaviors are particularly common in females; for example, in degus (a rodent native to South America), unrelated females share burrows, nurse each-other's young, and show coordinated behaviors during digging and foraging. The process by which initial strangers come to learn about one-another to coordinate their behavior is not well understood. To study the behavioral dynamics of this learning, and thereby gain insight into the processes that allow animals to learn about one-another over time, we examined interactions between strangers over a sequence of multiple, "reunion" social exposures. Pairs of female degus were exposed separately to stranger and cagemate conspecifics for 20 min periods, with each exposure taking place once every other day over a 20 day period. Strangers were then co-housed for 24 hours, followed by two additional exposures of pairings with these "new cagemate" dyads and, separately, with new strangers. We found that strangers showed more interactions than cagemates, including more anogenital sniffing, agonistic behaviors, and face-to-face encounters. Unexpectedly, however, these differences persisted over multiple sessions, including after the 24 hour cohabitation period. Continued analyses are examining whether interaction patterns are unique to each dyad, and whether these change with experience. These data provide a foundation for unpacking constructs like "social recognition" into multi-dimensional patterns, different components of which may be expressions of distinct motivation and learning processes.

Title: A developmentally conserved neural signature of social-vocal communication in the motor cortex of Egyptian fruit bats

Authors: *M. C. ROSE, T. A. SCHMID, J. E. ELIE, M. M. YARTSEV;
Univ. of California Berkeley, Berkeley, CA

Abstract: Across species social communication often occurs through vocal interactions, yet the brain mechanisms that mediate social-vocal communication signals, especially under natural conditions, remain poorly understood. To better understand its neural basis, we chose to study social-vocal communication in the Egyptian fruit bat (*Rousettus aegyptiacus*). We chose this species for its mammalian brain organization, diverse social-vocal repertoire and vocal plasticity capabilities. We used lightweight, wireless electrophysiology to record neural activity from the Frontal Motor Area (FMA) of freely behaving bats and on-animal audio systems and microphones to precisely measure vocal production and perception during social interactions. Because previous reports have indicated that the Egyptian fruit bat's vocal repertoire undergoes developmental changes over the age range examined here, we looked for corresponding differences in neural activity. Next, as vocal production is exclusively tied to social behavior in Egyptian fruit bats, we looked for correlation in activity across brains during vocalization events. Finally, we asked how neural activity is affected by artificial laboratory training by comparing FMA activity during naturalistic social-vocal behavior to highly-trained vocal production behavior. Taking this approach, we assessed vocalization related FMA neural activity for: 1) differences between juveniles and adults 2) cross-brain neural synchrony and 3) differences between naturalistic and highly-trained vocal behavior. Combined, we present first steps toward understanding how motor cortical activity functions during social-vocal interactions.

Title: Correlated neural activity across the brains of socially interacting bats

Authors: *W. ZHANG, M. M. YARTSEV;
Bioengineering, Univ. of California Berkeley, Berkeley, CA

Abstract: Social interactions occur between multiple individuals, but what is the detailed relationship between the neural dynamics across their brains? To address this question across timescales and levels of neural activity, we used wireless electrophysiology to simultaneously record from the frontal cortex of pairs of bats over ~100-minute-long sessions. During these sessions, the bats engaged in a wide range of natural social interactions, which we characterized at a detailed level. We found that neural activity was remarkably correlated between their brains over timescales from seconds to hours. The correlation depended on the two individuals sharing a social environment and was most prominent in high frequency local field potentials (>30 Hz) and local spiking activity, both of which are neural signals that were under-explored in similar previous studies in humans. Furthermore, the degree of neural correlation covaried with the extent of social interactions, and an increase in correlation preceded their initiation. Lastly, we characterized the neural representations of the social behaviors the interacting bats engaged in. Together, the results show that inter-brain neural correlation is an inherent feature of natural social interactions, reveal the domain of neural activity where it is most prominent, and provide a foundation for studying its functional role in social behaviors.

Title: Unraveling the evolution of brain networks for complex vocal behavior through comparative epigenomics across mammals

Authors: *M. WIRTHLIN[1], S. ANNALDASULA[1], I. KAPLOW[1], T. A. SCHMID[3], S. VERNES[5], W. R. STAUFFER[6], M. M. YARTSEV[4], A. R. PFENNING[2];

Abstract: Vocal behavior is a highly variable behavioral phenotype, ranging from simple grunts and hisses to the complex vocal learning exemplified by human speech. Although the neuroanatomical, electrophysiological, and molecular bases for this behavior are being explored in a handful of species, an overall picture of how genomic differences subserve this trait remain elusive. In the brain regions that control the production of learned vocalizations, we previously identified convergent changes in gene expression that were unique to multiple vocal learning species, and not present in their vocal non-learning relatives. Given the intriguing possibility suggested by these findings that there may exist fundamental genetic mechanisms for the evolution of this behavior, we sought to discover whether this convergence also exists at the level of the gene regulatory sequences that control gene expression. We assessed the epigenomic profile of several brain regions involved in vocal control in Rhesus macaque (Macaca mulatta) and the Egyptian fruit bat (Rousettus aegyptiacus) using ATAC-seq. Drawing from these and other publicly available open chromatin datasets, we developed and implemented an improved pipeline for mapping putative gene regulatory sequences across a wide range of mammalians species. Despite the extensive nucleotide sequence turnover occurring over the >150 million years of mammalian evolution, we were able to identify conserved sets of regulatory sequences displaying higher-than-expected overall conservation in brain-specific regulatory activity. We then analyzed the identified orthologous regulatory sequences to assess the possibility of sequence evolutionary rate convergence and differential transcription factor binding that could explain the differences in gene regulatory activity in brain regions specifically involved in vocal behavior, which could ultimately explain the evolution of phenotypic differences in vocal behavior observed across species. Our work points to genomic changes in gene regulatory sequences, rather than changes in genes themselves, as a hotbed for the evolution of mammalian vocal behavior. We discuss these findings within the framework of a novel hypothesis for the evolution of complex vocal behavior.

Title: Compensatory mechanisms affect sensorimotor integration during ongoing vocal-motor acts in marmoset monkeys

Authors: *J. LÖSCHNER, T. POMBERGER, S. R. HAGE;
CIN, Univ. of Tuebingen, Tuebingen, Germany

Abstract: In vertebrates, any transmission of vocal signals faces the challenge of acoustic interferences such as heavy rain, wind, animal, or urban sounds. Consequently, several mechanisms and strategies have evolved to optimize the signal-to-noise ratio. Examples to increase detectability are the Lombard effect, an involuntary rise in call amplitude in response to masking ambient noise, which is often associated with several other vocal changes such as call frequency and duration, as well as the animals' capability of limiting calling to periods where noise perturbation is absent. Previous studies revealed rapid vocal flexibility and various audio-vocal integration mechanisms in marmoset monkeys. Using acoustic perturbation triggered by vocal behavior, we show that marmosets are capable of rapidly modulating call amplitude and frequency in response to perturbing noise starting after call onset. The animals swiftly increased call frequency after noise onset indicating a rapid effect of perturbing noise on vocal motor pattern production. Call amplitudes were also affected. Interestingly, however, the marmosets did not exhibit the Lombard effect as previously reported but decreased their call intensity in response to perturbing noise. Our findings indicate that marmosets possess a general avoidance strategy to call in the presences of ambient noise and suggest that these animals are capable of counteracting a previously thought involuntary audio-vocal mechanism, the Lombard effect, presumably via cognitive control processes.

Title: Single unit recordings in the brainstem of vocalizing marmoset monkeys

Authors: *T. POMBERGER, S. R. HAGE;
CIN, Univ. of Tuebingen, Tuebingen, Germany

Abstract: Chronic recordings with multi-electrode arrays are widely used to study neural networks underlying complex primate behaviors. Most of these systems are designed for studying neural activity in the cortical hemispheres resulting in a lack of devices being capable of simultaneously recording from ensembles of neurons in deep brainstem structures. However, to fully understand complex behavior, it is fundamental to also decipher the intrinsic mechanisms of the underlying motor pattern generating circuits in the brainstem. We report a light-weight system that simultaneously measures single-unit activity from a large number of recording sites in the brainstem of marmoset monkeys. It includes a base chamber fixed to the animal's skull and a removable upper chamber that can be semi-chronically mounted to the base chamber to flexibly position an embedded micro-drive containing a 32-channel laminar probe to record from various positions within the brainstem for several weeks. The current system is capable of simultaneously recording stable single-unit activity from a large number of recording sites in the brainstem of vocalizing marmoset monkeys. We found single unit activity that is correlated to vocal-motor output as well as auditory activity in deep brainstem structures. The semi-chronic implantation of laminar electrodes into the brainstem of behaving marmoset monkeys opens new research possibilities in fully understanding the neural mechanisms underlying vocal pattern generation in marmoset monkeys.

Title: Arousal states underlying vocal behavior in macaque monkeys

Authors: *C. RISUENO SEGOVIA[1], P. CHAMPEROUX[2], S. R. HAGE[3];
[1]Werner Reichardt Ctr. For Integrative Neuroscien, Tübingen, Germany; [2]Ctr. de Recherches Biologiques, Baugy, France; [3]CIN, Univ. of Tuebingen, Tuebingen, Germany

Abstract: Long-tailed macaques (*Macaca fascicularis*) have an extensive vocal communication repertoire, which they use in a variety of behavioral contexts. However, the physiological states underlying this behavior are still largely unknown. According to recent publications, arousal dynamics are linked to vocal output in marmoset monkeys. In this study, we investigate the correlation of vocal behavior in freely moving cynomolgus monkeys with several measures of the autonomic nervous system. For that, we use wireless transmitters implanted in the monkeys to telemetrically monitor ECG, blood pressure and activity, and relate these measures with simultaneously recorded vocalizations. Our results indicate that the vocal production of cynomolgus monkeys is coupled with different parameters of the autonomic nervous system such as heart rate, respiratory rate, ECG waveform and blood pressure.

Title: Genomic responses to selection for behavior in tame and aggressive foxes

Authors: *A. V. KUKEKOVA[1], J. L. JOHNSON[1], H. M. RANDO[1], L. N. TRUT[2];
[1]Animal Sci., Univ. of Illinois at Urbana-Champaign, Urbana, IL; [2]Inst. of Cytology and Genet. of the Russian Acad. of Sci., Novosibirsk, Russian Federation

Abstract: Tame and aggressive strains of red fox (*Vulpes vulpes*) have been developed in the famous long-term selective breeding program known as the Russian farm-fox experiment. We sequenced and assembled the red fox genome and re-sequenced a subset of foxes from the tame, aggressive, and conventional farm-bred populations to identify genomic regions associated with the response to selection for behavior. Analysis of the resequenced genomes identified 103 regions with either significantly decreased heterozygosity in one of the three populations or increased divergence between the populations. A strong positional candidate gene for tame behavior was highlighted: *SorCS1,* which encodes the main trafficking protein for AMPA glutamate receptors and neurexins and suggests a role for synaptic plasticity in fox domestication. Other regions identified as likely to have been under selection in foxes during domestication include genes implicated in human neurological disorders, mouse behavior, and dog domestication. The fox represents a powerful model for the genetic analysis of affiliative and aggressive behaviors that can benefit genetic studies of behavior in dogs and other mammals, including humans.

Title: The effects of simulated predation on shoaling behavior in zebra fish (Danio rerio)

Authors: *J. BOLES, I. TILMONT, J. MONELLY, E. YORK, K. POND, O. TUMINELLI, A. JOHNSON, K. WIENS, A. VELKEY;
Christopher Newport Univ., Newport News, VA

Abstract: Zebrafish (Danio rerio) are emerging as a useful model to investigate cognitive and behavioral disorders, including anxiety and post-traumatic stress disorder. Individual zebrafish responses to anxiogenic stimuli have been well documented, but anxiety behaviors within a social context are less understood. Zebrafish innately form shoals with one another, and aggregated zebrafish exhibit unique behaviors, which makes shoaling a powerful tool in investigating how social interaction influences individual zebrafish behaviors. The current study seeks to understand the effects of a social context on fear responses in zebrafish. Using a novel

three-chamber stimulus avoidance paradigm, shoals of six zebrafish were exposed to models of a sympatric predator, a freshwater needle-nose gar (Xenentodon cancila), of varying fidelity. These models included a live needle-nose gar, a video recording of the needle-nose gar, and a realistic motorized lure. Behaviors were analyzed with an automated behavior tracking software for average distance between fish, time spent in each zone of the tank, number of transitions between zones, average swim speed, swim speed variability, and time spent freezing. Against all stimuli, shoals spent more time at the bottom of the observation tank, confirming the anxiogenic nature of these models, but the live predator elicited the most robust diving response. In addition, the live predator evoked the most distinct avoidance response, while the video yielded mixed zone preferences, and the motorized model appeared to induce an approach response. These findings suggest that zebrafish are able to distinguish between similar visual stimuli, such as a live predator and recorded predator, and shoaling may reduce the potency of these stimuli, making a more realistic stimulus necessary in research. This project serves as a basis from which experimenters can further dissect the anxiety responses in aggregated zebrafish, enhancing neuroscientists' understanding of the zebrafish behavioral model with respect to psychiatric disorders and social behavior.

Title: Sexually dimorphic behavioral responses in zebrafish social choice

Authors: T. BETTS[1], I. DANSTROM[1], J. BOLES[1], L. O'NEIL[1], E. YORK[1], K. POND[1], G. SCHOLERFIELD[1], J. PARKER[1], M. CIRA ANGEL[1], K. ELEFTERIOU[1], R. TALIBI[1], A. J. VELKEY[1], ***K. M. WIENS**[1,2];
[1]Christopher Newport Univ., Newport News, VA; [2]Bay Path Univ., Longmeadow, MA

Abstract: Zebrafish (*Danio rerio*) are an excellent model organism for the comparative study of vertebrate social behavior. One characteristic of zebrafish social behavior is their tendency to aggregate in groups, known as shoals. Zebrafish exhibit sexually dimorphic behavior in swimming patterns, shoal size preference, aggression, and habitat. However, it is unknown if zebrafish exhibit sex differences when subjects are given a choice between social stimuli of varying visual fidelity. This study examined the behavioral responses of male and female zebrafish after the presentation of three variations of social stimuli: live shoal, video-recorded shoal, and a motorized lure mimic. Responses were analyzed with Ethovision XT 10 to identify

behavioral response patterns related to location within the tank, swim velocity, moving versus freezing, or zone transitions. Consistent with our previous studies, both sexes displayed a preference for live conspecifics over motorized or video shoals. However, this new study indicated that males and females had distinct responses to the different stimuli. Males were more exploratory in all stimuli combinations, and tended to prefer the bottom corners of the tank. In contrast, female zebrafish generally used the entire column to inspect the preferred stimuli and were less exploratory across stimuli. Our findings suggest that this aspect of zebrafish social behavior is sexually dimorphic.

Title: Early social isolation reduces social interactions in adult planarians and reduces neural activation in sensory processing brain regions

Authors: *S. GUARIGLIA[1], S. M. ORTIZ[2], B. KOLSIN[2], C. KNAPSKI[2];
[1]New York State Inst. for Basic Res., Staten Island, NY; [2]St. Josephs by the Sea HS, Staten Island, NY

Abstract: Planarians are routinely used to study regeneration and early development. Following head amputation, planarians are capable of regenerating their brain within seven days. In an attempt to characterize planarians for their utility in studying neurodevelopment, our laboratory is interested in identifying and characterizing behaviors that are relevant to disorders of neurodevelopment, namely Autism Spectrum Disorders (ASD). Therefore, the objective of this work was to determine if planarians engage in social interactions and if so, to identify the anatomical regions in the planarian brain that are involved in the regulation of social behavior. To assess planarian social interactions, we developed and validated a novel behavioral assay that allows for rapid and reproducible identification of social interactions. In the assay, planarians are placed into a novel open field, and their spatial location is recorded every ten minutes. The nearest neighboring distance (NND) between planarians is averaged at each time point. We were able to demonstrate that exposure to MK-801, a potent NMDA receptor antagonist which is known to impair social interactions in other model organisms, increased the NND between planarians, suggesting that social interactions in planarians are also reduced. Once our assay was validated, we went on to determine if the environment of planarian development could influence

adult social behavior. In our first set of these experiments, we demonstrated that planarians who develop in isolation (individually housed planarians; IHP) are less social than planarians that are left to develop in a group setting (Group-Housed Planarians; GHP; $p < 0.0001$; $F(7,144) = 161.1$). We then went on to map the brain regions that are involved in the regulation of social behavior using c-fos expression as an indicator for neural activity. We were able to determine that GHP have a significant increase in neural activation as compared to IHP when presented with diffusible social cues from novel planarians ($p < 0.0001$; $F(3,8) = 215.8$). Finally, we were able to demonstrate that c-Fos expression patterns change and are most prevalent in the signal processing regions in cephalic branches IV-IX when they are presented with social cues. Together, our work introduces a novel, high throughput behavioral assay for the assessment of social interactions in planarians along with functional anatomical correlates of the planarian brain which regulate such social interactions. Since planarians share many primary neural correlates with vertebrate systems, our work may be useful for teasing out intricacies in the understanding of social behavior.

Title: Resting state functional connectivity under stress differs across the hormonal contraceptive cycle

Authors: *A. Y. HERRERA[1], P. NASSERI[2], K. GILLETTE[3], S. FAUDE[3], J. WHITE[3], R. VELASCO[3], M. MATHER[1];
[1]Leonard Davis Sch. of Gerontology, [2]Neurosci. Grad. Program, [3]USC, Los Angeles, CA

Abstract: Previous studies indicate a negative correlation between stress-induced change in cortisol and functional connectivity of memory circuits, including between right and left hippocampus and between parahippocampus and left middle temporal gyrus. However, this work is limited to men. Women using hormonal contraceptives (HC) are reported to show similar memory patterns to men, however, they also show smaller cortisol responses to stress than men. In this study, we aimed to investigate the relationship between cortisol response to stress and resting state functional connectivity (rsFC) after stress in women using hormonal contraceptives. We used pulsed arterial spin labeling (PASL) to investigate rsFC of memory circuit regions after stress in women using 28-day monophasic HC. To examine the effects of synthetic hormones,

we tested twenty healthy young women twice across the HC cycle, once during days 8 to 21 (hormone-present phase) and once during days 24 to 28 (hormone-absent phase). In each phase, women completed the cold pressor test to increase cortisol levels and completed a resting state scan 40 minutes after stress onset. Right and left hippocampus, bilateral parahippocampus and left middle temporal gyrus were selected as seed regions for rsFC analyses. Based on the associations between change in cortisol and rsFC summarized above, we specifically tested the association between change in cortisol from baseline to 40 minutes after stress onset and rsFC between: 1) left and right hippocampus and 2) bilateral parahippocampus and left middle temporal gyrus.We found that change in cortisol was significantly negatively correlated with rsFC between bilateral parahippocampus and left middle temporal gyrus during the hormone-present phase. We found no relationship between change in cortisol and rsFC between left and right hippocampus during this phase. No associations were found for hormone-absent phase.Our results suggest that stress exerts different effects on rsFC of memory circuit regions across the contraceptive cycle. Based on other work showing better verbal memory during the hormone-present phase and the role of left middle temporal gyrus in verbal learning and memory recall, our findings suggest women may be offered some protection against stress effects on verbal memory during the hormone-present phase. Further studies are needed to investigate the factors modulating this association across the contraceptive cycle.

Title: Alterations in progesterone activity affects serotonergic innervation of the medial prefrontal cortex and produces deficits in complex cognitive behaviors

Authors: *A. PHILLIPS[1], C. K. WAGNER[2];
[1]Univ. at Albany State Univ. of New York, Albany, NY; [2]Univ. Albany, Albany, NY

Abstract: The mesocortical serotonergic pathway, comprised of innervation of the medial prefrontal cortex (mPFC) arising from serotonergic neurons in the dorsal raphe nuclei (DRN) of the midbrain, regulates complex cognitive function in adulthood. Disruptions in the normal development of this pathway may produce deficits in complex cognitive behaviors in adulthood. Progesterone receptor (PR), a powerful transcription factor, is transiently expressed within the

DRN and layers II/III of the mPFC during periods of synaptogenesis in this circuit, suggesting that PR activity during postnatal life may play a critical role in the maturation of the mesocortical serotonergic pathway. In the present studies, pharmacological inhibition of PR activity or exposure to the synthetic progestin, 17α-hydroxyprogesterone caproate (17-OHPC), neonatally decreased the density of SERT-ir fibers in the prelimbic mPFC at P28 in layers I, V and VI. Further, decision making, as measured in the delay discounting task, was altered and anxiety-like behavior was increased in the elevated plus maze in adulthood following neonatal administration of 17-OHPC. These findings have clinical implications as 17-OHPC is administered to pregnant women at-risk for premature birth.

Title: Clinically relevant synthetic progestin alters medial prefrontal cortex microglial phenotype and density in a sex-specific manner

Authors: *M. LOLIER, C. K. WAGNER;
Univ. at Albany, Albany, NY

Abstract: 17-alpha-hydroxyprogesterone caproate (17-OHPC) is a synthetic progestin commonly prescribed to pregnant women at risk for recurrent preterm birth. 17-OHPC can be transferred from the maternal compartment to the fetal compartment of the placenta *in situ*, and is detected in the fetal plasma up to 44 days after the last injection. The potential impact on cortical development should not be overlooked, as the timing of 17-OHPC administration coincides with critical periods of mesocortical dopamine pathway development, a neural circuit that regulates complex cognitive behaviors. In rodent models, nuclear progesterone receptor (PR) is expressed in dopaminergic neurons in the ventral tegmental area (VTA) that project to the medial prefrontal cortex (mPFC). 17-OHPC administration during development results in significant changes in dopaminergic innervation of layer 5 of the prelimbic area (PL) of the mPFC in a sex specific manner. 17-OHPC treated females have a significantly narrower tyrosine hydroxylase-ir (THir) fiber dispersion than control females, with no treatment differences in males. The significant decrease in THir dispersion in 17-OHPC treated females abolishes a sex difference observed in control animals. These changes in early innervation are believed to contribute to the deficits in cognitive flexibility observed in adulthood. In the present study, the

effects of 17-OHPC on microglia were examined. Preliminary results demonstrate a sex difference in microglia morphology in which control females have more microglia with an activated phenotype than males. This sex difference is abolished with 17-OHPC treatment such that 17-OHPC treated females have significantly fewer microglia with an activated phenotype than control females, and have comparable numbers to 17-OHPC males. Additionally, there is a trend toward significant differences in the density of microglia, in which 17-OHPC females have fewer microglia than control females, and 17-OHPC males have more microglia than control males. Results suggest that exposure to 17-OHPC during development may fundamentally alter cortical development perhaps, in part, through changes in microglia function. Consideration should be given to the potential effects of 17-OHPC on neural development in children.

Title: Dose-dependent effects of testosterone on spatial learning strategies and brain-derived neurotrophic factor in male rats

Authors: *M. D. SPRITZER[1], K. J. ZHANG[1], R. A. RAMDEV[2], N. J. TUTA[2];
[1]Biol., [2]Neurosci., Middlebury Col., Middlebury, VT

Abstract: We have previously shown that testosterone has complex dose-dependent effects on spatial working memory in male rats. Additionally, a low physiological dose of testosterone biased males toward using a response strategy, whereas a high physiological dose biased males toward using a place strategy. The primary goal of this experiment was to determine whether the demonstrated preference for a particular learning strategy was associated with a better ability to employ that strategy on a spatial task. Additionally, we tested whether brain-derived neurotrophic factor (BDNF) might be a mechanistic link between testosterone and spatial memory. All rats (n = 10-15/group) were bilaterally castrated and given one of three daily injection doses of testosterone propionate (0.125, 0.250, or 0.500 mg/rat) or the drug vehicle (control group) starting 7 days prior to the first day of behavioral testing. A plus-maze was used to test rats on either a place task (learning the position of a goal arm relative to distal spatial cues) or a response task (learning to turn a particular direction). All rats were given 100 trials on the maze, and criterion was reached when a rat made 9 out of 10 correct choices. We found that a lower testosterone dose (0.125 mg) significantly improved rats' performance on a response task,

whereas a higher testosterone dose (0.500 mg) improved a rats' performance on a place task. Rats injected with an intermediate dose (0.250 mg) performed poorly on both tasks, presumably because these rats were unable to effectively employ either spatial strategy effectively. Brain tissue from the prefrontal cortex, hippocampus, and striatum was collected 24 h following behavioral testing, and ELISAs were used to quantify concentrations of brain-derived neurotrophic factor (pro- and mature-BDNF). Testosterone had significant dose-dependent effects on BDNF levels in the hippocampus and striatum, but not the prefrontal cortex. Though there were some differences between the place and response experiments, a low dose of testosterone (0.125 mg) increased total BDNF in the striatum, and a high dose (0.500 mg) increased total BDNF in the hippocampus. Mature BDNF and proBDNF levels correlated with each other. Learning the place-task relies on hippocampal function, whereas learning the response-task relies on striatal function. Thus, the same doses of testosterone that enhanced learning on the place and response tasks, enhanced BDNF levels in the expected brain regions, hippocampus and striatum, respectively.

Title: Cognitive impairments induced in a middle aged rodent model of androgen deprivation therapy for prostate cancer are reversed with the antidepressant vortioxetine

Authors: *A. M. SHARP[1,2], A. DORNBUSCH[3,4], J. GELFOND[5], T. L. JOHNSON-PAIS[3,4], R. J. LEACH[6,4,7], M. LISS[6,4,10], A. C. SULLIVAN[2,8,9], I. M. THOMPSON[6,11], D. Abstract: Androgen deprivation therapy (ADT) is the primary treatment for late-stage prostate cancer. However, it is associated with several serious side effects, including profound cognitive impairment that is observed in more than half of patients treated with ADT. This significantly

reduces quality of life for cancer survivors and their families. It is important to improve the cognitive side effects of ADT, as approximately 44.8% of patients will undergo this type of treatment. The most prominent deficits observed in patients are observed in cognitive domains mediated by the medial prefrontal cortex (mPFC) and hippocampus (Hipp), including executive function and spatial recognition memory, respectively. Thus, to address the mechanisms underlying these effects, we have used the Attentional Set-shifting Test (AST) and the Novel Object Location (NOL) Test to assess cognitive function after surgical castration as a rodent model of ADT. Preliminary studies in our lab indicate that ADT-induced cognitive impairments on these tasks in young-adult Sprague Dawley rats can be reversed with chronic administration of a novel multimodal antidepressant, vortioxetine (VTX; 28 mg/kg/day for 2 weeks). This suggests that VTX, which has proven efficacy in improving cognitive impairment associated with depression, may be a novel therapeutic to alleviate ADT-induced cognitive impairments as well. Because prostate cancer primarily afflicts men around the age of 65, cognitive impairments in ADT-patients may be influenced by age-related cognitive decline. Therefore, to investigate the potential interaction of age and ADT, we are investigating effects in middle-aged 12-month-old rats, an age at which mild age-related cognitive impairments begin to emerge. We hypothesize that castration will induce cognitive impairment in middle-aged rats as it did in young adult male rats, and the deficits may be exacerbated in the aged rats. Further, we hypothesize that VTX will reverse the deficits in castrated middle-aged animals, as it did in the younger population. Early results indicate that VTX is able to reverse deficits associated with ADT in middle-aged animals on the AST and NOL tests back to levels comparable to intact aged controls. These studies are ongoing. Experiments are underway to investigate changes in functional connectivity of the mPFC and dHipp in the aged population by measuring changes in evoked local field potentials. Overall, this project may identify new targets for reversing cognitive impairment after ADT for the treatment of prostate cancer.

Title: Mental rotation task performance in a gender diverse Thai sample: A test of neurohormonal theory

Authors: *L. T. THURSTON[1], M. N. SKORSKA[2], D. E. PERAGINE[1], L. A. COOME[1], D. P. VANDERLAAN[2];
[1]Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Psychology, Univ. of Toronto Mississauga, Mississauga, ON, Canada

Abstract: Sex differences in visuospatial cognition have been reported in cisgender individuals with an advantage for cismen; mental rotation task (MRT) performance shows this robust difference. MRT performance also varies by circulating hormone concentrations, with low-estrogen phases of the menstrual cycle associated with higher performance in naturally cycling ciswomen. The literature has yet to corroborate performance differences across gender identity (GI) *and* sexual orientation (SO), both of which could undermine the expected sex difference due to the neurohormonal hypothesis that GI and SO are influenced by the direction of masculinization or feminization of neurodevelopment. Organizational effects suggest that prenatal exposure to androgens alters the masculinization of the developing brain. Activational effects postulate that circulating androgens and estrogens, coupled with this prenatal organization, augment either more culturally masculine or feminine behaviour, respectively. To test whether sex differences in cognition are influenced by GI and SO, MRT performance was assessed in a gender diverse sample of Thai participants (*N=981*) and evaluated by hormone profile. To explore organizational effects, individuals were categorized by self-reported GI and SO. Where applicable, the recency and consistency of feminizing hormone therapy (HT) or menstrual cycle were considered on the pretense that the duration and regularity of estrogens negatively influence MRT score.
Our sample replicated the male advantage; straight cismen outperformed all groups. Gay cismen outperformed straight ciswomen but did not differ from *sao praphet song*, feminine third gender individuals assigned male at birth, who performed comparably to the assigned female at birth groups. These results could reflect prenatal feminization. Further, *sao praphet song* using HT had marginally lower scores than those not currently on HT, but the consistency and age of first HT use were not related to MRT score. In straight ciswomen, those in the follicular phase had similar performance to straight cismen, but those in higher estrogen phases had significantly lower scores. Overall, GI, SO, and current hormone profile were related to performance, suggesting that both organizational and activational effects impact the expected psychological sex differences. By examining visuospatial cognition in a non-Western, gender diverse sample, these data enhance our understanding of sex differences in cognition and emphasize the importance of recognizing GI and SO in future studies of visuospatial cognition.

Title: Examination of sex differences in the dorsal raphe serotonin

Authors: H. O. CAIOLA, *B. D. ROOD;
Cell Biol. and Neurosci., Rowan Univ. Sch. of Osteo. Med., Stratford, NJ

Abstract: Dysregulation of the serotonin (5-HT) system is common among a number of mental disorders that affect mood and social behavior; incidence and severity of disorders impacted by 5-HT dysregulation are often different between men and women. For example, women have a higher incidence of anxiety and depression, whereas autism and schizophrenia are more common in men. Cells that provide 5-HT throughout the forebrain are found in the dorsal raphe nucleus (DR). Because many 5-HT neurons express gonadal steroid receptors, it is possible that different levels of circulating gonadal steroid hormones or differential expression of receptors in 5-HT neurons could result in sex differences in mood and behavior. Notably, the sex hormone estradiol regulates 5-HT-related genes including those involved in 5-HT synthesis (tryptophan hydroxylase, TPH), 5-HT reuptake (5-HT transporter), and the 5-HT 1A receptor. In rats, males have higher basal firing rates of DR 5-HT neurons than females. Based on the presence of gonadal steroid receptors and evidence for sex differences in neuron function, we hypothesize that gonadal steroid hormones impact 5-HT cell physiology in mice, which could lead to sex differences in function. To test this hypothesis, we examined the co-localization of estrogen receptor alpha (ERα) and TPH throughout the DR of male and female mouse brains. We did not find any sex differences in the proportion of 5-HT (TPH+) cells containing ERα, but we did observe regional variation. In the lateral wings, approximately 20% of 5-HT neurons expressed ERα, whereas 25-45% of 5-HT neurons in the dorsomedial (DMDR) and ventromedial nuclei (VMDR) expressed ERα. In the VMDR and DMDR there was also a rostral to caudal gradient with a higher proportion of caudal TPH+ neurons co-localizing with ERα (ANOVA; VMDR: $F_{(3,39)}=6.955$, $p=0.0007$ and DMDR: $F_{(3, 39)}=5.716$, $p=0.002$). Using whole cell patch clamp techniques, we examined membrane characteristics (tau, resistance, resting membrane potential), action potential properties (threshold, duration, amplitude), and firing rates (spike induced by current injection from 0 to 180 in +20 pA steps) of 5-HT neurons in male (n=23 cells) and female (n=23 cells) mice. We did not observe sex differences in any of the measures listed above; however, we do not know whether or not recorded neurons contained estrogen receptors. Ongoing work seeks to determine whether gene expression differs between male and female

serotonin neurons and whether patterns of gene expression depend on the presence of gonadal steroid receptors. We are also examining whether the presence of ERα influences electrophysiological measures.

Title: Melatonin and 5-methoxytryptophol effects on locomotor activity, glycemic index, and weight of testes and seminal vesicles of young rats

Authors: *A. VAZQUEZ-ALVAREZ[1], F. ZAPATA DENOVA[2], B. PRIETO-GOMEZ[3], C. REYES-VAZQUEZ[4];

Abstract: Melatonin and 5-metoxyitryptophol, the main indol hormones secreted by the pineal gland, are considered modulators of various physiological activities. Many of their actions are only observed with pharmacological doses. In this project, these indols was administered to 54 male Wistar rats of 4 weeks old, weighing 120 to 140g. Two rats were placed in each acrylic box with woodchips bed, dark-light cycles 12:12, temperature of 22-24 °C and free access to water and food. The experiment was carried out following the norm NOM-062-ZOO-1999. Rats were divided into three groups, a control group that received vehicle 0.1 ml / kg / day, intraperitoneally (i.p.) for 1,2 or three weeks; group 2 received 5-methoxytryptophol i.p. 15mg / kg / day, for 1, 2 or 3 weeks, and group 3 received Melatonin i.p. 15mg / kg / day for 1, 2 or 3 weeks. At the end of the corresponding administration time, rats were individually subjected to spontaneous locomotor activity measurement, for 60 min at same time each day. In addition, glucose concentration was recorded. At the end of these experiments, rats were sacrificed with an overdose of sodium pentobarbital and the testicles and seminal vesicles were removed and weighted. Differential effects were observed between melatonin and 5-methoxytryptophol. Rats treated for 3 weeks after weaning with melatonin showed a locomotor activity, significantly higher than those treated with 5-methoxytryptofol or vehicle. The weight of the testes and the seminal vesicles was lower after the first week of administration with melatonin and from the second week with 5-methoxytryptophol. There were no significant differences between the groups in terms of blood glucose concentration. These results showed that both indoles had

effects on the spontaneous locomotor activity and the development of their sexual organs. However, the effects had different timing and intensity.

Title: Estrogen fluctuations modulate electrophysiological properties of ventral tegmental area dopamine neurons to alter event salience

Authors: *M. SHANLEY[1], Y. MIURA[1], R. KAMALETDINOVA[2], R. KARIM[2], E. BLICKER[2], A. K. FRIEDMAN[2];
[1]The Grad. Center, City Univ. of New York, New York, NY; [2]Hunter College, City Univ. of New York, New York, NY

Abstract: The ventral tegmental area (VTA) is a dopaminergic nucleus involved in regulating the behavioral response to reward and aversion. Dysregulation of VTA dopamine neurons has been associated with a wide array of neuropsychiatric conditions such as depression, anxiety, and addiction. Many of these disorders exhibit a sex difference and show cyclic changes in severity that coincide with hormonal fluctuations across the menstrual cycle. Despite these observations, the role of hormones in regulating the electrophysiological activity of VTA dopamine neurons remains understudied. Of the various hormones involved in the reproductive cycle, estrogens have been shown to alter the activity of neurons in several different brain regions through modulation of potassium (K+) channels via changes in transcription of channel subunits and post-translational modifications. Further, a population of VTA dopamine neurons expresses estrogen receptors. We hypothesize that estrogen signaling modulates the level of activity of K+ channels in the VTA, and this modulation primes dopamine neurons to respond differently to salient stimuli depending on local levels of estrogen. We utilize a mouse model (C57Bl/6J) to examine the how estrogen modulates experience-dependent plasticity of dopamine neurons. Female mice undergo a 4-5 day estrous cycle, in which serum estrogen levels decline rapidly during estrus. Using whole cell slice electrophysiology, we characterized the physiological response of VTA dopamine neurons to estrogen signaling and withdrawal. We found that both serum levels of 17β-estradiol, measured through ELISA, and *in vitro* bath application of 17β-

estradiol modulate the activity of A-type and M-type K+ currents. During estrogen withdrawal there is a significant reduction in K+ currents, which leads to an increase in neuronal excitability. To determine if the changes in neuronal activity, due to estrogen signaling, alter behavioral responses to a salient experience, we utilized a one-day acute stress model and pharmacologically manipulated local estrogen concentrations through a chronic cannula implant. We then examined the behavioral phenotype the following day. Infusing the estrogen receptor antagonist ICI 182,780 into the VTA of male and female mice during stress acquisition leads to reduction in social behaviors. We also demonstrate that disruption of local estrogen synthesis with an aromatase inhibitor during stress acquisition leads to a reduction in social behaviors. Together, our results indicate that the role of estrogen fluctuations in the VTA is a critical modulator determining the behavioral impact of stress.

Title: Prepubertal ovarian inhibition of exploration and novelty seeking in Siberian hamsters: Does estradiol play a role?

Authors: *A. BARRETT, R. F. KYNE, L. M. BROWN, M. J. PAUL;
Psychology, Univ. at Buffalo, SUNY, Buffalo, NY

Abstract: The overwhelming majority of research on the role of gonadal hormones in behavioral development has focused on perinatal, pubertal, or adult life stages. The juvenile period has been overlooked because it is thought to be a time of gonadal quiescence. In the present study, we tested whether prepubertal gonadectomy at postnatal day (P)15 impacts the behavior of male and female juvenile hamsters on the Light/Dark Box, Novel Object, and Social Approach tests at P30 (Experiment 1) and compared these findings to those obtained after adult gonadectomy, (surgery conducted at ~P80 and behavior testing at ~P106; Experiment 2). Prepubertal ovariectomy increased exploration (i.e. time spent in the light zone of the Light/Dark Box) and novel object investigation of juveniles indicating an inhibitory role for the juvenile ovary; social approach was unaffected. In contrast, adult ovariectomy and castration (both prepubertal and adult) had no effect on any behavioral measure. These findings suggest that ovarian inhibition of exploration

and novelty seeking is restricted to the juvenile phase. Experiment 3 tested whether rearing hamsters in a short day length (SD), which delays puberty in this species, extends the interval of juvenile ovarian inhibition on exploration and novelty seeking. We also tested whether provision of estradiol reverses the effects of prepubertal ovariectomy. SD-reared hamsters were gonadectomized or sham-operated and provided with blank, cholesterol, or estradiol capsules at ~P80 and underwent behavioral testing at ~P106; ages at which long day-reared hamsters are adult (as in Experiment 2), but SD-reared hamsters remain reproductively immature. Ovariectomy again increased exploration in the SD-reared juveniles despite the older age of surgery and testing. Estradiol treatment had no effect. These findings reveal a novel inhibitory role for the juvenile ovary in exploration and novelty seeking and suggest that estradiol on its own is not sufficient to mediate these inhibitory actions. Ongoing experiments administering letrozole to long day-reared juvenile Siberian hamsters are testing whether estradiol is necessary for juvenile ovarian inhibition of Light/Dark Box exploration.

Title: A specialized serotonergic neuron subtype responsive to dopamine and central to behavior

Authors: *K. LYON, S. M. DYMECKI;
Harvard Med. Sch., Boston, MA

Abstract: Serotonergic (5-HT) neurons modulate diverse behavioral and physiological functions. Increasingly, 5-HT neurons are described as a heterogeneous group comprised of distinct subpopulations specialized to regulate distinct biological processes and functions. One such subpopulation that modulates social behavior in mice is distinguished by expression of the type-II dopamine receptor (*Drd2*) and the pan serotonergic transcription factor Pet1. We refer to these as *Drd2- Pet1* 5-HT neurons. *In vivo* silencing of *Drd2-Pet1* 5-HT neurons drives heightened aggression and increased exploratory activity. While brain slice electrophysiology demonstrates that their excitability is inhibited cell-autonomously via DRD2 signaling, the requirement for DRD2 receptor activity in these serotonergic neurons for specific behavioral outcomes is unknown. To query the functional requirement for DRD2 in *Drd2-Pet1* 5-HT

neurons, we generated mice with serotonin specific deletion of the *Drd2* gene (*Drd2*-CKO) and administered a panel of behavioral assays. We find that *Drd2*-CKO males exhibit altered social dominance behavior. Further, *Drd2*-CKO females display altered acoustic responses compared to control littermates. These findings suggest an additional role for *Drd2-Pet1* 5-HT neurons in the modulation of auditory processing and/or sensorimotor gating. Interestingly, *Drd2-Pet1* 5-HT neurons have axonal projections to many brain regions involved in auditory processing. Using intersectional genetic tools to map the projections of *Drd2-Pet1* 5-HT neurons in both males and females, we seek to uncover sex-specific circuitry of this serotonergic neuron subtype that may underlie differential auditory processing as well as projections to brain regions involved in other sensory modalities.

Abstract: During cortical development, migrating neurons and pathfinding axons are guided by molecular cues within the extracellular matrix or on the surface of ambient cells. These cues are interpreted as attractive or repulsive, depending on the set of receptors and signal transducers the cell expresses. We previously identified fibronectin leucine-rich transmembrane protein (FLRT) family as a ligand of Unc5 proteins, a well-known Netrin receptors. FLRT2 is expressed in the cortical plate (CP) and inhibited migration of Unc5D+ cells in the subventricular zone (SVZ). The upper layer neurons in FLRT2 mutant mice showed earlier migration to CP, indicating the repulsive function of FLRT2. However, the behavioral phenotype of FLRT2 deficient mutant mice was unclear. Here, we comprehensively analyzed behaviors of Emx1 cre induced- FLRT2

conditional knock-out mice using the test battery, including rotarod, T-maze, Barns maze, fear conditioning, prepulse inhibition, tail suspension, forced swim, object location test, pattern separation test, open-field, light/dark transition, elevated plus maze, hot plate test and social interaction tests. Among these tests, we found that mutant mice showed significant enhancement of anxiety-like behaviors (light/dark transition and elevated maze tests), pain sensitivity (hot plate test) and social behavior (social-interaction test). Furthermore, exploratory locomotor activity was decreased (open-field and Y-maze tests). Next, we analyzed the amino acids contents in the brain by matrix-assisted laser desorption/ionisation (MALDI) imaging mass spectrometry. We found that serotonin content in the forebrain of FLRT2 cKO is higher than control mice. These results suggest that serotonin of forebrain might affect the behaviors of FLRT2 deficient mice resulting in increased social interaction.

Title: Alterations of estradiol-induced histone H3 acetylation in the preoptic area and anteroventral periventricular nucleus of middle-aged female rats

Authors: *Y. SUN, W. XU, J. HUANG, L. LI, X. ZHANG, Y. WANG;
Ob/Gyn Hosp. of Fudan Univ., Shanghai, China

Abstract: Histone acetylation has recently been implicated in gene expression and estradiol (E2) actions in the hypothalamus. This study aims to determine the characteristic of histone acetylation in the hypothalamus under E2 positive feedback to understand the mechanism underlying alterations of gene expression and LH surge dysfunction in female reproductive aging. Young and middle-aged female rats were ovariectomized (OVX) and treated with hormone or oil once per day for two days. At the time of the expected LH surge, blood samples were taken for LH assay. The anterior and posterior hypothalami were dissected, histone H3 acetylation was measured using Western blotting. Independent groups of animals were perfused, GnRH neuron co-localized with c-Fos in the preoptic area (POA) and acetylated histone H3 cells in the POA and anteroventral periventricular nucleus (AVPV) were quantified. *Esr1* target genes including *Kiss1* and *VGluT2* and genes known as *Esr1* coregulators with histone

acetyltransferases (HATs) activity expression in the anterior hypothalamus were evaluated. Our results show that in the young females, E2 markedly increased histone H3 acetylation in the anterior hypothalamus especially in the POA and AVPV, coincidence with an increased GnRH neuron expressing c-Fos in the POA. However, E2-induced alterations of histone H3 acetylation in the anterior hypothalamus were absent in middle-aged females. The histone H3 acetylation immunoreactive cells were decreased in the POA and were absent of change in the AVPV of middle-aged females, associated with attentuated LH release, reduced GnRH expressing c-Fos as well as down-regulation of *Kiss1* and *VGluT2* mRNA expression. E2 induces significant decreases of *Ncoa2* and *Crebbp* mRNAs expression in young but not middle-aged anterior hypothalamus. Taken together, these data suggest that alterations of histone H3 acetylation in the POA and AVPV and the missing responsiveness of *Esr1* coregulators *Ncoa2* and *Crebbp* to E2 in the middle-aged anterior hypothalamus may partially contribute to E2 target gene expression changes and GnRH neuron activation decline and consequently lead to LH surge dysfunction in female reproductive aging.

[1]Univ. of Michigan, Ann Arbor, MI; [2]Dept of Anat. and Neurobio., Univ. of Maryland Dept. of Anat. and Neurobio., Baltimore, MD

Abstract: Prohormone convertase 1/3 (PC1/3), encoded by the *PCSK1* gene, performs the initial processing step of a variety of prohormone and neuropeptide precursors to their bioactive forms. While hypomorphic mutations in *PCSK1* can disrupt precursor processing and lead to metabolic and hormonal phenotypes, other common nonsynonymous SNPs are associated with obesity risk. One rare human SNP causing a G209R mutation produces a severe neonatal malabsorption syndrome followed later by additional syndromic features of *PCSK1* malfunction. The goal of the current study was to mimic this catalytically dead mutation in a mouse model to investigate

the mechanisms underlying the evolving human phenotypes. A G209R (gga to aga) point mutation was introduced into exon 6 of mouse *Pcsk1* by homology-directed repair using CRISPR/Cas genome engineering. Two heterozygous C57BL/6J founders carrying the correctly mutated site were identified by sequencing of a PCR-amplified DNA fragment encompassing exon 6. Intercrosses of G209R heterozygous N2 mice revealed early postnatal lethality of most homozygous R/R pups. Fifty-six live pups of both sexes, collected at postnatal days one or two from 10 litters, had the following genotypes: 27% G/G, 41% G/R and 32% R/R. Bodyweights were identical across the three genotypes, and stomachs of all pups had milk, indicating suckling activity. Plasma corticosterone levels were normal; however, mean blood glucose levels were significantly lower in homozygous R/R (62 ± 6 mg/dl) vs. G/G wildtype (90 ± 3 mg/dl) pups. Insulin levels were much more variable in the R/R pups (range 0.1 to 3.5 ng/ml) than in the other genotypes (0.1 to 0.9 ng/ml); however, there was a significant direct correlation between insulin and glucose levels (linear regression: r^2=0.45, *P*=0.008) only for the R/R pups. Five male R/R pups survived past one week, were severely dwarfed, but otherwise appeared healthy up to age 16 weeks. In summary, the phenotypic effects of the missense G209R mutation in mice are more severe than that reported previously for a *Pcsk1* null allele. However, the dwarfism phenotype of the few mice surviving into adulthood resembles that of the *Pcsk1* null mutants and is likely caused by abnormal processing of the hypothalamic GHRH prohormone. Additional studies, including effects on hypothalamic and gastrointestinal precursor processing and cellular ER stress pathways, are needed to identify the specific cause of the early postnatal mortality seen in the G209R mouse.

Title: Estrogen signaling modulation by mammary tumors: A role in cognitive dysfunction?

Authors: *K. L. G. RUSSART, L. STREHLE, V. BURCH, A. OATES, A. THOMAS, A. LAHOUD, J. KAUR, L. PYTER;
Ohio State Univ., Columbus, OH

Abstract: Cognitive deficits are a common complaint in breast cancer patients. Recent studies indicate the cause of cognitive impairment is likely multi-modal; chemotherapy, tumor biology,

surgery, stress, and hormones are all potential contributors. The majority of breast cancer patients are post-menopausal, and therefore have low levels of circulating estrogens. Additionally, many survivors are treated with long-term (>20 years) estrogen-reducing pharmaceuticals. Therefore estrogens, which are involved in modulation of cognition, might be involved in cancer-related cognitive impairment. We investigated the effects of a breast cancer tumor and its removal on cognitive performance and serum estradiol-17β (E_2) in a mouse model of breast cancer. Intact and ovariectomized mice were given tumors, and half of the tumors were subsequently resected (survivors). OVX mice performed more poorly than intact mice during cognitive tasks such as the novel object recognition and fear conditioning tests, and the presence of a tumor reduced performance further. Uteri weighed less and serum E_2 concentrations were reduced with ovariectomy, but E_2 was modulated with a tumor and tumor resection. Intact mice with tumors had disrupted estrous cycles; they spent more days in diestrus (and fewer days in metestrus), and some tumor-bearing mice discontinued cycling. Lastly, hippocampal expression of estrogen receptor α, pro-inflammatory *Il-1β* and *Il-6*, and synaptogenesis genes *Syn* and *Bdnf* was modulated with tumors and tumor resection. Thus, neural inflammation and synaptic plasticity, both estrogen-mediated events, are potential contributors to the observed cognitive dysfunction.

Title: Temporal dynamics of the behavioral and endocrine response to an aggressive challenge in wild-type and fighter strains of the Siamese fighting fish Betta splendens

Authors: *D. GONÇALVES, A. RAMOS, S. D. CARDOSO;
Univ. of St. Joseph, Macao, Macao

Abstract: Domestication usually encompasses taming the behavior of wild animals with a concomitant reduction in aggression. However, in a few species domestication has been associated with selection for high aggression, either by cultural or research purposes. One such example is the Siamese fighting fish Betta splendens, where males have been selected for winning dyadic fights in street contests, in a process that is thought to be going on for several

centuries. By comparing selected “fighter” strains with unselected wild-type counterparts, it is possible to identify the genetic, physiological and behavioral consequences of this prolonged selection process. Here, we show that selecting males for winning fights not only increases the frequency and intensity of aggressive behaviors, presumably because more aggressive males will tend to win fights, but also changes the structure of fights, revealed by differences in the temporal sequence of behaviors and fight duration. Further, the temporal dynamics of androgens secretion in plasma, hormones associated to the modulation of aggression in fish, differed between fighter and wild-type males, suggesting that selection for winners resulted in shorter endocrine response latencies. The androgen response to the aggression challenge was pronounced, although of a similar amplitude in both strains. The activation of the stress axis during fights, as measured by plasma cortisol levels, was not significant in either strains. However, fighters had significantly lower baseline cortisol levels than wild-types and low cortisol has been associated with high aggression in fish. Taken together, the results suggest that chronic low cortisol levels, a fast androgen response and changes in fight structure favor winning dyadic encounters in the context of staged fights in B. splendens.

Title: Viral-mediated transgenesis of MAOA and AVP increases territorial aggression in stickleback

Authors: *N. J. JAMES[1], A. BELL[2];
[1]Neurosci., Univ. of Illinois at Urbana-Champaign, Urbana, IL; [2]Integrative Biol., Univ. of Illinois, Urbana Champaign, Urbana, IL

Abstract: Establishing a causal relationship between genes and social behavior is challenging. Threespine sticklebacks are a classic system for the study of behavior, ecology, and evolution. They are one of the best studied behavioral systems, with well described intra-specific variation in aggression, antipredator behavior, and parental care. During the breeding season, male sticklebacks defend nesting territories and are highly aggressive toward territorial intruders. Previous studies, ranging from QTL to RNAseq, have identified hundreds of genes that are

differentially expressed in the brain in response to a territorial intrusion, but we know little about the mechanisms by which changes in their expression relate to territorial aggression.
Here, we use viral-mediated transgenesis to test the effects of candidate genes in the brain on territorial aggression. This method is appealing because it is flexible, fast, and allows us to compare individual behavior before and after transgenesis. Specifically, we tested the effects of two candidate genes, monoamine oxidase (MAOA) and arginine vasopressin (AVP), on aggressive behavior in male sticklebacks. Based on the literature, we predicted that overexpression of MAOA would reduce territorial aggression, whereas overexpression of AVP would increase territorial aggression. Aggression was measured relative to a control group of fish injected with a novel fluorescent (EYFP) protein.
Individuals' behavioral response to a territorial intruder was recorded on four occasions - two before injection and two after the construct reached peak expression. Sticklebacks received transcranial injections of mammalian homolog cDNA packaged in a replication-deficient Herpes Simplex Virus 1 carrier. Two injections to the anterior diencephalon resulted in broad expression throughout the brain. Expression levels of the candidate genes were confirmed using qPCR. As expected, the behavioral response of males in the control group to a territorial intruder did not differ before versus after injection.
Consistent with our hypothesis, animals injected with the construct causing overexpression of AVP were more aggressive in response to a territorial intrusion after injection relative to before. Surprisingly, animals overexpressing MAOA also showed higher levels of aggression in response to a territorial intruder. Overall, these results show that viral-mediated transgenesis is a promising method for testing the function of candidate genes in this system. Additionally, candidate gene selection is not limited to native genes: widely available mammalian plasmids successfully altered behavior.

Title: Hypothalamic activation after restraint stress and social stress in C57Bl/6 mice

Authors: *A. P. ALMEIDA, S. C. MOTTA;
Anat., Inst. of Biomed. Sci. | USP, São Paulo, Brazil

Abstract: Entrapment is typically related to aversive situations, and it can depend on only physical limits, like restraint stress, or more than one type of limits, like psychological and physical during social confrontation. In Wistar male rats, a septo-hippocampal-hypothalamic path is likely to respond to the environmental boundaries, contributing to the organization of defensive behaviours during different threats. In order to better understand defensive behaviours and how this can be modulated by entrapment in C57Bl/6 male mice, we intend to analyse if the structure relationed with this path is also mobilized in response to different threats, as in Wistar rats. For this, we have compared the pattern of juxtadorsomedial of lateral hypothalamic area (LHAjd) , the ventrolateral part of the ventromedial nucleus (VMHvl) and dorsal premammillary nucleus (PMd) activation of animals submitted to social defeat (n = 7), restraint stress (n = 5) and controls animals (n = 5). The activation was evaluated measuring the density of Fos-immunoreactive neurons of the selected brain regions. Univariate ANOVAs showed significant group effects for all hypothalamic sites analysed ($F(2, 42) = 31.91$; $p < 0.0001$). Using *post hoc* pairwise comparisons (Tukey HSD) we noted that, compared to the Control and Immobilized groups, Defeated animals up-regulated Fos expression in the VMHvl ($p < 0.0001$). In addition, density of Fos-labeled cell of LHAjd and PMd was significantly greater in the Defeated (LHAjd, $p = 0.0040$; PMd, $p = 0.0041$) and Immobilized (LHAjd, $p = 0.0256$; PMd, $p = 0.0101$) groups than in the Controls. As expected, the VMHvl - an element of the social responsive circuit responded only situations with social cues; and the PMd - which seemingly works as a key player for the expression of some of the defensive behavioural responses, was activated on both restraint and social stresses. In accordance to the observed in Wistar rats, LHAjd also responded in both situations, which is expected if LHAjd is conveying environmental restriction information from septo-hippocampal system to PMd. All this support our idea that a septo-hippocampal-hypothalamic path, responsive to social and physical restraint, is modulating defensive behaviours and have motivated us to realize more morphofunctional studies for establish this likely path.

Title: Sex differences in the effects of social status and fluoxetine treatment on aggression in Syrian hamsters

Authors: *D. A. VOISIN[1], V. MICHOPOULOS[2], K. L. HUHMAN[1], H. ALBERS[1];
[1]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [2]Yerkes Natl. Primate Res. Ctr. and Dept. of Psychiatry and Behavioral Sci., Emory Univ., Atlanta, GA

Abstract: It has been proposed that phenotypes related to dominance and more active coping strategies are more resilient to disorders like anxiety and PTSD. While the underlying mechanisms of these disorders remain poorly understood, there are marked sex differences in their incidence in the population. Selective serotonin reuptake inhibitors (SSRIs) like fluoxetine are among the most widely prescribed drugs for the treatment of many of these disorders, yet basic research has shown that the effects of these drugs can be sex dependent. For example, in Syrian hamsters, injection of serotonin 1a agonists into the anterior hypothalamus reduces aggression in males and increases aggression in females. In the present study we investigated whether social status (dominant versus subordinate) influences the amount of aggression displayed by males and females towards a non-aggressive intruder placed in their home cage. We also determined that social status and sex alters the effects on aggression of fluoxetine injected IP. Here, we show that male dominants displayed more aggression than did male subordinates ($p<0.05$). In contrast, no status-related differences were observed in the amount of aggression displayed towards a non-aggressive intruder. In males, fluoxetine significantly ($p<0.05$) reduced the amount of aggression displayed by dominant males but had no effect on the duration of aggression displayed by subordinates. In females, by contrast, fluoxetine significantly ($p<0.05$) reduced aggression in subordinate females compared to controls but had no effect on aggression in dominant females. These data demonstrate that social status influences competitive aggression as well as the effects of fluoxetine on aggression in a sex-dependent manner. These data suggest that subordinate females, who may already be more susceptible to social stress-related insults may become less aggressive when using SSRIs, while dominant males who may have some intrinsic or acquired resilience to social stress may see this resilience reduced.

Title: Melatonin regulates seasonal variation in neurosteroid profiles and aggressive behavior in male Siberian hamsters

Authors: *K. M. MUNLEY, J. E. DEYOE, C. H. ADANIYA, A. M. NOWAKOWSKI, C. C. REN, G. V. MURPHY, J. M. REINHART, G. E. DEMAS;
Biol., Indiana Univ., Bloomington, IN

Abstract: Numerous studies across animal taxa have demonstrated a positive correlation between gonadal steroids and aggression during the breeding season. However, it is becoming increasingly clear that alternative neuroendocrine mechanisms, which are independent of circulating gonadal steroids, are critical in modulating aggressive behavior. Such mechanisms are particularly important for seasonally-breeding animals that are more aggressive during the short-day (SD) photoperiods of the non-breeding season, despite gonadal regression and reduced circulating steroid levels. While previous work from our lab suggests that the pineal hormone melatonin and the adrenal androgen dehydroepiandrosterone (DHEA) are important in facilitating non-breeding aggression in Siberian hamsters (*Phodopus sungorus*), it is unknown whether local changes in steroid hormone synthesis and metabolism within the brain are ultimately responsible for elevating aggression during the non-breeding season. To investigate the role of melatonin in mediating seasonal variation in neurosteroid profiles and aggressive behavior, we housed male hamsters in long days (LD) or SD, treated them with either timed melatonin or saline injections, and quantified aggression after 9 weeks of photoperiodic housing. Following behavioral testing, we assessed whether melatonin mediates seasonal changes in steroidogenesis by comparing circulating hormone levels and neurosteroid levels in regions of the social behavior network that are associated with aggressive or reproductive behaviors using liquid chromatography-tandem mass spectrometry (LC-MS/MS). LD hamsters administered melatonin (LD-M) exhibited SD-like levels of aggression. Interestingly, LD-M and SD animals reduced circulating DHEA and testosterone concentrations in response to an aggressive encounter, whereas LD animals elevated circulating androgen levels. Neurosteroid profiles will also be presented and compared across brain regions and seasonal phenotypes. Collectively, this study provides insight into how melatonin modulates the neuroendocrine circuits underlying seasonal aggression.

Title: Selection for aggression changes brain expression patterns in male and female Siamese fighting fish Betta splendens

Authors: *S. D. CARDOSO[1], A. RAMOS[1], M. HUAWEI[2], Q. JIANWEN[2], D. GONÇALVES[1]; [1]Univ. of St. Joseph, Macao, Macao; [2]Hong Kong Baptist Univ., Hong Kong, Hong Kong

Abstract: Dominance relationships within and between sexes are usually a characteristic trait of a species' social system and have implications for differentiated access to resources, predation, mating strategies, and life history patterns of both sexes. The expression of dominance is often linked to aggressive behavior and the response it elicits, but the proximate mechanisms (i.e. genetic, hormonal and neuronal) of this behavior are not yet well understood. Here we focused on the neurogenomic mechanisms mediating aggression in both males and females using the Siamese fighting fish *Betta splendens* as our model system. This species has been selected for fighting contests across several centuries in Thailand and other Asian countries, generating highly aggressive fighting strains of *B. splendens*, known as "plakat morh", that are notoriously different from their counterpart wild-types. This artificial selection procedure has presumably favored genetic variations that promote the phenotypic expression of traits that increase the probability of winning fights and presumably aggression. In this study, a strain of wild-types and a strain of fighters were reproduced under lab conditions for several generations and differences in behavior and in the brain transcriptome were compared between sexes and strains. As expected, when presented to an aggressive challenge, either a mirror image or an interacting conspecific, fighter males were more aggressive than wild-type males. Interestingly, these differences also occurred for females, although only males have been directly subject to artificial selection. Whole-brain gene expression analyses, using as a reference the *B. splendens* genome, revealed that the selection for aggression induced a markedly different neurogenomic baseline state and response to the challenge in fighters, as compared with wild-types. The study provides evidence on brain gene regulation associated with the expression of aggression and presents the first comparison of males and females for *B. splendens* strains, a promising species for the investigation of the proximate and ultimate mechanisms of aggression in vertebrates.

Abstract: Self-injurious behavior (SIB) is commonly observed in patients with neuropsychiatric disorders, as well as in nonclinical populations with stress-related mental-health problems. However, the exact circuitry mechanisms underlying SIB have remained poorly understood. Here, with a bilateral injection of muscimol into the entopeduncular nucleus (EP), we established a rat model of SIB. Following the muscimol injection, the male rats exhibited in a dose-dependent manner stereotypic self-biting behavior that lasted for hours and often resulted in wounds of various severities. The SIB was associated with an elevated level of serum corticosterone and could be exacerbated by enhancing the corticosterone signaling and, conversely, alleviated by inhibiting the corticosterone signaling. Activity mapping using c-fos immunostaining, combined with connectivity mapping using herpes simplex virus-based anterograde tracing from the EP and pseudorabies virus-based retrograde tracing from the masseter muscle, revealed the potential involvement of many brain areas in SIB. In particular, the lateral habenula (LHb) and the ventral tegmental area (VTA), the two connected brain areas involved in stress response and reward processing, showed a significant increase in neuronal activation during SIB. Furthermore, suppressing the LHb activity or modulating the GABAergic transmission in the VTA could significantly reduce the occurrence of SIB. These results demonstrate the importance of stress hormone signaling and the LHb-VTA circuit in modulating SIB resulting from EP malfunction and suggest potential targets for therapeutic intervention of SIB and related disorders.

Title: Control of social status is distributed across androgen receptor paralogs in a cichlid

Authors: *B. A. ALWARD[1], **C. J. SKALNIK**[1], R. A. YORK[1], S. A. JUNTTI[2], R. D. FERNALD[1];
[1]Biol., Stanford Univ., Stanford, CA; [2]Biol., Univ. of Maryland, College Park, MD

Abstract: Adaptations to the social environment require integrative responses involving physiological and behavioral plasticity. The mechanisms underlying these types of plasticity remain to be established. Here, we investigate the role of androgen receptors in the control of social status in the African cichlid fish *Astatotilapia burtoni*, a genetically tractable model system in which the mechanistic basis of social plasticity can be studied. In *A. burtoni*, males compete for rank along a social hierarchy, wherein dominant (DOM) and non-dominant (ND) males differ markedly in the behaviors they perform and their physiological state. DOM males are brightly colored, aggressively defend territories, and actively court females. In contrast, ND males are drably colored and rarely perform aggressive or courtship behavior. DOM males also possess larger testes and higher circulating levels of sex steroid hormones such as androgens and estrogens compared to ND males. Importantly, social status in *A. burtoni* is in flux, as DOM and ND males can rapidly alter certain aspects of their physiology and behavior in response to changes in the social environment. To test the role of androgen signaling in regulating social status, we generated using CRISPR/Cas9 gene editing *A. burtoni* with non-functional androgen receptor-α (ARα) or ARβ. Adult wild-type and mutant males were housed for 6-10 weeks in "stable-DOM" tanks, which include numerous territories and several other males and females. Stable-DOM tanks reliably induce the full suite of physiological and behavioral traits that characterize social dominance. Males were then assayed in a social dyad paradigm, where their interactions with a smaller male and three females were recorded. We find that ARβ is necessary for DOM-typical bright coloration and large testes, but not necessary for DOM-typical behavior. In contrast, ARα is not required for DOM-typical coloration, but is required for DOM-typical behavior (aggressive and courtship displays) and reducing testes growth. Thus, we demonstrate that AR paralogs are required for distinct traits underlying social status. Moreover, our findings

suggest that social status in *A. burtoni* is highly dissociable, a feature that may facilitate efficient social decision-making.

Title: CRISPR Cas9 generation and behavioral characterization of a syrian hamster V1a receptor knockout

Authors: *J. H. TAYLOR[1], J. C. WALTON[1], K. E. MCCANN[3], A. NORVELLE[1], Q. LIU[2], J. VANDER VELDEN[1], J. M. BORLAND[1], M. HART[2], C. JIN[2], K. L. HUHMAN[1], D. N. COX[1], H. ALBERS[1];
[1]Neurosci. Inst., [2]Georgia State Univ., Atlanta, GA; [3]NIH/NIEHS, Research Triangle Park, NC

Abstract: The advancement of CRISPR-Cas9 for genetic modification has made possible the generation of new knockout animal models. Syrian hamsters are an attractive target for CRISPR-mediated gene modification due to their widespread use in biomedical research, particularly as a model in preclinical studies of psychiatric disorders. . Numerous social behaviors in hamsters and other species are controlled by the nonapeptide neurochemical signal vasopressin and one of its receptor subtypes (V1aR). Notably, selective stimulation of V1aR increases inter-specific aggression and flank marking in male and female hamsters. Thus, we sought to disrupt the *AVPR1A* gene and to assess these two vasopressin-dependent behaviors. Hamster embryos were injected at the single-cell stage with Cas9 and gRNA targeting AVPR1A, producing hamsters carrying various mutant *AVPR1A*. Of these, a mosaic female produced offspring carrying an 11bp or a 10bp deletion, both at the start codon of *AVPR1A*. Radioligand binding assays showed little to no selective V1aR binding in knockout hamsters homozygous for the 11bp deletion or heterozygous for both deletion alleles, indicating that the function of AVPR1A was disrupted. When compared to WT and heterozygous (-11/WT or -10/WT) littermates, however, male and female knockout hamsters were more aggressive toward a same-sex conspecific ($p<.05$) and engaged in more odor-stimulated flank marking ($p<.01$). This behavioral result is in direct opposition to our prediction, given that we have demonstrated based on behavioral pharmacological data that the V1aR in the anterior hypothalamus facilitates these behaviors. These data suggest a novel hypothesis that *global* inactivation of V1aRs may not block the

expression of flank marking or aggression. Thus, we administered a selective V1aR antagonist into the cerebral ventricles of wildtype hamsters. As predicted, this treatment did not block aggression in male or female hamsters; additionally, the V1aR antagonist tended to increase flank marking in males (p=.067). These data demonstrate that V1aR activation is not required for the expression of flank marking or aggression in constitutive V1aR knockouts and suggest the possibility that there is V1a-mediated process outside the AH in wildtype hamsters that inhibits aggression and flank marking. Supported by NIH MH109302.

Title: Suffering from aggression? Use cage climbers in your mouse cage!

Authors: *M. A. VOGT[1], S. SERBA[1], R. PALME[2], S. CHOURBAJI[1];
[1]Interfacultary Biomed. Res. Facility (IBF), Univ. of Heidelberg, Heidelberg, Germany; [2]Unit of Physiology, Pathophysiology and Exptl. Endocrinol., Univ. of Vet. Med., Vienna, Austria

Abstract: While many neurobiological publications describe clear effects of enrichment on the animals' physiology and behavior in an experimental context, large-dimensional implementation in rodent facilities often lacks a systematic analysis of respective refinement measures. Here, we aimed at implementing a new and innovative tool to improve wellbeing without side effects. Thus, we focused on enrichment-induced changes in behavior and stress physiology especially emphasizing effects on data variability in male and female mice. For that purpose, recycled cage lids were formed and three types of shapes examined for different effects of different structures ('cage climber'):
1.) 'Triangle' Climber,
2.) 'Bridge' Climber and
3.) 'Round Arch' Climber.
The results demonstrate significant preferences of C57BL/6N mice for any of the three structures in comparison with a neutral object. Despite observable intense use of enrichment, there were no

behavioral alterations detectable in a test battery assessing anhedonia (sucrose consumption) locomotion (openfield, rotarod), exploration (novel object exploration), anxiety (dark-light box) and sociability as well as social memory. The structural supplement neither affected levels of fecal corticosterone metabolites nor general variability of data in both male and female mice. The only detectable effect was a 50% reducting in male aggression in cages equipped with 'round arch' type of enrichment in comparison to control cages with nest material only.To promote well-being of mice in a 3R-matched context, our study recommends the use of properly assessed structural enrichment, such as ‘cage climbers’ combined with nesting material to satisfy physical and thermal needs in the cage environment.

Title: The relationship between testosterone and isolation-induced aggressive behavior in male layer chicks

Authors: *S.-I. KAWAKAMI, Z. YAN;
Hiroshima Univ. Grad. Sch. of Biosphere Sci., Higashi-Hiroshima, Japan

Abstract: Testosterone (T) is known to induce aggressive behavior, mainly in male animals. It has not been known, however, whether rearing conditions such as isolated- or grouped-raising affect T-induced aggressive behavior and whether isolation-induced aggressive behavior is T-dependent in male chickens. The present study, therefore, aimed to examine (Exp. 1) the relationship between blood T concentration and aggressive behavior in group- and isolation-raised male layer chicks which were castrated and subcutaneously implanted T-filled silactic tubes; (Exp. 2) the effects of flutamide (F), a non-steroidal antiandrogen, on isolation-induced aggressive behavior of the castrated chicks. The Exp.2 was carried out because blood T concentration in the castrated chicks, probably derived from adrenal gland, was approximately 24 pg/ml in our previous study and therefore it is impossible to exclude completely the effect of lower concentration of blood T on chicken aggression only by castration. In the Exp. 1, the testes were bilaterally removed and silactic tubes of various lengths filled with crystalline T were subcutaneously implanted at 14 days of age, and a social interaction (SI) test was performed at 32 days of age to quantitatively assess aggressive behavior of the isolation- or group-raised chicks. Total aggression frequencies (TAF) and aggression establishment rate (AER) were used

to evaluate aggressiveness of the chicks (J. Poult. Sci., 54: pp. 296-302, 2017). The results of the Exp.1 showed that the TAF and AER were high irrespective of the plasma T concentrations in the isolation-raised chicks, but that in the group-raised chicks, the AER significantly increased only when plasma concentration of T was approximately 47 pg/ml. In the Exp. 2, the chicks were divided into three groups as follows: 1) intact male chicks; 2) the castrated ones in which blank tube were subcutaneously implanted; 3) the castrated ones in which F-filled tubes were subcutaneously implanted. After implantation, the chicks were reared in isolation and the SI test was performed at 32 days of age. In the Exp. 2, castrated chicks showed lower AER as compared with that of intact male chicks, and F-implantation lowered AER of the castrated chicks. These results suggest that both testicular and non-testicular T promote isolation-induced aggressive behavior in the male layer chicks.

Title: Evidence that differential expression of estrogen receptor alpha is causal for alternative behavioral phenotypes in a polymorphic species

Authors: *J. R. MERRITT, D. L. MANEY;
Emory Univ., Atlanta, GA

Abstract: The white-throated sparrow represents a powerful model for understanding the mechanisms underlying steroid-dependent behavior. In this species, two morphs differ with respect to both expression of estrogen receptor alpha (ERa) and sex steroid-dependent behaviors. Birds of the white-striped (WS) morph engage in higher levels of territorial aggression than those of the tan-striped (TS) morph. WS birds also show several-fold higher expression of ERa in nucleus taeniae of the amygdala (TnA), which is functionally homologous to the mammalian medial amygdala. In regression analyses, expression of ERa in TnA predicts territorial aggression even better than morph, plasma testosterone, or plasma estradiol (E2). Previously, we showed that administration of E2 rapidly facilitates aggression in WS, but not TS, birds, suggesting that the polymorphism in ERa could contribute to the behavioral polymorphism. Here, we tested the hypothesis that the differential effects of E2 on aggression are mediated by differential ERa expression in TnA. We used antisense oligonucleotides to knock down ERa

expression in TnA of WS and TS birds. Separate control groups of both morphs received scrambled oligos. We then administered a bolus dose of E2 and quantified aggression towards a conspecific 10 minutes later. The results in the control group were consistent with our previous study; E2 facilitated aggression in WS, but not TS birds. Knocking down ERa expression in TnA eliminated E2-induced aggression in WS birds, making their behavior more typical of TS birds. Additionally, individual differences in the expression of ERa, but not ERb, in TnA predicted the degree to which E2 facilitated aggression. Overall, our results are consistent with the hypothesis that ERa expression in TnA mediates the well-known morph difference in aggressive behavior in this species, and may contribute to the evolution of social behavior.

Title: Neurochemical phenotyping of dominance and submissiveness

Authors: *K. MURLANOVA[1,2], A. PINHASOV[1], I. MICHAELEVSKI[1], M. V. PLETNIKOV[2];
[1]Integrative Brain Sci. Ctr. - Ariel, Mol. Biol., Ariel Univ., Ariel, Israel; [2]Dept Psychiat & Behav Sci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: To determine the contributions of different monoaminergic neurotransmitter systems to the neurochemical mechanisms of dominant and submissive behaviors, we measured tissue content of major monoamines and their metabolites in Sabra mice that were selectively bred over 34 generations to exhibit strong and stable dominant (Dom) or submissive (Sub) behaviors in several tests for social interactions including Dominant-Submissive Relationship and Resident-Intruder tests. Using HPLC-ECD method, we assayed monoamine tissues concentrations in the prefrontal cortex (PFC), hippocampus (Hip), cerebellum (Cer) and brainstem (BS) of naïve 8-week-old male Dom and Sub mice (n=7). We have identified different patterns of alterations in the monoaminergic systems between Dom vs. Sub mice behavior driven by distinct social rank status. Compared to Dom mice, Sub animals had decreased levels of norepinephrine (NE) in PFC and Hip, 5-hydroxytriptamine (5-HT) in BS and elevated levels of dopamine (DA) in all tested regions, which was associated with decreased DA turnover in Sub mice. Decreased 5-HT level in BS was associated with increased 5-HT turnover in Sub mice. Our findings suggest that different patterns of monoamine brain regional tissue content in Dom and Sub mice may explain stable differences in their social behavioral features with potential relevance to major psychiatric disorders.

Title: Methylphenidate-mediated inhibition of dopamine transporter-expressing non-dopaminergic neurons in the mouse ventral premammillary nucleus that control aggression

Authors: *L. T. A. HEIKKINEN[1], C. BROBERGER[1,2];
[1]Dept. of Neurosci., Karolinska Institutet, Stockholm, Sweden; [2]Dept. of Biochem. and Biophysics, Stockholm Univ., Stockholm, Sweden

Abstract: A population of neurons in the ventral premammillary nucleus that can be identified through expression of the dopamine transporter ("PMv^{DAT} cells") have recently been shown to control aggression and social dominance in male mice. Despite the robust expression of DAT in these cells, however, studies indicate that they neither synthesize nor release dopamine. This unorthodox neurochemical profile suggests that DAT may have a non-canonical function in the PMv. Intriguingly, the non-selective DAT-inhibitor, methylphenidate (MPH), commonly prescribed for attention deficit hyperactivity disorder, has been reported to reduce aggressive behaviour in both animal models and in human patients. To address the cellular bases for these issues, we used whole-cell patch clamp recordings in acute hypothalamic slices from male juvenile DAT-tdTomato mice. Recent work has identified several membrane properties of PMv^{DAT} neurons that make them conducive to persistent, regenerative discharge. Bath application of MPH (500μM) suppressed several of these features. Thus, both the number of spikes during a depolarizing current pulse injection, as well as during rebound firing in response to hyperpolarization, were decreased by 50%. Paradoxically, and pertinent to the latter, the amplitude of the depolarizing "sag", commonly attributed to the hyperpolarization-activated mixed cation current (h-current) appeared to be increased. Furthermore, the repolarization after current injection was delayed, suggesting an action on A-type potassium currents. The successive decrease in action potential amplitude observed during a burst was also enhanced, indicating a faster onset of depolarization block. Curiously, these effects were not observed during bath

application of the DAT-selective antagonist, GBR-12783 (10μM). - Together, these data indicate that MPH can interfere with the recurrent excitation mechanisms operating within the PMv, suggesting a means whereby this drug may suppress aggression. The pharmacological profile of these actions indicate that underlying non-conventional transporter actions are involved. The behavioural implications of these findings are currently under investigation.

Title: Effect of early-life knock-down of DNMTs and TETs on sex differences in cell type in the hypothalamus

Authors: *L. R. CORTES[1], C. D. CISTERNAS[2], N. G. FORGER[1];
[2]Neurosci. Inst., [1]Georgia State Univ., Atlanta, GA

Abstract: One type of sex difference in the brain involves differences in the number of cells expressing a particular marker. For example, females have more cells expressing estrogen receptor alpha (ERa) in the ventrolateral region of the ventromedial nucleus of the hypothalamus (VMHvl), while males have more cells expressing calbindin in the sexually dimorphic nucleus of the preoptic area (CALB-SDN). DNA methylation and hydroxymethylation are crucial for the differentiation of neuronal cell phenotype during development, and we hypothesize that they may also play a role in the sexual differentiation of cell phenotype. To test this, we first treated newborn mice with zebularine, a global inhibitor of DNA methyltransferases (DNMTs). Zebularine treatment had lasting effects on the number of cells expressing ERa and calbindin and reduced or eliminated sex differences in these markers (Mosley et al. 2019). DNA methylation and de-methylation are carried out by DNMTs (DNMT1, DNMT3b, and DNMT3a) and TET enzymes (TET1, TET2, TET3), respectively. We find that expression of these enzymes is much higher early in life compared to adulthood, and there are sex differences in the expression of all TETs and of DNMT1. To test whether these sex differences in enzyme expression underlie sex differences in cell phenotype, we used small interfering RNAs (siRNA) to down-regulate DNMT1/DNMT3a or TET2/TET3. We found that injecting 2 microliters of 400pmol siRNA into the ventricles of male and female pups on P5 leads to a robust (~40%) down-regulation of expression compared to animals given control siRNA. Animals will be sacrificed at weaning,

and we will determine whether neonatal DNMT or TET knockdown alters the number of cells expressing ERa in the VMHvl and medial POA and calbindin in the SDN-POA and bed nucleus of the stria terminalis.

Title: JNK controls hippocampal circuit dynamics assessed by fiberphotometry in behaving mice

Authors: J. JOHN[1], N. TIWARI[2], P. HOLLOS[3], F. MARCHISELLA[3], V. FAGERHOLM[1], S. HUUSKONEN[4], *E. T. COFFEY[5];

Abstract: Our lab has previously shown that inhibition of JNK solely in adult born granule cells of the dentate gyrus (DG) decreases anxiety-like behavior in mice (Mohammad et al, Mol. Psychiatry, 2018). To understand how the action of JNK in a sub-population of cells in hippocampus can influence behavior, we analyzed whether inhibition of JNK in hippocampal neurogenic niche cells altered neural activity of pyramidal neurons in CA3 and CA1 sub-regions. We used a customized retroviral inhibitor of JNK that expreses specifically in newly born DG granule cells and measured neural activity from CA3 or CA1 pyramidal neurons expressing a GCaMP6s reporter using fiberphotometry in behaving mice undergoing a battery of anxiety-inducing tests. We find that inhibition of JNK in adult born neurons of DG alters hippocampal circuit activity. Moreover, we show that activity of CA3 neurons is altered in a battery of behavior tests and when JNK is inhibited in DG, shows strong correlation with low anxiety traits. These results identify JNK as a molecular driver of circuit activity in hippocampus.

Title: Learning expression of neurophysiological stress markers in honey bees

Authors: *T. E. BLACK[1], O. FOFAH[2], T. GIRAY[3], C. I. ABRAMSON[1];
[1]Psychology, [2]Entomology, Oklahoma State Univ., Stillwater, OK; [3]Dept. of Biol., Univ. of Puerto Rico, Carolina, PR

Abstract: Stress is defined as any deviation form an organism's baseline levels. As such, introduction of new stimuli and information, such as in learning, can be defined as a stressor. A large body of research exists examining the role that stress plays in learning, but virtually none addresses whether or not learning itself is a measurable cause of stress. The current study used a shotgun approach to examine learning in conjunction with stress and interpret whether or not learning was a sufficient stressor to elicit a transcriptional change. Researchers examined changes in expression of ten stress related genes in various physiological systems in domesticated honey bees (*Apis mellifera*) as a result of exposure to an aversive conditioning task. Gene expression was explored using quantitative real time polymerase chain reaction. Results were analyzed using a series of ANOVA.

Title: Parallel prefrontal-periaqueductal gray circuits mediate active and passive coping behaviors in response to stress

Authors: *S. B. JOHNSON[1], R. T. LINGG[2], T. D. SKOG[1], S. A. ROMIG-MARTIN[2], R. T. LALUMIERE[2], J. J. RADLEY[2];
[1]Interdisciplinary Neurosci. Grad. Program, [2]Dept. of Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: The behavioral, neuroendocrine, and autonomic features that constitute the stress response may be coordinated by higher-order brain regions and their projections to downstream effectors. Among these features, it has been widely held that active behavioral coping can have buffering effects on other aspects of the stress response. However, this idea has garnered little direct support and the mechanisms underlying this phenomenon remain obscure. Here we employed an optogenetic approach to probe the contributions of medial prefrontal cortical (mPFC) pathways to the midbrain periaqueductal gray (PAG), a prominent behavioral effector, on coping during the shock probe defensive burying test (SPDB). In this test, rats are exposed to an electrified probe mounted within their cage, whereby after receiving electric shock, they display both active (probe burying with cage bedding) and passive (immobility) coping behavior that is monitored over a 10-min period. We found that photoinhibition of the rostral mPFC-ventrolateral PAG pathway enhanced, and photoexcitation diminished immobility relative to controls ($p < 0.05$ for each), but these had no effect on burying. By contrast, we found that photoexcitation of the caudal mPFC-dorsal PAG pathway enhanced active coping (probe-burying, $p < 0.05$) while immobility remained unaffected. As activity in this pathway is sufficient to drive active coping behavior, we next interrogated whether activating it in a setting where rats are forced toward passive coping, i.e. by removing the cage bedding during SPDB, could have stress-buffering effects. In the no-bedding condition, rats deprived of active coping responses exhibited increased immobility, ultrasonic vocalizations, autonomic, and HPA output, whereas pathway activation rescued each of these effects. These results show that latent, stress-buffering effects of caudal PL-dorsal PAG photoexcitation are uncovered in situations where active coping is prevented. Together, these experiments provide support for separate mPFC-PAG pathways that impart distinct functional consequences during acute stress exposure. The rostral mPFC-ventrolateral PAG pathway may bias the animal away from passive responses, while the caudal mPFC-dorsal PAG pathway may support active responses and their attendant stress-buffering effects.

Title: Social dominance alters both coping style and stress resilience

Authors: *M. CANNON, E. GRAHAM, M. BURZINSKI, N. SAGARAD, M. COOPER; Psychology, Univ. of Tennessee, Knoxville, TN

Abstract: There are a great deal of individual differences in how humans and other animals cope with stress. Variation in coping strategies is linked to several environmental factors, including social dominance. The present study investigated whether coping responses predict the acquisition of social dominance in male and female Syrian hamsters, establishing dominance relationships alters the development of coping responses, and changing dominance status further modifies coping. We also examined whether social dominance alters behavioral responses to social defeat stress as well as markers of neural activity in the nucleus accumbens, such as deltaFosB. We hypothesized that maintenance of dominance relationships would increase proactive coping in dominants and reactive coping in subordinates. Also, we hypothesized that dominant, proactive coping animals would show less defeat-induced social avoidance and greater deltaFosB expression in the nucleus accumbens compared to subordinate, reactive animals. To establish dominance relationships, male and female hamsters were paired with a same-sex partner in daily aggressive encounters for two weeks. To assay coping responses before and after formation of dominance relationships, we tested animals in a series of behavioral tests, including open field, novel object exploration, elevated zero maze, light/dark transition, and Porsolt forced swim. Finally, to measure stress susceptibility we exposed subjects to acute social defeat stress and subsequent social interaction testing. We found that after establishing social dominance, females spent more time in the light area of a light/dark transition test and approached a novel object more quickly than subordinate females, which suggests that establishing social dominance promotes proactive coping in female hamsters. Interestingly, when dominant females lost their dominance status they also lost their proactive coping responses. Contrary to our prediction, we found that dominant females showed increased social avoidance after defeat, which suggests that proactive coping does not promote stress resilience in female hamsters. We are currently testing male hamsters to investigate potential sex differences in coping responses and stress susceptibility. We are also quantifying deltaFosB expression in the nucleus accumbens in both females and males. These preliminary findings indicate that social dominance modulates both

coping responses and stress susceptibility and will address potential sex-differences and cellular mechanisms.

Title: The effects of minocycline on acute defeat-induced social avoidance and microglial activity in the hamster vmPFC

Authors: *T. T. CLARITY[1], A. GRIZZELL[2], M. A. COOPER[2];
[1]The Univ. of Tennessee, Knoxville, Knoxville, TN; [2]Dept. of Psychology, Univ. of Tennessee, Knoxville, TN

Abstract: Neuroinflammation is a key risk factor in the etiology of stress-related psychopathologies. Exposure to social stress in rodents can increase activation of microglia, the brain's resident immune cells. The ventral medial prefrontal cortex (vmPFC) is a limbic region involved in top-down regulation of behavior and emotion, and has been implicated in resilience to traumatic stress. We and others have shown that disruption of vmPFC activity contributes to enhanced behavioral susceptibility to acute traumatic stress. However, it is unknown whether microglia contribute to such susceptibility. This study seeks to determine whether acute stress induces microglial activation in the vmPFC and, moreover, whether systemic administration of the microglial inhibitor, *minocycline*, reduces acute social defeat-induced social avoidance. Adult male Syrian hamsters were treated with *ad libitum* minocycline in drinking water (4 mg/ml; 130 mg/kg/day) starting 48-hours prior to stress (Day 1) and continuing until euthanasia 48 hours following stress (5 days total). On Day 3, minocycline and water-drinking controls were exposed to acute social defeat stress, which consisted of three 5-minute aggressive encounters in the home cages of three novel resident aggressors at 5-minute inter-trial intervals. On Day 4, defeat-induced social avoidance was assessed using conditioned defeat (CD) and social interaction (SIT) tests, which were counterbalanced across all treatment levels and spaced with 30-minute inter-assay intervals. On Day 5, animals were euthanized and brains extracted for immunolabeling of the microglial activation markers ionized calcium-binding adaptor protein (Iba-1) and Cluster of Differentiation 68 (CD68). Preliminary results suggest that acute social defeat increases Iba-1 expression in the vmPFC. We are currently using an amino cupric silver

stain to determine whether social defeat increases cellular degeneration. Also, ongoing experiments are testing the effects of minocycline treatment on microglial activity and morphology in the vmPFC and defeat-induced social avoidance. Given that vmPFC neuronal activity is necessary for protection against the adverse effects of stress, it is important to determine whether acute defeat-induced neuroinflammation in the vmPFC contributes to social avoidance. Overall, this study addresses whether halting microglial activity during acute social defeat protects vmPFC anatomical integrity and restores behavioral function, and might serve as a novel approach for pharmacological interventions used to treat traumatic stress exposure.

Title: Microglial contributions to acute stress-induced perturbations of the vmPFC in male Syrian hamsters

Authors: *A. GRIZZELL[1], T. T. CLARITY[3], M. A. COOPER[2];
[2]Dept. of Psychology, [1]Univ. of Tennessee, Knoxville, TN; [3]The Univ. of Tennessee, Knoxville, Knoxville, TN

Abstract: The ventromedial aspect of the prefrontal cortex (vmPFC) plays a particularly important role in mediating resilience to acute and chronic psychological stress. Accordingly, work in our laboratory has shown that vulnerability to an acute social defeat stressor, such as that conferred by the maintenance of a subordinate social status, is associated with reduced neuronal activity in the vmPFC. Similarly, pharmacological inhibition of vmPFC projection neurons via muscimol attenuates the stress resistance conferred by a dominant social status. It is unknown what factors disrupt vmPFC recruitment in vulnerable populations, though recent findings suggest that excessive innate immune function could be implicated. In a series of studies, we sought to determine whether an acute social defeat stressor drives vmPFC microglial activity in a manner that contributes to status-dependent, stress-induced social avoidance. In Experiment 1, we identified whether acute social defeat primes an enhanced microglial response to a subsequent immune challenge [systemic lipopolysaccharide (LPS) injections]. We immunolabeled ionized calcium binding adaptor molecule (Iba-1) and CD68, a marker of

phagocytic activity following social defeat and/or LPS treatment and performed morphometric analysis of microglia in the vmPFC. Using similar immunolabeling techniques in Experiment 2, we sought to determine whether microglia activity was attenuated with systemic *minocycline* and, moreover, whether such treatment reduced acute social defeat-induced social avoidance in the conditioned defeat and social interaction tests. In Experiment 3, we sought to determine whether the development and maintenance of a subordinate social status for 14 days leads to greater vmPFC microglial recruitment and cellular degeneration in a manner correlated with acute defeat-induced social avoidance. Preliminary results suggest that acute defeat does indeed increase expression of Iba-1 as well as enhance ramification of microglial processes. Overall, this findings suggest that neuroinflammation in the vmPFC increases behavioral susceptibility to acute traumatic stress.

Title: Chronic social defeat stress to adolescent mice induces anxiety-like behavior with reduced oligodendrogenesis

Authors: *T. SHIMIZU, A. ISHIDA, N. TAJIRI, H. HIDA;
Dept. of Neurophysiol. and Brain Sci., Nagoya City Univ., Grad. Sch. of Med. Sci., Nagoya, Aichi, Japan

Abstract: Myelination is dependent on neuronal activity and is modulated by various environmental changes in postnatal mice. Recent studies demonstrate that the myelin remodeling is involved in motor learning and social interaction. Our previous paper revealed that the average length of the myelin sheath formed by individual oligodendrocytes changed depending on sensory-input deprivation of neuronal axons. To investigate neuron-glial interactions and glial cell property itself in higher brain function and neurological disorders, we challenged to know whether psychosocial experience during adolescent period influences oligodendrocyte generation or its property using chronic social defeat stress to adolescent mice, a model for the examination of stress-related disorders in rodents. The socially defeated mice showed more anxiety-like behavior in the open field. The social defeat stress to adolescent mice led to decrease in the number of newly-born oligodendrocytes in the prefrontal cortex and in the number of PLP+ mature oligodendrocytes in the corpus callosum. In both of these regions of socially defeated mice, the number of BrdU-incorporated CC1-positive mature oligodendrocytes was also decreased. To assess whether oligodendrocyte remodeling plays roles in the anxiety-like

behavior caused by the social defeat stress, we applied drug modulating oligodendrocyte generation to socially defeated mice. We found that the drug treatment rescued the behavioral abnormalities, suggesting that the promotion of oligodendrogenesis can ameliorate depressive symptoms by the social defeat stress. Taken together, these findings suggest that oligodendrocyte remodeling under psychosocial environments plays important roles in mental disorder.

Title: Distinct environmental stress response of mice with high and low immobility traits through the analysis of ultrassonic vocalization and chronic unpredictable stress exposure

Authors: *T. M. REIS-SILVA, A. C. S. SAMPAIO, P. S. RODRIGUES, M. C. GALVAO, E. P. SILVA, N. MOREIRA, L. S. MEDEIROS, K. E. KIATAQUI, M. M. BERNARDI; Post-Graduate Program of Envrn. and Exptl. Pathology, Paulista Univ., Sao Paulo, Brazil

Abstract: This study evaluated the response of high and low stress reactivity mice in the chronic unpredictable stress protocol to better understand and access possible biological mechanisms associated with the stress and resilience response. For this, 57 Swiss male mice with high (HI) and low immobility (LI) traits selected in the tail suspension test (TST), a screening protocol for antidepressant drugs, underwent 3, 10 and 21 days of chronic unpredictable stress. Behaviour analyses in the dark/light box were assessed and adrenal glands collected. During the TST, an ultrasonic vocalization (USV) test was also performed. Significant differences were determined by student t test and two-way ANOVA when pertinent. Our results show an increased frequency of rearing in the light zone after 10 days of stress [F (2, 23) = 9.176; P=0.0012] of LI group while HI displayed increased rearing frequency after 3 and 10 days and decreased frequency after 21 days [F (2, 23) = 7.458; P=0.0032] was observed. No differences in anxiety-like behaviour were observed. Adrenal weight of LI and HI group was elevated after 3 days of stress [F (1, 46) = 5.489; P=0.0235] when compared to 10 and 21 days. Regarding USV, HI animals presented elevated time (t test p=0.0006) and frequency (t test p=0.0045) of 22KHZ vocalization compared to LI group, revealing an aversive disposition to the TST inescapable stress. A previous work of our group showed rearing and corticosterone differences between HI and LI mice after restraint stress (Reis-Silva et al., 2019) and how those traits may be linked to

resilience response. Here, we suggest that the rearing response variation may also indicate changes in norepinephrine levels in areas such as the *locus coeruleus* and adrenal differences may refer to a distinct neuroendocrine activity via the hypothalamic-pituitary-adrenal axis. Finally, the USVs of 22 KHZ indicate a distinct sensibility to environmental stress between behaviours. We propose that animals of HI display a more sensibility to stress whereas LI resemble traits of stress resilience.

Title: Perception of beauty during and after stress: The ugly becomes less uglier

Authors: *R. K. NARAYAN[1], A. KUMAR[1], V. PAREEK[2];
[1]Anat., All India Inst. of Med. Sci., Patna, India; [2]Computat. Neurosci. and Neuroimaging Div., Natl. Brain Res. Ctr., Manesar, India

Abstract: Introduction: Beauty lies in the eyes of the beholder', a paraphrase of a statement by Greece philosopher Plato, has often found its ground in the empirical studies. Though, how perception of the beauty changes during stress has been scarcely investigated until yet. We selected a paradigm of examination stress to investigate this question.
Materials and Methods: Ninety-one 1st professional MBBS students (72 males, 19 females) were presented with four types of pictures grossly representing three variations in perception of beauty: 1& 2-human figures toned with sexual fervour: that of a youthful man and a youthful woman, 3-the sex neutral aesthetic perception: a scene of nature, and 4-the ugliness: a human with an aggressive tumor on face) at the time of Anatomy viva voce examination, and 10 days after it. The participants were asked to evaluate the attractiveness of each picture with an ascending scale of marks ranging from 0 to 10.
Results: There were no distinct variances in the scores for the pictures during and after examination except that representing the ugliness. About 50% of the participants, irrespective of the gender, had given higher score for this picture in the post examination evaluation (which was considered free of stress) which meant they found it less ugly when were supposedly free of stress.
Discussion: The beauty is largely a subjective perception which may vary with the physiological conditions of the subject. Professional examinations are considered as stressful, which may

induce transient neuroendocrine changes, consequently may alter the aesthetic perception of the individuals. Though, direct literature evidence is scarce supporting increased sense of ugliness, an increase in the disgust sensitivity is known during stress, which closely relates to it. The altered perception of beauty during stress may have applied importance in aesthetic decision making during stressful conditions.

Title: Role of Kalirin-7 in the mPFC in depression-like behaviors

Authors: C. WANG, *X. MA;
Shaanxi Normal Univ., Xi'an, China

Abstract: Depression is a common and severe psychiatric disorder, but the underlying mechanisms are still not entirely clear. Alterations in the structure and function of dendritic spines are associated with psychiatric diseases. The medial prefrontal cortex (mPFC) plays a critical role in the integration of cognitive and emotionally relevant information. Kalirin-7 (Kal-7), a major isoform of Kalirin in adult rodent brain, plays an essential role in the regulation of dendritic spine formation and synaptic plasticity. Therefore, this study was designed to investigate the effect of Kalirin in the mPFC on depressive-like behaviors using chronic unpredictable mild stress (CUMS), an animal model of depression. We showed that CUMS-induced depressive-like behaviors were accompanied by a decrease in Kal-7 levels in the mPFC in rats, which is consistent with the spine loss in this area. This finding raised our hypothesis that kalirin plays a critical role in CUMS-induced depression-like behaviors. The following experiment was designed to test this hypothesis.
Adults Sprague-Dawley male rats were divided into two groups: Kalirin knockdown and control (n=16), and an adeno-associated virus (AAV) encoding GFP-Kal-7 shRNA or scrambled shRNA was injected into their mPFC, respectively. Expression of Kal-7 shRNA resulted in a decrease in Kal-7 expression in GFP positive neurons of the mPFC compared with the mPFC neurons expressing scrambled shRNA.
Behavioral tests showed that, Kal-7 shRNA-mediated decrease in the level of Kal-7 induced depressive-like behaviors characterized by a decrease in sucrose preference ($p=0.005$) , rearing times ($p=0.001$) and time in center area(%) ($p=0.028$) in open field test, and an increase in

immobility time in tail suspension test (p=0.005). Depression-like behaviors induced by decreased Kal-7 level were accompanied by a marked decrease in spine density in spine density (p<0.001) and alterations in the morphology of dendritic spine in the mPFC. Western blot analysis showed that the levels of NR2B and GluA1 were significantly reduced (p=0.001, p=0.003) in the mPFC expression Kal-7 shRNA in comparison with the control group expressing scrambled shRNA. This study showed that reduced expression of Kalirin-7 in the mPFC contributes to depressive-like behaviors induced by CUMS.

Title: Mice susceptible to chronic stress display a broadening of orientation tuning in microcircuits of the primary visual cortex

Authors: *H. BACKHAUS[1], N. BUERGER[1], P. KAPLICK[1], A. STROH[1,2];
[1]Inst. of Pathophysiology, Univ. Med. Ctr., Mainz, Germany; [2]German Resilience Ctr., Mainz, Germany

Abstract: Resilience towards chronic stress may not only be reflected in regions such as the dmPFC or VTA, but also in cortical areas not directly implicated in higher order behavior such as the primary visual cortex. Indeed, mounting evidence suggest, that stress resilience might be encoded already in the ability of an organism to differentiate between stimuli. To explore this hypothesis, we conducted two photon calcium imaging in layer II/III of visual cortex in mice previously categorized in terms of their response to chronic stress. We first submitted 8-week-old BL6 mice to a chronic social defeat paradigm, where the animals are exposed to physical attacks of a conditioned aggressor CD1 mouse for 10 consecutive days. Afterwards, the mouse remains in the same cage as the aggressor, but the aggressor is now physically separated, unable to attack. We classified the animals in resilient and susceptible subgroups by measuring the time spent in close proximity to the aggressor in a Social Interaction Test: Resilient mice continue to explore the aggressor that is safely kept in a mesh, whereas susceptible mice tend to avoid the vicinity of the aggressor. Upon implantation of a chronic optical window and the injection of the calcium indicator GCaMP6f, we conducted video-rate microcircuit imaging in resilient vs susceptible

awake mice, placed head-fixed on a jet-ball allowing for assessing locomotion. Mice were subjected to static and drifting grating stimulations in a virtual reality setting. Specifically in the susceptible mice, in excitatory neurons in layer II/III of primary visual cortex, we identified an increase of spontaneous, task-free, activity, both reflected in an increase of the number of spontaneous active neurons, as well as in the frequency of calcium transients. Upon grating stimulation, susceptible mice exhibited a significantly broader orientation tuning compared to their resilient litter mates. These findings imply that resilient and susceptible behavior is already reflected in neuronal activity patterns in primary sensory cortical areas. Indeed, susceptible mice might be less able to discriminate between threatening and safety cues, also at least partially based on their inferior perceptual abilities that are mediated by primary cortical areas.

Title: Oxytocin intranasal administration promotes exercise and decrease anxiety-like behaviors in rats

Authors: *P. A. MUÑOZ RODRÍGUEZ, L. G. RODRÍGUEZ SANTOS, W. NORZÉ, A. P. RAMOS ROLÓN, V. S. ENCARNACIÓN CORTES, F. M. GONZÁLEZ HERNÁNDEZ, E. OLMEDO LÓPEZ, C. S. MALDONADO-VLAAR;
Biol., Univ. of Puerto Rico, Rio Piedras Campus, San Juan, PR

Abstract: Oxytocin (OT) is a neuropeptide primarily synthesized in the hypothalamus associated with social behaviors, stress responses, and drug addiction. Previous work from our laboratory showed a cross-talk between the endocannabinoid system (ECS) and OT receptors within the mesolimbic system to modulate anxiety behavior. Studies have demonstrated how ECS is crucial for voluntary wheel running performance. As a model for exercise, voluntary wheel running is endowed with anxiolytic properties due to increases in serum endocannabinoid concentrations. The purpose of the present study was to examine: (A) whether OT enhances voluntary wheel running behavior and potentiates the anxiolytic properties of exercise in adults male Sprague-Dawley rats and (B) characterize possible pathways mediating this effect within the mesolimbic system by assessing changes in OT and CB1 receptors expression. Rats were divided into two groups, the first group received intranasal infusions of OT 1 μg /μl, 10 μl or vehicle in each nostril before exposed to the running wheel two hours daily for 10 consecutive days. The second

group received the same dose of OT or vehicle and was not exposed to the running wheel. Results showed a tendency to increase wheel running behavior in rats treated with OT compared to the vehicle group. Results also showed the anxiolyticeffects of OT in sedentary rats were higher than the rats exposed to exercise by using Elevated Plus Maze (EPM). Further biochemical studies will examine cross-talk between OT and the endocannabinoid system as mediators of exercise performance and the implications it can have as a treatment on drug addiction, sedentary lifestyle and anxiety behaviors.

Title: Neural mechanisms underlying stress-resilience effects of by immunization with mycobacterium vaccae in rats

Authors: *C. A. ZAMBRANO[1], M. G. FRANK[2], H. M. D'ANGELO[2], K. M. LOUPY[1], S. F. MAIER[2], C. A. LOWRY[1];
[1]Dept. of Integrative Physiol., Univ. of Colorado, Boulder, CO; [2]Dept. of Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: Anxiety disorders and trauma- and stressor-related disorders are the most commonly occurring mental disorders, with estimated lifetime prevalence as high as 25%. Evidence suggests that inappropriate inflammation may be a risk factor for anxiety disorders, as well as

trauma- and stressor-related disorders, such as posttraumatic stress disorder (PTSD). Several studies have now demonstrated that psychobiotic treatments such as *Mycobacterium vaccae* (*M. vaccae*) are anxiolytic and induce a stress resilient phenotype. This induction of a stress resilient phenotype occurs, in part, through enhanced immunoregulation. We have recently found that administration of a heat-killed preparation of the anti-inflammatory and immunoregulatory bacterium, *M. vaccae* (NCTC 11659), a saprophytic bacterium found in soil, water, and mud, increases hippocampal expression of the anti-inflammatory cytokine interleukin 4 (IL-4) and IL-4-responsive genes, including CD200R1 and CD206, and prevents stress-induced microglial priming and anxiety (Frank et al., 2018, *Brain, Behavior, and Immunity*, 73, 352-363). Our goal here was to study the neural mechanism(s) involved in the effects of *M. vaccae* on hippocampal gene expression implicated in stress resilience. First, we confirmed that immunization with *M. vaccae* (0.1 mg s.c., in 100 µl borate-buffered saline on days -21, -14, and -7) increased hippocampal expression of IL-4 and IL-4-responsive genes, including CD200R1 in both male and female rats. To validate methods of blocking IL-4 signaling, we demonstrated that administration of the IL-4 blocker, soluble IL-4 receptor alpha (sIL-4ra; 5 µg, intra-cisterna magna [i.c.m.]) prevented the effects of co-administration of recombinant IL-4 (100 ng, i.c.m.) on hippocampal CD206 mRNA expression. Finally, to determine if blocking IL-4 signaling could prevent the effects of *M. vaccae* on hippocampal gene expression, we immunized adult male rats with *M. vaccae* or vehicle on days -21, -14, and -7, followed by i.c.m. injection of sIL-4ra or vehicle on day -1, and collected hippocampal tissue 24 h later. *M. vaccae* increased hippocampal IL-4, CD200R1, and CD206 mRNA expression, as expected. sIL-4ra had no effect on *M. vaccae*-induced increases in hippocampal IL-4 mRNA expression but prevented hippocampal CD200R1 and CD206 mRNA expression. Taken together, our results support the hypothesis that *M. vaccae* enhances immunoregulation in the CNS by increasing IL-4 and IL-4-dependent signaling, which might mitigate stress-induced neuroinflammatory and behavioral effects, thereby augmenting stress resilience.

Title: Identifying the brain networks altered by gaming disorder defined by ICD-11: Cluster analysis by permutation test in calculating functional connectivity

Authors: *Y. OKAZAKI[1], S. KURIKI[2], H. KOBAYASHI[2], H. NAKAYAMA[3], S. MIHARA[3], S. HIGUCHI[3], A. ISHIYAMA[1];
[1]Waseda Univ., Shinjuku, Japan; [2]Tokyo Denki Univ., Tokyo, Japan; [3]Natl. Hosp. Organization Kurihama Med. and Addiction Ctr., Kanagawa, Japan

Abstract: We developed a new data-driven approach to estimate networks in the whole brain that were associated with Gaming Disorder (GD). There are many previous studies that have compared functional connectivity (FC) of healthy control (HC) and the population having disorders related to Internet-use and/or online-gaming. The FC is the correlation of time-series signals of resting state functional MR imaging (res-fMRI) between two brain regions. These papers have reported various brain regions having altered FC values in the disordered individuals. In this paper, in a FC analysis for the patients diagnosed with GD, we introduced Permutation Test (PMT) to control family wise error and estimated a cluster of brain areas which were linked to a core brain node having altered functional connectivity.
The experiment was conducted with the approval of the Ethics Committees of Kurihama Hospital, Tokyo Denki and Waseda Universities and with the informed consent of the subjects. We obtained res-fMRI data by using a 3T scanner for 30 HC participants and 26 GD patients. The patients were diagnosed with GD based on the 11th Revision of the International Classification of Diseases (ICD-11). We parcellated the whole brain into areas according to Automated Anatomical Labeling (AAL), excluding the cerebellum. We also divided the subjects into two subgroups, under 17 and over 18 years of age. We underwent a new approach for each of the two subgroups, as follows. We calculated FC values in all the connections of AAL areas and conducted Welch's t-test between HC and GD patients. Next, we identified pair-wise significant connections (or links) ($p<0.05$) with reduced FC (HC > GD), and increased (GD > HC). We performed PMTs in such a way that all subjects were randomly assigned into HC and GD groups and Welch's t-test was conducted. On each trial, we recorded the node with the largest cluster size and, after 5000 repetitions, obtained a histogram that showed the relation between the maximum cluster size and the frequency of its occurrence. The larger the cluster size was, the smaller frequency was. We found a cluster-level significant size ($p < 0.05$) from the histogram and selected the cluster of node-links whose size was larger than the critical size. From the result, we found core nodes of the links having reduced FC value in the frontal region and the occipital/parietal region for the GD group under 17 years, and the hippocampus and paracentral areas for the GD group over 18 years. These core nodes mainly linked to the cortical areas. Thus, we found obvious distinction of the core node areas between the young- and elder-age subgroups. Significant clusters of links having increased FC value in the GD patients were not found.

Title: Somatosensory area 3b network is a composite of multiple distinct networks in macaque monkeys and humans

Authors: *J. THOMAS, D. SHERON, S. MOHANTA, N. JAIN;
NBRC, Manesar, India

Abstract: In the primary somatosensory cortex (area 3b) different somatotopic representations have different anatomical connectivity reflecting differences in functions of the body parts. However, the resting state functional network of the somatosensory cortex is traditionally taken to be a single network considering the entire area 3b as a single entity. We hypothesized that different somatotopic representations in area 3b will have different functional networks reflecting differences in their functions and the anatomical connectivity. Here we determined resting-state functional connectivity of the entire area 3b and its three sub-regions in two primate species - macaque monkeys and humans. We divided area 3b into three somatotopic regions - face (face 3b), hand (hand 3b) and rest of the medially represented body parts (med 3b). MRI scans of anesthetized macaque monkeys (n=5) and awake humans (n=23) were acquired using a 3T magnet (Philips Achieva). Studies were approved by institutional animal and human ethics committees. Data was analyzed using SPM8 following standard pre-processing steps which included slice-time correction, motion correction, co-registration, and smoothing. Functional MRI images were further processed and seed-based region-to-region and region-to-brain correlation analyses were performed using *CONN*. The regions of interest (ROIs) were drawn on subject-specific high-resolution MRI brain images for macaque monkeys and the standard MNI space for humans based on anatomical atlases, published data, and our fMRI scans and the electrophysiology mapping data. Data revealed that in both humans and monkeys, face 3b had higher overall connectivity than hand 3b and med 3b. Face 3b also had stronger connectivity with areas secondary somatosensory cortex (S2) and pre-motor ventral (PMv). In both the primate species, face 3b and med 3b showed homotopic bilateral connectivity while hand 3b had such bilateral connections only in humans. Strong connections between the three somatotopic ROIs were observed in humans but not in macaques. However, the connections of all the three topographic ROIs to adjacent representations in area 4 were stronger than intra-areal area 3b

connections. Our results show that different topographic representations have specific and distinct networks. The differences in the connectivity likely reflect differences in the functional usage of different body parts and its underlying anatomical connectivity. Results also suggest that considering the entire somatosensory area as a single unit in functional connectivity analysis will likely not reveal the complexity of the functional networks.

Title: Effects of isoflurane anesthesia on functional networks in marmosets: Comparison to fully awake resting state functional magnetic resonance imaging

Authors: *Y. HORI, D. J. SCHAEFFER, K. M. GILBERT, L. K. HAYRYNEN, J. C. CLÉRY, J. S. GATI, R. S. MENON, S. EVERLING;
The Univ. of Western Ontario, London, ON, Canada

Abstract: The common marmoset (*Callithrix jacchus*), a New World Primate, is becoming increasingly popular as a non-human primate model for human brain function and dysfunction. To identify the functional network in marmoset, resting state functional MRI (RS-fMRI) is often used under anesthesia, despite clear evidence that anesthetics affect brain activation, in particular of the thalamus. However, it remains unclear how anesthetic agents affect functional network (FC) in marmosets. Here, we investigated the effects of isoflurane on FC by comparing RS-fMRI under a fully awake state with that under 1.5% isoflurane anesthesia. We had two primary objectives: The first was to elucidate the global changes of functional networks caused by anesthesia in marmosets. The second was to assess which thalamic FC is altered by anesthetics. Three marmosets were used in this study. To quantitatively compare the resting-state functional networks between awake and anesthetized groups, we used a dual regression technique that allows for voxel-wise comparisons of resting-state functional maps. To identify the strength of FC from left and right thalamus, the time courses from left and right thalamus were extracted for each scan and correlation maps (z-score maps) between thalamus and every other voxel in the brain were calculated. Here, the strength of FC was defined as the z-value. Our main results showed that: (1) isoflurane globally decreased FC in resting-state networks, but the structure of

the networks was preserved except for the default mode network; (2) isoflurane altered frontal-thalamic, cerebellar-thalamic and interhemispheric thalamic FC (Fig. 1). These findings bridge the gap between resting-state FC studies under anesthesia and awake conditions and provide insights into the effects of isoflurane on functional brain networks in primates.

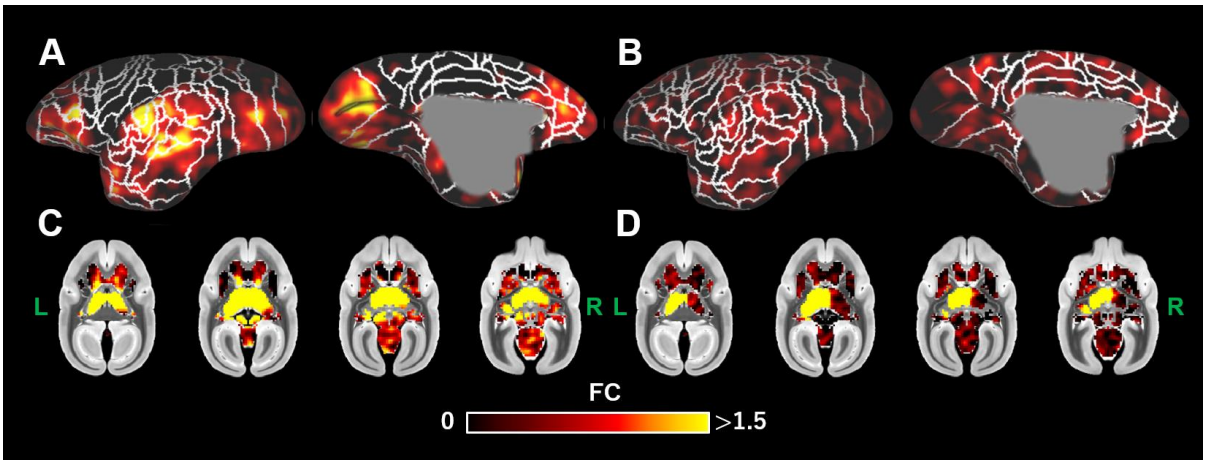

Fig. 1 Seed-based FCs from left thalamus for awake (A, C) and anesthetized marmosets (B, D).

Title: Baseline functional connectivity predicts successful weight loss at six months after bariatric surgery

Authors: *W. ZHANG[1], G. LI[1], Y. HU[1], L. LIU[1], Y. WANG[1], Y. DING[1], C. HU[1], J. LI[1], G. JI[2], P. MANZA[3], G.-J. WANG[3], Y. ZHANG[1];
[1]Sch. of Life Sci. and Technology, Xidian Univ., Xi'an, China; [2]Natl. Clin. Res. Ctr. for Digestive Dis. and Xijing Hosp. of Digestive Diseases, Fourth Military Med. Univ., Xi'an, China; [3]Lab. of Neuroimaging, Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD

Abstract: Laparoscopic-sleeve-gastrectomy (LSG) is one of the most effective treatments for obesity, and neuroimaging studies have shown LSG-induced brain functional and structural alterations in regions involved in food-intake control, cognitive-control and learning/memory. However, LSG's long-term therapeutic effects are varied among individuals with obesity. Therefore, we investigated whether pre-LSG brain resting-state functional connectivity (RSFC) could predict successful weight loss at six months post-LSG, using fMRI in 33 patients with obesity. Based on average percentage excess weight loss at six months, we performed a median split to divide participants into high and low weight-loss groups. First, functional MRI volumes were divided into 246 regions of interests (ROI) based on the Brainnetome Atlas and each subject had an 30135-feature vector RSFC vector (i.e., the bottom triangle of a 246 x 246 region connectivity matrix). Then, median absolute deviation (MAD), filter method (mutual information) and linear kernel principal component analysis (Kernel PCA) were used to eliminate redundant features and reduce the dimension of the feature set (**Fig 1A**). Next, 13 principal components (PCs) accounting for 60% of the variance were fed into the Siamese network and K-Nearest Neighbors (K-NN) classifier, which were trained and tested using leave-one-out cross validation (**Fig 1A**). This model was successful at predicting degree of weight loss: average accuracy = 84.85% and area under the curve = 0.85. The RSFCs located in the top fifth percentile of the RSFC weight distribution across each iteration were selected as the dominant RSFCs in each PC. The top PC (representing ~13% of the variance) was associated with a network that was dominated by brain regions involving insula, superior parietal lobule, striatum, pre- and postcentral gyrus, precuneus (**Fig 1B**). These findings reveal that brain functional connectivity can be used to predict successful weight-loss after bariatric surgery, and provide neurobiological insight into the heterogeneous outcomes associated with LSG.

Abstract: Modern studies argue that factors such as obesity lead to alterations in brain connectivity. Bariatric surgery is currently an available treatment that consistently maintains substantial weight loss, however, it is unknown if gastric bypass is a factor that leads to normal brain connectivity.
To analyze the above, functional magnetic resonance scans were obtained in the resting state (rs-FMRI) in 27 women with morbid obesity (body mass index of 40.4095±4.5 Kg/and body weight of 104.381±15.06 Kg) using a magnetic resonator GE 3.0 Teslas Discovery MR 750 ® with multiband gradient sequences. Data were collected in a longitudinal study one week before undergoing gastric bypass surgery and six months later.
A total brain functional connectivity matrix was constructed with normalized correlation coefficients using wavelet decomposition scales between regional signals dependent on BOLD blood oxygenation level and its coregistration in the JD Power atlas of 264 brain regions. The properties of the network were calculated in connectivity matrices with a connection density of 10-50%. Permutation tests were performed to evaluate the group differences ($p < 0.05$) for each network metric and each density.
The rs-FMRI data obtained pre-surgery showed an increase in the characteristic path length and a decrease in the weighted overall efficiency compared to their corresponding to six months, where an increase in the grouping coefficient, modularity, asortativity and strength for different densities was observed. However, these differences were not statistically significant.
The results obtained are consistent with studies comparing people with obesity *vs*. normal weight. The values obtained from the networks show that after gastric bypass, connectivity tends to that shown in normal weight subjects.

Title: Modeling the pial network: Linear hexagonal network that includes realistic vascular parameters

Authors: *X. ZOU, J. KIM, D. RESS;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Introduction: The human brain has a highly interconnected pial network to distribute blood from the large cerebral arteries to the penetrating arterioles and capillaries and eventually to veins. Accurate understanding of vascular functions is important to understand popular brain imaging methods that rely on the hemodynamic response function (HRF) to brief neural activation. The HRF typically has a positive peak at ~6 s and a form of underdamped oscillation with frequency f ~0.1 Hz and damping time tau ~3 s. Most neurovascular coupling models do not accurately portray the vascular topology and morphometry. It remains unclear how brief neural activation can provoke sluggish underdamped HRF through microscopic brain vessels. Here we present a linear lumped model based on the hexagonal idealization of the pial network. We postulate that the network has poles and zeros that create the observed HRF.
Methods: In our model (Fig. A), pial arteries form the edges of a hexagonal grid, and each edge has a branch at its center representing a penetrating arteriole and associated capillaries and venous drainage. An open arm originating at each vertex connects the grid to other pial arteries. The dynamic analogy of blood flow in a pial artery is that this rigid-pipe segment has a resistance and an inertance as functions of the blood density, the blood kinetic viscosity, the arterial radius, and the arterial length. Each penetrating branch is represented by a resistance and a parallel compliance because that penetrating arterioles and capillaries have very small radius and that downstream veins have compliant walls. We estimated the Ra, La, and Rp based on literature values of the human vascular dimensions and simulated the system response over a range of Ro, Lo, and Cp.
Results: An exemplary simulation of flow responses in each branch is shown in Fig. B.
Conclusions: Our results confirm that the hexagonal network can create underdamped HRF with f ~0.1 Hz. The flow response depends on the topological distance. The simulated tau is shorter than observed, suggesting that multiple hexagonal grids must be engaged.

Title: Silenced but still connected: Chemogenetic inactivation of the prefrontal cortex results in brain-wide fMRI hyper-synchronization

Authors: *C. CANELLA[1,2], F. ROCCHI[1,2], D. GUTIERREZ BARRAGAN[1], M. PASQUALETTI[1,3], A. GOZZI[1];

Abstract: Resting-state brain functional networks are characterized by regions exhibiting high connectivity density and centrality, for fast integration of neural processing. Consistent with a prominent role of these brain regions as “connectivity hubs”, it has been recently shown that their anatomical location is evolutionary conserved in primates and rodents (Liska et al., 2015), and encompasses higher-order polymodal neocortical areas, such as the medial prefrontal cortex (PFC). Importantly, the high level of centrality of functional connectivity hubs render them possible points of vulnerability for the integrity of brain networks, susceptible to disconnection and dysfunction in developmental and psychiatric disorders. According to this view, functional interference of connectivity hub regions would lead to brain-wide network de-synchronization. However, empirical confirmations of this hypothesis in the living brain are lacking. Here we used chemogenetic-fMRI (“chemo-fMRI”, Giorgi et al., 2017) to causally probe a role functional connectivity hubs as key stabilizers, and points of network vulnerability, in the mouse brain. Specifically, we used DREADD chemogenetics to obtain a sustained pan-neuronal silencing of the mouse anterior cingulate cortex, a core component of the mouse default-mode network, and a brain region exhibiting hub-like properties in the mouse and in primates (Liska et al., 2015). To inhibit this region, we bilaterally injected a recombinant adenovirus expressing the inhibitory DREADD receptrs hM4Di (or GFP) in the PFC of adult male C57BL6 mice (hM4Di group n=40, control group=40). Brain-wide network connectivity was mapped by using resting-state fMRI (rsfMRI) as previously described (Sforazzini et al., 2014) during chemogenetic silencing of the PFC, obtained upon an intravenous injection of CNO, or clozapine. The employed approach permits to remotely silence neuronal activity, with the aim to induce targeted and

reversible “virtual lesions” during resting-state fMRI acquisitions. We expected hub manipulations to result in widespread network disruption. Surprisingly, we found that chemogenetic silencing of the mouse PFC results in a paradoxical rsfMRI hyper-synchronization (i.e. functional over- connectivity) of the mouse default mode network, an effect that appeared to be relayed to other neocortical areas by thalamic nuclei. This effect was found to be associated with a dramatic reconfiguration of rsfMRI network coupling. Our results challenge the prevailing interpretation of functional connectivity alterations and network hub dysfunction in brain disorders.

Title: The neurovascular response is attenuated by focused ultrasound-mediated disruption of the blood-brain barrier

Authors: ***N. TODD**[1], Y. ZHANG[1], M. S. LIVINGSTONE[2], D. BORSOOK[3], N. MCDANNOLD[1];
[1]Brigham and Women's Hosp., Boston, MA; [2]Harvard Med. Sch., Boston, MA; [3]PAIN Res. Group, Boston Children's Hosp., Boston, MA

Abstract: Focused ultrasound (FUS) with microbubbles can transiently open the blood brain barrier (BBB) for targeted delivery of pharmaceuticals into the brain. This method of BBB permeablization also leads to several secondary effects on the immune response, neuronal function and vascular hemodynamics. In this study, we use functional MRI to characterize the effects that FUS-BBB opening has on the neurovascular response to external stimuli in the rat brain. N=9 Sprague Dawley rats underwent separate MR imaging sessions with and without FUS-BBB opening. Functional MRI data was acquired using two different imaging sequences: blood-oxygen level dependent (BOLD) imaging captured the hemodynamic response associated with standard fMRI and arterial spin labeling (ASL) imaging was used to isolate cerebral blood flow (CBF) in particular. BBB disruption was targeted to the right somatosensory cortex in one hemisphere only. Bilateral hind paw electrical stimulation was used to activate the somatosensory cortex in both hemispheres at short (6 s) and long (18 s) stimulus durations. FUS-

BBB opening leads to a marked decrease in the changes in the BOLD response due to stimulation. There was no difference in baseline blood flow between the targeted hemisphere and the non-targeted hemisphere. However, changes in blood flow due to stimulation were almost completely suppressed in the targeted hemisphere. Results from the 6-second stimulation and baseline flow measurements are shown in Figure 1. It appears that FUS-BBB opening, at this low power level and one hour after sonication, affects either the signaling mechanism from the neurons to the vessels that is supposed to initiate increased blood flow to the active region or the ability of the vessels to respond to this signal.

Abstract: Multiple sclerosis (MS) is an autoimmune-mediated neurodegenerative disease that includes processing speed-related cognitive impairments, the neural basis of which remains unknown. Recent research has suggested that cerebellum dysfunction plays a role in MS-related processing speed impairment. Due to extensive cortico-cerebellar connectivity, and the demyelinating nature of the MS disease course, we hypothesize that MS alters the connectivity between the cerebellum and cortical areas associated with cognitive abilities. MS and healthy control (HC) participants were scanned using a 3T MRI scanner with an echo-planar imaging scan during rest. All preprocessing and analyses were performed using Analysis of Functional NeuroImages. Average timeseries were created for each participants' cerebellum region of interest (cROI) and a Pearson's correlation coefficient was computed between the cROI and all cortical voxels. Correlation coefficients were then transformed to z-scores for between-group comparison. Results from the independent-samples t-test showed that MS had significantly lower z-scores in cuneus and cingulate gyrus. The results suggest MS-related reductions in cortico-cerebellar connectivity. MS alters connectivity between the cerebellum and cortical areas within the default-mode and executive control networks that are associated with cognitive impairments.

Title: Prediction of individual cognitive ability using resting-state functional connectivity

Authors: *E. DHAMALA[1], K. JAMISON[2], S. DENNIS[3], A. KUCEYESKI[2];
[1]Neurosci., [2]Radiology, Weill Cornell Med., New York, NY; [3]Sarah Lawrence Col., New York, NY

Abstract: Resting-state functional connectivity (rsFC) measures temporal correlation of spontaneous blood-oxygen-level dependent (BOLD) signal among spatially distributed brain regions. Intrinsic functional connectivity has been shown to reflect performance variability in several cognitive domains in healthy individuals (Seeley, WW. *et al.*, 2007; van den Heuvel, MP. *et al.*, 2009). A recent study used rsFC to predict 58 different behavioural measures with

prediction accuracies ranging from 0 to 0.45 (Li, J. *et al.*, 2019). Thus, rsFC may hold promise to reveal functional biomarkers underlying cognitive abilities. Using publicly available data from the Human Connectome Project, we examined resting state BOLD time series data from 1003 subjects (469 males; ages 22-35). Zero-lag Pearson correlation with regression of the global signal and its temporal derivative were used to generate a rsFC matrix for each subject using an 86 region FreeSurfer atlas (34 cortical areas and 9 subcortical areas per hemisphere). Each subject's rsFC matrix was Fisher's z-score transformed. Cognitive measures used in this study were the fluid cognition composite, crystallized cognition composite, and total cognitive function composite, all of which are based on an individual's performance on different NIH Toolbox tests. The data were separated into training (90%) and testing (10%) subsets. Linear ridge regression with leave-one-out cross validation and grid search were used to optimize the regularization strength hyperparameter. We were able to predict an individual's cognitive score using their rsFC with a coefficient of determination (R^2) of 0.12, 0.10, and 0.19 for fluid, crystallized, and total cognition composites, respectively, with corresponding Pearson correlation values of 0.38. 0.42, and 0.46. Overall, rsFC accounted for 12.0%, 16.3%, and 21.2% of the explained variance score for fluid, crystallized, and total cognition composites, respectively. For each of the three models, we found that cortico-cortical functional connectivity was most important for the prediction.

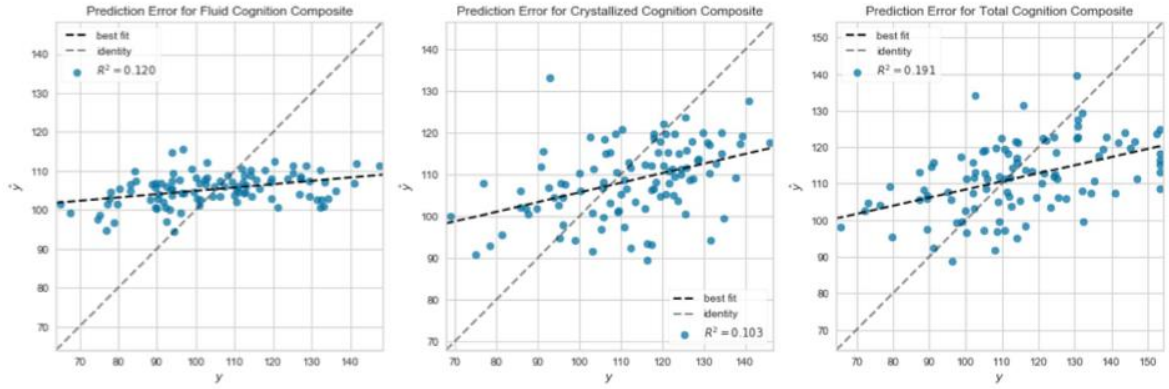

Fig. 1: Prediction errors for fluid (left), crystallized (middle), and total (right) cognition composite. True values (y) are plotted on the x axis and predicted values (ŷ) on the y-axis. The coefficient of determination (R^2) for each prediction is shown on the graph. Pearson correlation between the true and predicted values are 0.38 (fluid), 0.42 (crystallized), and 0.46 (total). Resting-state functional connectivity accounted for 12.0% (fluid), 16.3% (crystallized) and 21.2% (total) of the explained variance.

Title: An MRI compatible headstage for simultaneous electrophysiology and fMRI recording

Authors: *M. SORENSON[1], Y.-Y. I. SHIH[2], S.-H. LEE[2], R. FRANKLIN[1], M. GERHARDT[1], F. SOLZBACHER[3];
[1]Blackrock Microsystems, Salt Lake City, UT; [2]Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [3]Univ. of Utah, Salt Lake City, UT

Abstract: Motivation/problem statement:
Electrophysiology recordings from implanted electrodes while simultaneously performing MRI scans presents challenges. The MRI machine can induce noise into electrophysiology recordings. Likewise, electronics and/or cables inside the MRI can induce artifacts into the MRI images. Safety issues, based on material choices, are also a concern.
Methods/ approach:
We designed an MRI compatible headstage preamplifier capable of recording local field potentials (LFP) and single unit activity from a microelectrode array. The approach taken was to buffer the neural signals close to the electrode to reduce noise pickup from antenna effects and then transfer the buffered signal through a shielded cable to a recording system located outside of the MRI environment.
The headstage was bench tested to show comparable performance to non-MRI compatible headstages used for LFP and single unit recording. It was then tested in an MRI for signal quality during scans as well as for imaging artifacts. Finally, it was tested in conjunction with an MRI compatible electrode in a rat model to show efficacy.
Results:
Bench testing of the MR-compatible headstage showed similar quality to existing headstages in terms of noise and frequency response. Testing in the MRI showed minimal imaging artifacts in the area of interest at the electrodes and acceptable noise levels in the electrophysiology recordings. In-Vivo testing proved efficacy of the MRI compatible headstage.
Conclusion/implications:
The MRI compatible headstage designed provides simultaneous electrophysiology recording and fMRI imaging. This provides researchers with a new tool for their work.

Title: Hemodynamic correlates of posterior alpha rhythm during eyes-open and eyes-closed states: A simultaneous EEG-fMRI study

Authors: *J. E. GALLEGO RUDOLF[1], E. H. PASAYE-ALCARÁZ[1], M. CORSI-CABRERA[2];
[1]Inst. de Neurobiologia, UNAM, Queretaro, Mexico; [2]Facultad de Psicología, UNAM, Mexico City, Mexico

Abstract: Introduction: Simultaneous Electroencephalography and functional Magnetic Resonance Imaging recording (EEG-fMRI) is a multimodal neuroimaging tool that intends to assess the electrophysiological and hemodynamic correlates of brain activity. Despite efforts, data quality remains an important issue, especially for EEG. In this work, we compared different ballistocardiographic (BCG) artifact correction methods applied to EEG data collected during EEG-fMRI. We evaluated both artifact reduction and EEG signal preservation (focusing on posterior alpha rhythm). Next, we performed an EEG-informed fMRI analysis using EEG alpha power fluctuations as a BOLD signal predictor. Method: EEG was recorded from 20 healthy subjects outside the MR environment and during EEG-fMRI while they performed a simple eyes-closure, eyes-opening block-design task (EC-EO task). Gradient artifact (GA) was removed using artifact template subtraction (ATS). BCG artifact was corrected using either ATS, Optimal Basis Set (OBS), Independent Component Analysis (ICA) or the combination of OBS and ICA. Efficacy of artifact removal was assessed by comparing EEG power between the corrected EEG-fMRI and the outside data. Signal preservation was assessed by evaluating alpha power reactivity to the EC-EO task in the corrected signals. For EEG-informed fMRI analysis, ICA was used to extract alpha power fluctuations. Resulting time series were convolved with a hemodynamic response function and used as BOLD signal predictors in the subject-level analysis. Group analysis was performed using permutation-based inference. Results: Satisfactory GA cleaning can be performed using ATS approach. Although all methods reduce the BCG artifact, residuals remain. ICA feature extraction rescues posterior alpha activity from the contaminated signals. Back-reconstructed EEG signal shows a clear reactivity to the EC-EO task. Group analysis revealed an inverse relationship between alpha power fluctuations and BOLD signal in occipital and parietal cortices. EEG-informed fMRI derived results show great similarity to the results

obtained when using conventional task-design predictor inference. Conclusion: EEG alpha power fluctuations can be preserved after correcting the data obtained from simultaneous recordings and using feature extractions tools such as ICA. The inverse relation between EEG alpha power and BOLD signal in visual cortices is a consistently observed phenomenon in EEG-fMRI studies. These findings support EEG-informed fMRI analysis as a valuable tool that can be used to investigate the interactions between electrophysiological and hemodynamic responses in the human brain.

Title: Development of the functional ultrasound imaging platform for awake and behaving mice in preclinical drug discovery

Authors: *A. SHATILLO, H. VAHERTO, J. KOPONEN, D. MISZCZUK;
Charles River Discovery, Kuopio, Finland

Abstract: Anesthesia in preclinical functional neuroimaging is one of the major confounding factors, hindering the application of the technology for drug discovery and lowering the translational value of the obtained results. Substantial effects on the basic vital functions and physiology, interference with brain neurotransmitter systems and inhibition of the neuronal activity are the most common negatives.
Functional ultrasound (fUS) is a novel imaging technique that was recently introduced to the field of preclinical CNS research. Method utilizes latest technological advancements for ultrafast plane-wave acquisition of doppler ultrasound signal with real-time data processing. Applied to neuroimaging in laboratory animals, this approach enables high sensitivity functional measurement of relative cerebral blood volume (rCBV) changes with excellent spatio-temporal resolution. Combined with the imaging depth to cover the brain in coronal dimension in both rats and mice it makes a perfect platform for functional studies similar to fMRI in humans and animals. Moreover, non-invasive signal recording and small footprint of the fUS sensor creates a perfect opportunity for awake imaging in non-anesthetized animals with minimal stress and habituation period, making it much more cost-effective and feasible alternative to awake fMRI. In this methodological study we sought to setup a robustly working platform for awake fUS imaging in mice that can be routinely used for preclinical drug discovery in CNS.
fUS prototype device (Iconeus, Paris, France) and MobileHomeCage v5 (MHC, Neurotar,

Helsinki) with platform tracking were used for habituation and awake imaging purposes. Mice (C57bl/6J) were surgically implanted with MHC-compatible 3D-printed titanium alloy head plates positioned over the occipital bone. After one week of recovery, training protocol that consisted of 8 training sessions of increasing duration (5 to 45 min) was initiated, starting with basic handling on D1, fixation in MHC on D2-3 and mock imaging on D4. Actual data acquisition was performed on D5 and consisted of two 10 minutes-long resting state imaging sessions with 400 ms temporal resolution. Full power doppler time series from selected brain regions were split into 3-4 artifacts-free epochs, low-pass filtered for the correlation analysis and visualized by connectivity matrices.
Awake fUS imaging platform established and described within this study, demonstrates the utility and benefits of this cost-efficient methodology when applied to preclinical translational research and drug discovery as a powerful alternative to awake fMRI or imaging in anesthetized animals.

Title: 7t MRI: Combined fMRI-fMRS of m1 during rest and motor tasks, linking bold and neurochemicals

Authors: *J. M. LEVENSTEIN[1,2], W. CLARKE[1], B. IP[1], U. EMIR[3], P. BANDETTINI[2], C. J. STAGG[1];

Abstract: Functional magnetic resonance spectroscopy (fMRS) is an in-vivo imaging technique that shows promise towards measuring task-relevant modulation of neurotransmitters in the human brain. To more fully understand the metabolism underlying brain function, this is the first study in the motor cortex to apply a novel MR sequence acquiring concurrent measures of BOLD and fMRS.
Twenty-four participants were recruited into study1 (n=12,6f) and study2 (n=12,6f). fMRS data

were analyzed with MRspa and LCmodel (fig1A). fMRI data were analyzed using FSL. In study1, participants performed a 1Hz block-design finger-tapping task. Fig.1B demonstrates significant task BOLD activity in the MRS voxel. The first fMRS analysis processes the data across-time (fig.1C). The second analysis applies the timings of the task to create baseline and task condition spectra (fig.1D). The final analysis generates time-locked epochs(fig.1E). Group-level correlations between task fMRS and BOLD timecourses demonstrate a significant negative correlation with GABA (R^2=0.15, p=0.028). Applying a 32 second shift to the BOLD timecourse results in a significant positive correlation with glutamate (R^2=0.44, p<0.001). Applying the task timings to generate condition specific spectra resulted in a significant GABA decrease during the 1Hz task (t(8)=3.77, p=0.006). Epochs of MRS spectra show decreasing GABA during tapping periods (fig.1F1), with significant decreases in task-minus-baseline (t(8) =3.01, p=0.017).

These results demonstrate a decrease in GABA concentration during 1Hz finger tapping compared to rest. Task-induced changes in glutamate positively correlate with the BOLD timecourses when a 32 second lag is applied, suggesting a potential task-induced neurochemical delay. While these preliminary findings still require further investigation, the results highlight the need for greater understanding of metabolism dynamics in the human brain, and their relation to BOLD imaging. Our forthcoming study2 results aim to address these needs.

Title: Differential effects of the anaesthetic agents sevoflurane and isoflurane on functional connectivity in the rhesus macaque cortex

Authors: C. B. C. R. POULLIAS[1], K. L. MURPHY[2], *K. KRUG[1], J. SALLET[1];
[1]Oxford Univ., Oxford, United Kingdom; [2]Newcastle Univ., Newcastle, United Kingdom

Abstract: The study of resting state connectivity detects temporal correlation in the spontaneous blood oxygen level-dependent (BOLD) signal for subjects at rest in an MRI scanner - a useful means of investigating the brain's functional organization and potential neurological alterations. Better behavioural control makes acquiring resting-state data in awake humans straightforward. This is more challenging for non-human primates like the Rhesus macaque - a major model of human brain function. Thus, many studies acquire resting state data in anaesthetized animals. However, different anaesthetic agents may have differential effects on brain physiology and thus functional connectivity. To investigate their impact, we compared directly functional connectivity with two commonly employed, volatile anaesthetic agents. We acquired two resting state MR datasets (EPI sequence; 800 or 1600 volumes) from 24 Rhesus macaques. The animals scanned under isoflurane or sevoflorane were matched for depth of anaesthesia (assessed by the min. alveolar concentration (MAC) value), age, delay between sedation and data collection, and physiological values (blood pressure, heart rate, exhaled CO2 concentration). The first group was anesthetized using sevoflurane (MAC value range: 0.78-1.3, 10 animals), the second using isoflurane (MAC value range: 0.61-1.23, 14 animals). We combined seed based analysis (SBCA) and individual component analysis (ICA, using the FSL function MELODIC with 30 individual components) to investigate the differential impact of isoflurane and sevoflurane on functional connectivity, especially on networks related to visual and decision processes. The results from both SBCA and MELODIC revealed higher z-score correlation values for sevoflurane than isoflurane. However, the functional maps obtained were less spatially selective under sevoflurane than isoflurane. Our results show that the two agents despite maintaining anaesthesia

at comparable depths differentially impact brain activity. Therefore the type of anaesthetic agent constitutes a key parameter for interpreting functional connectivity data.

Title: Using multimodal MRI to investigate brain structure, function, and capillary density in a genetic model of diabetes

Authors: *C. LAWSON, K. RENTRUP, J. QIAO, X. CAI, P. KULKARNI, C. FERRIS; Psychology, Northeastern Univ. Dept. of Psychology, Boston, MA

Abstract: Type 2 Diabetes (T2D) is a serious metabolic disorder affecting 16 million people in the US, with prevalence expected to reach more than 54.9 million Americans by 2030. Small vessel disease is prominent in T2D as evidenced by the high incidence of retinopathy, nephropathy and gangrene. The present study used non-invasive multimodal magnetic resonance imaging (MRI) to characterize small vessel disease in the brain and the neuropathological features of late-stage diabetes using the transgenic BBZDR/Wor rat, an animal model of T2D provided by Biomere (Worcester, MA). Imaging was performed on BBZDR/Wor rats and their age-matched wild type controls using a 7.0T MRI scanner. The imaging modalities included T1 weighted voxel-based morphometry, diffusion weighted imaging with quantitative anisotropy, resting state BOLD functional connectivity, ferumoxytol contrast-enhanced imaging and finally quantitative ultrashort TE contrast enhanced MRI (QUTE-CE). This final imaging technique was particularly relevant as it allows visualization brain vasculature and cerebral blood volume using iron oxide nanoparticles to track blood throughout the brain. All images were registered to a 3D MRI Rat Atlas with 171 segmented and annotated brain areas used to generate an unbiased computational analysis of all data. Cognitive decline, alterations in hippocampal volume and reduced functional connectivity across multiple neural circuits are clinical features of T2D. As such, it was hypothesized that T2D rats would show similar problems in cognition and neuroradiological evidence of alterations in brain areas and neural circuits involved in learning and memory. Specifically, it was predicted that T2D rats would present with hypovascularity in the hippocampal complex and loss of vascular responsivity to carbon dioxide challenge as compared to age-matched. Both anatomical brain area scans and neural circuitry imaging revealed significant differences between the wild type and T2D rat brains throughout the cortex and areas of the hippocampus. The angiopathy associated with diabetes was consistent in the

central nervous system of the T2D rats, with decreased capillary density and microbleeds throughout the brains.

Title: Probing the potential biophysical mechanisms of fast fMRI signals

Authors: *J. E. CHEN[1], G. H. GLOVER[2], N. E. FULTZ[3], N. A. OHRINGER[3], B. R. ROSEN[4], J. R. POLIMENI[5], L. D. LEWIS[6];

Abstract: fMRI studies have mostly focused on slow signals due to the presumed slow speed of the hemodynamic response, which was thought to limit neural signals to the <0.3 Hz range. However, recent resting state and task fMRI studies have detected neural fluctuations at frequencies of up to 0.75 Hz, well above the limits predicted by the canonical hemodynamic response function (HRF). The mechanisms of these fast fMRI signals are not known, limiting our analysis and interpretation of these signals. In this study, we examined two potential biophysical mechanisms that may underlie high-frequency fMRI signals. **Mechanism I: tasks with lower contrast levels elicit faster HRFs.** As resting-state neural activity likely comprises low intensity levels relative to task-driven responses, we asked whether low-intensity stimuli could reproduce the observed fast hemodynamic responses, which would in turn lead to high-frequency fMRI signals. Two sensory tasks with graded contrast levels were performed to test this hypothesis: (1)

8 subjects received a vibrotactile stimulation at three contrast levels; and (2) 10 subjects received visual stimulation with a checkerboard pattern flickering at two luminance contrasts. In both tasks, HRFs at lower contrast levels exhibited shorter time-to-peak and narrower full-width-of-half-maximum. Using simultaneous EEG, we found no salient distinctions in steady-state visual evoked potential amplitudes between different visual contrasts, suggesting these faster HRFs were due to altered hemodynamics. **Mechanism II: high spatial resolution can enhance the sensitivity of fMRI to high-frequency oscillations.** Smaller voxel sizes can reduce contamination from large veins that have slow responses, and mitigate phase cancellation among distinct HRFs within one voxel. Furthermore, as the voxel size decreases to the sub-millimeter regime, alternative, faster non-BOLD signals (e.g., inflow and dynamic partial volume effects) may become more evident, and classical hemodynamics may no longer apply. To test this hypothesis, we evaluated the inter-voxel variability of HRFs evoked by an event-related visual stimulus at very high spatial resolutions: 5 subjects at 3T (1.23X1.23X1.5 mm^3), and 5 subjects at 7T (0.8 mm^3 iso.). We observed notable variability across voxels, with the slowest HRFs being approximately twice long as the fastest ones; and a large number of voxels exhibiting much faster responses than the canonical HRF. Collectively, our results suggest that both low-intensity task contrasts and high spatial resolution can result in much faster HRFs than conventional models, supporting the potential of fast fMRI for mapping brain oscillations.

Title: Effect of ApoE ε4 carriers on BBB permeability, Amyloid-b and Tau in cognitively normal subjects - A multimodal MRI/PET study

Authors: A. C. CHAKHOYAN[1], A. MONTAGNE[1], M. D. SWEENEY[1], D. A. NATION[1], J. PA[2], T. BENZINGER[4], J. C. MORRIS[5], H. C. CHUI[3], A. W. TOGA[2], B. V. ZLOKOVIC[1]; [1]Dept. of Physiol. and Neuroscience, Zilkha Neurogenetic Institute, Keck Sch. of Med., [2]Lab. of

Neuro Imaging, USC Stevens Neuroimaging and Informatics Inst., [3]Alzheimer's Dis. Res. Ctr., USC, Los Angeles, CA; [4]Mallinckrodt Inst. of Radiology, [5]Dept. of Neurol. and The Hope Ctr. for Neurodegenerative Disorders, Washington Univ. in St. Louis Sch. of Med., St. Louis, MO

Abstract: Purpose: Early blood-brain barrier (BBB) breakdown is an early biomarker of human cognitive dysfunction independent of Amyloid-β and Tau. ApoE4 is a major genetic risk factor for Alzheimer's disease. Here, we determined cross-sectionally the effect of ApoE4 gene on vessel permeability, and Amyloid-β and Tau biomarkers in cognitively normal patients by using advanced imaging techniques - MRI and PET.
Methods: Sixty-one subjects were included in this study. Out of 61 subjects, 37 were ApoE4 non-carriers (3/3) and 24 ApoE4 carriers (3/4+4/4). In ApoE4 non-carriers and carriers, 70.2% and 66.2 were female with no difference in age (median: 68 vs. 67 years) and years of education (median: 17.5 vs. 17.3 years), respectively. Amyloid-β and Tau PET images were first converted to standardized uptake value (SUV) then normalized by whole cerebellum (SUVR). DCE-MRI was used to extract volume transfer constant (Ktrans) which reflects the influx rate of gadolinium contrast from blood plasma into the brain tissue extravascular space. The medio-temporal (MTL) lobe was considered as a principal region of interest segmented on high resolution 3D-T1w images.
Results: Results suggest that Amyloid-β and Tau were not significantly different in MTL region between ApoE4 non-carriers and carriers. Interestingly, only Ktrans values were significantly higher in ApoE4 carriers. Linear regression analyses revealed no correlation between Ktrans values, Amyloid-β and Tau SUVR.
Conclusions: Multimodal MRI/PET demonstrate BBB breakdown in cognitively normal ApoE4 carriers compared to non-carriers that is not affected by Amyloid-β and Tau.

Title: Loneliness is associated with altered regional cerebral blood flow: An arterial spin labeling imaging study

Authors: *Y.-W. CHEN[1], T. CANLI[2];
[1]State Univ. of New York at Stony Brook, Stony Brook, NY; [2]Dept Psychol, Stony Brook Univ. Dept. of Psychology, Stony Brook, NY

Abstract: Perceived social isolation, commonly referred to as loneliness, is defined as the subjective feeling that one's social needs are not satisfied by both quantity and quality of one's social relationships. Loneliness has been linked to a broad range of adverse physical and mental health consequences. Thus, there is an interest in identifying the neural regions and underlying molecular processes by which subjective social isolation adversely affects health. Prior imaging studies reported that high levels of loneliness were associated with increased activation to unpleasant social stimuli in the visual cortex, and with decreased activation to pleasant social stimuli in the ventral striatum. Another study reported an increased functional connectivity density cluster that was centered over the lingual gyrus. Whereas prior study results were based on indirect measures of neural activation (i.e., blood-oxygenation-level-dependent imaging), the current study was based on direct measures of regional cerebral blood flow (rCBF) using resting-state Pulsed Arterial Spin Labeling (PASL) imaging, which is thought to be highly correlated with cerebral metabolism. Eight-two healthy young adults (M = 21.51, SD = 4.64, 49 females) were included in our current study. We examined the association between individual perceived loneliness (Revised UCLA Loneliness Scale, M = 42.29, SD = 10.01) and resting-state rCBF. Whole-brain regression analyses (uncorrected $p < .005$, extend 50 voxels) revealed negative associations between loneliness and left-lateralized rCBF in the insula, postcentral gyrus, lingual, middle occipital, and parahippocampal gyri. These results replicate and further extend prior work implicating a widespread network of regions involved in somatosensory, visual and affective-cognitive processing.

Title: Temporal stability of the hemodynamic response function in human cortex

Authors: *A. TAYLOR, X. ZOU, J. KIM, D. RESS;
Baylor Col. of Med., Houston, TX

Abstract: Introduction: We recently found that a brief stimulus with speeded task will evoke the hemodynamic response function (HRF) across most of cortex. Here, we measure HRFs within healthy subjects over the course of four sessions separated by intervals of three hours, three days,

and three months to quantify HRF variations over time.**Methods:**Subjects (*N*=8) performed an audiovisual sequence detection task for 2 seconds (Fig A). The visual stimulation consisted of three circular regions of randomly flickering colored dots with a corresponding audio stimulus of bandpass-filtered white noise. 80 HRFs were collected per session. Imaging was performed on a 3T Siemens Trio scanner with a 32-channel head coil. FMRI data were collected using SMS-accelerated EPI (2-mm voxels; TR = 1.25 s; 57 slices; whole-cortex Rx). These data were registered to anatomical images (0.7-mm MP-RAGE) that was segmented using FreeSurfer to delineate cortical gray matter. HRF time series data from central gray matter layers were parameterized for each voxel. **Results:**Surface maps (Fig B) of HRF parameters show highly correlated spatial patterns across the four time points for activation (R= 0.73±0.15) and peak amplitude (R= 0.68±0.18). Temporal parameters, TTP (R = 0.20±0.08) and FWHM (R = 0.17±0.06), are much less spatially correlated. Principal component analysis (Fig C) of the HRF time series across voxels show strong correlations (PC1: R= 0.96; PC2: R= 0.93), suggesting stable temporal dynamics across time points. **Discussion:**Across a long time span, HRF amplitude parameters are strongly spatially correlated whereas the temporal parameters showed greater variation. However, principal component analysis suggest that temporal dynamics are reasonably consistent across time within each subject. More detailed voxel-by-voxel analysis of the temporal dynamics is in progress. Our observations are inconsistent with fMRI studies at coarser resolutions that showed significant variations across sessions, suggesting that the HRF is more stable within cortical gray matter than in superficial vascular structures.

Title: Disruption of midbrain functional connectivity in cerebral small vessel disease: Evidence from CADASIL

Authors: *D. SCHOEMAKER[1], Y. ZULUAGA[2], L. VELILLA[2], C. OSPINA[2], F. LOPERA[2], J. ARBOLEDA-VELASQUEZ[3], Y. T. QUIROZ[4];
[1]Psychiatry, Massachusetts Gen. Hospital/Harvard Med. Sch., Boston, MA; [2]Grupo de Neurociencias de Antioquia, Medellín, Colombia; [3]Schepens Eye Res. Inst., Boston, MA; [4]Massachusetts Gen. Hosp., Boston, MA

Abstract: The brain-stem is vulnerable to the effects of cerebral small vessel disease (SVD), a prevalent condition in the aging population that contributes to the risk of neurodegeneration and cognitive decline. However, the impact of SVD on brain-stem functional connectivity is undocumented. We examined resting-state functional connectivity in individuals with CADASIL, a hereditary condition caused by mutation on the NOTCH3 gene and leading to the early onset of SVD and vascular cognitive impairments.
Resting State fMRI was acquired in 25 individuals with CADASIL (mean age=50.52 +/-9) and 25 non-carriers (mean age=43.92 +/-10) and analyzed using *CONN* (Whitfield-Gabrieli et al., 2012). Functional connectivity between the brain-stem (seed region) and cortical regions-of-interest (ROIs) was compared between groups, while adjusting for age. Areas of significant between-group differences were identified using a stringent threshold (p-FDR=.01). Connectivity values in regions of significant differences were extracted for each subject, averaged across regions, and correlated with the overall volume of white matter lesions and cognitive performance.
Compared to non-carriers, CADASIL subjects showed reduced connectivity between the brain-stem and multiple cortical areas (Figure 1). Mean brain-stem connectivity was negatively correlated with age in CADASIL (r=-0.47, p=0.02), but not in non-carriers (p>.05). In CADASIL, mean brain-stem connectivity was associated with the volume of white matter lesions (r=-0.58, p=0.003), and performance on the INECO Frontal Screening (IFS, r=0.59, p=0.002) and the CERAD (r=0.51, p=01).
Overall our results showed a reduction in connectivity between the brain-stem and multiple cortical brain regions in CADASIL. Our results further revealed associations between brain-stem

connectivity, the burden of white matter lesion and cognition. Altogether, these findings suggest that SVD may contribute to early disruption in brain networks and onset of cognitive symptoms.

Title: Data quality and safety of simultaneous EEG-fMRI using multi-band fMRI sequences

Authors: *M. K. EGAN[1,2], R. LARSEN[2], B. P. SUTTON[2,3], S. SADAGHIANI[1,2];
[1]Psychology, [2]Beckman Inst., [3]Bioengineering, Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: Simultaneously recorded electroencephalography and functional magnetic resonance imaging (EEG-fMRI) is a highly informative imaging technique for brain function, but there exists little information about the data quality and safety when used with newer multi-band (MB) fMRI imaging sequences. As Brain Products (BP), manufacturer of MR-compatible EEG amplifiers, has no recommended MB protocol, we tested an MB sequence with lower radiofrequency deposition (RFD) than the nonMB sequence that they recommend. In a Siemens Prisma 3T scanner, we first tested an MB sequence (TR = 440 ms, flip angle = 40, nSlices = 28, MB factor = 4, GRAPPA factor = 2) against a modern nonMB sequence (TR = 1800ms, nSlices = 34, GRAPPA = 2) using only fMRI. Two pilot subjects underwent functional localizer tasks targeting auditory, face-selective, and emotion sensitive areas, once with each sequence. The MB sequence showed higher functional contrast than the nonMB sequence in both subjects, likely due to its high temporal and spatial resolution. Prior literature suggests that EEG electrode temperature is linearly proportional to RFD of concurrent fMRI. However, this literature did not include MB sequences, so we first examined the safety of electrode heating in the MB sequence. We compared the same MB sequence as above against the maximum intensity nonMB sequence considered safe for electrode heating in EEG-fMRI as recommended by BP (TR = 2000 ms, nSlices = 25) using 64 channel EEG on an impedance-matched head phantom. Temperature changes were measured by inserting Luxtron fluoroptic thermometer probes underneath ECG and TP7 (i.e. those with the longest leads / strongest RF absorption). Three 15-minute runs were acquired for each sequence, alternating in order, with a pause of 5 minutes between runs. The average temperature increase over the scanning period was a factor of 0.62 lower at ECG and 0.81 lower at TP7 for the MB than for the non-MB sequence, in accord with the calculated RFD. Next, we tested the EEG quality (64 channels, impedances <5 kOhm) using the MB sequence during a 10-minute eyes-closed resting state scan for 7 human subjects (4 females). Following MR and cardioballistic artifact rejection with procedures traditionally applied to nonMB sequences, spectrograms for all subjects showed a clear alpha peak at ~12Hz. Only a minimal peak remained in each spectrogram due to residual MR artifact at the RF repetition frequency. We conclude that EEG electrode heating for the above-described MB sequence is proportional to the calculated RFD and lower than the BP recommended nonMB sequence. The MB sequence provides high spatiotemporal resolution with no adverse effects on data quality.

Title: The effect of sleep deprivation on the brain-gut axis

Authors: *Y.-L. SHEN[1], D.-F. YANG[2], C. WU[1], Y.-T. TUNG[2];
[1]Grad. Inst. of Mind, Brain and Consciousness, [2]Grad. Inst. of Metabolism and Obesity Sci., Taipei Med. Univ., Taipei, Taiwan

Abstract: Sleep deprivation is resulting from increased workload, shift work and various other challenges imposed by modern society may represent serious threat for health and well being. The increased BMI was seen when adult slept less than 7 hours per day. The impairment of spatial and emotional learning and memory can be detected after the deprivation of the slow-wave sleep and REM sleep in animals. In order to learn more about the effect of sleep deprivation on the physiology and brain of the organisms, the present study conducted the sleep deprivation by placing the mice on the grid over water for 72 h and collected the behavioral, biochemical changes and fMRI imaging thereafter. Firstly, our results showed that sleep deprived mice significantly reduced body weight and increased food intake. But their emotion and spatial learning were not affected by this stressful experience. We also found that the organ/body weight was increased in the kidney, but we did not see this in the liver, spleen and soleus. However, we did not detect any significant differences in the plasma biochemistries, such as AST, ALT, Albumin, LDH and CPK. For the fMRI, we did collect the activations in the visual cortex by manipulating the light stimulation in the mice subjects. Together, our results demonstrated that 72h on the grid over water is stressful for mice and this manipulation increased the weight of kidney. We did collect the light stimulation induced activation in mice in the fMRI and their resting-state fMRI remained to be determined.

Title: Mapping brain hemodynamic signals and autonomic activity related to slow yoga breathing techniques and working memory performance

Authors: *S. DEEPESHWAR[1,2], R. B. BUDHI[3], T. SHETTY[4], M. N. KRISHNAMURTHY[4];
[1]Yoga and Life Sci., Swami Vivekananda Anusandhana Samsthana (S-VYASA), Bangalore, India; [2]Dept. of Yogic Art & Sci., Visva Bharati, A Central Univ., Santiniketan, India; [3]Yoga and Life Sci., [4]Swami Vivekananda Yoga Anusandhana Samsthana (S-VYASA), Bangalore, India

Abstract: Yoga breathing is a slow, controlled and rhythmic activity which has been used for centuries to promote balance state of mind and cognitive processes. The combination of mental activity and slow breathing may influence cerebral oxygenation and autonomic nervous system activities. Therefore, the current study aimed to investigate the interaction between hemodynamic responses at the prefrontal cortex (PFC) and autonomic functions measured through heart rate variability (HRV) following a neurocognitive performance before and after yoga breathing practice. Forty healthy male volunteers were assessed during yoga breathing and spontaneous breathing sessions in two groups of yoga practitioners. The first group (n=20) received one-month yoga breathing orientation (YBO) at the rate of 6 breath per minute (bpm) over a period of one month before data collection and the second group (n=20) were assessed without any yoga breathing practice (NBT). The selected yoga practitioners had more than 12 months of experience, and none of them had any neurological or pathological conditions. We have used fNIRS to compare the relative changes in oxyhemoglobin (DHbO), deoxyhemoglobin (DHbR) and total hemoglobin (DTHb), in three yoga breathing practices *viz.* (i) left nostril breathing (LNB), (ii) right nostril breathing (RNB); and (iii) alternate nostril breathing (ANB) and compared with breath awareness (BAW). Relative changes in hemodynamic responses during yoga breathing sessions showed increased prefrontal oxygenation during ANB and RNB sessions that reflected in the improvement of participants performance in working memory task. The HRV results showed that all yoga breathing sessions at 6 bpm increases LF band, LF/HF ratio, mean HR, SDNN, TINN and decreases HF band, and mean RR. Moreover, the working memory performance was increased concomitantly with HRV, after RNB and ANB sessions. The outcome of the study suggests that yoga breathing enhances oxygenation at prefrontal PFC which is associated with better cognitive control over the task and parasympathetic withdrawal when compared with spontaneous breathing of BAW session. This indicates that yoga breathing enhances cognitive processes with better control over HRV.

Title: Acute exposure to dim light at night is sufficient to induce neurological changes and depressive-like behavior

Authors: W. H. WALKER, II[1], J. C. BORNIGER[2], M. M. GAUDIER-DIAZ[3], O. H. MELÉNDEZ-FERNÁNDEZ2[1], J. L. PASCOE[1], A. C. DEVRIES[1], *R. J. NELSON[1]; [1]Neurosci., West Virginia Univ. Sch. of Med., Morgantown, WV; [2]Psychiatry & Behavioral Sci., Stanford, Stanford, CA; [3]Psychology & Neurosci., Univ. of North Carolina, Chapel Hill, NC

Abstract: The advent and wide-spread adoption of electric lighting over the past century has dramatically affected the circadian organization of physiology and behavior for many individuals in industrialized nations; electric lighting in homes, work environments, and public areas has extended daytime activities into the evening, thus, increasing night-time exposure to light. Although initially assumed to be innocuous, chronic exposure to light at night (LAN) is now associated with increased incidence of cancer, metabolic disorders, and affective problems in humans. However, little is known about potential acute effects of LAN. To determine whether acute exposure to low level LAN alters brain function, adult male and female mice were housed in either typical light days and dark nights (LD; 14h of 150 lux:10 h of 0 lux) or light days and low level light at night (LAN; 14h of 150 lux:10 h of 5 lux). Mice exposed to LAN on three consecutive nights increased depressive-like responses compared to mice housed in dark nights. Additionally, female mice exposed to LAN increased central tendency in the open field. LAN was associated with reduced hippocampal vascular endothelial growth factor-A (VEGF-A) in both male and female mice, as well as increased VEGFR1 and interleukin-1β mRNA expression in females and reduced brain derived neurotrophic factor mRNA in males. LAN significantly reduced active blood vasculature in the dentate gyrus, hilus, granular cell layer, and CA1, but not CA3 region of the hippocampus. Further, LAN significantly altered circadian rhythms (activity and temperature) and circadian gene expression in female and male mice respectively. Altogether, this study demonstrates that acute exposure to LAN alters brain physiology and can be detrimental to wellbeing in otherwise healthy individuals.

Title: Neurovascular function in J20 Alzheimer's mice and cardiovascular disease/mixed dementia mouse models

Authors: *O. SHABIR, P. S. SHARP, B. J. PENDRY, M. L. FLOARE, C. HOWARTH, P. HEATH, J. SIMPSON, S. B. WHARTON, S. E. FRANCIS, J. BERWICK;
Univ. of Sheffield, Sheffield, United Kingdom

Abstract: Background: Neurovascular coupling is the mechanism by which the brain regulates cerebral blood flow to localised neural activity. The breakdown of this relationship can trigger or contribute to many neurological conditions, including Alzheimer's disease (AD).
Aims: Firstly, to investigate neurovascular function in young AD mice. Secondly, to investigate if neurovascular function in mid-age atherosclerotic and mixed-dementia mouse models is altered.
Methods: 6-9m male WT C57BL/6J mice (n=8) and J20-hAPP (n=9) mice were used to investigate early-AD. 9-12m male WT C57BL/6J (n=4), J20-hAPP (n=4), rAAV8-mPCSK9-D377Y + Western Diet (n=5) and rAAV8-mPCSK9-D377Y-J20-hAPP + Western Diet (n=3) were used. Briefly, a thinned cranial window surgery was performed to reveal cortical vessels. Mice were recovered for 2-weeks before imaging. Animals were anaesthetised and imaged using 2D-optical imaging spectroscopy. Mechanical whisker stimulations of either 2s or 16s were performed under 100% oxygen and 21% oxygen conditions. A week later, a final imaging session was performed where an electrode was inserted into the cortex to record neural responses and haemodynamics simultaneously. At the end of terminal acute experiments, mice were transcardially perfused with saline and the brains were dissected for immunohistochemistry and gene expression studies.
Findings: Blood volume (HbT) is significantly higher in 6-9m J20 mice compared to WTs in response to stimulations (p=.004). Furthermore, under 100% oxygen, the baseline HbT is significantly higher in J20's (p=.0005), with significant arterial and venous dilation, compared to WTs. When transitioning from 100% oxygen to 21% oxygen, there is a decrease in HbT in J20s, but not WTs. Finally, stimulation-evoked multi-unit activity is significantly higher in J20s (p=.0001) compared to WTs. In the second study, we see a reduction of HbT in mPCSK9-atherosclerotic mice, in response to stimulations. The mPCSK9-J20 mixed dementia mouse models show significant perturbations to physiological stimulations, which worsen under 21% oxygen (mild gas challenge) conditions.
Conclusions: The neural abnormalities coupled with haemodynamic differences could serve to be effective biomarkers in certain forms of AD, and point towards a potential therapeutic strategy. Secondly, we have novel insights into how cardiovascular disease can affect cerebral haemodynamics and the brain as a whole.

Title: Multitaper spectrograms reveal opiate specific changes in mouse electroencephalogram

Authors: *C. B. O'BRIEN[1], C. E. LOCKLEAR[1], Z. T. GLOVAK[1], H. A. BAGHDOYAN[1,2,3], R. LYDIC[1,2,3];
[1]Psychology, [2]Anesthesiol., Univ. of Tennessee, Knoxville, TN; [3]Oak Ridge Natl. Lab., Oak Ridge, TN

Abstract: Electroencephalographic (EEG) data traditionally have been analyzed in the frequency domain to characterize levels of behavioral and neurophysiological arousal (*J Vis Exp* 117: e54908, 2016). The multitaper spectrogram transforms EEG waveforms into time and frequency domains. This enables visualization of state-dependent changes in EEG power and frequency (*Physiology* 32: 60, 2017). The present study is testing the hypothesis that intraperitoneal injection of the opiates buprenorphine, morphine, and fentanyl differentially alters EEG activity in C57BL/6J (B6) mice. Adult males (n = 4) were anesthetized and implanted with telemeters (DSI HD-X02) connected to cortical EEG electrodes and neck muscle electromyogram (EMG) electrodes. The recordings of EEG and EMG activity were wirelessly transmitted from freely behaving mice and used to objectively score states of sleep and wakefulness for 4 h after injection of saline (vehicle control) and antinociceptive doses of each opiate (see companion abstract by C. E. Locklear et al). The results revealed unique features in the cortical EEG caused by the different opiates. Buprenorphine and morphine caused similar changes in the spectrograms relative to saline, with increases in EEG power at 1 to 3 Hz and 8 to 9 Hz. Spectrograms after administration of fentanyl were most similar to spectrograms recorded after saline, with maximal average power bands at 3 Hz and 7 Hz. The EEG power distributions were further analyzed across frequency bands including delta (1-4 Hz), theta (4-8 Hz), alpha (8-13 Hz), and beta (13-30 Hz). Compared to EEG power measured after saline administration, the percent change in power was differentially altered by buprenorphine: delta -64, theta -89; alpha 140, beta -43; morphine: delta -55, theta -86, alpha 58, beta 5; and fentanyl: delta -65, theta -76, alpha -22, beta -57. ANOVA revealed that EEG power in the delta, theta, and alpha bands was significantly ($p<0.01$) different from EEG power after saline for all three opiates. There was not a significant power change in EEG beta. Multiple comparisons tests revealed that EEG power was significantly ($p=0.03$) different between buprenorphine and fentanyl in theta and alpha bands. Multitaper spectrograms provide a nuanced perspective of EEG traits that characterize obtunded states of wakefulness and the inhibition of NREM and REM sleep caused by opiates.

Ongoing studies are increasing the number of mice. Future studies will quantify state-dependent variations in EEG spectrograms caused by chronically administered opiates.

Title: Systemically administered opiates disrupt the architecture of sleep and wakefulness in mouse

Authors: *C. E. LOCKLEAR[1], C. G. BUSTAMANTE[1], Z. T. GLOVAK[1], D. ZEBADUA UNZAGA[1], C. B. O'BRIEN[1], R. LYDIC[1,2,3], H. A. BAGHDOYAN[1,2,3];
[1]Psychology, [2]Anesthesiol., Univ. of Tennessee, Knoxville, TN; [3]Oak Ridge Natl. Lab., Oak Ridge, TN

Abstract: Opioid use disorder (OUD) is a major public health burden yet the opiate buprenorphine is FDA-approved for treatment of OUD. Opiates long have been shown to disrupt sleep, and sleep disruption enhances the likelihood of addiction relapse in humans (*Med Hypotheses* 74: 928, 2010). The current study is testing the hypothesis that acute administration of buprenorphine, morphine, and fentanyl differentially alters sleep/wake architecture in C57BL/6J (B6) mice. Adult males (n = 4) were housed in a temperature-controlled environment and a 12:12 light:dark cycle with ad libitum access to food and water. Mice were anesthetized with isoflurane for implantation of a telemeter (DSI HD-X02) and electrodes for recording cortical electroencephalogram (EEG) and dorsal neck muscle electromyogram (EMG). These signals were used to objectively quantify states of wakefulness, NREM sleep, and REM sleep in 10-s bins. Recordings began two weeks after the mice recovered from surgery. Every mouse received at least one intraperitoneal injection (0.3 mL) each of saline (vehicle control) and an antinociceptive dose of buprenorphine, morphine, and fentanyl. Injections were performed within 90 min of light onset. Repeated injections in the same mouse were separated by at least one week. Each 4-h recording was scored independently by two individuals, one of whom was blinded to the treatment condition. Sleep scoring concordance was greater than 90%. Data from repeated injections of the same drug into the same mouse were averaged in order not to inflate degrees of freedom. These preliminary results, expressed as percent change from saline, summarize 29 recordings. Buprenorphine increased wakefulness (190%), eliminated NREM sleep, and eliminated REM sleep. Morphine increased wakefulness (167%), decreased NREM sleep (-87%), increased latency to onset of NREM sleep (357%), and eliminated REM sleep.

Fentanyl increased wakefulness (105%), decreased NREM sleep (-54%), increased NREM sleep latency (193%), decreased REM sleep (-69%), and increased REM sleep latency (39%). The three opiates also differentially altered EEG power (see companion abstract C.B. O'Brien et al). These emerging results support the hypothesis that buprenorphine, morphine, and fentanyl differentially alter sleep/wake architecture in male B6 mice. Ongoing studies are increasing sample size and evaluating the extent to which opiate-induced sleep disruption is dose dependent and blocked by naloxone. Future studies will evaluate sex as an independent variable in B6 mice and mice with diet-induced obesity, as well as effects of chronic opiate administration on sleep/wake architecture.

Title: Sleep improves when hyperbaric oxygen therapy administered before and after methadone dose reduction for adults with opioid use disorder

Authors: *R. M. QUOCK[1], M. WILSON[2], L. SKEIKY[3], K. STANEK[5], T. ODOM-MARYON[2], D. HANSEN[3], M. LAYTON[4];
[1]Psychology, Washington State Univ., Pullman, WA; [2]Col. of Nursing, [3]Sleep and Performance Res. Ctr., [4]Col. of Med., Washington State Univ., Spokane, WA; [5]Spokane Hyperbaric Ctr., Spokane Valley, WA

Abstract: Sleep disturbances are a significant problem for adults prescribed opioids for pain control and medication-assisted treatment for opioid use disorder [Cheatle and Webster, *Pain Med*, 16:S22-S26, 2015; Sharkey *et al*., *Drug Alcohol Depend*, 113:245-248, 2011]. As much as 80% of adults enrolled in medication-assisted behavioral treatment for opioid use disorder report reduced sleep quality and quantity [Sharkey *et al*., *Drug Alcohol Depend*, 113:245-248, 2011], which can interfere with substance use recovery goals [Stein *et al*., *J Subst Abuse Treat*, 26:175-180, 2004]. Preclinical research has found that HBOT—100% oxygen at greater-than-atmospheric pressure—suppresses physical signs of naloxone-precipitated withdrawal in morphine-dependent mice [Nicoara *et al*., *Brain Res* 1648:434-437, 2016]. HBOT has been shown to improve self-report and objective measures of sleep in human subjects being treated for various illnesses [Uezato *et al*., *Psychiatry Clin Neurosci* 71:73-74, 2016; Long *et al*., *Neurol*

Res 39:239-247, 2017]. In order to investigate the role of HBOT on self-report and objective measures of sleep in adults with opioid use disorder, 31 participants (11 males, 20 females) were randomized into HBOT (n=17) or control (n=14) arms. HBOT was administered for five consecutive days in 90-min sessions at 2.0 atmospheres absolute with 100% oxygen via individualized oxygen hoods in a 12-seat sealed, pressurized chamber. Participants agreed to a 10% reduction in current methadone dose or 5 mg, whichever was smaller, to occur on Day 2 after HBOT pretreatment on Day 1. The short-form PROMIS Sleep Disturbance scale, an assessment of self-reported sleep quality (*e.g.*, trouble falling asleep, feeling rested, restless sleep), was the primary sleep measure collected at baseline, and post-treatment at 1 week, 1 month, and 3 months. For a sub-sample (n=7) of those in the HBOT arm, objective sleep measures were captured one week pre- and post-HBOT via wrist-worn actigraphy. PROMIS Sleep Disturbance results showed that the mean sleep disturbance for the control group increased from baseline to post-intervention at each measurement timepoint while it trended downward for the HBOT group, indicating less sleep disturbance at each timepoint after HBOT. Post-treatment actigraphy results support the self-report findings, showing an approximate 30-min increase in total sleep time and a 10-min reduction in sleep onset latency in the week following HBOT. These findings support the working hypothesis that clinically significant improvements in sleep duration and time to fall asleep are possible when HBOT is administered before and after opioid dose reduction.

Title: Antioxidant supplementation augments gamma activity during sleep deprivation

Authors: *P. N. BUSHANA[1,2], M. A. SCHMIDT[1], B. A. SORG[3,2], J. P. WISOR[1,2];
[1]Biomed. Sci., Washington State Univ., Spokane, WA; [2]Neurosci., Washington State Univ., Pullman, WA; [3]Integrative Physiol. and Neurosci., Washington State Univ., Vancouver, WA

Abstract: Cognitive impairment is one of the most robust and reliable indicators of sleep deprivation (SD), impacting tasks that require sustained attention, memory, and performance. Such demanding attentional tasks are mediated by gamma oscillations (60-90 Hz) in the waking brain. Gamma oscillations are also compromised by sleep deprivation and byproducts of

oxidative metabolism, which build up in the brain during periods of prolonged wakefulness. Our current studies assess the efficacy of long- and short-term exogenous antioxidant treatments in mitigating gamma-suppressing effects of sleep deprivation. In the long-term supplementation study, adult mice (12 weeks old; n=23) were placed on a control or antioxidant-enriched diet (nicotinamide riboside [NR]; 400 mg/kg/day) for 10 weeks. At 14 weeks of age, mice were instrumented for sleep recordings. Baseline and sleep-deprived recordings were taken at 4, 6, 8, and 10 weeks on diet to assess the effect of accumulating NR on sleep parameters. The second study demonstrates the effects of short-term antioxidant supplementation via intraperitoneal injections of N-acetylcysteine (NAC; 600mg/kg/injection) in adult mice (12 weeks old; n=25). Baseline and sleep deprived recordings were taken on the day of NAC administration. While no changes were observed in sleep architecture with either treatment (i.e. sleep fragmentation or distribution of sleep throughout the 24-hour day), gamma activity increased during sleep deprivation in mice undergoing either antioxidant supplementation. After 6 weeks on NR-enriched diet, mice demonstrated roughly two-fold increases in gamma oscillations (measured in $\mu V^2/Hz$) during SD when compared with SD mice on an isocaloric control diet. This change persisted through week 10 of the dietary manipulation. NAC also produced nonsignificant increases in gamma oscillations during SD within an hour of administration ($p>0.05$). Collectively, our data indicate that prophylactic treatments that are capable of increasing antioxidant defense in the brain (NAC and NR) may preserve brain function during and after sleep deprivation, potentially staving off sleep deprivation-related cognitive impairment.

Title: Sleep loss increases membrane fluidity of myelin sheaths

Authors: A. ABOUFARES EL ALAOUI[1], R. FIORINI[2], M. FABRI[1], ***M. BELLESI**[3]; [1]Dept. of Exptl. and Clin. Med., [2]Dept. of Life and Envrn. Sci., Marche Polytechnic Univ., Ancona, Italy; [3]Sch. of Physiology, Pharmacol. & Neurosci., Univ. of Bristol, Bristol, United Kingdom

Abstract: Using electron and confocal microscopy we recently showed that prolonged sleep restriction (~5 days) reduced myelin thickness and increased node of Ranvier length without

affecting internodal length, thus suggesting that sleep loss can lead to plastic remodeling of myelin. Since optimal plasma membrane fluidity is an essential requirement for cellular plasticity, we hypothesized that the fluidity of membranes forming myelin could be affected by sleep loss. Membrane fluidity of myelin enriched brain samples from sleeping (S, n=6, killed after 6 hrs of sleep during the light cycle) and sleep deprived C57BL/6 mice (SD, n=6, killed after 4 hrs of enforced wake during the light cycle) was assessed by steady-state fluorescence spectroscopy. Two fluorophores were used, 2-dimethylamino-(lauroyl)-naphtalene (Laurdan) located at hydrophobic-hydrophilic interface of the membrane, and 1,6 diphenyl-1,3,5-hexatriene, incorporated in hydrophobic lipid region. Moreover, in mouse forebrain samples, genome-wide analysis of messenger RNA profiling of oligodendrocyte lineage was conducted as a function of S and SD to detect differentially expressed genes. A significant increase in membrane fluidity was found in myelin membrane core in SD relative to S (DPH anisotropy: S [0.231±0.008]; SD [0.222±0.005], $p<0.00019$), while no differences were detected at the polar headgroups level. In addition, analysis of the oligodendroglia transcriptome revealed the up-regulation of *Fad3* in SD (+176%; p=0.004). *Fad3* codes for a fatty acid desaturase that regulates unsaturation of fatty acids and thus influences membrane fluidity. In conclusion, increased fluidity of the inner myelin membrane region could contribute to morphological modifications of myelin induced by sleep loss.

Title: Estradiol action modulates adenosinergic sleep pressure

Authors: *P. C. SMITH[1], D. J. PHILLIPS[1], S. S. VIECHWEG[1], A. POCIVAVSEK[2], J. A. MONG[1];
[1]Univ. of Maryland SOM, Baltimore, MD; [2]Pharmacology, Physiology, and Neurosci., Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: Primary sleep disorders are among the most common medical conditions, and clinically, women are more likely than men to experience symptoms of insomnia over their lifespan. This increased risk emerges at puberty and is associated with fluctuations in ovarian

steroids, particularly estradiol (E2), suggesting that gonadal steroids and biological sex are risk factors for sleep disruptions. In female rodents, studies consistently show sleep time is significantly reduced when endogenous ovarian steroids or exogenous E2 are elevated. Our work has demonstrated that E2 effects on sleep are mediated through the inhibition of sleep-active neurons in the median preoptic nucleus (MnPN). However, what is less clear is how E2 is suppressing sleep; one potential mechanism is the attenuation of signaling pathways necessary for maintaining sleep homeostasis. To test this possibility, we sleep deprived oophorectomized rats, with and without E2 replacement, for three or six hours by gentle handling, and quantitatively analyzed sleep behavior and power spectra for the subsequent six hours of recovery. We found that E2-treated animals require less recovery sleep under deprivation, and show a greater increase in delta power, a measure of sleep efficiency, relative to baseline. The nucleoside adenosine is a mediator of homeostatic sleep pressure, with established actions at the MnPN. Next, we tested the hypothesis that E2 attenuates the ability of adenosine signaling to stimulate sleep behavior in female rats. Oophorectomized rats were treated with a constant low-dose of E2, which was not sufficient to suppress sleep, or oil vehicle. Following a baseline recording, animals were treated with injections of 24nmol of the adenosine 2A receptor agonist CGS21680, at a dose sufficient to induce sleep in male animals, or DMSO vehicle, with animals receiving the opposite treatment three days later. Sleep behavior was analyzed six hours following each injection. In the oil treated animals, the infusion of agonist led to a decrease in wake time as expected. However, in the E2 group, the effect of the agonist on wake time was significantly attenuated. Studies are ongoing to determine if the amount of extracellular adenosine present in the MnPN differs with and without E2. These data suggest the ability of adenosine to generate sleep pressure, and the effect of E2 on wake, are modulated by an interplay between estrogen and adenosine.

Title: SUVN-G3031, histamine H3 receptor inverse agonist preclinical evaluation for the treatment of excessive daytime sleepiness in narcolepsy

Authors: *G. BHYRAPUNENI, V. BENADE, S. DARIPELLI, V. KAMUJU, A. SHINDE, R. ABRAHAM, R. NIROGI, V. JASTI;
Suven Life Sci. Ltd., Hyderabad, India

Abstract: Numerous studies have demonstrated that brain histamine plays a crucial role in maintenance of wakefulness, attention, learning and other cognitive processes. SUVN-G3031, a potent histamine H3 receptor inverse agonist is being developed for the treatment of narcolepsy and other sleep related disorders. SUVN-G3031 is one of the lead molecules with hKi of 8.7 nM and has more than 100 fold selectivity against the related GPCRs. SUVN-G3031 exhibited desired pharmacokinetic properties and brain penetration. SUVN-G3031 blocked R-α-methylhistamine induced water intake and increased tele-methylhistamine levels in brain and cerebrospinal fluid. In the present study, SUVN-G3031 was evaluated in brain microdialysis and rodent models of electroencephalography (EEG). SUVN-G3031 was evaluated in brain microdialysis for evaluation of neurotransmitters like acetylcholine, histamine, dopamine and norepinephrine in male Wistar rats. EEG was used to evaluate the effects on sleep/ wake profile in rats and mice.A single oral administration of SUVN-G3031 produced significant increase in acetylcholine, histamine, dopamine and norepinephrine levels in the cortex. SUVN-G3031 produced no change in the dopamine levels of striatum and nucleus accumbens indicating that SUVN-G3031 may not have addiction liabilities. Narcoleptic-like sleep behavior was observed in rats injected with hypocretin-2-saporin in lateral hypothalamus. SUVN-G3031 produced significant increase in wakefulness with concomitant decrease in rapid eye movement (REM) sleep in these animals. These results are in agreement with EEG studies carried out in healthy male Wistar rats. Results from current studies provide strong evidence for the potential of SUVN-G3031 in the treatment of excessive daytime sleepiness associated with narcolepsy. First in human, Phase 1 studies for SUVN-G3031 are completed under US IND and SUVN-G3031 has shown desirable pharmacokinetic profile with safety and tolerability in healthy human volunteers. Phase 2 study for the treatment of excessive daytime sleepiness associated with narcolepsy is currently ongoing in USA.

Title: Melatonin and recovery sleep ameliorate anxious behaviour and impairment in hippocampal neurogenesis induced by sleep deprivation

Authors: *R. CHITTORA[1], A. JAIN[2], M. BHATNAGAR[1];
[1]ZOOLOGY, Univ. Col. of Science, Mohan Lal Sukhadia, UDAIPUR, India; [2]Univ. Col. of Science, Mohan Lal Sukhadia Univ., UDAIPUR, India

Abstract: Abstract
Sleep deprivation (SD) is commonplace occurrence in modern society. SD is associated with reduced short term memory, learning ability and loss of some forms of behavioral control. Thus, we hypothesized that whether sleep deprivation would impact learning-induced neurogenesis in concert with its behavioural outcome which could be improved by administering natural antioxidant and Enriched environment. The aim of this study was to assess the effect of melatonin and subsequent recovery sleep on adult neurogenesis in the hippocampus and behaviour of adult mice exposed to 6 days of total sleep deprivation (TSD). Adult male Swiss Albino mice were sleep deprived for 6 days using manually designed SD apparatus. Melatonin (10 mg/kg BW/day) was administered intraperitoneally to mice once every day during SD. Some mice received additional recovery sleep for 2 days after 6 days TSD. Adult neurogenesis was assessed by Immunohistochemical markers Doublecortin (DCX), neuronal nuclei antigen (NeuN) and anxious behaviour was evaluated by Open Field Test and Elevated plus Maze Test. Immunohistochemical analysis demonstrated that SD reduced the number of migrating neuroblasts and immature neurons i.e. DCX positive cells in dorsal and ventral blades of Dentate Gyrus. SD also decreased number of NeuN+ mature neuronal cells in CA1, CA3, DG sub region of hippocampus. Sleep deprived mice presented an increased number of entries and time spent in closed arms in elevated plus maze test and decreased center square entries, Reduced rearing, Grooming and increased Fecal boli counts in the open field test. Melatonin co-administration and recovery sleep significantly improved these neurogenesis and anxious consequences. These findings reveal that exogenous administration of melatonin and environmental enrichment induced recovery sleep have the potential to diminish the negative effects of SD on neurogenesis and behavior.

Title: Differential impact of light or dark phase kynurenine challenge in male and female rats: Biochemical alterations and disruptions in sleep-wake behavior

Authors: A. M. LEWIS[1], N. T. J. WAGNER[1], K. M. RENTSCHLER[1], S. A. BUCK[2], A. BARATTA[4], S. BEGGIATO[5], J. A. MONG[3], ***A. POCIVAVSEK**[1];
[1]Pharmacology, Physiology, and Neurosci., Univ. of South Carolina Sch. of Med., Columbia, SC; [2]Maryland Psychiatric Res. Center, Dept. of Psychiatry, [3]Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD; [4]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA; [5]Life Sci. and Biotech., Univ. of Ferrara, Ferrara, Italy

Abstract: Tryptophan metabolism via the kynurenine pathway (KP) may represent a key molecular link between sleep loss and cognitive dysfunction. Modest increases in the KP metabolite kynurenic acid (KYNA), which acts as an antagonist at N-methyl-D-aspartate (NMDA) and α7 nicotinic acetylcholine (α7nACh) receptors, and an agonist at the aryl hydrocarbon (AhR) receptors, result in cognitive impairments. These disruptions may be causally related to impairments in sleep-wake behavior with KYNA elevation (Pocivavsek et al. Sleep, 2017). Presently, we further explored this hypothesis in adult cohorts of both male and female Wistar rats. In consideration of the circadian rhythm, animals were treated with vehicle or kynurenine (100mg/kg; intraperitoneally), the direct precursor to KYNA, at the beginning of the light phase, zeitgeiber time (ZT) 0, or at the beginning of the dark phase, ZT12. *In vivo* microdialysis, collected from the dorsal hippocampus in 30-min fractions, confirmed significant formation of KYNA with kynurenine challenge during both phases. In controls, we demonstrate a phase x time interaction (**P<0.0001) and a significant main effect of time (**P<0.01). Specifically, extracellular KYNA levels decreased across time in the light phase and increased across time in the dark phase. In separate animals, we acquired polysomnographic recordings that combine electroencephalogram (EEG) and electromyogram (EMG). Animals were treated with vehicle or kynurenine at ZT 0 or ZT 12, respectively. Analysis of vigilance state-related parameters categorized as wake, rapid eye movement (REM) and non-REM (NREM) were assessed for 24 h after treatment. Kynurenine treatment at ZT 0 significantly reduced REM duration compared to vehicle treatment (*P<0.05) during the 12 h of the light phase in both male and female rats. Conversely, kynurenine treatment at ZT 12 did not immediately impact vigilance state duration during the 12 h of dark phase, but significantly affected REM duration, in males only, during the subsequent light phase (*P<0.05). Separate animals were tested in the novel object recognition (NOR) task assessing hippocampal-dependent recognition memory. Task performance was negatively impacted by kynurenine challenge during both light and dark phase. Taken together, our results and future complementary experiments provide significant mechanistic value to understanding the role of KYNA in modulating a relationship between sleep, circadian systems and cognition.

Abstract: Dysfunction in the kynurenine pathway (KP) of tryptophan metabolism has been implicated in the pathology of schizophrenia (SZ). The KP metabolite kynurenic acid (KYNA) is an endogenous antagonist of α7 nicotinic acetylcholine (α7nACh) and N-methyl-D-aspartate (NMDA) receptors, and an activator of aryl hydrocarbon receptors (AhR). KYNA has been linked to cognitive impairments in SZ and may also contribute to sleep disturbances in patients. To further understand the role of KYNA in SZ etiology, we developed an experimental system in rats (Pocivavsek et al., *Psychopharm.*, 2014) where kynurenine (kyn; 100 mg/day) is fed to pregnant Wistar dams from embryonic day (ED) 15 to ED 22 (control: ECon; kyn-treated: EKyn) to elevate KYNA in the fetal brain. The present study was designed to investigate 1) KP metabolism during the light (ZT6) and dark phase (ZT18) and 2) sleep-wake behavior during both phases in male and female adult (postnatal day 56 -85) offspring from ECon and EKyn litters. Cortical KYNA levels were increased (+128%) at ZT6 in male, but not female, EKyn compared to ECon (**P<0.01). No differences were found at ZT18. Adult offspring were implanted with telemetric devices to acquire polysomnographic recordings to combine electroencephalogram (EEG) and electromyogram (EMG) readings (N=6-8 per group). Analyses of vigilance state parameters categorized as wake, rapid eye movement (REM) and non-REM (NREM) were assessed. Our findings indicate distinct sex differences in sleep disturbances among ECon and EKyn offspring. EKyn males had significantly less REM duration during the light phase (*P<0.05, -21%). EKyn females had less frequent wake bouts (*P<0.05, -30%), which were also longer in duration (***P<0.001, +37.5%), and less frequent NREM bouts (*P<0.05, -28%) during the dark phase. Delta and theta power were assessed during each vigilance state to define deficits in sleep oscillations. Taken together, our data demonstrate a striking sex- and light phase-dependent increase in cortical KYNA and sleep alterations in EKyn

offspring. We are continuing to investigate elevated prenatal kynurenine exposure to further understand the interplay between KP metabolism in psychiatric illness, sleep disturbances, and cognitive outcomes.

Title: Regulation of pS6 and Arc in the hippocampus by sleep and learning

Authors: ***V. K. KODOTH**[1], J. DELORME[1], S. J. ATON[2];
[2]Molecular, Cellular, and Developmental Biol., [1]Univ. of Michigan, Ann Arbor, MI

Abstract: The activity-regulated cytoskeleton associated protein (Arc) is an immediate early gene whose mRNA accumulates in recently-activated neurons, where it can undergo activity-dependent translation to affect synaptic function. Recent data from our lab has shown that after a brief period of sleep deprivation (relative to a similar period of ad lib sleep), there is increased total Arc mRNA in the hippocampus but decreased Arc protein-expressing neurons in the dentate gyrus of the hippocampus. At the same time, sleep deprivation increases both Arc mRNA and protein in the cortex. This suggests that sleep may play a role in promoting translation of Arc protein in the hippocampus, which may have a major impact on sleep-dependent memory processes. Moreover, protein synthesis may be generally reduced in the hippocampus during sleep deprivation. Ribosomal subunit S6 is phosphorylated on several serine residues by activity-regulated kinases; these phosphorylation events are thought to regulate translation by the ribosome. Here we characterize the degree of phosphorylation of S6 on sites targeted by neuronal activity (pS6 244-247) within the hippocampus. We find that over 3 hour periods of sleep deprivation, there is a selective reduction of S6 phosphorylation in the cell bodies of hippocampal subregions CA1 and CA3, and in dentate gyrus (DG) neurons. We also quantify colocalization between Arc protein and pS6 244-247 throughout the hippocampus. pS6 244-247 and Arc colocalize in dentate gyrus neurons in both sleep and sleep deprived animals, although total levels of both are reduced after sleep deprivation. These findings better characterize the cellular mechanisms that may disrupt hippocampal memory consolidation during sleep loss.

Title: Neural substrates underlying the homeostatic sleep response in mouse basal forebrain

Authors: C. YANG[1], H. BOUAOUDA[1], C. SHUKLA[1], K. DEISSEROTH[2], S. WINSTON[1], Y. BOLORTUYA[1], J. M. MCNALLY[1], J. T. MCKENNA[1], ***R. BASHEER**[1];

Abstract: Optogenetic stimulation of cholinergic (ChAT+), vesicular glutamate transporter2-expressing glutamatergic (vGluT2+) or parvalbumin-expressing GABAergic (PV+) neurons in the basal forebrain (BF) cause arousal responses. However, little is known about their role in the homeostatic sleep response (HSR). BF ChAT+ neurons are thought to play a privileged role in HSR, since selective lesions of these neurons abolish the HSR. Previous *in vitro* work from our and other laboratories have revealed local interaction among BF ChAT+, vGluT2+ and PV+ neurons. Here, we explore the interactive role of BF ChAT+ and vGluT2+ neurons as well as PV+ neurons in HSR using *in vivo* pharmacological and optogenetic approaches combined with conventional electroencephalogram/electromyogram recordings. C57BL/6 (WT) mice were sleep deprived (SD) 6h with and without reverse microdialysis of cholinergic or glutamate receptors antagonists into BF to examine the effect of pharmacological blockade of the cholinergic and glutamatergic receptors on rebound recovery sleep and non-rapid-eye-movement (NREM) delta activity (0.5-4.5Hz), the markers of HSR. We transduced AAV-ChR2-EYFP in BF of ChAT-Cre, vGluT-Cre and PV-Cre mice and examined the effect of 4-6h optical stimulation (5s/min, 10 Hz for ChAT+, 20 Hz vGluT2+ and 40Hz for PV+) on HSR during the 2h post-stimulation period by comparing to time-matched sham stimulation. Furthermore, we performed microdialysis of cholinergic/glutamatergic receptor antagonists during the optical stimulation of ChAT+/vGluT2+ neurons and examined the HSR. In WT mice (n=4) cholinergic antagonists did

not prevent SD-induced HSR as evaluated by an increased sleep (+36.74±5.65%) and the NREM delta power (+13.82±3.62%). Microdialysis of AMPA or NMDA receptor antagonists in another set of WT mice (n=3) showed a tendency towards attenuated recovery sleep by -5.06±7.35% and -11.72±4.05%, respectively. Optogenetic stimulation of ChAT+ neurons (n=3) as well as vGluT2+ neurons (n=3) led to HSR. While cholinergic receptor antagonist failed to block cholinergic neuronal activation-induced HSR, the glutamatergic receptor antagonists attenuated glutamatergic neuronal activation-induced HSR. PV+ neuronal-stimulations failed to induce HSR. Our preliminary results suggest that both BF cholinergic and glutamatergic neurons, are important for HSR. BF glutamatergic neurons induce HSR by acting on local cholinergic neurons while other BF non-cholinergic neurons (PV+) are unlikely to play any role in HSR.

Title: Sleep deprivation and how it affects the neuropil

Authors: S. GABULYA[1], A. T. BRODIN[1], L. OLSON[2], ***T. E. KARLSSON**[1];
[1]Neurosci., Karolinska Institutet, Solna, Sweden; [2]Dept. of Neurosci., Karolinska Inst., Solna, Sweden

Abstract: Sleep deprivation is a common problem and often occurs as a part of a bigger disease spectrum such as depression or PTSD. Contrary to common belief, sleep is a rather active time window during which many functions in the central nervous system are carried out. Among these are clearing of waste products and replay and stabilization of memories. Disruptions of these processes, as caused by sleep deprivation, has severe consequences such as impaired memory function. There have been recent reports by others suggesting that the structure of neurons can change dramatically during situations of sleep deprivation. We studied this further using THY1-GFP mice and light sheet microscopy. Mice were subjected to sleep deprivation for five hours using a gentile method of manually pushing on mice that tended to fall asleep. These mice were compared to two other groups, one that underwent the same episode of sleep deprivation but then

allowed to have three hours of recovery sleep and a control group that did not receive sleep deprivation. We then analyzed the branching pattern of the apical dendrites of CA1 pyramidal neurons in hippocampus. Overall, neither the length, nor the branching pattern of the apical dendrite was affected by sleep deprivation. We conclude that 5 h of (gentile) sleep deprivation does not cause overt alterations of dendritic length or branching patters of hippocampal CA1 pyramidal cells. Ongoing work will analyze a possible role of sleep deprivation on spine density in the same neurons.

Title: Sleep duration influences the amount and clearance of stress granules in *Caenorhabditis elegans*

Authors: *M. K. DOUGHERTY, C. SAUL, L. CARMAN, M. D. NELSON, J. C. TUDOR; Biol., St. Joseph's Univ., Philadelphia, PA

Abstract: Stress granules are non-membrane bound aggregates of messenger ribonucleoproteins that are biomarkers of cellular stress. It has been shown in cells *in vitro* that suppression of the mammalian target of rapamycin (mTOR) pathway and its non-mammalian orthologue target of rapamycin (TOR) is associated with an increase in stress granule formation. It has also been shown that the mTOR pathway is suppressed in response to sleep deprivation in mice. Despite the possible connection via the TOR/mTOR pathway, there has not been any previous evidence linking sleep deprivation with stress granule formation. Our present investigation uses the nematode *Caenorhabditis elegans* to model how stress granule formation and clearance are modified by sleep duration. *C. elegans* experience two different types of sleep: developmentally-timed sleep, which occurs between the different larval stages of the worm, and stress-induced sleep, which occurs in response to a stressor such as heat shock. These different types of sleep are mediated by distinct mechanisms and there are known mutants and genetic manipulations that produce either sleep deprived or sleep enhanced animals for each type of sleep. Through employing these techniques and genetic crosses, we developed novel strains of *C. elegans* that model each type of sleep deprivation or enhancement and have RFP-labeled PAB-1 protein, a key component of stress granules. In addition to modifying sleep duration via genetic means, we also sleep deprived wildtype fluorescently labeled animals using mechanical disturbances.

Animals genetically deprived of developmentally-timed sleep appear to have more stress granules in the middle of their sleep period than the sleeping wildtype. Animals with enhanced stress-induced sleep have stress granules that are smaller in size and cleared faster than wildtype, while sleep deprived animals have granules that are slower to clear. Animals that were manually deprived of stress-induced sleep were similarly slower to clear stress granules. This work explores novel mechanisms, such as stress granules, by which sleep deprivation affects the flow of genetic information inside cells.

Title: Where does the dreamless mutation take effect?: Generation of NALCN-FLEx and NALCN-flox knock-in mice

Authors: *T. FUJIYAMA[1], S. MIZUNO[2], M. ABE[3], S. KANNO[1], M. KAKIZAKI[1], K. IWASAKI[1], A. IKKYU[1], N. HOTTA-HIRASHIMA[1], M. YAMADA[1], C. MIYOSHI[1], M. SATO[1], T. KANDA[1], K. SAKIMURA[3], S. TAKAHASHI[2], H. FUNATO[1], M. YANAGISAWA[1];

Abstract: Although sleep is a ubiquitous animal behavior, the molecular/neural basis mechanism of REM sleep (REMS) remains unknown. We performed high-throughput screening of ENU-mutagenized mice in order to identify genes regulating sleep/wake behavior, and established the *Dreamless* mutant pedigree shows about 50% reduction in 24-h REMS time. We identified a nucleotide change specific to *Dreamless* mutant mice within the exon9 in *Nalcn* gene. The single nucleotide substitution leads to a single amino acid substitution (N315K) of the gene product leak cation channel NALCN that we termed *Dreamless*. We adopted CRISPR/Cas system to recapitulate *Dreamless* phenotype, then confirmed that the one base substitution was responsible

for REMS abnormality, suggesting that the identified gene is related to the regulation of daily REMS time. To elucidate the molecular/neural basis of REMS regulation by NALCN, we utilized genome editing tools and generated genetically-modified *Nalcn* mutant bearing flox and FLEx (flip and excision) knock-in mice for loss-of and gain-of-function studies, respectively. In *Nalcn-FLEx* mice, we observed that the mice with a systemic Cre-expressing line *Actb-iCre* showed the *Dreamless*-like phenotype on the electroencephalogram and electromyogram (EEG/EMG) analysis. On the other hand, in *Nalcn-flox* mice, we confirmed the neuronal subtype-specific deletion of *Nalcn* mRNA expression in adult brain tissue. Now we are planning to analyze sleep and wakefulness by using these two *Nalcn* gene mutant mouse lines.

Title: Melatonin modifies SOX2+ cell proliferation in dentate gyrus and modulates SIRT1 and MECP2 in long-term sleep-deprivation

Authors: *A. HINOJOSA GODINEZ[1], G. LOPEZ-ARMAS[2], M. E. FLORES SOTO[3], L. JAVE-SÚAREZ[4], M. LUQUÍN DE ANDA[1], A. GÁLVEZ CONTRERAS[1], I. RUSANOVA[5], O. P. GONZALEZ-PÉREZ[6], R. E. GONZALEZ-CASTAÑEDA[1];

Abstract: Melatonin is a pleiotropic molecule that, after a short-term sleep deprivation, promotes the proliferation of neural stem cells in the adult hippocampus. However, this effect has not been observed in long-term sleep deprivation. The precise mechanism exerted by melatonin on the modulation of neural stem cells is not entirely elucidated, but evidence indicates that epigenetic regulators may be involved in this process. In this study, we investigated

the effect of melatonin treatment during a 96-h sleep-deprivation and analyzed the expression of epigenetic modulators predicted by computational text mining and keyword clusterization. Our results showed that the administration of melatonin under sleep-deprived conditions increased the MeCP2 expression and reduced the SIRT1 expression in the dentate gyrus. We observed that Let-7b, miR-132, and miR-124 were highly expressed in the dentate gyrus after melatonin administration, but they were not modified by sleep-deprivation. In addition, we found more Sox2+/BrdU+ cells in the subgranular zone of the sleep-deprived group treated with melatonin than the untreated group. These findings may support the notion that melatonin modifies the expression of epigenetic mediators that, in turn, regulate the proliferation of neural progenitors in the adult dentate gyrus under long-term sleep-deprived conditions.

Title: Sleepstate modulation in calcium transients in CAMKII CA1 hippocampal neurons in APP knock-in mice varies with genotype

Authors: P. V. FENIK[1], C. LIU[2], K. PULLUM[1], ***S. C. VEASEY**[1];
[2]Perelman Sch. of Med., [1]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Introduction: We find that chronic short sleep induces hippocampal neural injury. Hippocampal (HC) calcium/calmodulin kinase II (CAMKII) neurons are some of the most vulnerable neurons in Alzheimer's disease. We hypothesized that calcium transient frequencies in HC CAMKII neurons increase in active wakefulness and that CSS may further perturb CAMKII neuron calcium homeostasis, thereby contributing to CSS injury to the HC.
Methods: Amyloid precursor knock-in mice with the NL or NL+G+F mutations (3 mos, male

and female) were stereotaxically-injected with AAV5 GCamp6f into HC, then implanted with a Grin lens to focus on HC CAMKII neurons and later a baseplate for *in vivo* microscopy. Baseline sleep/wake recordings were obtained at 9 mos. The frequency of single neuron calcium transients in discrete neurons (50-150/mouse) was analyzed across active wake (exploratory AW), quiet wake (in nest head up, QW), behavioral sleep (S).
Results: Significant sleep state and genotype differences in transient rates were observed. Specifically, NL mice showed baseline calcium transient frequencies for AW, QW and S of 1.3±0.09, 0.5±0.07 and 0.15±0.03 bursts/minute. Although periods of behavioral phasic rapid-eye-movement (REM) sleep (ear and whisker twitches with postural atonia) were quite brief, calcium transients increased with apparent phasic REM sleep. AW rates were higher than in QW ($t=8.5$, $p<0001$) and S ($t=12.0$, $p<0.0001$), and QW was greater than S ($t=3.8$, $p<0.001$). In NLGF mice, behavioral state differences were also observed for AW vs QW ($p<0.01$), AW vs S ($p<0.0001$), but were of lesser magnitude, 0.5±0.03; 0.3±0.03; 0.2±0.02 for the two genotypes, and the AW transient frequency in NLGF mice was far less than in NL mice ($t=8.0$, $p<0.001$), while not different across strains for QW or S. Two findings specific to NLGF mice were synchronous and prolonged fluorescence of 5-9 adjacent cells firing during AW or upon arousal, and far higher αf/fx for NLGF mice was far higher than for NL mice, despite lower transient rates, $p<0.001$.
Conclusion: Active exploratory wakefulness increases calcium transients significantly and may thereby perturb metabolic homeostasis in CA1 CAMKII neurons. NLGF mice, at an age when plaques and memory impairments are seen, show greater calcium αf/fx in AW, despite lower transient frequencies, supporting the concept that wake-induced calcium perturbation may contribute to CAMKII neuron vulnerability.

Title: Synchronisation of UP-state termination during SWS is driven by thalamic inputs onto L1 interneurons

Authors: *Y. HAY, T. FUCHSBERGER, A.-L. KOERLING, T. QUARRELL, O. PAULSEN; Univ. of Cambridge, Cambridge, United Kingdom

Abstract: The neocortex is composed of excitatory and inhibitory neurons that are massively interconnected, allowing for the generation of sustained pattern of activity. During slow-wave sleep, anaesthesia, and quiet wakefulness, neuronal network is synchronised and fluctuates between periods of high synaptic activity (UP-states) and periods of relative quiescence (DOWN-states). UP-states may terminate spontaneously by synaptic depression and/or build-up of activity-dependent potassium conductances. It has been proposed that GABAB receptors (GABABRs) activation contributes to the increase of activity-dependent potassium conductance and thus would promote the termination of UP-states. Furthermore, neurogliaform interneurons (NGFCs), a class of Layer 1 (L1) GABAergic interneurons, have been shown to activate post-synaptic GABABRs located on the dendritic tree of L2/3-L5 pyramidal neurons. This induces a long-lasting hyperpolarization of pyramidal distal dendritic tree that reduces the neuronal excitability. We propose that activation of L1 NGFCs promotes UP-state termination. Finally, higher-order thalamic nuclei strikingly project to L1 of most cortical areas and could thus have a major effect in the synchronisation of UP-state termination. Our results show that higher-order thalamic neurons preferentially target L1 NGFCs and indirectly activate GABABR-mediated conductances in L2/3 pyramidal neurons. We suggest that higher-order thalamic nuclei activation could mediate the synchronous termination of UP-states throughout cortical areas during slow-wave sleep.

Title: Control of wakefulness and cortical electrical activity by basal forebrain Lhx6 and Npas1 neurons in the mouse

Authors: *C. YANG[1], J. T. MCKENNA[1], J. M. MCNALLY[1], M. ANDERSON-CHERNISHOF[1], S. WINSTON[1], S. CHAN[2], R. E. BROWN[1];
[1]Harvard Med. School/Va Boston Healthcare Syst., West Roxbury, MA; [2]Dept. of Physiol., Northwestern University, Feinberg Sch. of Med., Chicago, IL

Abstract: The basal forebrain (BF), an important brain region for regulating sleep-wake, attention and reward processing, contains a large and diverse population of GABAergic neurons. However, the physiological role of different GABAergic subpopulations is still unclear due to the limitations of existing markers for identification. Here, we investigated two strains of mice expressing Cre Recombinase and a fluorescent marker under the control of transcription factors active in areas of the developing brain which generate forebrain GABAergic neurons, as well as in adults: Lim-homeobox 6 (Lhx6) and neuronal PAS domain 1 (Npas1). Immunohistochemical staining revealed that Lhx6+ neurons represented a mixed population, including many of the parvalbumin (PV+) neurons which we previously showed promote cortical gamma activity (Kim et al., 2015), and a subset of cholinergic neurons. In contrast, Npas1+ neurons were not PV+ or cholinergic. Using a chemogenetic approach combined with conventional frontal cortex electroencephalogram (EEG)/neck muscle electromyogram (EMG) recordings, we examined alterations of sleep patterns and cortical activity by bilaterally exciting the BF Lhx6+ and Npas1+ neurons. CNO (0.3 mg/kg) alone had no significant effect on sleep-wake behavior or cortical EEG in mice without transduction of BF neurons, when compared to vehicle (saline) injections (N=4). Chemogenetic activation of BF Lhx6+ neurons significantly increased wakefulness after IP injection of CNO as compared to IP injection of vehicle (wake percentage within 1.5h after IP injection, CNO vs. vehicle: 82.0±5.2% vs 42.8±4.6%, N=7, p=0.0011, paired-t-test), accompanied with an immediate increase in frontal cortical gamma band power (14.4±5.3% increase within 30min after IP injection, N=7, p=0.0313, Wilcoxon matched-pairs signed rank test) and an increase in locomotor activity (59.7±7.1% increase within 30min after IP injection, N=3). Chemogenetic activation of BF Npas1+ neurons even more strongly increased wakefulness (wake percentage within 1.5h after IP injection, CNO vs. vehicle: 93.5±6.5% vs 33.3±3.6%, N=2). However, the gamma band power during wakefulness or locomotor activity were not markedly altered. Our data indicate that Lhx6+ neurons, generated in the medial ganglionic eminence and implicated in neuropsychiatric disorders, include BF PV neurons and other BF neurons which promote wakefulness, cortical gamma activity and locomotor activity. Npas1+ neurons represent a novel subtype of BF wakefulness-promoting neurons.

Abstract: In order to keep the homeostasis, certain hormones are usually released at certain moments of the day. By altering the sleep, it is altered the circadian rhythm, so the metabolic pathways that function the best with this system, start to be dysregulated. This can lead to non communicable chronic diseases, that includes obesity, insulin resistance, hypertension and dyslipidemia. It's been reported that the deprivation of sleep during the pregnancy produce a higher blood pressure in the rat's offspring.The alteration given the chronodisruption in animal models could lead to morphological changes in organs such as the kidneys and pancreas. The aim of the present study was to investigate the effect of sleep chronodisruption on the metabolic components of offspring rats. All experiments were conducted in accordance with the NOM-1997 for the Care and Use of Animals. For this purpose, were used female rats were paired with 4 male rats. The experimental rats were maintained in a disrupted light cycle (each 4h) with lights on at 0700 h and lights off 1100 h in a first day pregnancy . The control group were manteined to a 12L:12D light cycle with lights on at 0700 h . At birth were sacrificed 2 pups by rat/group to obtain serum for samples to measure glucose, insulin, cholesterol, triglycerides, leptin and grelin. The weight and long were measured as well, and the time of the development for the audition and vision senses were reported, taking as reference the separation of their ears from the head and the openness of the eyes. Preliminary results showed that there were no statistically ($P>0.05$) difference between the number of the breeding. Although one experimental group has shown lower weight and long and has been the smaller (10 pups), the other experimental group showed more consistent weights and had the bigger offspring (13 pups). The measurements of this later group is similar to the control groups. The results of the glucose,

insulin, cholesterol, triglycerides, ghrelin and leptin are still in hold.

Title: Voltage-gated potassium channel shaker promotes sleep via thermosensitive GABA transmission

Authors: *J.-H. KIM, Y. KI, H. LEE, M. HUR, J.-H. HUR, C. LIM;
UNIST, Ulsan, Korea, Republic of

Abstract: Genes and neural circuits coordinately regulate sleep homeostasis. However, it remains elusive how these endogenous factors shape animal sleep in response to environmental changes. Here, we found that *Shaker* (*Sh*)-expressing GABAergic neurons projecting onto dorsal fan-shaped body (dFSB) constitute a neural pathway important for temperature-adaptive sleep behaviors in *Drosophila*. Loss of *Sh* function potently suppressed sleep at low temperature whereas light and high temperature cooperatively gated *Sh* effects on sleep. RNA interference-mediated depletion of *Sh* expression in GABAergic neurons partially phenocopied *Sh* mutants. Moreover, trans-heterozygous mutations that decrease GABA transmission rescued *Sh* mutant sleep. Transgenic mapping further revealed that the ionotropic GABA receptor, *Resistant to dieldrin* (*Rdl*), in dFSB neurons acts downstream of *Sh* and antagonizes the sleep-promoting effects of *Sh*. In fact, *Rdl* inhibited the intracellular cAMP signaling of constitutively active dopaminergic synapses on dFSB neurons at low temperature. On the other hand, high temperature silenced GABAergic synapses onto dFSB neurons, thereby potentiating the wake-promoting dopamine transmission. We propose that temperature-dependent switching between these two synaptic transmission modalities may adaptively tune the neural property of dFSB neurons to temperature shifts and reorganize sleep architecture for the benefit of animal fitness.

Title: Diurnal fluctuations of perineuronal nets in the rat medial prefrontal cortex

Authors: *J. H. HARKNESS[1], P. N. BUSHANA[2], E. T. JORGENSEN[5], A. E. GONZALEZ[3], D. M. HEGARTY[7], S. A. AICHER[8], T. E. BROWN[6], J. P. WISOR[2], B. A. SORG[4];

L334, Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Extracellular matrix aggregations called perineuronal nets (PNNs) surrounding synapses of fast-spiking, parvalbumin (PV) -containing GABAergic interneurons and are important for stabilization of synapses following learning and for limiting plasticity after the critical period. Additionally, PNNs provide oxidative buffering capacity for PV cells. Chondroitin sulfates, which make up the majority of PNNs, provide substrates for oxidation/reduction reactions, thus acting as a source of protection against oxidative stress. Oxidative stress increases in the brain during periods of wakefulness, and is alleviated by sleep. We have previously shown that PNN intensity fluctuates with memory, experience, and drug exposure. Here, we investigated whether PNN intensity (measured by *Wisteria floribunda* agglutinin, WFA) also fluctuated throughout the diurnal and sleep/wake cycles and whether diurnal fluctuation also occurred in the AMPA/NMDA ratio in PV+/WFA+ cells in the medial prefrontal cortex (mPFC). PNNs, oxidative stress (8-oxo-dG), and PV intensity were quantified in the mPFC at four time points (ZT0, ZT6, ZT12, & ZT18) during the diurnal cycle. PNN intensity was decreased at ZT6 compared to ZT0, and increased at ZT12 and ZT18. PV intensity was also increased at ZT18 compared to ZT0. 8-oxo-dG intensity was decreased at all time points compared to ZT0. AMPA/NMDA ratios were increased ($p = 0.06$) at ZT18 compared to ZT0. Pilot studies show that excitatory (vGlut1) but not inhibitory (GAD65/67) puncta surrounding PV+/WFA+ cells are elevated at ZT18 vs. at ZT6. These data indicate that PNN,

PV, and oxidative stress intensity fluctuate throughout the sleep/wake cycle, with increases in PV and PNNs during the most active phase and oxidative stress marker lowest after maximal sleep. Additionally, the AMPA/NMDA ratio appears to follow fluctuations in PNN intensity. These findings suggest that diurnal fluctuations in PNN intensity could be important to other effects of PNNs on learning, memory, and behavior.

Title: Nitrogen metabolism regulates sleep homeostasis

Authors: ***J. L. BEDONT**[1], A. KOLESNICK[1], D. MALIK[1], M. DAVIDOV[1], A. WELJIE[1], A. SEHGAL[2];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA

Abstract: It is increasingly appreciated that metabolism and sleep are heavily coupled, with recent studies demonstrating associations of sleep homeostasis with lipid processing and carbohydrate metabolism, among many other biochemical pathways. However, many of these studies have been descriptive, leaving the causal relationships underlying even most known metabolite / sleep correlations poorly understood. We attempted to assess what metabolic pathways might be centrally important regulators or effectors of sleep homeostasis by conducting mass spectroscopy on heads from a panel of several severely sleep-deficient Drosophila melanogaster mutants. The most consistently affected pathways included acyl-carnitine synthesis and, interestingly, a wholesale remodeling of nitrogen metabolism. Ammonia equivalents in the form of arginine or ornithine can be transformed into less toxic forms suitable for excretion or re-use by over half a dozen different biochemical pathways. These equivalents seem to be funneled into the specific branch identified in our mass spectroscopy screen by transcript-level changes in enzyme expression in the sleep mutants. We have also found, through RNAi and dietary supplementation experiments, that manipulation of this pathway is sufficient to regulate sleep

amount and consolidation. This may be due to modulation of neurotransmitter levels downstream of the nitrogen processing network. We are actively testing whether this same pathway has similar cause-effect relationships during more acute perturbations of sleep. Ultimately, these studies have important implications for understanding physiological sleep homeostasis, and perhaps even for pathological changes such as neurodegeneration that have been associated with chronic perturbations of sleep.

Title: Metabolic regulation of sleep: The role of lateral hypothalamic leptin circuit

Authors: *U. SINGH[1], B. A. TOTH[1], K. C. DAVIS[1], K. SAITO[1], J. JIANG[1], G. F. BUCHANAN[2], H. CUI[1];

Abstract: Adequate body energy store and sufficient sleep are essential for health, and any disruptions in these physiological processes can lead to serious health consequences including obesity, diabetes, and cardiovascular diseases. Literature support an intimate association between sleep and energy balance - short sleep duration and poor sleep quality are associated with weight gain and obesity, whereas obesity has been identified as an independent risk factor for poor sleep quality and excessive daytime sleepiness. Despite this bidirectional, feedforward, pernicious association between obesity and sleep disorders, the neural substrates underlying this association remain poorly understood. Adipocyte-derived metabolic hormone, leptin, exhibits diurnal rhythm in circulation and regulates energy balance and rhythmic expression of behaviors such as sleep and daily locomotor activity, yet the underlying neural circuits mediating these effects are unclear. Here we show that leptin acts on a subset of lateral hypothalamic area (LHA) GABAergic neurons to affect sleep and energy balance. Selective deletion of leptin receptor (LepR) in the LHA of adult mice resulted in increased body fat gain, decreased locomotor activity, frequent sleep onset and increased sleep time especially in subjective day, resembling excessive daytime sleepiness in human. Chemogenetic activation of this subpopulation of LHA GABAergic neurons completely disrupts sleep and dramatically increases exploratory locomotor

activity. These findings identify the LHA as a critical site where circulating metabolic hormone leptin acts to affect sleep and provide a possible explanation why severely obese patients who are commonly associated with leptin resistance often experience poor sleep quality and excessive daytime sleepiness.

Title: Typical and atypical spindles found in rapid eye movement sleep

Authors: *C. GONZALEZ[1], K. SWIFT[3], K. KEUS[1], G. R. POE[2];
[2]Dept. of Integrative Biol. and Physiol., [1]UCLA, Los Angeles, CA; [3]Mol. and Integrative Physiol., Univ. of Michigan, Los Angeles, CA

Abstract: Sleep spindles are short bursts (0.5-2s) of high frequency (11-15 Hz) electrical activity in the cerebral cortex and hippocampus that have been directly linked with the formation and consolidation (or "storing") of memories across multiple species. They are produced by activity in two connecting regions of the brain: the thalamus and the cortex. The cortex is the final destination of stored memories and is associated with higher cognitive functions. Sleep spindles have long been a hallmark of non-rapid eye movement (NREM) sleep, and their possible presence in rapid-eye movement (REM) sleep has been distinctly ignored. While a handful of studies have identified the presence of REM sleep spindles, a thoroughly descriptive study of such phenomenon is necessary. **We predict these REM spindles will behave in a manner that is distinct from their NREM counterparts.** We utilized EEG recordings in the medial prefrontal cortex, the parietal cortex, and CA1 of the hippocampus during sleep in rats and identified the presence of two phenomena atypical to REM sleep: the presence of spindles in a typical 10-15 Hz range as well as waxing and waning spindle-like behavior in the 5-9 Hz theta range. We analyzed for spindle density and length in these three areas, as well as power spectral data. We also analyzed the occurrence of these phenomena across the female estrous cycle. In addition, in the coming months we will use the novel object placement task to look for behavioral markers and impacts on memory. These data will be the first to rigorously characterize, define, and examine the presence of these typical and atypical REM spindles.

Title: Sleep facilitates insight into temporal hidden patterns

Authors: *R. S. GUTHRIE[1], K. KEUS[2], C. GONZALEZ[3], J. YANO[1], J. HOLLOWAY[4], K. CLARK[5], M. A. GLUCK[6], I. LERNER[7], B. A. GROSS[8], G. R. POE[8];

Newark, Newark, NJ; [7]Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ., Newark, NJ; [8]Dept. of Integrative Biol. and Physiol., UCLA, Los Angeles, CA

Abstract: Findings reported in human studies indicate that sleep facilitates insight. One proposed view suggests that ***key elements in the environment necessary for insight are already encoded in part during waking, then replayed during sleep, allowing the pieces to self-assemble into insight***. Further, a novel computational hypothesis called *temporal scaffolding* suggests that sleep-dependent insight is more likely to occur when requiring the detection of hidden temporal patterns. Here, we tested this hypothesis by developing a novel task for rodents that measures whether sleep facilitates insight into a hidden temporal rule. Animals were exposed to a track with three sequential choice points where the first and second were forced choices and at the final point animals chose freely the left, center, or right path. Animals needed to choose the same path as the first forced choice to receive a reward. Thus they needed to learn a hidden temporal rule. Five sequence trials were given in each session with 3 hours of sleep or sleep deprivation occurring between sessions, all on the same day. We found that rats who slept for 3 hours between sessions improved their ratio of correct sequence choices from random to nonrandom, demonstrating the sleep period facilitated a gain of "insight" into the hidden temporal rule. The performance of those deprived of sleep over the same period remained static. This study demonstrates the feasibility of insight-like tasks in rodent models and may facilitate future work using in-vitro electrophysiological techniques to study replay.

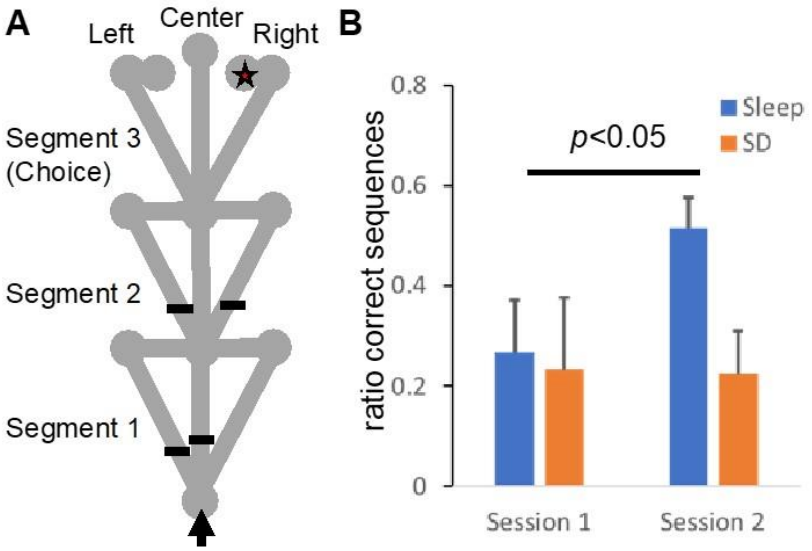

Figure 1. A) Insight track layout from above. Arrow indicates the starting point of all trials. Black lines indicate blocked paths. In this case the rat was forced to go Right in segment 1, Center in segment 2, then only rewarded (rad star) when choosing Right for segment 3. Five sequence trials were given in each session with 3 hours of sleep or sleep deprivation occurring between sessions, all on the same day. **B**) Ratio of correct to total performed sequences on the sequential choice insight task before (Session 1) vs. after (Session 2) sleep (n=6) or sleep deprivation (SD, n=4).

Title: Early not delayed propranolol injection enhances fear extinction recall after trauma exposure in rats

Authors: J. A. HOLLOWAY, Y. CABRERA, B. A. GROSS, *G. R. POE;
Integrative Biol. and Physiol., UCLA, Los Angeles, CA

Abstract: Sleep disturbance is a significant underlying factor in the development of maladaptive responses to emotionally traumatic events. Heightened sympathetic nervous system activity is a hallmark of post-traumatic stress disorder (PTSD), and sleep is known to be an important regulator of both emotion and autonomic nervous system function. Recent studies from our lab and other groups show that changes in sleep after traumatic stress exposure can predict PTSD symptomatology. We have also found that an activity increase in the sympathetic locus coeruleus during sleep causes the same sleep changes as trauma-exposed animals who display PTSD symptoms. The locus coeruleus fires at all times except throughout REM sleep and for seconds prior to each sleep spindle in non-REM sleep. Thus, noradrenergic receptors are occupied except during these times. Beta adrenergic receptors enhance long term potentiation and prevent its reversal, depotentiation. Depotentiation is necessary for the consolidation of reversal learning including the extinction of fear that allows resilience after trauma. We hypothesize that continuous activity in the noradrenergic locus coeruleus during sleep leads to PTSD by preventing the depotentiation-dependent consolidation of extinction (e.g. safety) contexts. We tested whether the intervention of blocking beta noradrenergic receptors during sleep after extinction training, using propranolol (40 mg/kg) would confer resilience to trauma-exposed animals. As the critical window for memory consolidation is 4-5 hours after learning, we delayed propranolol injection in a control group by 5 hours. We found that immediate post-extinction propranolol enhanced fear extinction recall, reducing freezing to levels shown in non-trauma-exposed animals, whereas later propranolol injection impaired extinction memory such that freezing levels were similar to those of untreated trauma-exposed animals. Thus, blockade of noradrenergic pathways in the immediate period following extinction training enhances extinction memory consolidation in trauma-exposed groups, presumably by supporting sleep-dependent depotentiation of fear circuits which requires low noradrenergic tone.

Title: Post-stress sleep features in gonadally intact females affect fear learning

Authors: *Y. CABRERA[1], J. HOLLOWAY[1], J. JIMENEZ[1], K. SWIFT[3], G. R. POE[2]; [2]Dept. of Integrative Biol. and Physiol., [1]UCLA, Los Angeles, CA; [3]Mol. and Integrative Physiol., Univ. of Michigan, Ann Arbor, MI

Abstract: Sleep is essential in the memory consolidation process. Specific sleep stages are characterized by patterns of neural activity that facilitate strengthening, weakening, and reorganization of memory networks. Rapid eye movement (REM) sleep is important in the consolidation of emotional memories like fear conditioning and extinction. Recently, we showed the importance of locus coeruleus (LC) silence during REM sleep to support proper reversal learning in males. As the LC is the primary producer of norepinephrine (NE) in the cortex, LC silence signifies a pause in NE and its long-term potentiation enhancing effects, allowing flexible modification of memory synapses via depotentiation processes. Malfunctions in this system or conditions of high stress could contribute to excess NE release during REM sleep, increasing susceptibility to fear memory processing disorders. Since there are well known sex differences in prevalence of anxiety and fear memory disorders like PTSD, we explored whether sleep after stress differs in high hormone vs. low hormone stage female rats. The major estrous cycle hormones, estrogen and progesterone, modulate mood, cognition, and autonomic nervous system, and receptors for these hormones are known to be present in memory- and stress-related regions like the hippocampus, amygdala, and the LC. These may directly affect sleep-dependent memory processes and contribute to deficits in adaptive fear learning (i.e. poor extinction recall). Rats were implanted with probes to determine sleep/wake state and identify electrophysiological activity patterns congruent with memory processes. Upon examination of baseline sleep architecture, we found that REM sleep is selectively suppressed in females during the dark phase of proestrus, and that spectral power in the theta range (5-9 Hz), the predominant oscillatory frequency in REM sleep, also increases in the high hormone phases. Analysis of post-stress exposure sleep showed fragmentation of REM sleep bouts and decreased theta spectral power in REM, particularly in the low hormone phases, and these were linked to poorer extinction recall. Thus, estrous cycle effects on sleep affect fear memory consolidation processes, and may increase vulnerability to fear disorders.

Title: Changes in neuronal synchrony alter slow wave activity across infraslow cycles

Authors: *M. B. DASH, **A. GREEN**;
Middlebury Col., MIddlebury, VT

Abstract: Slow wave activity (SWA; the EEG power between 0.5 and 4 Hz during non-rapid eye movement sleep), is the best electrophysiological marker of sleep need. Given the apparent importance of this patterned neuronal activity for sleep function, it is critical to understand the physiological mechanisms that regulate the expression of SWA. In male Sprague-Dawley rats, we observed that SWA exhibits pronounced variability across infraslow timescales (~40 - 120s periods). Infraslow fluctuations in SWA were coordinated across the cortex and characterized by distinct alterations to individual slow waves (i.e. increased slope, amplitude, and duration and a concomitant reduction in the total number of waves and proportion of multipeak waves were associated with peaks in infraslow SWA). To investigate the physiological underpinnings of infraslow SWA, we used a freely available dataset comprised of extracellular unit recordings during consolidated NREM episodes in male Long-Evans rats. We observe that infraslow SWA was associated with alterations in neuronal synchrony surrounding "On"/"Off" periods and changes in the number and duration of "Off" periods. By contrast, changes in the firing rates of either excitatory or inhibitory neurons within the cortex were not associated with infraslow SWA. Together, these observations characterize a novel regulatory mechanism of SWA and highlight that SWA expression is regulated across shorter timescales in addition to its well-characterized homeostatic decline. With the ability to modulate SWA throughout the cortex, infraslow fluctuations may contribute to sleep function by coordinating local and global expressions of SWA.

Title: Chemogenetic activation of melanin concentrating hormone neurons attenuates sleep disturbances and contextual conditioning in predator odor trauma mouse model of PTSD

Authors: S. KUMAR[1], R. SHARMA[2], P. SAHOTA[3], *M. M. THAKKAR[1];
[1]Neurol., HSTMV Hospital/University of Missouri, Columbia, MO; [2]Truman VA Med. Center/University of Missouri, Columbia, MO; [3]Neurol., Univ. of Missouri, Columbia, MO

Abstract: BACKGROUND: Insomnia and associated sleep disturbances are amongst severe and persistent symptoms observed in individuals with post-traumatic stress disorder (PTSD). In fact, insomnia is believed to maintain and/or exacerbate PTSD symptoms. Effective treatment to attenuate sleep disturbances may accelerate recovery however; current medications are

ineffective. We have recently reported that mice exposed to predator odor trauma (POT) display contextual conditioning along with severe and protracted insomnia. Since melanin-concentrating hormone (MCH) is implicated in sleep regulation, we hypothesized that chemogenetic activation of MCH neurons will attenuate sleep disturbance and normalizes sleep. To test our hypothesis, we performed contextual conditioning, with predator odor (soiled cat litter) as the unconditional stimulus (US), contextual cage as the conditional stimulus (CS) and examined the effects of chemogenetic activation of MCH neurons on contextual conditioning and sleep. **METHODS:** Transgenic MCH-cre mice (expressing Cre-recombinase under MCH promoter control) were used as our animal model. Standard surgical protocol was used to perform bilateral infusion of excitatory DREADD (AAV/hSyn-DIO-hM3Dq-mCherry; 600nL/side) in MCH rich lateral hypothalamus followed by unilateral implantation of wire electrodes to record hippocampal field potentials. **Day 1:** Memory acquisition was performed by replacing the recording cage of MCH-cre mice with CS and allowing them to explore for 30 minutes followed by exposure to US for 90 minutes. On completion, CS were replaced with respective recording cages. **Day 2:** MCH neurons were activated by systemic (intraperitoneal) infusion of clozapine-N-oxide (CNO, 5 mg/Kg; CNO group) or saline (Controls) just before light (sleep) onset. **Day 3:** Memory recall testing was performed by exposing the mice to contextual cages (without US) for 120 min. On completion, mice were euthanized; brain removed and processed for immunofluorescence to quantify MCH neurons with DREADD expression. **RESULTS:** DREADD induced activation of MCH neurons resulted in a significant reduction in wakefulness with a concomitant increase in NREM sleep during light period on Day 2. Furthermore, during memory recall testing, while the controls displayed electrophysiological indicators of traumatic memories including increase in hippocampal theta and gamma activities along with increased wakefulness, no such effects were observed in the CNO group. **CONCLUSION:** Our results suggest that chemogenetic activation of MCH neurons attenuates sleep disorders and contextual conditioning in the predator odor trauma, mouse model of PTSD.

Title: Neuronal activity of brainstem reticular formation neurons across the sleep-wake cycle in the domestic chicken

Authors: *O. LYAMIN[1,2], A. BAKHCHINA[2,3], I. SHAMSIEV[2,4], J. SIEGEL[1];
[1]Dept Psychiat, Univ. California Los Angeles, North Hills, CA; [2]A.N. Severtsov Inst. of Ecology and Evolution, Moscow, Russian Federation; [3]Inst. of Psychology, Moscow, Russian Federation; [4]Inst. of Higher Nervous Activity and Neurophysiol., Moscow, Russian Federation

Abstract: In contrast to mammals, rapid eye movement (REM) sleep or paradoxical sleep (PS) in most bird species lasts only 5-10 seconds when scored based on conventional polygraphic criteria (cortical arousal, muscle tone reduction and rapid eye movements). The neuronal activity, which underlies REM sleep has never been recorded in birds. The aim of this study was to examine neuronal discharge of the brainstem neurons in the domestic chicken *(Gallus gallus domesticus)* during the sleep-wake cycle to better understand the nature of REM sleep in birds. EEG, neck electromyogram, electrooculogram and single neuron activity were recorded in 5 freely-moving domestic chickens (4-5 mo old) across the sleep-wake cycle. Twenty one of the recorded neurons were located in the area of midbrain reticular formation and 16 neurons in the pontine reticular formation. The unit activity (average and instantaneous discharge rate) was analyzed in 4-sec epochs. Fifteen out of 37 neurons (41% of the recorded cells) had higher firing rates both in waking and REM sleep when compared to non-REM sleep or slow wave sleep (W+R+ cells). Among them, 9 neurons (24%) discharged during REM sleep with a greater rate than during active wakefulness (AW) (W+R++ cells). Additional 8 neurons (22%) selectively increased the firing rate in REM sleep while their discharge rate in AW, quiet wakefulness and non-REM sleep was low (0.01-1.20 Hz; R+ cells). Only two cells (5%) were classified as “max-active” in AW when compared to other states (W+ cells). Twelve cells (32%) were classified as state indifferent (less than 50% change across sleep waking states). Therefore, based on the profile of the discharge of reticular neurons, the described cell types in the chicken are similar to that in mammals (cats, rats and mice). Rapid eye movements is the key parameter, which unambiguously indicates REM sleep in the chicken. At the same time, the degree of cortical EEG arousal and muscle tone reduction (the hallmark of REM sleep / PS in mammals) during REM sleep in the chicken is greatly variable as also described in other bird species. Thus, we have found that up to 35 % of episodes of REM sleep in different chickens were recorded during EEG slow waves showing some similarity with the data previously reported in the echidna, platypus and in the ostrich. Our neuronal and polygraphic data supports the idea that REM sleep in the chicken may occur at the level of brainstem (midbrain and pontine reticular formation) without cortical activation and that this may be the case in other birds.

Title: MiR-190 acts in the pupal nervous system to affect the arousal system and sleep behavior in *Drosophila melanogaster*

Authors: *E. J. RIVERA-RODRÍGUEZ[1], M. HOBIN[2], P. CHEN[2], L. C. GRIFFITH[2];
[1]Neurosci., [2]Brandeis Univ., Waltham, MA

Abstract: Sleep is a widely conserved behavior, known to influence many cognitive and physiological functions. Studies have implicated microRNAs in the regulation of gene expression changes that control sleep behavior. The Griffith lab screened a library of 141 microRNA sponges using the fruit fly *Drosophila melanogaster*, in order to find microRNAs involved in sleep regulation (Goodwin et al., 2018). This screen showed miR-190 to be involved in the regulation of sleep. Flies expressing the miR-190 sponge (*miR-190SP)* in a pan-neuronal manner showed decreased and fragmented sleep, as well as changes in other sleep parameters. Expressing *miR-190SP* in a limited number of cells in different brain regions by means of the *Gal4/UAS* system showed that disruption of miR-190 function must occur in a large number of neurons to affect *Drosophila* sleep regulation. At the molecular level, RNA sequencing of adult heads showed that pan-neuronal expression of *miR-190SP* induces an up or downregulation of multiple genes, among those, 9 genes which are intimately involved in dopamine (DA) signaling, the major pro-arousal system of the fly. Feeding flies pan-neuronally expressing the miR-190 sponge a low dose of the tyrosine hydroxylase inhibitor 3IY rescues their sleep phenotype, causing an increase in total sleep without significant effects on control animals. Temporally limiting expression of *miR-190SP* to early larval or adult stages does not affect sleep. Pan-neuronal-pupal inhibition of miR-190, however, results in a significant decrease in sleep, phenocopying the results obtained by expressing the miR-190 sponge throughout development. This suggests that miR-190 acts to establish adult sleep behavior during the pupal stage. Taken together, our results suggest that miR-190 acts during development to specify the activity of the adult arousal system and adult sleep behavior.

Title: Examination of a role for the locus coeruleus in CO_2-induced arousal from sleep

Authors: *C. J. HAUSER[1], A. L. ZOCHER[1], G. F. BUCHANAN[2,3];
[1]Heath and Human Physiol., Univ. of Iowa, Iowa City, IA; [2]Neurol., Carver Col. of Medicine, Univ. of Iowa, Iowa City, IA; [3]Iowa Neurosci. Inst., Iowa City, IA

Abstract: CO_2-induced arousal is a critical protective mechanism. Under normal conditions, if the airway is occluded, arterial partial pressure of CO_2 ($PaCO_2$) rises. This can happen repeatedly during sleep, in conditions like obstructive sleep apnea. The elevated $PaCO_2$ acts as a powerful arousal stimulus. Once awake, airway tone increases thereby correcting the obstruction, allowing breathing to resume, and returning $PaCO_2$ to baseline. Impaired CO_2-induced arousal may contribute to multiple fatal conditions during sleep such as sudden infant death syndrome (SIDS) and sudden unexpected death in epilepsy (SUDEP). In these conditions, individuals do not arouse in response to increased $PaCO_2$ resulting in acidosis and eventual death. Mechanisms of CO_2-induced arousal from sleep are not well understood. Determining these mechanisms may provide insight to the pathophysiology underlying these conditions and lead to the development of preventive therapies. Previous research has shown that dorsal raphe nucleus (DRN) serotonergic (5-HT) neurons and external lateral parabrachial calcitonin gene-related peptide expressing neurons ($PBel^{CGRP}$) are necessary for CO_2-induced arousal. These structures are interconnected with the locus coeruleus (LC), which also plays a role in regulating arousal through its extensive noradrenergic (NA) projections to wake-promoting regions such as the cortex and thalamus. Here we tested the hypothesis that the NA neurons in the LC are involved in CO_2-induced arousal. Adult, male and female, C57BL/6J mice were treated with DSP-4 (50 mg/kg, *i.p.;* two injections, seven days apart), a neurotoxin selective to LC NA neurons, or saline. Mice were implanted with epidural EEG and nuchal EMG electrodes, allowed to recover, and habituated to the gas chamber. During non-rapid eye movement (NREM) sleep, mice were exposed to 7% CO_2 (CO_2; in 21% O_2 and balance N_2) or room air (RA; 21% O_2 and balance N_2) and arousal latency was recorded. All trials were performed within the first six hours of the light phase. DSP-4-treated mice exhibited no significant difference in arousal latency to CO_2 or RA (3.461 ± 0.455 min vs. 2.493 ± 0.564 min; $p = 0.104$; $n = 6$). Control mice exhibited normal, robust CO_2 responsiveness during sleep with a significant reduction in arousal latency to CO_2 compared to RA (1.074 ± 0.071 min vs. 3.347 ± 0.652 min; $p = 0.017$; $n = 6$). This finding of decreased CO_2 responsiveness during sleep upon partial LC NA neuronal destruction suggests a role for the LC in CO_2-induced arousal. Further research into the extent of this role and the signaling pathways between these implicated structures is warranted.

Title: Frequency-dependent modulation of sleep and wakefulness via optogenetic stimulation of the basal forebrain parvalbumin neurons

Authors: *J. HEO, J. LEE, C. KIM, T. KIM;
Dept. of Biomed. Sci. and Engin., Gwangju Inst. of Sci. and Technol., Gwangju, Korea, Republic of

Abstract: The basal forebrain (BF) parvalbumin (PV) neurons have been known for controlling sleep and wakefulness. Optogenetic stimulation of BF PV neuron in mice regulates the gamma band oscillations in the cortex via corticopetal projection, and also induces arousal state, supporting the wake-promoting property of BF PV neurons. Interestingly, BF PV neurons also project to TRN of which intermittent stimulation at 8 Hz generates sleep spindles and protects NREM sleep. Indeed, our preliminary results from unilateral optogenetic stimulation of the BF PV neurons at 8 Hz showed a slight increase in NREM sleep. However, the function of this anatomical connection in sleep-wake control is still unclear. Therefore, we sought to investigate the effects of bilateral BF PV neuron stimulation to confirm the frequency-dependent bidirectional modulation of sleep and wakefulness. For selective stimulation of the BF PV neurons, we stereotaxically injected double-floxed ChR2-eYFP viral vector (AAV5-DIO-ChR2-e YFP) into PV-Cre transgenic mice (strain 012358, Jackson Lab) of BF region bilaterally (AP=0, ML=1.6 and -1.6, V=-5.5 from the bregma). After 2weeks electrodes for EEG were implanted on the frontal and parietal lobe of the left hemisphere and optical fiber (200μm, 0.22 NA) in BF region of both hemispheres. Laser light was generated from 473nm Blue DPSS laser driver. The light was delivered via fiber-optic cable connected to fiber optic cannula. The baseline EEG of 24-hour sleep-wake behaviors was recorded, followed by 6-hour EEG recordings including 2-hour optogenetic stimulation with intermittent 8Hz (from ZT06 to ZT08) and tonic 40Hz (from ZT18 to ZT20) stimulation protocols. We compared the evoked gamma power between unilateral and bilateral stimulation by giving 40Hz optical stimulation and analyzed sleep-wake behaviors after manual scoring. Bilateral hemisphere evoked gamma power was stronger than unilateral counterpart (bilateral to ipsilateral ratio 1.46 in the frontal EEG). We are expecting that intermittent stimulation at 8 Hz of the bilateral BF PV neurons will increase NREM sleep during stimulation and post-stimulation periods, and the bilateral stimulation at 40Hz will also decrease NREM like our previous preliminary data with a stronger effect than that of the unilateral stimulation. The final results are pending. We found that the increment of NREM sleep by intermittent stimulation of bilateral BF PV neurons at 8 Hz and the decrement of

NREM by 40 Hz were more clearly validated with bilateral stimulation of BF PV neurons. It may suggest that the BF PV neurons have a dual function of sleep- and wake-promotion depending on the rate and mode of neuronal firings of them.

Title: Scully in sleep regulation and dementia

Authors: *A. ARZOLA, Jr, P. SABANDAL, K.-A. HAN;
Biol. Sci., Univ. of Texas at El Paso, El Paso, TX

Abstract: Sleep is an important physiological process for memory, metabolic waste clearance in the brain, and other cognitive functions. The fruit fly *Drosophila melanogaster* and humans share aging-associated sleep features including reduced sleep time and fragmented sleep architecture. Sleep dysfunction is a common feature of Alzheimer's disease and related dementia; however, the mechanism by which sleep dysfunction contributes to dementia is not well understood. We found that the *scully* mutant flies have abnormal sleep. Scully is the fly homolog of 17-β-hydroxysteroid dehydrogenase 10 (HSD17β10), a versatile mitochondrial enzyme known to bind amyloid β-peptide and is overexpressed in the brain of Alzheimer's disease patients. Interestingly, *scully* mutant flies show the features of dementia that include dysfunctional inhibitory control and memory loss. To investigate whether abnormal sleep in *scully* is linked to dementia, we are investigating whether reinstatement of normal sleep in *scully* would rescue the dementia phenotypes and whether overexpressed *scully* causes sleep anomaly or dementia or both. The progress of the study will be presented. This study may provide novel insights in the role of *scully* in Alzheimer's disease and related dementia.

Title: Sex differences in active-phase sleep amount are partially driven by X chromosome dosage

Authors: *I. S. N. NICHOLS, S. ANDERSON, H. HRNCIR, Z. HERNANDEZ, A. P. ARNOLD, K. N. PAUL;
Integrative Biol. and Physiol., Univ. of California Los Angeles, Los Angeles, CA

Abstract: Sex differences in total sleep amount in mammals are largely dependent on gonadal hormones. However, there are a number of sex differences in sleep traits that are not driven by gonadal hormones. The most prominent of those are total sleep amount during the active phase and sleep amount/intensity during recovery from sleep loss. Female mice consistently exhibit less sleep amount during the active phase, and less sleep amount and intensity during recovery from sleep loss than males. We have previously shown that these effects are related to sex chromosome complement. The current study sought to determine if the effects of the sex chromosomes are due to X chromosome dosage (total number of chromosomes), or the presence of the Y chromosome. This experiment takes advantage of a mouse line that alters the dosage effects of sex chromosomes and sex-linked genes. The XY star line (denoted as XY*) is comprised of four sex chromosome complement phenotypes: XO (phenotypic female), XX (phenotypic female), XXY (phenotypic male), XY* (phenotypic male). This mouse line allows the investigation of: 1) dosage effects of the X chromosomes, and 2) the presence or absence of the Y chromosome. This mouse line also serves as a model for Turner Syndrome and Klinefelter syndrome. Adult mice were implanted with four stainless steel electroencephalograph (EEG) and electromyography (EMG) recording electrodes. Mice were subjected to 24 hrs of baseline (spontaneous) sleep-wake recording. Following baseline, mice were subjected to six hrs of sleep deprivation via a gentle handling procedure (starting at the onset of the light phase) and allowed to recover during the remainder of the 24-hr recording period. X dosage had an effect on active-phase baseline sleep amount, but no effects during recovery from sleep loss. Repeated measures ANOVA revealed an interaction between phase and genotype ($F_{3,8}$= 8.956, p=.006). XY mice had more sleep than XO mice (p=0.030) and slightly, but not significantly, more sleep than XX mice (p=.051). XXY mice were not different from any other groups. These results suggests that the ability of the Y chromosome to influence sleep in mice is dependent on X dosage. These

results also suggest that the ability of sex-linked genes to influence sleep is independent of phenotypic sex.

Title: Time restricted feeding (TRF) improves sleep in a mouse model of Huntington's disease

Authors: Y. TAHARA[1], S. ANDERSON[2], *I. S. NICHOLS[2], C. A. GHIANI[3], ***K. N. PAUL**[2], C. S. COLWELL[4];

Abstract: Disturbances in the daily sleep-wake cycle are a common feature experienced by individuals with neurodegenerative disorders. Huntington's disease (HD) is the most common genetically determined neurodegenerative disease. Patients with HD exhibit a variety of sleep abnormalities that include difficulty initiating sleep at bedtime, and more frequent nighttime arousals. Mouse models of HD exhibit similar sleep deficits. Using a mouse model of HD that expresses the human mutation (BACHD), we have successfully improved behavioral and autonomic deficits using a time restricted feeding (TRF) protocol that limits the daily food intake into a 6-hr window during the animal's active phase. In this study, we sought to determine whether TRF was sufficient to improve sleep-wake phenotypes in the BACHD mouse. Adult male mice were anesthetized and implanted with electroencephalograph (EEG) and electromyograph (EMG) electrodes for the 24-hr recording of sleep and wake states. Multivariate ANOVA revealed that during baseline recording of spontaneous sleep and wake states, BACHD mice exhibited more total wakefulness ($p=.034$) than wild-types (WT). TRF dramatically improved the temporal pattern of sleep behavior. The BACHD mice on TRF spent more time sleeping during the day compared to untreated BACHD mice ($p=.026$). However, the overall amount of total sleep over 24 hrs. was not altered. These effects of TRF were more prominent in BACHD mice than WTs. To our knowledge, this is the first demonstration that TRF can improve sleep parameters in a mouse model of HD. A critical gap in our knowledge is whether TRF specifically alters the temporal pattern of sleep stages, sleep homeostasis, or cortical up/down states that reflect slow wave activity.

Title: Transcriptomic analysis of sleep states

Authors: ***A. KULKARNI**[1], T. BJORNESS[2], A. SUZUKI[2], G. KONOPKA[1], R. GREENE[2]; [1]Neurosci., [2]Psychiatry, Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Sleep deprivation has detrimental effects on a wide array of biological processes. A leading, yet controversial proposal for sleep function is a weakening and/or pruning of synaptic connections and net decrease in synaptic strength that can aid in metabolic homeostasis and memory. It is possible that both strengthening and weakening processes can occur during sleep. Neuronal activity and gene expression during sleep or in response to the loss of sleep can provide a window to the enigma of sleep function. Sleep-loss is associated with characteristic rebound and resolution of slow wave sleep - slow wave activity (SWS-SWA), and an increase in pyramidal cell mini-frequency and amplitude, reflecting changes in synaptic strength, that recover with recovery sleep (RS). Here, we examine the gene expression landscape in response to sleep deprivation and recovery sleep against ad-lib sleep in mouse frontal cortex as this region is associated with highest intensity of slow wave activity during slow wave sleep and shows greatest change in SWS-SWA in response to loss of sleep. We observed a sleep-loss induced differential gene expression of almost one half of the expressed frontal cortical transcriptome. Genes shared by both sleep-loss and RS with significantly increased expression suggests roles in lipid mobilization for energy utilized during protein metabolism as well as involvement in neuropsychiatric disorders such as cognitive deficits, Parkinson disease and epilepsy. Consistent with reduction in synaptic strength during sleep, shared genes with significantly reduced expression across sleep-loss and RS suggests their contribution in controlling synaptic strength and connection to neurological diseases such as, autism spectrum disorders intellectual disability, mental retardation, etc. Together, these findings facilitate the molecular underpinning of the sleep function and contribute to the better understanding of pathways leading to detrimental effects of sleep deprivation.

Authors: *M. A. F. FRAZER[1], G. R. POE[2];
[1]Univ. of California Los Angeles, Los Angeles, CA; [2]Dept. of Integrative Biol. and Physiol., UCLA, Los Angeles, CA

Abstract: The necessity of sleep to learning and memory processing is well-established. The specific mechanisms that facilitate memory consolidation during each stage of sleep, however, are still an area of active investigation. To explore further the underlying mechanisms of sleep, we have used *in vivo* calcium imaging in freely-behaving mice to record from hippocampal CA1 cells across sleep stages. We have found that each sleep stage demonstrates unique population activity, likely underlying each stage's role in sleep-dependent memory consolidation.

Physiol., UCLA, Los Angeles, CA; [6]Mol. and Integrative Physiol. Dept., [7]Molecular, Cellular, and Developmental Biol. Dept, Univ. of Michigan, Ann Arbor, Ann Arbor, MI

Abstract: There are marked differences in the makeup of sleep in both males and females, with some studies indicating that sleep is undeniably altered by the menstrual cycle in women. However, not much is known about the electrophysiological makeup of sleep in gonadally intact female rodents. Using electroencephalographic (EEG) activity, we show that the estrous cycle alters sleep states and features in multiple cortical areas and the hippocampus in males and free-cycling females. Namely, we found that, compared with males and other phases of the estrous cycle, time spent awake increases during proestrus, sacrificing time spent in non-rapid eye movement (NREM) and rapid eye movement (REM) sleep. As a result, the estrus phase showed rebound in sleep architecture with increases in REM and NREM. Further, spectral power also fluctuates in accordance with the estrous cycle. Proestrus shows increased delta (0.5-4 Hz) and gamma (30-60 Hz) power, where as REM theta (5-9 Hz) increased during both proestrus and estrus compared to other phases. Proestrus also showed an increase in slow wave activity (SWA) and cortical sleep spindle density during NREM, and increases in interregional NREM and REM spectral coherence. This data demonstrates the wide impact of the estrous cycle on sleep, providing the foundation for future research to use gonadally intact male and female rats during sleep studies.

Title: Evidence for a role of tachykinin-1-expressing preoptic area neurons in isoflurane-induced unconsciousness

Authors: *S. L. REITZ, M. B. KELZ;
Anesthesiol. & Critical Care, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Though anesthetics have been used in the medical field for over 150 years and are currently used in over 300 million surgeries annually, the precise mechanisms by which this diverse category of drugs produces a state of unconsciousness are not fully understood.

Similarities between anesthetic-induced unconsciousness and the state of non-rapid eye movement (NREM) sleep has led to the hypothesis that anesthetics produce unconsciousness in part through the endogenous pathways that regulate sleep and arousal. Previous work has shown that isoflurane, a volatile anesthetic, activates sleep-promoting neurons (SPNs) in the ventrolateral preoptic area (VLPO) as well as the supraoptic nucleus (SON). Additionally, manipulations of either of these SPN populations affect the response to isoflurane anesthesia, further suggesting that SPNs in the POA may mediate isoflurane-induced unconsciousness. However, the VLPO and SON are not the only POA regions known to contain SPNs, and it is unclear whether isoflurane also activates SPNs across the broader POA. Labeling SPNs in this region has proved challenging due to a lack of unique markers capable of identifying them within the highly heterogeneous POA. However, recent work has shown that tachykinin-1 (Tac1) expressing neurons in the POA promote NREM sleep when activated, and thus provide a reliable marker for SPNs throughout the POA. Given the evidence in VLPO and SON, we hypothesized that activation of POA SPNs is involved in producing isoflurane-induced unconsciousness. Using loss of righting reflex as a proxy for unconsciousness, induction and emergence dose-response curves for isoflurane were measured in adult Tac1-Cre mice before and after a lesion or sham lesion of Tac1 POA neurons. Tac1 POA neurons were lesioned using bilateral stereotaxic injections of a virus encoding a Cre-dependent diphtheria toxin A subunit, while controls received injections of a Cre-dependent mCherry fluorescent protein. Post-lesion, we observed a rightward shift of the entire dose-response curve, with the EC_{50}, or dose at which 50% of the population had lost the righting reflex, shifting from 0.73% (95% CI: 0.71%-0.76%) isoflurane at baseline to 0.85% (95% CI: 0.80%-0.89%) at 3 weeks post-injection. Sham lesioned animals showed a leftward shift of the curve, with the EC_{50} shifting from 0.72% (95% CI: 0.69%-0.76%) to 0.57% (95% CI: 0.55%-0.60%) isoflurane. Interestingly, no significant effects were detected in the emergence dose-response curve. These results suggest the intriguing possibility that Tac1 POA neurons play a role in the induction of isoflurane-induced unconsciousness, but not in emergence from the anesthetic state.

Title: Coupled sleep, attention and dopamine receptor deficits after early life stress

Authors: *Y. MAKINO[1,2], K. OSADA[1], T. K. HENSCH[1,2];
[1]Dept. of Mol. and Cell. Biol., Harvard Univ., Cambridge, MA; [2]Dept. of Neurol., Boston Children's Hosp., Boston, MA

Abstract: Early life adversity results in a variety of neural and behavioral deficits later in life. Particularly, sleep regulation and attentional function are susceptible to early life stress (ELS), leading to insomnia and inattentive behavior. However, the association between sleep and attentional deficits after ELS as well as its molecular basis remains largely unknown. Here, we employed the fragmented maternal care model (Rice et al. 2008) in mice to investigate the influence of ELS on later sleep and attention as well as the underlying molecular changes. In adult (>P90) male mice, sleep regulation (-7% NREM, +8% wake duration; $p<0.05$ vs control care), prefrontal gamma oscillation during waking (+13% relative power with aberrant peaks; $p<0.05$) and attentional function (-11% correct on a touchscreen 2-choice visual task; $p<0.05$ vs control care) were disrupted after fragmented maternal care between postnatal days P2-P9. Acute experimental sleep deprivation (4-hour gentle handling) led to comparable attentional reduction in normally-reared adult mice (-12% correct; $p<0.01$ vs baseline), while no further attentional reduction by acute sleep deprivation was observed in mice after early life fragmented care. This suggests that persistent, poor sleep signatures caused by ELS might underlie their attentional impairment in adulthood. At a molecular level, both fragmented care and acute sleep deprivation induced a parallel increase of dopamine D2 receptors and decrease of D4 receptors in the adult anterior cingulate cortex (ACC), which correlated with attentional performance. Thus, altered dopamine signaling in the ACC caused by insufficient sleep might be a basis for attentional impairment. Strikingly, neither sleep impairment, altered gamma oscillation nor ACC dopaminergic changes were observed in female mice after fragmented care, revealing unanticipated gender differences in the susceptibility to ELS for these particular physiological measures. Our findings reproduce in mice the insomnia and inattentiveness in humans after early adversity and offer a mechanistic association between them, which is potentially mediated by altered D2/D4 dopaminergic transmission in the ACC.

Title: Basolateral amygdala projecting anterior cingulate cortex neurons control reward devaluation

Authors: *Z. YUAN, Z. QI, Y. CUI, Q. FENG, M. LUO;
Natl. Inst. of Biol. Sciences, Beijing, Beijing, China

Abstract: The incentive value of food is not only determined by its physical characteristics, but also by the homeostatic state of animals. For instance, water is a strong reward for thirsty, rather than water-satiated, animals; sucrose, a natural reward stimulus, can become less attractive as the intake volume increases. These phenomena could be referred to as reward devaluation. Disorder in reward devaluation may result in obesity or anorexia, even drug addiction. Here, we show that anterior cingulate cortex (ACC) is involved in the process of reward devaluation. First, fiber photometry revealed that CaMKII positive neurons in ACC were silenced when mice were either drinking voluntarily or receiving water passively, and the inhibition strength was gradually weakened with increased water intake. Furthermore, lesion or inhibition of ACC neurons slowed the devaluation process and gave rise to over-intake of reward (water). In contrast, activation of ACC neurons accelerated reward devaluation and led mice to consuming less reward. In addition, we found that basolateral amygdala (BLA) projecting ACC neurons underlie this effect. In conclusion, BLA-projecting ACC neurons contribute substantially to bidirectional regulation of reward intake by modulating its devaluation process.

Title: Increased noradrenergic activity within the basolateral amygdala enhances appetitive extinction

Authors: *L. H. CORBIT;
Dept. of Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Noradrenergic signaling has been shown to facilitate extinction in both appetitive and aversive conditioning paradigms. Converging evidence also suggests that the basolateral amygdala (BLA) is part of the neural circuitry that underlies extinction, and may play a role in the noradrenergic modulation of extinction memory. This study investigated effects of manipulating noradrenergic activity within the BLA on the long-term expression of extinction of stimulus-reward associations. Rats surgically implanted with cannulae aimed at the BLA were trained to lever-press for food reward in the presence of three discriminative stimuli. Responding was then extinguished over two consecutive days. Prior to the third extinction session, rats received intra-BLA infusions of either saline, noradrenaline (NA), or a specific NA agonist (clenbuterol) or antagonist (propranolol). Spontaneous recovery of responding was assessed four weeks later. We found that treatment with NA or the beta-2-receptor agonist clenbuterol enhanced, whereas blockade of beta-adrenergic receptors with the antagonist propranolol impaired extinction learning evidenced by changes in spontaneous recovery compared to a saline control. These results demonstrate that manipulations that increase noradrenergic activity in the BLA increase the long-term efficacy of extinction of appetitive learning.

Title: Role of basolateral amygdala to nucleus accumbens projections in mediating flexibility of sign- and goal-tracking rats

Authors: *D. E. KOCHLI, S. E. KEEFER, U. GYAWALI, D. J. CALU;
Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The psychological and neurobiological mechanisms underlying individual differences in addiction vulnerability require further investigation. A hallmark of addiction is behavioral inflexibility of drug use in the face of negative consequences. Previous studies suggest that even prior to drug experience, goal-tracking rats remain sensitive to changing outcome value, while

"addiction-vulnerable" sign-tracking rats demonstrate inflexible responding that does not reflect the current value of the outcome. The present work utilizes an outcome specific satiety devaluation in a Pavlovian lever autoshaping (PLA) procedure to test the hypothesis that sign-tracking rats rely on the basolateral amygdala (BLA) to nucleus accumbens (NAc) pathway to rigidly encode appetitive cue value that is insensitive to changes in outcome value. Using a chemogenetic disconnection design, we inactivate BLA-NAc pathway during outcome specific satiety devaluation and measure lever- and foodcup-directed behaviors in the PLA task. In this procedure, a brief lever insertion predicts non-contingent delivery of a food pellet reward. While no interaction with any stimulus is necessary, sign-trackers preferentially interact with lever predictive cues, whereas goal-trackers preferentially interact with the food cup. Intermediate rats interact with both the lever and food cup. Prior to non-reinforced PLA test sessions, all rats (mCherry, hM4Di-mCherry) received systemic clozapine (0.1 mg/kg) injections and were either sated on the training pellet (devalued condition) or homecage chow (valued condition). We conducted two non-sated PLA tests under non-reinforced or reinforced conditions. Data suggest BLA-NAc pathway supports lever-directed behavior for sign-tracking rats independent of outcome value (valued, devalued) and motivational state (sated, non-sated). Intermediate rats display increased behavioral flexibility when BLA-NAc pathway is inactivated, seemingly unmasking devaluation sensitivity in the intermediate rats that do not otherwise display differential responding to valued and devalued outcomes. This suggests appetitive cue value encoding in BLA-NAc may hinder expression of flexible behavior when outcome value changes. Goal-tracking rats' food cup responding is behaviorally sensitive to satiety devaluation and ongoing studies determine the extent to which activity in BLA-NAc mediates flexibility in goal-tracking rats. A more sophisticated understanding of the circuitry underlying individual differences in addiction vulnerability will inform translational efforts to improve addiction prevention, diagnosis and treatment.

Title: Role of basolateral amygdala to insular cortex projections in mediating individual and experience-dependent differences in flexibility of sign- and goal-tracking rats

Authors: *S. E. KEEFER, D. E. KOCHLI, S. Z. BACHARACH, D. J. CALU;
Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Recent studies have shown goal-tracking (GT) rats are sensitive to outcome devaluation while sign-tracking (ST) rats are not. With extended training, we observed GT rats display more ST responses, suggesting GT may become insensitive to devaluation with more training. To determine the effects of limited and extended training on devaluation sensitivity in GT and ST rats, we used a within subject satiety-induced outcome devaluation procedure. We sated rats on training pellets (devalued condition) or homecage chow (valued condition) prior to brief non-reinforced test sessions at limited (sessions 5/6) and extended training (after sessions 17/18) time points. Consistent with our prior study, after limited training, GT rats were sensitive to outcome devaluation, while ST rats were not. After extended training, GT rats remained sensitive to devaluation, while surprisingly, ST rats now showed devaluation sensitivity. The results confirm devaluation sensitivity is stable in GT rats and extended training unmasks flexibility in ST rats, suggesting distinct, potentially shifting neural mechanisms that decipher reward value. Because the basolateral amygdala (BLA) to anterior insular cortex (IC) pathway mediates devaluation, we sought to test the role of this pathway in mediating GT and ST differences in flexibility across training. We predicted after limited training, inactivating BLA-IC would abolish devaluation sensitivity in GT rats and not affect devaluation insensitivity of ST rats. After extended training, we predicted inactivating this pathway would block devaluation sensitivity in both GT and ST rats. We injected inhibitory DREADDs (hM4D-mcherry) or control (mCherry) virus bilaterally into the BLA and implanted bilateral cannulae into the IC for clozapine-*N*-oxide (CNO; 1mM, 0.25 µl/side) infusions to temporarily inactivate BLA terminals during devaluation tests. After limited training rats were sated on training pellets (devalued condition) or homecage chow (valued condition) and all rats received bilateral CNO infusions into the IC prior to brief non-reinforced test sessions. Preliminary results replicate devaluation sensitivity in control GT rats, while hM4D GT rats show blunted responding to both the devalued and valued conditions. Control and hM4D ST rats remained insensitive to devaluation after limited training. Ongoing studies are examining the effect of BLA-IC disconnection after extended training in GT and ST rats. These results demonstrate BLA-IC mediates behavioral flexibility and furthers our understanding of individual differences by recognizing behavioral and neural differences that relate to addiction vulnerability.

Title: A reciprocal cortical-amygdala circuit for the encoding and retrieval of detailed associative reward memories

Authors: *A. SIAS[1], A. K. MORSE[1], C. SHIEH[1], S. M. HOLLEY[2], V. GREENFIELD[3], C. CEPEDA[2], M. S. LEVINE[2,4], K. M. WASSUM[1,4];

Abstract: Adaptive reward-related decision making requires anticipation of potential future rewarding events. This expectation is enabled by predictive environmental stimuli. These cues trigger the retrieval of often quite detailed memories of their associated rewards, which then inform adaptive reward pursuit and bias decision making. But very little is known of the neural circuits that mediate the encoding and subsequent retrieval of unique stimulus-reward associative memories. We addressed this gap in knowledge by combining optogenetics, chemogenetics, serial circuit disconnection, and a translationally-relevant behavioral task designed to assess the encoding and retrieval of detailed stimulus-reward memories. Using optical inhibition, we found basolateral amygdala (BLA) principle cells to be necessary for encoding detailed stimulus-reward memories. BLA inhibition upon reward delivery/consumption during Pavlovian stimulus-reward conditioning did not disrupt acquisition of a simple Pavlovian conditional approach response, but did prevent subjects from learning the unique stimulus-reward relationships, as evidenced by their inability to subsequently use such memories to guide choice behavior (Pavlovian-instrumental transfer) or adaptive conditional responding following outcome-specific devaluation. This result was replicated using optical inhibition of lateral orbitofrontal cortex (lOFC) terminals in the BLA, indicating lOFC-->BLA projections are critical for encoding stimulus-reward memories. Tract tracing revealed reciprocal connectivity between the BLA and lOFC and previously we showed that BLA-->lOFC, but not lOFC-->BLA projections are necessary for retrieving detailed stimulus-reward memories. Thus, we suspected that lOFCàBLA projections might enable the encoding of stimulus-outcome memories that are later retrieved via BLA-->lOFC projections. We found support for this hypothesis by multiplexing optogenetic and chemogenetic inhibition for a serial circuit disconnection. Collectively, these data reveal the lOFC-->BLA-->lOFC circuit to be essential for the encoding and retrieval of detailed stimulus-reward associative memories crucial for adaptive decision making.

Title: Midbrain dopaminergic input to basal amygdala gates state-dependent learning of salient cues

Authors: *A. LUTAS, H. KUCUKDERELI, O. ALTURKISTANI, C. CARTY, K. FERNANDO, A. U. SUGDEN, V. DIAZ, V. FLORES-MALDONADO, M. L. ANDERMANN; Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: The acquisition of responses in basal amygdala (BA) neurons to sensory stimuli that predict either salient appetitive or aversive outcomes is crucial for associative learning. We found that ventral tegmental area dopamine axons innervating BA ($VTA^{DA>BA}$) were activated by *both* rewards and punishments, and acquired responses to cues predicting these salient outcomes during learning. BA neurons downstream of these actions also acquired cue responses with learning, but separate populations represented reward-paired and punishment-paired cues. Following satiation, responses to reward cues in $VTA^{DA>BA}$ axons and BA neurons were attenuated, while responses to cues predicting aversive outcomes persisted or increased, indicating a shift in BA responses from reward related activity to threat related activity. We confirmed that dopamine levels increased in the BA during both reward and punishment predicting cues leading us to ask how this signal might control plasticity. Brain slice studies suggested that $VTA^{DA>BA}$ inputs may boost plasticity by increasing cAMP signaling across BA excitatory neurons, while restricting plasticity by enhancing lateral inhibition via BA interneurons. Preliminary *in vivo* imaging of cAMP in BA support this model of broad permissive plasticity during triggered by salient events. Through these actions, the same $VTA^{DA>BA}$ axons may provide a reinforcement signal of motivational salience that promotes learned responses to appetitive or aversive cues in distinct, intermingled sets of BA excitatory neurons.

Title: Hierarchical amygdala network dynamics reflect learning of adaptive behavioral patterns

Authors: ***Y. BITTERMAN**[1], J. COURTIN[1], J. GRÜNDEMANN[2], A. LÜTHI[1,3];
[1]Friedrich Miescher Inst. For Biomed. Res., Basel, Switzerland; [2]Dept. of Biomedicine, [3]Univ. of Basel, Basel, Switzerland

Abstract: Classically, the basolateral amygdala has been studied mainly in the framework of Pavlovian conditioning, leading to the identification of circuit elements that underlie stimulus related plasticity at the single-cell and neural-ensemble levels. However, we have only a rudimentary understanding of how learning of adaptive behavioral patterns relates to amygdala network dynamics. Using calcium imaging, we monitored with cellular resolution the activity of neuronal populations in the basolateral amygdala, as mice underwent partially-stochastic instrumental training that resulted in stereotypical, self-paced behavioral sequences. We used a data driven approach to identify structures in the dynamics of the population activity without additional behavioral or environmental information. The seemingly complex network activity was composed of simple latent dynamics that emerged consistently with learning, albeit variability in the neural representation of events across mice. Furthermore, the hierarchical structure of the network dynamics reflected the abstract structure of the learned behavioral patterns. Thus, latent dynamics provided a unified framework to study the relations between neural network activity and behavior, with testable predictions as to the system's susceptibility to specific behavioral and neuronal perturbations. Our results point to an amygdala function in driving state- and input- dependent behavioral patterns, with possible insights to amygdala maladaptive function in pathological conditions.

Title: The effects of lesions of the amygdala and periaqueductal gray on learning from gains and losses

Authors: *C. A. TASWELL[1], V. D. COSTA[1], E. A. MURRAY[2], B. B. AVERBECK[2]; [1]Section on Learning and Decision Making, NIH/NIMH, Bethesda, MD; [2]NIMH/NIH, Bethesda, MD

Abstract: Adaptive behavior requires learning to gain rewards and avoid losses. Most work on learning has focused on learning to gain rewards. Therefore, we have developed a paradigm that allows us to examine whether the same or different neural systems underly learning from gains vs. losses. We have previously shown that Ventral Striatum plays a specific role in learning to select between rewarded outcomes (Taswell, C, et al, 2019). These results suggest that there is different neural circuitry that underlies learning from losses. Two areas of the brain that are good candidates and often thought to underlie different types of aversive learning are the amygdala and the periaqueductal gray. To assess whether one, both, or neither area is involved in learning from loss, we tested monkeys with lesions to the amygdala (n = 4) and monkeys with lesions to the periaqueductal gray (n = 4) on the same experiments used in the study above. We conditioned tokens as reinforcers in a task where animals could both gain and lose tokens. We ran four experiments; three used deterministic reinforcement and one used stochastic reinforcement. In all experiments, novel images were introduced at the beginning of blocks of about 100 trials, and the animals had to learn the gains or losses associated with each experiment. In the first deterministic experiment we introduced four images in each block which had associated outcomes of +2, +1,-1,-2 tokens. In the second experiment we added a cue with a value of 0 to the set (+2, +1, 0, -1, -2). In the third experiment mimicked the first, except 75% of the time, the outcome was the value of the cue, and 25% of the time, the outcome was 0. In the final experiment, -4 replaced -2 as the large token loss. The animals had to learn over trials, in each block, the outcomes associated with each cue, and choose the best cue in each trial. Our current results have found no deficits in learning for either group. However, the data for the monkeys with amygdala lesions shows some differences in actions typically associated with motivation. Specifically, monkeys with amygdala lesions take significantly more time to make choices (reaction time). In addition monkeys with amygdala lesions abort significantly more trials, which is a failure to make a choice after the options are presented.

Title: A brainstem circuit controlling the expression of natural and addiction memory

Authors: *R. LIN, J. LIANG, R. WANG, T. YAN, Z. GUO, Y. LIU, M. LUO;
Natl. Inst. of Biol. Sci., Beijing, China

Abstract: Persistent memories of addiction drive drug cravings and relapse. By co-opting the dopamine (DA) population in the ventral tegmental area (VTA), addictive drugs—for example, opioids—induce excessive learning signals and the subsequent formation of drug-associated memories. However, little is known about whether the DA system is involved in the expression of memory under normal circumstances or in addiction. Here, we identify a unique midbrain DA population in the dorsal raphe (DRN) that is segregated from the canonical VTA DA population and functions as a critical component in controlling memory expression. Both rewarding and aversive stimuli activate DRN DA neurons in a learning-dependent manner, and the activity of these neurons is required for the expression of appetitive and fear memory. DRN DA neurons are also activated during the expression of opioid addiction memory, and ablation or inhibition of DRN DA neurons blocks the expression of memories that are associated with opioid seeking and withdrawal. Using the rabies screen, we found a glutamatergic input from an upstream brainstem area to DRN DA neurons that is enhanced by morphine administration. These upstream neurons show morphine-triggered increase in excitability, and silencing these neurons selectively impairs the expression of reward memories associated with opioids or foods while leaving the expression of aversive memories associated with opioid withdrawal or fear intact. These results pinpoint the essential functions of DRN DA neurons in regulating memory expression and highlight new targets for developing future addiction intervention strategies.

Title: Role of the cerebral ganglion in the shift of taste-preference by learning of *aplysia*

Authors: *N. TESHIMA[1], K. UMETA[1], Y. KATSUMATA[1], Y. YOSHIMI[1], T. NAGAHAMA[2];
[1]Aplied Chem., Shibaura Inst. of Technol., Tokyo, Japan; [2]Teikyo Heisei Univ/ Fac Hlth. Med. Sci., Tokyo, Japan

Abstract: Taste is an important sense to determine whether an intaken food should be ingested or rejected for survival. A marine gastropod *Aplysia* indicates clear taste preferences, which can be modified by experience and learning. For example, *Aplysia* prefers *Nori* extract but hates distilled water (DW). However, giving DW immediately after *Nori* extract makes *Aplysia* dislike *Nori* extract. In this work we attempted to reveal the role of cerebral ganglion in the taste-preference modification by the learning. Buccal mass and buccal ganglion and cerebral ganglion were isolated with retaining the connection with nerve bundles. The preparation was fixed under a microscope to observe the movement of the buccal mass responding to the administration of the Nori extract, DW or artificial sea water (ASW) to the radula. Only the administration of DW triggered the vigorous movement of the radula which probably indicates rejection of the tasting fluid. After the test sequential administrations of the *Nori* extract and distilled water to the buccal mass were repeated 20 times. After the sequential administration, the rejective movement of the buccal mass was observed responding to the administration of the *Nori* extract as well as the DW. The same experiments performed except for removing the cerebral ganglia. In this case, the rejective movement occurred responding to the administration of the DW but did not to the Nori extract even after the sequential administrations. Those results indicate that the learning by the sequential administration of the preferred and unpreferred tastes is processed by the cerebral ganglia in the preparation. The analysis of the neural network in the cerebral ganglion would clarify the mechanism of the learning. The imaging of cerebral ganglion sensitized with fluorescent serotonin-imprinted polymer nanoparticles were observed through microscope. Spike fluorescent changes indicating the serotonin secretion responding to each tastes were detected in the experiment. The serotonin-imaging may be potential tool for revealing the neural network for modification of the taste preference through the learning.

Title: Characterization of prefrontal-subcortical circuitry in execution and inhibition of reward seeking behaviors

Authors: *J. P. CABALLERO, D. E. MOORMAN;
Psychological and Brain Sci., Univ. of Massachusetts Amherst, Amherst, MA

Abstract: The rodent prelimbic cortex (PL) plays an important role in the learning and regulation of actions, including those directed to rewards. PL, however, is a heterogeneous region composed of neurons projecting to various areas throughout the brain, each of which play different roles in behavioral control. These different PL networks likely have diverging roles in the context of reward seeking, learning, and action control that have not yet been thoroughly elucidated. The goal of this research is to characterize the role of specific PL ensembles, defined by their projection targets, in the context of the learning, expression, and inhibition of reward seeking. Our focus is on PL neurons projecting to three areas receiving some of the most dense efferent projections: mediodorsal thalamus (MD), ventral striatum (VS), and lateral hypothalamus (LH). In these studies, male Long-Evans rats receive retrograde AAV in each PL target region to express cre recombinase in neurons projecting to that area. In the same surgery, rats receive a cre-dependent hM4Di inhibitory DREADD in the PL, thus producing selective hM4Di expression in PL neurons projecting to one of the three selected targets. Post-surgery, food and fluid-restricted rats are then trained on a fixed ratio 1 (FR1) sucrose seeking task and then tested in FR1 acquisition, FR1 expression, early extinction, late extinction, and cue-induced reinstatement. During FR1, each nose poke results in a tone and delivery of 0.1 ml 20% sucrose in a well. Responding is then extinguished by eliminating the tone and reward following a nose poke. During cue-induced reinstatement, each nose poke results in a tone, but no sucrose is delivered. At each test stage, rats receive inactivation of PL circuits via clozapine-N-oxide (CNO; 3 mg/kg) or vehicle. Preliminary findings (n=3) show that inactivation of PL-to-VS projections during FR1 expression decreased rewarded well entries, but increased overall non-specific well-entries. Additionally, all rats exhibited longer latency to attempt to collect reward during inactivation of acquisition of cue-induced reinstatement (leaving the nose poke to enter

the well to collect reward). Although preliminary in nature, our results thus far indicate an important role of the PL-to-VS projection in regulation of operant reward seeking, in line with previous work. Further analysis and comparison with diverging targets will reveal selective contributions of subsets of PL networks to execution and suppression of reward seeking, both during and after learning.

Title: Inverse gating of discrimination learning by dopamine D2 receptors in the nucleus accumbens

Authors: *T. SAWADA, Y. IINO, K. YAMAGUCHI, S. YAGISHITA, H. KASAI;
The Univ. of Tokyo, Tokyo, Japan

Abstract: Dopamine 2 receptors (D2R) are densely expressed in the striatum, and are related to the psychotic symptoms of schizophrenia. With its high-affinity binding to dopamine, D2R has implicated in the detection of transient reduction in dopamine concentration (DA dip). However, the nature of D2R-dependent behaviours and cellular mechanisms which can account for the antipsychotic effects of D2R antagonists has been elusive. Here, we found in mice that tone-induced reward-prediction learning in the nucleus accumbens (NAc) was markedly generalized in a D1R-dependent manner, and discrimination learning refined the prediction by DA dip and D2R dependent mechanism. Interestingly, neither DA dip nor D2R was involved in the extinction context. In NAc slice, narrow DA dip (0.4 s), was detected by D2R to disinhibit the adenosine 2A receptor (A2AR) mediated enlargement of dendritic spines of D2R expressing spiny projection neurons (D2-SPNs). CaMKII and A2AR in NAc, which mediated plasticity of D2-SPN, were also required for the discrimination learning, indicating that the DA dip was detected by D2-SPN. Moreover, we found that the discrimination learning was impaired by a repeated methamphetamine treatment, a model of psychosis, and was rescued by D2R

antagonist. Thus, our data demonstrate that D1R and D2R competitively refine the reward prediction, and suggest a novel hypothesis that the inability to learn from the absence of predicted results causes salience misattribution, as seen in subjects with schizophrenia, which can be mitigated by antipsychotics through the D2R-mediated plasticity mechanisms.

Title: Chronic stress causes a lasting increase in relapse-like behavior following punishment-induced abstinence from palatable food seeking, an effect mediated by dopamine D_1-like receptors

Authors: *K. T. BALL, S. HOLBROOK, R. PHELPS, J. ROE;
Bloomsburg Univ, Pennsylvania, Bloomsburg, PA

Abstract: Long-term success of dietary treatments is low because most individuals relapse to unhealthy eating habits within months of starting treatment. Although chronic stress has long been associated with relapse vulnerability in the clinical literature, relatively few pre-clinical studies have used models of relapse that incorporate a chronic stressor. In previous studies, we added a chronic stress component to two widely used animal models of craving and relapse: the extinction/reinstatement model and the related forced abstinence model. We showed that animals with a history of chronic stress displayed greater relapse to food seeking compared to unstressed rats for up to 1 week following the termination of stress. We also demonstrated that systemic dopamine D_1-like receptor (D_1R) antagonism during chronic stress attenuated the effects of the stress on subsequent relapse-like behavior. Building on these findings, we aimed to determine the effects of chronic stress on relapse to palatable food seeking following punishment-induced (self-imposed) abstinence. Rats were trained to press a lever for highly palatable food reinforcers in daily 2-hr sessions. Delivery of food was accompanied by a 5-s tone + light conditioned stimulus. During a subsequent punishment phase, 50% of the reinforced lever presses resulted in the concurrent delivery of a 0.5-s footshock through the grid floor. Footshock began at 0.12 mA and increased by 0.06 mA every day for a total of 7-8 punishment sessions. To model chronic stress, rats were placed in restrainers (120 min/day) or returned to their home cage (unstressed) after each punishment session. To assess dopaminergic involvement, each group received

injections of either the selective D_1R antagonist SCH-39166 (20.0 μg/kg; i.p.) or vehicle prior to each daily treatment. Cue-induced relapse tests were conducted on the 1st and 8th days after the last session of the punishment phase. Pellet priming-induced relapse tests were conducted on the 8th day following punishment. No significant differences in responding among treatment groups was observed during cue-induced relapse tests on either test day. However, rats with a history of chronic stress displayed increased pellet priming-induced relapse, and SCH-39166 combined with chronic stress prevented this effect. These results are the first to demonstrate that chronic stress causes lasting vulnerability to relapse following punishment-induced abstinence. Moreover, our findings with SCH-39166 are in agreement with our previous studies using other models of relapse and highlight the important role of D_1R signaling in the effects of chronic stress on palatable food-seeking.

Title: The role of n-methyl-d-aspartate receptors in the insular cortex during a motivational conflict task: Updating from an appetitive to an aversive memory

Authors: *M.-J. OLVERA-CALTZONTZIN, M. I. MIRANDA;
Neurobiología Conductual y Cognitiva, Inst. de Neurobiología, UNAM, Univ. Nacional Autonoma De Mexico, Queretaro, Mexico

Abstract: Normally taste is learned in a variety of contexts that could alter its inherent hedonic valence. Thus, sweet taste is inherently appetitive or pleasant and carries positive valence during association; whereas, for example, a mild electric shock is inherently aversive and has negative valence. Furthermore, these two stimuli with opposite valences may also compete during memory updating, from an appetitive to an aversive association. Brain cortical participation during valence processing has been recently proposed during re-learning and memory updating. Particularly, the insular cortex (IC) is involved during taste memory updating as well as during context learning related tasks. Therefore, the purpose of this research was to evaluate the

involvement of NMDA receptors (NMDAR) activity in the IC during a motivational conflict task, based on the inhibitory avoidance (IA) learning procedure, where taste memory was updated from an appetitive/neutral context (chamber no shock) to an aversive one (chamber with electric shock). Accordingly, we used a modified IA chamber that had a graduated bottle at the end of the dark compartment (DC), filled with water or sugar. In this condition rats were pre-exposed to the DC and the next day were subjected to IA acquisition, receiving a mild electric foot shock (negative valence) when entering the DC that also had water or sugar (positive valence). Three parameters were measured during pre-exposure, IA acquisition and IA retrieval: 1) Entry latency to DC, 2) Sugar latency consumption and 3) liquid volume consumption. Rats were bilaterally injected with NMDA (6.8 μM) in the IC, five minutes before IA acquisition. The results indicate that sugar at the end of the DC induced a lower entry latency during IA retrieval; e.g., increasing the latent inhibition of the IA, no changes were observed in groups with NMDA injections. Also, consumption latency decreased when sugar was available at the end of the DC, instead of water; nonetheless, NMDAR activation produced a decrease only for water consumption latency. Furthermore, either water or sugar volume consumption remained similar during retrieval, without any NDMDA effect. Overall, these results indicate that sugar but not water pre-exposure in a context to be aversive (DC), induces an increase in IA latent inhibition, e.g., positive valence, regardless of whether NMDAR are activated. Nevertheless, NMDAR only increased the appetitive response for water under an aversive context, suggesting that sugar increases appetitive memory updating during a motivational conflict task and NMDAR activation increases this memory updating for more neutral stimuli such as water.

Title: NMDA receptor-dependent plasticity in the nucleus accumbens underlies acquisition of cued reward-seeking behavior

Authors: M. VEGA VILLAR[1,2], J. C. HORVITZ[1], ***S. M. NICOLA**[2];
[1]Dept Psychology, City Col., New York, NY; [2]Dept Neurosci., Albert Einstein Coll Med., Bronx, NY

Abstract: Animals learn associations between contextual cues and the natural rewards they predict (e.g., food, water, sex). As a result, reward-predictive cues come to trigger approach to locations where rewards are available. The nucleus accumbens (NAc) is implicated in the expression of such cued reward-seeking behaviors. Consistent with this idea, many neurons in the NAc become excited upon presentation of an already-learned reward-predictive cue (e.g., McGinty et al., *Neuron* 2013). Cue-evoked excitations encode the motivational value of the stimulus and are required for expression of the subsequent approach behavior (e.g., Caref & Nicola, *eLife* 2018; Du Hoffmann and Nicola, *J Neurosci* 2014). However, whether and how cue-evoked excitations emerge during learning has not yet been established. In Experiment 1, we recorded the unit firing activity of NAc core neurons as rats learned to approach a reward receptacle upon presentation of a cue. Our results indicate that cue-evoked excitations begin to increase a few trials before cued approach behavior is detected and they continue to escalate as cued reward-seeking responses become more vigorous.
Because infusion of NMDA receptor antagonists into the NAc during training impairs acquisition of similar cued approach behaviors (e.g., Di Ciano et al., *J Neurosci.* 2001), we hypothesized that the emergence of cue-evoked excitations during cued approach learning is due to NMDA receptor-dependent plasticity within the NAc. In Experiment 2, we performed colocalized simultaneous unit recordings and NMDA antagonist microinfusions in the NAc. We found that the potentiation of learning-related cue-evoked signals in the NAc depends on NMDA receptor-dependent plasticity within this structure, and that this effect is independent of NMDA receptor contributions to behavioral performance. Our results link NAc plasticity, changes in striatal activity and the emergence of conditioned behavior, revealing a neural mechanism via which the NAc participates in associative learning.

Title: Activation of oxytocin receptor expressing neurons in the ventral tegmental area that project to nucleus accumbens can be rewarding or aversive

Authors: *J. PERIS, K. TOTTEN, D. MONTGOMERY, K. A. SCOTT, E. G. KRAUSE; Pharmacodynamics, Univ. of Florida, Gainesville, FL

Abstract: Oxytocin receptors (OXTR) are expressed by nondopaminergic ventral tegmental area (VTA) neurons that project to multiple forebrain targets, including the nucleus accumbens shell (shNAc). We hypothesize that OXTR-expressing VTA glutamate neurons send projections to shNAc that control reward. Male mice (n=4) expressing Cre recombinase under control of the *Oxtr* promoter were unilaterally injected in the NAc with a Cre-inducible retrograde adeno-associated virus (AAV) expressing yellow fluorescent protein (YFP). YFP-labeled soma in the VTA expressed vGluT mRNA, indicating that OXTR-expressing glutamate neurons send projections to the NAc. Next, we bilaterally injected VTA with a Cre-inducible AAV expressing YFP alone (Sham; n=3) or with channel rhodopsin 2 (ChR2; n=4) and bilaterally implanted fiber optics into the shNAc to optogenetically stimulate axons originating from OXTR-expressing neurons in the VTA. Three weeks later, mice were trained to operantly respond for optic fiber stimulation (1 sec of 40 Hz). After 9 sessions, the number of active responses was greater in mice expressing ChR2 relative to Sham (88.5±44.2 vs 10.7±4.8) with lower responding in the inactive port (20.0±7.6 vs 9.3±4.8). The ratio of active responses to total responses was significantly greater in ChR2 vs Sham mice on the last 2 days of testing (0.75±0.03 vs 0.52±0.17; $F(1,5) = 8.29$ $p < 0.05$). However, when a real time place preference paradigm was implemented, the pattern of stimulation greatly affected the amount of time spent on the side paired with optical stimulation. Optical stimulation of 1 sec 40 Hz on/1 sec off significantly decreased time spent on the paired side compared to pretest in ChR2 mice (16.5%±1.66 vs 34.0%±4.96) but not in Sham mice (25.8%±2.98 vs 27.5±3.17; Virus X Test Day $F(1,4) = 10.41$, $p < 0.05$). Conversely, optical stimulation of 1 sec 40 Hz on/9 sec off significantly increased time spent on the paired side compared to the pretest in ChR2 mice (38.0%±3.75 vs 30.1%±1.34) but not in Sham mice (31.6%±2.39 vs 32.0±6.60; Virus X Test Day $F(1,5) = 7.33$, $p < 0.05$). These results suggest OXTR are expressed on glutamatergic VTA neurons whose projection to the shNAc may confer reward or aversion depending on the pattern of neural activity delivered.

Title: Chemogenetic activation of orbitofrontal striatal circuitry increases flexibility in rats that have developed habitual behavior on a modified t maze task

Authors: *J. J. STOTT, K. S. SMITH;
Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: The orbitofrontal cortex (OFC) and medial striatum (MS) are involved in outcome valuation, and these areas are necessary for certain kinds of goal-directed behavior, including sensitivity to reinforcer devaluation. We asked whether chemogenetic activation of this pathway could produce an enhancement of flexible behavior in animals that had already developed a maze-running habit, and if so, what aspects of maze running were affected.
Rats were run on a novel plus maze-type task which consisted of an elevated track with four arms, each with a reward site. To make a correct response and obtain reward, rats had to follow a simple turn-right rule. Reward sites had a unique combination of reward magnitudes (Large or Small), and pellet flavor (Banana or Chocolate).
To characterize the development of habits on this task, three groups of rats were run without surgery, varying in the amount of training they received. Rats received Low, Moderate, or High amounts of training before undergoing three pairings of a pellet reward with LiCl (0.3M) in an empty cage. After devaluation of one of the rewards, rats were returned to the task for 1 session in extinction (Probe), and 5 additional sessions with pellet delivery (ReAcquisition).
An additional group of animals underwent surgery prior to the start of the experiment. These rats were injected with a Cre-containing retrograde virus (CAV-Cre or AAVrg-Cre) into the DMS and a Cre-dependent Gq-coupled DREADD or control virus into the ventrolateral OFC. These rats were given injections of CNO (0.1mg/kg) 30 min prior to the Probe and ReAcquisition sessions.
Rats quickly learned the task, increasing their accuracy over days to >90%. Rats rejected all pellets after 3 LiCl pairings. In the Probe Session, rats were still likely to visit the all the maze arms, indicating habitual behavior. However, the Moderate and Gq rat groups exhibited more pauses before entering the devalued feeder arms, suggesting that there was some recognition of the new outcome value and that OFC-MS activation restored that in highly trained rats.
In Reacquisition, rats in the High training groups continued to turn right on each lap. In contrast, rats in the Low and Moderate training groups slowly developed new a strategy, learning to avoid the devalued arms. The number of non-devalued pellets earned per lap increased over days. This was also true for Gq animals, though to a lesser extent. Therefore, stimulation of DMS-projecting OFC cells was able to partially rescue flexible behavior during trial and error learning after a change in task contingency. Neural recordings in the OFC and DMS are being performed to characterize the neural underpinnings of this change in strategy.

Title: Fos expressing neuronal ensembles in ventromedial prefrontal cortex mediate acquisition of food seeking

Authors: *A. A. GENOVESE[1], R. QUINTANA-FELICIANO[2], G. LOYOLA[3], B. L. WARREN[3];
[2]Dept. of Pharmacodynamics, [3]Pharmacodynamics, [1]Univ. of Florida, Gainesville, FL

Abstract: Aims: We previously found that functionally distinct neuronal ensembles in the ventral medial prefrontal cortex (vmPFC) mediate self-administration and extinction of food seeking in well-trained rats. In the present study, we examined whether neuronal ensembles also mediate acquisition of food seeking.
Methods: We allowed transgenic Fos-LacZ rats to lever press for palatable food pellets. Rats self-segregated into "learners" that pressed more than 50 times in a single session and "non-learners" that failed to press more than 50 times in a single session. We then tested rats' recall of food-seeking in a 15 min probe test intended to reactivate acquisition ensembles and induce Fos and B-Gal expression. We then used vehicle or Daun02 inactivation to selectively ablate Fos-expressing neuronal ensembles within the vmPFC that were associated with acquisition of food seeking. Two days later, we tested the rats' ability to recall the food-seeking memory.
Results: During the induction session, learners pressed the active lever significantly more than non-learners. During the test session, Daun02 inactivation significantly reduced active lever presses in learner rats, but had no effect in non-learners.
Conclusions: Taken together, these data suggest that neuronal ensembles within the vmPFC mediate acquisition of food-seeking.

Title: Fos-expressing neuronal ensembles projecting from ventromedial prefrontal cortex to nucleus accumbens are activated during acquisition of food seeking

Authors: *G. LOYOLA[1], R. QUINTANA-FELICIANO[1], A. GENOVESE[1], L. F. KANE[2], B. T. HOPE[2], B. L. WARREN[1];
[1]Dept. of Pharmacodynamics, Univ. of Florida, Gainesville, FL; [2]Behavioral Neurosci., Natl. Inst. On Drug Abuse, NIH, Baltimore, MD

Abstract: Aims: We previously found that functionally distinct neuronal ensembles in the ventral medial prefrontal cortex (vmPFC) mediate self-administration and extinction of food seeking in well-trained rats. In the present study, we examined whether neuronal ensembles were activated by acquisition of food seeking. We then tested whether neuronal ensembles associated with acquisition of food self-administration project to different subregions of the nucleus accumbens (NAc).
Methods: We allowed rats to lever press for palatable food pellets. Rats self-segregated into "learners" that pressed more than 50 times in a single session and "non-learners" that failed to press more than 50 times in a single session. We then tested rats' recall of food-seeking in a 15 min probe test intended to reactivate acquisition ensembles and induce Fos. We then characterized these Fos expressing neurons using Fos immunohistochemistry and *in situ* hybridization for *Fos, Vgat,* and *Vglut1*. Lastly, we used the fluorescently labeled retrograde tracer CTb to determine whether acquisition of food-seeking activated vmPFC neuronal ensembles projecting to NAc.
Results: Learners pressed the active lever significantly more in the probe test than non-learners. vmPFC Fos expression was increased in the learners when compared to non-learners. However, the *in* situ analysis revealed that the phenotype of activated neurons did not differ between learners and non-learners. The tracing experiment indicated that activated neurons associated with acquisition of food seeking project to the NAc.
Conclusions: Taken together, these data suggest that neuronal ensembles within the vmPFC are recruited during acquisition of food-seeking. Furthermore, these ensembles are made up of heterogenous populations of neurons, and these neurons project to the NAc.

Title: Transcriptional profiles in reinforcement learning across brain regions reflect associative structure and reward history

Authors: S. BINDAS, C. S. CHEN, D. WEAVER, ***N. M. GRISSOM**;
Univ. of Minnesota, Minneapolis, MN

Abstract: Forming associations between our behaviors and specific positive outcomes they elicit, such as food or social interaction, is critical to survival. However, the intracellular and transcriptional processes that regulate operant learning are very poorly understood, compared to the mechanisms which govern pavlovian associations. To address this, we have examined the induction of transcription in multiple brain regions known to be critical to reinforcement learning in the brains of male and female mice as they underwent operant training. We tested animals who had experienced one of four conditions: a) well trained on a fixed-ratio (FR) operant task, b) had newly acquired the response contingency in the FR task that day, c) received yoked reward with no operant requirement, and d) home cage controls. Using high-throughput qrtPCR arrays, we assessed transcription patterns in the mouse amygdala, nucleus accumbens, and dorsomedial striatum. For this screen we tested forty-six transcripts, including immediate early genes known to be induced in pavlovian learning, transcripts important to dopamine function, and genes which have been linked with autism spectrum disorders, as animal models of autism and humans on the autism spectrum have challenges making reward guided choices. Thus far, we have observed broad transcription patterns that correlated with task learning and reward exposure across experimental groups. In male animals, broad transcriptional signals in the amygdala were lowest in animals who had learned the operant association, compared to yoked animals, suggesting the act of acquiring an operant response may require the suppression of mechanisms that support pavlovian associations. In contrast, transcription in the nucleus accumbens had its strongest relationship to the number of reinforcers an animal received, regardless of the associative contingency (operant or yoked). These results suggest distinct molecular mechanisms operating in the accumbens and amygdala when learning an operant response.

Title: Murine genetic variance in muscarinic cholinergic receptor antagonism of fat intake and acquisition and expression of fat-conditioned flavor preferences in three inbred mouse strains

Authors: B. ISKHAKOV, P. DOHNALOVA, J. ISKHAKOVA, T. MUSTAC, A. YUABOV, J. MACANIAN, E. ISRAEL, N. LOCURTO, N. FRANZ, G. FAZILOV, M. SHENOUDA, *R. J. BODNAR;
Psychology, Queens Col., Flushing, NY

Abstract: Muscarinic cholinergic receptor antagonism differentially alters sweet intake as well as the expression (maintenance) and acquisition (learning) of sucrose-conditioned flavor preferences (CFP) in inbred mice. Sucrose and saccharin intakes were significantly and more potently reduced following scopolamine (SCOP) in C57BL/6 and BALB/c mice relative to SWR mice. SCOP significantly reduced the expression of sucrose-CFP in BALB/c, but not C57BL/6 or SWR mice. SCOP eliminated the acquisition of sucrose-CFP in BALB/c mice, reduced its magnitude in SWR mice, but failed to affect this response in C57BL/6 mice. Fat (Intralipid) intake and fat-CFP are robustly elicited in BALB/c, C57BL/6 and SWR mice. Given that the dopamine D1, opiate and NMDA receptor antagonist pharmacological profile of sweet and fat intake and CFP differs across inbred mouse strains, the present study examined whether SCOP differentially altered fat (Intralipid) intake as well as the expression and acquisition of fat-CFP in BALB/c, C57BL/6 and SWR mice. The first experiment evaluated the systemic dose-dependent effects of SCOP (0.1-10 mg/kg) on Intralipid (5%) intake over a 2 h time course in the three strains. Intralipid intake was significantly reduced in all three strains across all doses and the entire time course. In fat-CFP expression experiments, food-restricted mice alternately consumed a flavored (CS+, e.g., cherry Kool Aid, 5 sessions) Intralipid (5%) solution and a differently-flavored (CS-, e.g., grape Kool Aid, 5 sessions) Intralipid (0.5%) solution. Two-bottle CS choice tests with the two flavors mixed in 0.5% Intralipid solutions occurred following vehicle or SCOP at doses of 1 or 5 mg/kg. SCOP minimally altered the magnitude of the expression of fat-CFP in BALB/c and C57BL/6, but not SWR mice. In fat-CFP acquisition experiments, separate groups of BALB/c, C57BL/6 and SWR mice were treated prior to the ten acquisition training sessions with vehicle or 2.5 or 5 mg/kg SCOP doses that was followed by six two-bottle CS choice tests without injections. SCOP eliminated the acquisition of fat-CFP in BALB/c and C57BL/6 mice, and dose-dependently reduced its magnitude in SWR mice. Thus,

muscarinic cholinergic receptor signaling is essential for the learning of fat-CFP in BALB/c and C57BL/6 mice and, to a lesser degree, in SWR mice while maximally inhibiting fat intake in the three strains. Therefore, murine genetic variance differentially modulates muscarinic cholinergic receptor control of sweet and fat intake per se as well as their learned preferences.

Title: Early adolescent adversity inflates periaqueductal gray/dorsal raphe cue responding but diminishes threat signaling in female adult rats

Authors: *M. MOADDAB, K. M. WRIGHT, M. A. MCDANNALD;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Childhood adversity increases adult risk for stress and anxiety disorders. A contemporary view of the link between early adversity and adult psychiatric disorders is of latent vulnerability. Early adversity reshapes processing in neural circuits underlying fundamental behavioral processes, leaving these circuits impaired and vulnerable through adulthood. We tested the hypothesis that early adolescent adversity (EAA) alters adult threat processing in the ventrolateral periaqueductal gray (vlPAG) and dorsal raphe (DR). Female Long Evans rats received a battery of discrete stressors during early adolescence. In adulthood, control (n = 8) and EAA (n = 12) rats were implanted with drivable microelectrode bundles just above the vlPAG and driven following each session, eventually reaching DR. Single-unit activity was recorded while rats underwent fear discrimination, in which three auditory cues predicted unique foot shock probabilities: danger (p = 1.00), uncertainty (p = 0.375) and safety (p = 0.00). In controls, one population of vlPAG/DR neurons (32/151, ~22%) was excited during cue presentation and a slightly larger population (48/151, ~32%) was inhibited. Cue-excited neurons showed graded cue firing: high to danger, intermediate to uncertainty and low to fear; with regression revealing these neurons signaled threat probability. Cue-inhibited neurons maximally decreased firing to danger and signaled a mix of threat probability and fear output. A larger proportion of units were cue-responsive in EAA rats: cue-excited (49/203, ~24%) and cue-inhibited (84/203, ~41%). Cue-excited neurons from EAA rats showed inflated neural activity to

danger, uncertainty and safety at cue onset and diminished differential cue firing as cues progressed. Yet, these same cue-excited neurons showed reduced threat probability signaling. Cue-inhibited neurons from EAA rats showed exaggerated inhibition to danger in early cue presentation. These same neurons initially signaled a mix of threat probability but switched to exclusively signaling fear output midway through cue presentation. Early adolescent adversity inflates vlPAG/DR activity to threat related cues, reduces flexible signaling of threat probability and favors more rigid signaling of fear output.

Title: Zona incerta gabaergic output controls a signaled locomotor action in the midbrain tegmentum

Authors: S. HORMIGO, J. ZHOU, *M. A. CASTRO-ALAMANCOS;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The zona incerta is a subthalamic nucleus that has been proposed to link sensory stimuli with motor responses to guide behavior, but its functional role is not well established. Using mice of either sex, we studied the effect of manipulating zona incerta gabaergic cells on the expression of a signaled locomotor action, known as signaled active avoidance. We found that modulation of gabaergic zona incerta cells, but not of cells in the adjacent thalamic reticular nucleus, fully controls the expression of signaled active avoidance responses. Inhibition of zona incerta gabaergic cells drives active avoidance responses, while excitation of these cells blocks signaled active avoidance by inhibiting cells in the midbrain pedunculopontine tegmentum (PPT), not by inhibiting cells in the superior colliculus or posterior thalamus. The effects of manipulating zona incerta gabaergic cells on signaled active avoidance are similar to the effects of manipulating substantia nigra pars reticulata gabaergic cells -a main output of the basal ganglia. Thus, gabaergic outputs from the zona incerta and the basal ganglia provide independent channels to regulate a signaled locomotor action in the PPT, which may operate depending on behavioral contingencies.

Title: Dorsolateral periaqueductal gray activates antipredatory neural responses in the amygdala in foraging rats

Authors: *E. KIM[1], M.-S. KONG[1], S. PARK[4,5,6,7], J. ROMANI[1], S. KIM[2], J. CHO[4,5], J. J. KIM[1,3];
[1]Psychology, Univ. of Washington, Seattle, WA; [2]Computer Sci. and Software Engin., Univ. of Washington, Bothell, WA; [3]Program in Neurosci., Univ. of Washington, Seattle, WA; [4]Catholic Kwandong Univ., Gangneung, Korea, Republic of; [5]Catholic Kwandong Univ. Intl. St. Mary's Hosp., Incheon, Korea, Republic of; [6]Korea Univ. of Sci. and Technol., Daejeon, Korea, Republic of; [7]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: The dorsolateral division of the periaqueductal gray (dlPAG) and the amygdala are known to direct defensive responses (Bandler & Shipley, 1994; Fanselow, 1994). We have previously reported that electrical stimulation of the dlPAG caused rats foraging for food in an ecologically-relevant environment to escape to the safe nest (Kim et al., 2013). This fleeing response was blocked by amygdalar lesions and inactivation, suggesting that the dlPAG-amygdala pathway is crucial to the brain's innate defensive system. Recently, we also found that dlPAG neurons responded to a looming robotic predator and that optogenetic excitation of the dlPAG neurons elicited neural activity in the amygdala. However, the specific function of the dlPAG-amygdala neurotransmission when animals encounter predatory risks is unknown. To address this issue, we employed single unit recording and optogenetic techniques in our 'approach food-avoid predator' paradigm (Choi & Kim, 2010; Kim et al., 2018). Specifically, male Long-Evans rats were implanted with tetrode arrays into the BLA (basolateral amygdala) or CeA (central amygdala) and injected with AAV-CaMKIIα-hChR2-EYFP into the dlPAG. After recovery, rats maintained on ~85% normal body weight underwent successive stages of habituation, baseline foraging, and optogenetic dlPAG stimulation (473 nm; 10 ms pulses at 20 Hz; 2 s) and robot (Lego Mindstorms) testing, during which BLA and CeA units were collected. We found that optical dlPAG stimulation increased neuronal activity in both BLA and CeA and caused naive rats approaching a food pellet to instantly flee to the nest. The dlPAG photostimulation-responsive BLA neurons also exhibited rapid phasic spiking to the looming robot whereas the photostimulation-responsive CeA neurons showed delayed tonic spiking.

Furthermore, higher proportions of photostimulation-responsive neurons in BLA and CeA also reacted to the robot compared to photostimulaton-nonresponsive neurons. These results suggest that functional interaction between dlPAG and amygdalar neurons subserve antipredatory defensive mechanisms.

Title: Role of the cerebellum-periaqueductal grey pathway in fear conditioning

Authors: ***E. PACI**[1], C. LAWRENSON[1], R. MORAN[2], B. LUMB[1], R. APPS[1];
[1]Univ. of Bristol, Bristol, United Kingdom; [2]King's Col., London, United Kingdom

Abstract: Auditory cue fear conditioning is a well-established behavioural paradigm to study the neural networks involved in acquisition, expression and extinction of fear. Indeed, the role of areas such as prefrontal cortex, amygdala and periaqueductal grey (PAG) has now been characterised in the context of conditioned fear. More recently the cerebellum has also been included in this 'fear network', as studies have shown that it is implicated in the acquisition of fear memories as well as in the expression of fear-conditioned freezing behaviour.Anatomical and physiological studies from our laboratory and other groups have shown that the PAG, specifically the ventrolateral (vl) sector, projects to vermal lobule VIII of the cerebellar cortex, and that the medial cerebellar nuclei in turn projects to the vlPAG. However, the role of this reciprocal pathway in fear conditioning is unclear.To better understand the functional role of these connections we have recorded local field potential (LFP) activity simultaneously from the cerebellum and PAG while rats were exposed to an auditory cue conditioned fear paradigm.Preliminary results show in the cerebellum that, relative to baseline, there is an increase in LFP power in delta and theta frequencies during acquisition, and a decreased power in these frequencies during extinction. In the PAG there is also an increase in delta power during acquisition that is reversed during extinction, but no change in theta power relative to baseline. The present results suggest both similarities and differences in the pattern of LFP activity in the cerebellum and PAG during fear conditioning.

Title: Anatomical and functional characterization of RMTg-projecting PFC neurons

Authors: E. M. STARR[1], W. N. WAYMAN[2], J. J. WOODWARD[2], L. CHANDLER[3], ***E. J. GLOVER**[1];
[1]Dept. of Psychiatry, Ctr. for Alcohol Res. in Epigenetics, Univ. of Illinois at Chicago, Chicago, IL; [2]Neurosci., Med. Univ. of South Carolina, Charleston, SC; [3]Dept Neurosci., Med. Univ. S Carolina, Charleston, SC

Abstract: Exposure to aversive stimuli is associated with enhanced activity within the rostromedial tegmental nucleus (RMTg) and activation of the RMTg facilitates aversive responding. The medial prefrontal cortex (mPFC) provides input to the RMTg and activity within this region has also been implicated in many of the same endpoints. However, little is known about the anatomy and function of this projection. To better characterize the density of the mPFC input to the RMTg, Long-Evans rats were injected with a retrograde tracer into the RMTg. Two weeks after injection, cell body labeling was apparent throughout the entire medial and orbital walls of the PFC and spanned the entire rostrocaudal extent of the region. Labeling was also observed in the anterior insular cortex. RMTg-projecting cell bodies were restricted primarily to cortical layer V, though a small number of cells were also consistently observed in the deepest portion of layer VI. Quantification of tracer labeled neurons relative to NeuN labeling found that approximately 14.21% ± 0.38 of layer V prelimbic mPFC neurons projected to the RMTg. Quantification of other subregions is ongoing. RNAscope combined with retrograde tracing revealed a subpopulation of RMTg-projecting mPFC neurons expressing either D1, D2, or both D1 and D2 dopamine receptors. Stimulation of RMTg-projecting mPFC inputs using in vivo optogenetics produced significant real-time place avoidance, the magnitude of which was similar to that produced by stimulation of lateral habenula inputs to the RMTg ($p \leq 0.01$) indicating that activation of this pathway can induce aversive responding. In addition, rats

presented with a shock or a tone predictive of shock exhibited a significant increase in cFos expression in RMTg-projecting mPFC neurons compared to rats exposed to neutral stimuli ($p \leq 0.05$). Using whole-cell patch-clamp slice electrophysiology, we found that exposure to a single episode of 10 consecutive footshocks resulted in a significant decrease in the frequency of evoked firing in RMTg-projecting prelimbic neurons compared to unshocked controls ($p \leq 0.0001$). Ongoing work is exploring the effect of repeated footshock on structural plasticity in mPFC-RMTg neurons. Together, these results demonstrate involvement of mPFC input to the RMTg in the behavioral response to aversive stimuli, and further reveal significant plasticity as a result of exposure to aversive stimuli. Alterations within this neural circuit may be critically involved in neuropsychiatric illnesses associated with disruption of the balance between signaling of rewarding and aversive outcomes including addiction and mood disorders.

Title: Striatal beta oscillation and neuronal activity in the primate caudate nucleus differentially represent valence and arousal under approach-avoidance conflict

Authors: *K.-I. AMEMORI[1], S. AMEMORI[2], D. J. GIBSON[2], A. M. GRAYBIEL[2];
[1]Kyoto Univ., Inuyama, Japan; [2]McGovern Inst. for Brain Res., MIT, Cambridge, MA

Abstract: An approach-avoidance (Ap-Av) conflict arises when an individual has to decide between acceptance and rejection of a compound offer that has positive and negative attributes. During the conflicting judgment of likes and dislikes, motivational responses simultaneously emerge and influence reaction times and the frequency of behavioral errors. Based on the differential influences of reward and aversiveness, we dissociated the neural processes of valence and arousal responding to the conflict offers. The primate caudate nucleus (CN) has been

implicated in affective judgment, but it is still unclear how the CN neural responses represent the decision-related variables. To address this issue, we recorded spikes and local field potentials (LFPs) from the CN while the subject macaques perform the Ap-Av conflict task. In this task, monkeys reported their decisions by moving a joystick within 3 seconds to the Ap or Av target. We analyzed 450 unit and 667 LFP activities recorded during the performance of the Ap-Av conflict task, and 120 units and 230 LFPs recorded during the approach-approach (Ap-Ap) conflict task. With the trial-by-trial spike and beta oscillatory LFP activities, we performed all-possible subset regression analyses using five selected behavioral variables, consisting of the offered reward size (Rew), offered airpuff size (Ave), value judgment (ChV: chosen value), reaction time (RT) and behavioral performance (FOE: frequency of omission error). By comparing the unit and beta responses, we found differences in the groups representing value judgment and arousal responses. Whereas CN units represented both positive and negative values (positive: n = 26, negative: n = 14), the beta responses almost exclusively represented positive value (positive: n = 93, negative: n = 1), exhibiting a significant difference in the proportion (Fisher's exact test, $P < 0.001$). CN units also represented both positive and negative FOE (positive: n = 17, negative: n = 9), but the beta responses representing FOE were almost exclusively positive (positive: n = 22, negative: n = 1), leading to a significant difference in the proportion (Fisher's exact test, $P < 0.05$). We further confirmed that those representations were preserved in the Ap-Ap task in which the subjects made decisions only by reward sizes. These dissociable features of unit and beta responses suggest distinctive roles of CN beta oscillations in facilitating positive value judgment and suppressing arousal motivation, whereas specific CN neurons respond to a broader range of features in decision-making under conflict.

Title: Medial prefrontal cortex projection to lateral habenula is functional and modulated by dopamine

Authors: *H. LI[1], J. TSAI[1], A. BUXBAUM[1], Y. AYOUB[1], R. MALINOW[2];
[1]Neurosciences, UCSD, San Diego, CA; [2]Neurosciences and Biol., UCSD, La Jolla, CA

Abstract: Lateral habenula (LHb) neurons are activated by aversive stimuli that may normally participate in negative reinforcement learning. As LHb hyperactivity may contribute to depression, identifying and characterizing excitatory inputs to the LHb is important. The medial prefrontal cortex (mPFC) participates in various higher cognitive functions that could modulate aversive coding. While previous work showed that mPFC neurons send projections to LHb, their function has not been well studied. Here we report that mPFC neurons make long range excitatory synaptic projections to LHb modulated by dopamine (DA). Anterograde labeling by injecting AAV-synaptophysin-citrine in the mPFC show synapses in LHb. To test for functional connections, we injected AAV-ChR2-tdTomato in mPFC and AAV-GCaMP6f in LHb. Three weeks later, we prepared LHb slices and imaged with two-photon microscopy. Blue light pulses evoked responses in LHb cell bodies and dendrites, largely blocked by NBQX. Such responses were also reduced by dopamine. By injecting retro-AAV-ochief-tdTomato in LHb, using whole-cell recordings and two-photon microscopy imaging in mPFC slices, we find that LHb projecting neurons reside mostly in layer 5 of mPFC and make strong excitatory and inhibitory local connections. Overall, we have identified a population of mPFC neurons that make local circuit connections within mPFC and functional LHb connections negatively modulated by dopamine. Such mPFC inputs may control an LHb-VTA mutual inibition circuit.

Title: Connections of the laterodorsal tegmental nucleus with the medial prefrontal cortex and habenular-interpeduncular-raphe system

Authors: R. SOUZA, D. BUENO, L. B. LIMA, I. C. FURIGO, J. DONATO, Jr, *M. METZGER;
Dept. of Physiol. & Biophysics, Inst. of Biomed. Sciences, Univ. of São Paulo, São Paulo, Brazil

Abstract: The laterodorsal tegmental nucleus (LDTg) is an underexplored major cholinergic cell group in the periventricular mesopontine tegmentum, traditionally thought to be involved in

mechanisms of arousal, induction of REM sleep, and the control of the firing pattern of midbrain dopamine cells. Nowadays, there is increasing evidence that LDTg is also engaged in mechanisms of anxiety/fear and promotion of emotional arousal under adverse conditions. Interestingly, LDTg appears to be connected with other regulators of aversive motivational states, including the medial prefrontal cortex (mPFC), lateral habenula (LHb), medial habenula (MHb), interpeduncular nucleus (IP), and median raphe nucleus (MnR). However, the circuitry between these structures has hitherto not been systematically investigated. Here, we placed iontophoretic injections of retrograde or anterograde tracers into the LDTg, LHb, IP, MnR and mPFC of male Wistar rats. We also examined the transmitter phenotype of LDTg afferents to IP by combining retrograde tracing with immunofluorescence and in situ hybridization techniques. We found that LDTg receives abundant inputs from all major subregions of the mPFC. Robust direct LHb inputs to LDTg mainly emerged from the medial division of the LHb (LHbM), which also receives minor axonal inputs from LDTg. MHb is indirectly linked to the LDTg via the MHb-IP axis. The reciprocal connections between IP and LDTg displayed a pronounced lateralized organization, with LDTg inputs to IP being predominantly GABAergic or cholinergic and mainly directed to the contralateral IP. Moreover, we disclosed reciprocal LDTg connections with structures involved in the modulation of hippocampal theta rhythm including the oral part of the pontine reticular nucleus, MnR, nucleus incertus, and supramammillary nucleus. Our findings indicate that the habenula is linked with the LDTg either by direct bilateral projections from/to LHbM or indirectly via the MHB-IP axis. These findings support a potential role of LDTg in the processing of aversive information. Moreover, they further characterize LDTg as part of an authentic state-setting neuromodulatory projection system, and LHb and PFC as master-controllers of such systems, exposing that both are settled to impact not only dopaminergic and serotonergic, but also cholinergic modulatory systems.

Title: Quantitative determination of the GABAergic cell number in the lateral and basal nuclei of the amygdala using unbiased stereology in mice

Authors: *V. K. VERECZKI[1], É. KRIZSÁN[2], O. I. PAPP[2], K. MÜLLER[2], N. HAJOS[2];
[1]Dept. of Anatomy, Histology and Embryology, Fac. of Med., Semmelweis University,

Budapest, Hungary, Budapest, Hungary; [2]Inst. Exp Med. Hungarian Acad Sci., Budapest, Hungary

Abstract: The lateral and basal nuclei of the amygdala belong to the cerebral cortex, a brain structure in which the majority of neurons are glutamatergic excitatory neurons giving rise to both local collaterals and long-range projections. In addition to these neurons, distinct types of GABAergic inhibitory cells are also present in all cortical networks. Evidence suggests that the network operations in the lateral and basal nuclei during both physiological and pathological processes are under tight control of GABAergic inhibition. Yet, there is no data available how many GABAergic cells are present in these two nuclei and what is the ratio of distinct GABAergic cell types. To quantify the number of GABAergic neurons within the lateral and basal amygdala nuclei, we applied unbiased stereology with the aid of optical fractionator on tissue samples taken from Vesicular GABA Transporter (VGAT)-IRES-Cre mice crossed with a reporter mouse line, Gt(ROSA)26Sor_CAG/LSL_ZsGreen1. The borders of the lateral and basal nuclei was determined by revealing cholinergic afferents. We found that in the lateral nucleus the ratio of VGAT+ neurons were between 16-17% and 14-18 % in male and female mice, respectively. In the basal nucleus, a significantly higher ratio of GABAergic cells has been found: 23-24% in males and 21-23% in females. In addition, using immunocytochemistry on sections prepared from distinct transgenic mouse lines (PV-Cre, SOM-Cre, VIP-Cre, NPY-Cre), where interneurons were visualized upon injection of DIO-EYFP construct packed into AAV, we estimated the ratio of different interneuron types within the GABAergic cell populations. Our data show that there is no major difference in the number of GABAergic neurons between the two hemispheres or the two sexes in mice. Defining the exact number of GABAergic cells as well as the ratio of distinct inhibitory cell types in the lateral and basal amygdala nuclei may pave the way for further studies investigating the changes in inhibitory cell populations that may occur in different mental disorders such as anxiety, PTSD or schizophrenia.

Title: Whole-brain mapping of neuronal activation during formation, consolidation and retrieval of aversive memories

Authors: *A. FRANCESCHINI[1], A. COSTA[2], I. COSTANTINI[1], B. RANI[2], G. MAZZAMUTO[1], A. P. DI GIOVANNA[1], P. BLANDINA[2], M. B. PASSANI[3], F. S. PAVONE[1], L. SILVESTRI[1];
[1]LENS European Lab. for Non-Linear Spectroscopy, Univ. of Florence, Sesto Fiorentino, Italy; [2]Dept. di Neuroscienze, Psicologia, Area del Farmaco e Salute del Bambino, [3]Dept. di Scienze della Salute, Univ. of Florence, Florence, Italy

Abstract: The understanding of neuronal and molecular behavioural mechanisms that concern fear and stress have received wide coverage in the last years and various preclinical studies have addressed the treatment for patients affected by mental disorders. The central histaminergic system is an important modulator of memory related to adverse events and the use of antihistaminic drugs in the treatment of the abovementioned diseases is being currently studied often as a prelude to the investigation of effects on anxiety.
In this context, it is essential to understand the spatio-temporal frames allowing the central nervous system to organize behavioural responses associated with adverse events. For this purpose, we analyze whole-brain neuronal activation patterns involved in aversive memory at single-cell resolution.
Fear learning models have been very useful for studying memory consolidation as a whole. Here, we use a classical paradigm for passive inhibitory avoidance (step-through), where mice learn to avoid an electrified cage compartment, analysing whole-brain neuronal activation patterns in both male and female subjects at selected time points (immediately after foot shock, after 1 day, after 1 week). To this end, we use a transgenic mouse model (Fos-TRAP), where permanent expression of a fluorescent protein (tdTomato) is induced in transiently activated neurons (expressing the immediate early gene c-fos) by injection of tamoxifen. To quantify the presence of c-fos-positive cells in an unbiased and comprehensive way, we use the light-sheet microscopy coupled with chemical tissue clearing. This approach does not require sample cutting and enables three-dimensional extensive mapping of activated neurons across the entire mouse brain. Finally, we selectively label histamine-positive neurons in the previously clarified Fos-TRAP brains with whole-mount immunohistochemistry. In this way we quantify the number of histaminergic neurons recruited during different memory phases and localize them with high-throughput algorithms. The combination of behavioral, transgenic, optical and computational methods presented here allows to examine different activation patterns at the selected time points, representing an important tool to understand the neuronal pathways involved in formation, consolidation and retrieval of emotional memories.

Title: Lsfmpy: Open-source toolkit for brain-wide neural activity mapping in optically cleared mouse brain

Authors: *S. BEDNAREK[1], N. JERMAKOW[1], M. STEFANIUK[1], M. PAWŁOWSKA[1], R. REHMAN[2], K. NOWICKA[1], L. BIJOCH[1], F. ROSELLI[2], D. K. WÓJCIK[1], P. MAJKA[1]; [1]Nencki Inst. of Exptl. Biol., Warsaw, Poland; [2]Dept. of Neurol., Ulm Univ., Ulm, Germany

Abstract: The emergence of effective tissue clearing methods enabled volumetric imaging of intact biological samples on unprecedented scale. For neuroscience, the key advantage is the ability to analyze interdependent activity of large populations of neurons in whole-brain context. However, a strong limiting factor of this approach is the lack of adequate computational tools for systematic handling and analysis of the terabytes of data generated in the process. We propose an open-source solution that combines a data model for efficient storage and retrieval of imaging data with multimodal registration pipeline and deep-learning based methodology for object detection and quantification. The data container builds on the Hierarchical Data Format 5 (HDF5) and transforms a series of 2D images, obtained from light sheet fluorescence microscopy (LSFM), into one three dimensional object with precisely defined spatial attributes (voxel spacing, physical coordinates and anatomical orientation). Internally data are structured as a precomputed pyramid of resolutions, facilitating all further processing by providing spatially-aware access to the image across multiple scales. To overcome challenges of multimodal registration, for which typically used metrics, such as mutual information, do not yield satisfactory results, we utilized anatomical label maps to guide the registration process. To this end, Deep Convolutional Neural Networks (DCNN) were trained on manually curated datasets to segment out main white matter tracts, dentate gyrus and the brain outline. We observed significant improvement of the registration accuracy, especially for smaller structures. We also deployed a 3D UNet DCNN to detect c-Fos positive nuclei in iDISCO cleared mouse brains. The pipeline was applied to over 40 sets of images of whole mouse hemispheres from two independent behavioral experiments, where patterns of c-Fos expression were investigated to elucidate neural activity in alcohol addiction and in appetitive and aversive learning paradigms. In addition, we processed LSFM images of virally injected mice, where we evaluated ZSGreen positive cells in cortex and hypothalamus. The results demonstrate that the developed

computational pipeline is suitable for analyzing voluminous datasets collected with modern imaging techniques.

Title: *In vivo* whole cell recordings from the amygdala

Authors: ***Y. SATO**, Y. IKEGAYA;
The Univ. of Tokyo, Tokyo, Japan

Abstract: The basolateral amygdala (BLA) is a brain deep region that contributes to emotional processing and may be activated together with the hippocampus. For example, the BLA and the dorsal hippocampus are coactivated during emotional memory consolidation. However, the neural basis of such coactivation has not been addressed, mainly because it is difficult to identified projecting neurons using extracellular recordings, which are widely used to record neuronal firing activity. On the other hand, the *in vivo* patch-clamp technique, an intracellular recordings, enables us to record synaptic inputs and label the projection of the recorded neurons. However, there are few reports using *in vivo* whole-cell recordings from the BLA because it is difficult to attain giga-ohm seal, which is a critical step for the whole-cell mode, because of impurities on pipette tips. Here, we have developed a new method to achieve whole-cell recording from *in vivo* mice deep brain regions. We elaborated double tubes; one is a guide cannula for patch-clamp pipettes, and the other is a tissue-boring stick. Using them, we more easily achieved *in vivo* whole-cell recordings from deep brain regions because the pass length for which the pipettes needed to go through the brain parenchyma were reduced. In this poster, we will present examples of recordings from BLA neurons which is located about 4 mm deep from the brain surface, together with recordings of local field potentials from the dorsal hippocampus.

Title: Extended amygdala circuits are differentially activated by context fear conditioning in male and female rats

Authors: L. URIEN, R. NORDLICHT, ***E. P. BAUER**;
Neurosci., Barnard Col., New York, NY

Abstract: The bed nucleus of the stria terminalis (BNST) contributes to anxiety-like behaviors, responses to stress, and the expression of context fear conditioning. However, most of these behavioral studies have been performed in male rodents, whereas it is known that the BNST is a sexually dimorphic structure. We thus evaluated the contribution of the BNST to context fear expression in female rats. Animals (male and female adult Sprague Dawley rats) received three unsignaled shocks (1 sec, 0.5mA), or no shocks as a control. 24 hours later, they were tested for the expression of context fear for 10 minutes. 45-60 minutes later, they were perfused and brains processed for immunohistochemistry to label ARC- or FOS-positive cells as markers of neuronal activity. Fear conditioned male and female rats exhibited similar levels of freezing behavior during testing. Context fear expression was associated with greater numbers of FOS-positive and ARC-positive cells in the anterolateral portion of the BNST (BNST_AL) compared with no-shock controls or homecage controls in male rats. However, no difference was observed in FOS or ARC immunoreactivity between groups in females. Rather, we observed increased neuronal activity, quantified by FOS expression, in the central nucleus of the amygdala (CE) in female rats. However, bilateral non-specific extensive lesions of the BNST with ibotenic acid (6mg/μL concentration, 0.3μL per side) blocked expression of context fear expression in both sexes, suggesting that another portion of the BNST, and a different extended amygdala circuit, could be necessary for the expression of context fear in female rats. To test this hypothesis, we are using optogenetic strategies to investigate the contribution of the BNST_AL - CE pathway in both males and females to cued and context fear conditioning. These data contribute to our understanding of the neural circuits underlying context fear learning and expression in females.

Title: Anatomical and functional characterization of ventral subiculum projections to the BNST

Authors: *L. URIEN, S. COHEN, R. NORDLICHT, E. P. BAUER;
Neurosci., Barnard Col. of Columbia Univ., New York, NY

Abstract: The ventral subiculum (vSUB), a major output of the hippocampus, contributes to the acquisition and expression of fear conditioning and regulates responses to stress through inhibition of the HPA axis. The bed nucleus of the stria terminalis (BNST) is necessary for the expression of context fear conditioning and anxiety-like behaviors. It has also been implicated in processing stressful events and unpredictable threats. Interestingly, despite the anatomical connectivity of these two brain structures and their common involvement in fear conditioning, the projection from the vSUB to the BNST has not been well-characterized. Here, using a combination of retrograde tracing techniques, behavioral testing and quantification of neuronal activity with FOS immunohistochemistry, we characterized the output from the vSUB to the BNST. Animals (adult male Sprague Dawley rats) received infusions of cholera toxin subunit B fused to the fluorescent marker Alexa-488 into the BNST. We first show that outputs from the vSUB to the BNST are organized topographically, with more anterior portions of the vSUB projecting to more anterior portions of the BNST such as the anteromedial BNST, while the posterior vSUB projects to the posterior BNST including the medial and ventral portions. Next, we assessed the contribution of this pathway to context fear conditioning. Two weeks after surgery, animals underwent context fear conditioning using a standard protocol of 3 unsignaled footshocks (1 sec, 0.5mA), or no footshocks as a control. 24 hours later, they were placed in the conditioning chamber and freezing behavior was assessed for 10 min. 45-60 min later, they were perfused and brains processed for FOS immunohistochemistry. Animals receiving footshocks on training day froze significantly to the context on testing day. Both the overall number of FOS-expressing neurons in the vSUB, as well as the percentage of BNST-projecting vSUB neurons expressing FOS were significantly higher in fear-conditioned animals compared with controls. These data contribute to our understanding of how context fear information is relayed from the ventral hippocampus to the BNST.

Title: Amphetamine sensitization under reward uncertainty has opposing effects on conditioned approach and conditioned reinforcement to serial cues

Authors: *K. A. CAPLAN, A. S. KNES, C. CLIBANOFF, H. O. RODRÍGUEZ-CRUZ, C. M. FREELAND, M. J. F. ROBINSON;
Wesleyan Univ., Middletown, CT

Abstract: Pathological gambling is a behavioral disorder affecting 1-2% of the U.S. adult population. Gambling games such as slot machines persistently expose players to audiovisual stimuli (e.g., celebratory sounds, flashing lights, spinning wheels) prior to and during reward delivery. Over time, these cues may become attractive, motivating individuals to continue playing. In those affected by gambling addiction, these reward-paired cues may also trigger cravings and relapse. However, such cues unreliably predict reward outcomes by appearing both in the presence and absence of a reward. Although their predictive value is degraded under uncertainty, animal studies suggest that the attractiveness of these cues is heightened as evidenced by heightened sign-tracking behavior in rats. Repeated exposure to drugs of abuse such as amphetamine can further sensitize the underlying mesolimbic dopaminergic circuits, resulting in even greater incentive value attributed to these cues. Here, we explored the impact of reward uncertainty (probability and magnitude) and prior amphetamine sensitization on incentive salience attribution to serial Pavlovian cues that vary in degree of predictive and incentive value. Male Sprague-Dawley rats were exposed to repeated injections of either amphetamine (1 to 4 mg/kg) or saline over a period of 14 days. After two weeks of incubation, rats were trained in a Pavlovian autoshaping task involving two sequential lever + distinct auditory cues (CS1, CS2) under either Certain (100% -1) or Uncertain (50%-1-2-3) reward conditions. During autoshaping, sign-tracking to the CS1/CS2 levers versus goal-tracking to the pellet-dispensing magazine was assessed. The relative reinforcing properties of either CS1 or CS2 was evaluated next with a one-day conditioned reinforcement task. Rats then underwent autoshaping again to assess the impact of acute amphetamine or nicotine exposure on cue attraction. Our results suggest that Uncertainty enhanced attraction toward the more reward-proximal cue (CS2). However, prior sensitization and Uncertainty reversed this effect, enhancing attraction toward the more predictive reward-distal CS1. Both the CS1 and CS2 acquired conditioned reinforcing properties, despite the CS2 being otherwise ignored in all groups besides the Uncertain reward condition.

However, sensitization and Uncertainty resulted in significantly more interaction with the CS2 lever upon its presentation. This observed discrepancy in cue attraction and rewarding value suggests a possible dissociation between the attractiveness of a cue and its rewarding qualities, particularly for cues proximal to reward delivery.

Title: Optogenetic inhibition of the AIC and OFC during risky decision making

Authors: *A. S. KNES[1], C. M. FREELAND[2], K. A. CAPLAN[1], M. J. F. ROBINSON[1]; [1]Psychology, [2]Biol. Dept., Wesleyan Univ., Middletown, CT

Abstract: Adaptive decision-making is a complex process that often requires weighing the costs and benefits associated with different options of varying reward magnitudes and probability. The ability to integrate information regarding the probability of reward, loss, and/or adverse consequences requires the cooperation of multiple neural operations to guide optimal behavior. The anterior insular cortex (AIC) and orbitofrontal cortex (OFC) have been implicated in outcome evaluation and decision-making. However, the temporal and functional involvement of these regions in processing and tracking outcomes under risky and uncertain conditions remains largely unknown. In the present study, female rats were trained on a risky decision-making task involving the choice between a Safe option that offered a small, certain reward (1 sucrose pellet) and a Risky option that offered a large, certain reward (3 pellets) with an uncertain and increasing risk of punishment across each session (0%, 25%, 75% risk of foot shock). Animals were trained on this task daily until establishing stable baseline performance. To examine the roles of the AIC and OFC throughout the decision-making process, the AIC or OFC was optogenetically inhibited, via activation of halorhodopsin using green laser light (532 nm), at one of five discrete time points throughout the task: pre-choice, post-choice following Risky punished outcomes, post-choice following Risky unpunished outcomes, post-choice following Safe choices, and between choice trials. The impact of AIC or OFC inhibition at each of the five time points on the proportion of risky choices was compared both within and between animals. Our results suggest that OFC inactivation during post-choice risky unpunished outcomes increased risky behavior despite the increasing likelihood of foot shock. We found no effect of

laser inhibition during inter-trial intervals, verifying that laser inhibition did not produce non-specific or carry-over effects on choice performance during the task. While it is generally accepted that the prefrontal cortex is implicated in decision-making, the manner by which specific cortical regions influence risky behavior and the temporal window in which they act remains largely unknown. These results help address that gap with the potential of providing a better understanding of the pathologic mechanisms involved in maladaptive decision-making.

Title: Reward uncertainty elicits cue-triggered craving for predictive and incentive cues

Authors: *N. ROME, J. M. CHABOT, T. PENG, H. XU, M. MUSTO, M. J. F. ROBINSON; Wesleyan Univ., Middletown, CT

Abstract: Flashing lights and sounds in gambling settings are repeatedly associated with reward outcomes. Even though these cues are often presented in the absence of reward, they become attractive and acquire the ability to increase the desire to gamble. It is believed that the reward uncertainty of gambling attributes excessive motivational value to these cues, thereby contributing to the urge to gamble. Cues preceding rewards contain both predictive and incentive value. Previous research suggests that while reward uncertainty degrades a cue's predictive value, it simultaneously increases its incentive value. Here we use a Pavlovian-to-Instrumental Transfer design in rats to study how reward uncertainty affects the ability of these cues' values to induce craving. Trials in the Pavlovian training sessions consisted of the presentation of an auditory cue (CS1) for 8 seconds, followed by another distinct auditory cue (CS2) concomitant with the last 4 seconds of the CS1 ending with a reward outcome that was either certain or uncertain in probability and magnitude. In marking the beginning of each trial, the CS1 takes on the majority of predictive value. The CS2 adds little predictive information but its temporal proximity to the reward-event lends it mostly incentive value. During subsequent instrumental training, rats were trained to press an active lever over a control lever to receive a sugar pellet. Finally, animals were given access to levers under extinction and the CS1, CS2, and CS1+CS2 were presented in a random counterbalanced order. Cue-triggered craving was measured by spikes in active lever presses and magazine entries during cue presentations. Our results indicate

that rats in the uncertain reward condition exhibited surges of reward-seeking behavior during CS1, CS2, and CS1+CS2 presentations. In contrast, animals in the certain condition only displayed signs of increased craving during the CS1 and CS1+CS2 presentations, and were unaffected by isolated CS2 presentations. These findings suggest that even though reward uncertainty degrades predictive value, it imbues cues with greater incentive value, rendering them capable of inducing cue-triggered craving. These results help us understand how cues can induce a strong urge to continue gambling.

Title: Frequency response of optically stimulated, midbrain dopamine neurons

Authors: ***P. SHIZGAL**[1], V. PALLIKARAS[1], F. CARTER[1], D. N. VELÁZQUEZ-MARTINEZ[2], A. ARVANITOGIANNIS[1];
[1]Psychology / CSBN, Concordia Univ., Montreal, QC, Canada; [2]Dept. de Psicofisiologia, Univ. Nacional Autonoma de Mexico, Mexico City, Mexico

Abstract: Rodents will work indefatigably to trigger optical stimulation of midbrain dopamine (DA) neurons. It has not yet been established definitively how the parameters of the optical pulse train translate into the DA firing rate and the intensity of the rewarding effect. These functions must be determined in order to model and optimally manipulate the optical intracranial self-stimulation (ICSS) phenomenon. We characterized frequency-following properties of optically stimulated DA neurons by psychophysical means. Viral transfection and Cre-lox recombination were used to drive expression of Channelrhodopsin-2 in midbrain DA neurons of male TH-Cre rats. A chronically implanted optical fiber was aimed at the ventral tegmental area. The rats were trained to accumulate time on a response clock so as to obtain the optical reward: Depressing a lever for a cumulative time of 2 s triggered delivery of a 1 s train of 31.6 mW, 462 nm optical pulses. The dependent measure was time allocation (TA): the proportion of trial time that the lever was depressed. The pulse duration was fixed within the 50-s trials and stepped downwards in eight equal proportional steps from trial 2 to trial 10 of each sweep; trial 1 was a warm-up trial offering the same pulse duration as trial 2. Ten sweeps were run in each test session, and at least five sessions were run at each pulse frequency. The position of the TA-vs-pulse-duration (TA-d)

curves along the pulse-duration axis served as the scale for estimating the firing-rate changes produced by variation of the pulse frequency. This scaling method is analogous to the one developed by Solomon et al. (Behav. Brain Res., 292, 327-341) for electrical ICSS. Decreasing the optical pulse duration reduces the time available for the photocurrent to reach the firing threshold, thus shrinking the size of the region in which DA neurons are fired and the number of activated neurons. Thus, reductions in pulse duration compensate for, and can serve to scale, increases in firing rate. In 3/5 cases, increasing the pulse frequency from 7-40 pulses per second (pps) shifted the TA-d curves leftwards, implying that the DA neurons fired more frequently in response to the higher pulse frequencies. In the remaining 2 cases, the effective pulse-frequency range extended only to 28 pps. The trade-off between pulse frequency and pulse duration suggests that the intensity of the rewarding effect subserving optical ICSS depends on the aggregate rate of induced firing in the DA neurons, which plateaus at a rate that may depend on opsin expression. These data provide a foundation for describing the growth of reward intensity as a function of DA firing and for modelling brain reward circuitry.

Title: Questioning the role of phasic dopamine signaling in reinforcement learning

Authors: *F. CARTER, V. PALLIKARAS, P. SHIZGAL;
Psychology / CSBN, Concordia Univ., Montreal, QC, Canada

Abstract: According to an enormously influential hypothesis, reward-prediction errors (RPEs), encoded in the firing of dopamine (DA) neurons, determine reward expectations and action values. RPEs arise from discrepancies between experienced and predicted outcomes. As learning progresses, the RPEs "predict themselves away," diminishing progressively as reward forecasts and action proclivities converge on optimal values. Abundant correlational evidence is consistent with this "RPE-DA" hypothesis, and there is supporting causal evidence from associative-conditioning studies. Here, we present operant-conditioning data that challenge the RPE-DA hypothesis. Viral transfection and Cre-lox recombination were used to express Channelrhodopsin-2 (ChR2) in midbrain DA neurons of male TH-Cre rats. A chronically implanted optical fiber was aimed at the ventral tegmental area (VTA). Depressing a lever for a

cumulative time of 2 s triggered a 1 s train of 31.6 mW, 462 nm, 5 ms optical pulses. The 4-min trials were grouped in 15 repeating triads per session. The optical reward was strong (high optical pulse frequency) on the leading trial of a triad and weak on the trailing trial. On the middle trial, reward strength was determined randomly to be either weak, moderate, or strong. The diameter of the optical probe (300 um) is ~10x larger than a DA soma, and ChR2 is found throughout the electrically excitable compartments of the neuron. Thus, DA neurons near the tip should be fired unconditionally by the optical pulses, as voltammetric data attest. The RPE-DA hypothesis predicts that over repeated trials, such unconditional DA bursts will ineluctably increment, and eventually saturate, synaptic weights subserving reward prediction and reward-seeking actions. If so, performance for optical rewards of intermediate strength must increase progressively until its maximum is attained. In contrast, we found that performance for the moderate reward on the middle trials was non-maximal and either stable or decreasing. Moreover, performance differed in two additional ways from what is typical of the model-free, temporal-difference learning originally posited by the RPE-DA hypothesis: 1) response latencies prior to receipt of the first reward on a trial show that the rats could predict the position of the trial in the triad, and 2) performance adjusted abruptly once the strength of the reward on the middle trials was revealed. Thus, specific activation of DA neurons in the absence of cues can drive learning about the sequence of environmental states, and receipt of disambiguating information produces immediate behavioral change, as in model-based learning.

Title: The trade-off between optical power and pulse duration in optical excitation of midbrain dopamine neurons

Authors: *V. PALLIKARAS[1], F. CARTER[1], D. VELAZQUEZ-MARTINEZ[2], A. ARVANITOGIANNIS[1], P. SHIZGAL[1];
[1]Psychology / CSBN, Concordia Univ., Montreal, QC, Canada; [2]Dept. de Psicofisiologia, Univ. Nacional Autonoma De Mexico., Mexico, D.F., Mexico

Abstract: Rodents will work vigorously to deliver optical stimulation to midbrain dopamine neurons. However, many of the biophysical properties governing the optical activation of the dopamine neurons are still under investigation. We have addressed this issue by applying

psychophysical methods to characterize the interaction between optical power and pulse duration in determining the impulse flow in midbrain dopamine neurons that causes reward-seeking behaviour. The goal was to evaluate if pulse duration can effectively control the behavioural effectiveness of optical stimulation. A cre-dependent viral vector containing the transcript for Channelrhodopsin-2 was infused in the Ventral Tegmental Area (VTA) of 6 TH:Cre rats, and chronically implanted optical probes were anchored above the VTA. Stimulation was delivered at a frequency of 40 pulses per second in 1s trains. Subjects were trained to hold down a lever for 2 s to receive the optical reward. We measured time allocation (TA), the proportion of total trial time allocated to work during each trial. Sessions consisted of 10 pulse duration sweeps each consisting of 10 50 s trials. Trials were 50 s in duration, and the ITI was 10 s. The pulse duration was fixed within trials and stepped downwards in eight equal proportional steps from trial 2 to trial 10 of each sweep; trial 1 was a warm-up trial offering the same pulse duration as trial 2. The range of pulse durations tested was customized for each rat. Five sessions were run at each of a series of powers, ranging from 10 to 50 mW. TA grew in a sigmoidal fashion as pulse duration increased. If the rewarding effect depends on the aggregate rate of induced firing in the dopamine neurons, each level of TA reflects the firing of a corresponding number of dopamine neurons. If so, the lateral position of the TA-vs-pulse-duration curves across different powers reflects the trade-off between power and pulse duration in determining the size of the population of excited dopamine neurons. As expected, the TA-vs-pulse-duration curves shifted leftward over some portion of the range of optical powers. This implies that manipulation of the pulse duration can control the intensity of the optically induced rewarding effect and serve to estimate critical properties of the dopamine neurons, such as their firing fidelity as a function of optical stimulation pulse frequency.

Title: Evolution of phasic dopamine release in limbic, associative, and sensorimotor domains of the striatum during the development of habitual reward seeking

Authors: *W. VAN ELZELINGEN[1,2], W. E. BASTET[1], J. M. MATOS[1], D. SMULDERS[1], I. WILLUHN[1,2];

[1]The Netherlands Inst. for Neuroscience, Royal Netherlands Acad. of Arts and Sci., Amsterdam, Netherlands; [2]Dept. of Psychiatry, Amsterdam UMC, Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: Goal-directed behavior that reliably results in desired outcomes is often automated and executed habitually after repeated performance. Evidence suggests that this switch in behavioral strategy may be paralleled by a shift in dopamine efflux from the limbic, ventromedial striatum (VMS) to the sensorimotor, dorsolateral striatum (DLS). Other work implicates a competitive interplay between DLS and the associative, dorsomedial striatum (DMS), which is associated with goal-directed behavior. Thus, we used fast-scan cyclic voltammetry (FSCV) in freely-moving rats to investigate how dopamine signaling in VMS, DMS, and DLS evolves during the development of habitual reward seeking. Male Long-Evans rats were conditioned to seek food pellets on a chained seeking-taking reinforcement schedule in an operant box. Pressing the seeking lever (distal operandum) under a VI60 schedule provided access to a taking lever (proximal operandum). Subsequent responding on the taking lever under a FR1 schedule resulted in the delivery of a food pellet. Over the progression of behavioral training, different probe tests were performed to assess how habitual the animals responded for food. FSCV measurements were conducted repeatedly throughout training to detect changes in dopamine release during habit development. Our results demonstrate no difference in task-relevant dopamine release in VMS between habitual and non-habitual states, based on comparison of early and late training time points, as well as comparisons between rats that became habitual and rats that remained non-habitual. In contrast, animals that developed seeking habits exhibited differences in both DMS and DLS dopamine that were already apparent early in training. Habits were associated with more pronounced dopamine release during distal responses (seeking lever) and decreased signaling during proximal responses (taking lever). In addition, we found decreased dopamine reactivity to unpredicted reward delivery in DLS of habitual rats, but not in DMS. Taken together, our findings do not support the hypothesis of a dopamine shift between striatal domains during habit formation, but surprisingly indicate that differential dopamine signaling in DMS and DLS is pre-existent or is recruited prior to habit formation.

Title: Differences in phasic dopamine release during Pavlovian and operant conditioning in ventromedial and ventrolateral striatum

Authors: *J. N. GOEDHOOP[1,2], I. WILLUHN[1,2];
[1]Netherlands Inst. For Neuroscience, Royal Netherlands Acad. of Arts and Sci., Amsterdam, Netherlands; [2]Dept. of Psychiatry, Amsterdam UMC, Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: Dopamine neurons are known for their responses to rewarding events and their predictors. However, the precise information conveyed by dopamine signals (e.g., reward prediction error, value, motivation, or movement) and their regional specificity are under active debate. The striatum receives the largest projection from dopamine neurons and consists of functional domains that are defined by their afferents. The ventromedial striatum (VMS) receives predominantly limbic input and the ventrolateral striatum (VLS) mainly input from the insula cortex. To further characterize dopamine signaling in VMS and VLS, we directly compared Pavlovian and operant conditioning and systematically varied several task parameters.
Adult, male Long-Evans rats (n = 18) with chronically implanted electrodes for fast-scan cyclic voltammetry (FSCV) in VMS and VLS were trained on either an appetitive Pavlovian or instrumental conditioning paradigm in which a conditioned stimulus (CS) predicted the delivery of a reward or the opportunity to execute an action to obtain a reward. Task conditions were kept the same with the exception of the operant-lever response requirement.
We observed differences in VMS dopamine release between Pavlovian and instrumental conditioning during presentation of either CS or unconditioned stimulus (US). Specifically, in addition to reward prediction, VMS dopamine appeared to encode the anticipation to execute the operant action, characterized by sustained release during CS presentation until lever press. In VLS, we observed overall smaller CS- and US-induced dopamine, an incomplete transfer of dopamine from US to CS during Pavlovian conditioning, and a lack of a sustained CS response in instrumental conditioning.
Our results demonstrate that dopamine release induced by reward presentation and its CS predictor is region-specific, differing in size and signal allocation between VMS and VLS. In addition, our findings suggests that, specifically in VMS, dopamine signals convey not only information consistent with a reward prediction error or value signal, but also other information not captured by these concepts. Potentially somewhat related to motivation, it appears that dopamine release in this region is also shaped by the anticipation to perform a rewarding action.

Title: Nutritional programming during pregnancy and lactation sensitizes food addiction like behavior in offspring of rats

Authors: *L. MONTALVO MARTINEZ[1], G. CRUZ CARRILLO[1], L. FUENTES MERA[1], R. ORTIZ LÓPEZ[2], A. CAMACHO MORALES[1];
[1]Biochem. and Mol. Med., Autonomous Univ. of Nuevo León, Monterrey, Mexico;
[2]Technological Inst. and of Superior Studies of Monterrey, Monterrey, Mexico

Abstract: Obesity associates to excessive hypercaloric food intake leading to increase in body mass index. Incentive motivation to hypercaloric foods is partly related to an addictive like behavior phenotype. Addiction correlates with selective changes in gene expression in specific brain reward regions, including the Nucleus Accumbens (NAc), which might be potentially transmitted to the offspring by transgenerational inheritance. Here, we used a murine model of maternal nutritional programming to determine whether: 1) addiction like behavior of mothers is transmitted to male offspring (F1), and 2) candidate genes for food addiction in the NAc of addicted F1, correlates to aberrant synaptic plasticity gene profile found in drug addiction. We used 9 groups of Wistar rats (8-10 weeks), including 2 groups of females (F0) exposed for 9 weeks (premating, pregnancy and lactation) to hypercaloric diet (HD) or control diet (CD). All groups were trained by operant conditioning protocols (FR1, FR5, PR, 12 days) using a Skinner type box, following by chocolate pellets as a reward to determine its addiction like behavior. Microarray analysis from the NAcshell of the offspring was performed to identify candidate genes. Our results show that F0 females fed with CD exhibit an enhanced motivation to hypercaloric rewards compared to F0 females fed HD. Nevertheless, addiction like behavior from F0 females fed HD was efficiently transmitted to the F1 offspring in compare to F0 females fed CD. Likewise, global expression microarrays analysis showed that addiction like behavior subjects exhibit alteration in the expression of several genes involved in drug addiction such as: DR2, GluA1, GluA2, GluA3, BDNF, CREB, FosB, SIRT1, HDAC1, MEF2. Genomic interaction pathways demonstrated interactive nodes involved in synaptic plasticity and neuronal function. Our results demonstrate that maternal hypercaloric programming sets food addiction like behavior susceptibility which positively is transmitted to male offspring showing selective gene expression changes in NAc shares during drug addiction phenotype.

Title: Cholinergic basal forebrain neurons can drive motivated behavior by serving as a conditioned stimulus

Authors: *E. Y. KIMCHI[1,2], A. BURGOS-ROBLES[2], G. A. MATTHEWS[2], T. L. CHAKOMA[2], M. PATARINO[2], J. C. WEDDINGTON[2], W. YANG[2], R. SIMONS[2], S. FOUTCH[2], M.-F. FONG[2], M. F. BEAR[2], K. M. TYE[3];
[1]Neurol., Massachusetts Gen. Hosp., Boston, MA; [2]Picower Instiute of Learning and Memory, MIT, Cambridge, MA; [3]Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: During motivated behavior, subjects actively interpret external cues to determine whether to seek rewards or avoid punishments. Basal forebrain cholinergic circuits are thought to modulate how neural circuits process these cues, either by increasing attention to specific sensory stimuli or by augmenting the effects of reinforcers on learning and memory. Less is known, however, regarding whether phasic activation of basal forebrain cholinergic neurons impacts motivated behavior even in the absence of other cues. We trained head-fixed ChAT::cre mice to lick to collect fluid rewards. Phasic optogenetic stimulation of nucleus basalis cholinergic neurons triggered reward collection, even prior to training with other sensory stimuli (ChR2 n=17, eYFP n=10, linear mixed effects model p = 0.025). Mice expressing ChR2 in cholinergic neurons initiated licking after photostimulation with a median lick latency of 427ms (n=17, interquartile range 207-682ms) as compared to a median lick latency of 991 ms in eYFP mice (n=10, interquartile range 754-1036ms; signrank p = 0.006). Licking after cholinergic stimulation was dependent on pairing with reward; phasic cholinergic stimulation that was not paired with reward did not trigger reward collection (ChR2 n=17, eYFP n=10, linear mixed effects model p = 0.834). The effects of phasic cholinergic stimulation on reward collection were impaired by an antagonist of muscarinic cholinergic receptors (intraperitoneal scopolamine, 0.3 mg/kg, vs. saline, n=6, signrank p = 0.031), but not nicotinic cholinergic receptors

(intraperitoneal mecamylamine, 1 mg/kg, vs. saline, n=6, signrank p=0.188). Similar increases in reward collection behavior were seen with photostimulation of cholinergic terminals in the basolateral amygdala (ChR2 n=8, eYFP n=4, linear mixed effects model p=0.017). Preliminary results suggest that photoactivation of cholinergic terminals in the basolateral amygdala suppressed neural activity, both in vivo and ex vivo. Preliminary analysis of ex vivo recordings suggest that basolateral amygdala projection neurons were monosynaptically inhibited via muscarinic receptors, whereas GABAergic neurons were monosynaptically excited via nicotinic receptors. These results reveal a novel mode of action for basal forebrain cholinergic neurons, suggesting that phasic cholinergic activation can impact motivated behavior with subsecond precision via muscarinic receptors, even in the absence of other cues. Basal forebrain cholinergic neurons therefore may not only amplify neural processing or plasticity of sensory stimuli, but also may function as conditioned stimuli in and of themselves.

Title: Amygdalostriatal transition zone circuits mediating associative learning and motivated behaviors

Authors: ***F. MILLS**[1], H. S. CHEN[2], S. SHAO[1], M. E. LEMIEUX[1], C. R. LEE[3], K. M. TYE[1]; [1]The Salk Inst. for Biol. Studies, La Jolla, CA; [2]MIT, Cambridge, MA; [3]Univ. of California San Diego, La Jolla, CA

Abstract: The ability to respond appropriately to stimuli that predict rewards or punishments lies at the core of evolutionary fitness, and is disrupted in a number of neuropsychiatric disease states. Although relatively unexplored, the amygdalostriatal transition zone (ASt) may play a crucial role in parallel with the amygdala in mediating associative learning and behavioral responses to salient stimuli. Like the amygdala, the ASt receives converging input from two major streams of sensory information, the thalamic and cortical pathways. However, the

downstream projections of the ASt are distinct from the canonical outputs of the amygdala complex, and are integrated with striatal circuits involved in action selection. Despite this intriguing circuit connectivity, the function of the ASt is almost completely unknown, resulting in a major gap in our knowledge of circuits underlying motivated behaviors. In the present study, our data show that optogenetic activation of the ASt is sufficient to produce aversive behavioral responses. Unilateral activation of ChR2-expressing neurons in the ASt drives robust freezing behavior (83% increase in ChR2 group vs. -2% in eYFP controls; p=0.0015, unpaired t-test) and real-time place avoidance of areas paired with ASt stimulation (32% reduction of time in 'ON'side vs. eYFP controls during last 10 min; p=0.012 unpaired t-test. N=8 mice ChR2, 10 mice eYFP). Additionally, using *in vivo* electrophysiology and optogenetic-mediated 'phototagging' we identify distinct populations of ASt neurons that encode opposing conditioned responses to cues predicting rewarding and aversive stimuli (N=6 mice, n=31 neurons). Finally, in loss-of-function experiments we find that optogenetic inhibition of a subpopulation of ASt neurons causes a striking reduction in conditioned fear responses to a shock-predicting cue (51% decrease in freezing, p=0.00086, paired t-test, N=6 mice NpHR, n=8 mice eYFP). Consequently, we believe that the ASt may be an overlooked and critical structure in mediating responses to conditioned stimuli, and may also contribute to behaviors which have traditionally been attributed to canonical amygdala circuits.

Title: Wireless recording of projection-defined PFC neurons during a novel social dominance task

Authors: *N. PADILLA-COREANO[1], J. C. WEDDINGTON[2], R. ZHANG[2], R. R. ROCK[2], C. CHANG[2], S. B. HAUSMANN[1], G. MATTHEWS[2], J. P. CURLEY[3], K. M. TYE[1];

Abstract: Both humans and mice live in groups organized by social hierarchies. By adjusting behavior based on their social rank, animals decrease unnecessary aggression and save energy. Although hierarchies are central to successful group dynamics, the neural basis of dominance behaviors remains poorly understood. Cross-species evidence suggests that the medial prefrontal cortex (mPFC) is crucial for social dominance behaviors (Wang et al., 2011, Zhou et al., 2017, Zink et al., 2008). Given the role of the lateral hypothalamus (LH) in homeostatic functions, and its connectivity with the mPFC, it is well-positioned to help modulate social behaviors in a rank-dependent manner. Considering that dominant animals typically exercise priority access to resources, we designed a novel behavioral task, the “reward competition assay”. This assay utilizes a trial structure to facilitate statistical comparisons wherein mice compete for a reward that is signaled by a tone. Mice were food restricted and trained to associate a tone with a palatable reward (Ensure). Once mice learned the task, they were paired with a cage mate to compete for the reward. To validate this task, we ranked mice using the tube test (Wang et al., 2011) and tested them on the reward competition assay. Across the session, dominant mice (as defined by tube rank) won more rewards than subordinates, as the percent of rewards obtained for the dominant mice was higher (paired t-test; % rewards subordinate vs dominant $p<0.01$; n=12). Using this novel reward competition assay we investigated the role of mPFC->LH projectors in social dominance. Our preliminary data show that optogenetic stimulation of the mPFC->LH projectors increased winning in subordinate mice (paired t-test; % rewards obtained OFF vs ON sessions $p=0.0047$; n=5). However, we saw no effects of stimulation when mice were performing the reward task alone, indicating that mPFC->LH projectors modulate social competition for a reward, but not reward-seeking behavior. Furthermore, we used wireless electrophysiology to investigate how mPFC activity relates to social dominance during the reward competition assay. We recorded mPFC single units in both dominant and subordinate mice (n=4) while they competed for Ensure rewards. Preliminary data suggest that mPFC single units represent competition as they fired differentially in trials when there were high vs low levels of competition for the reward (n=74 single units recorded). We hypothesize that these “competition cells" in the mPFC may project to the LH in order to inform social homeostatic circuits and integrate these signals with other homeostatic systems such as those regulating energy balance (hunger).

Title: Ventral pallidum neurons signal reward prediction errors consistent with reinforcement learning

Authors: *D. J. OTTENHEIMER[1], B. A. BARI[1], E. SUTLIEF[1], J. M. RICHARD[4], J. Y. COHEN[1,2], P. H. JANAK[1,2,3];
[1]Solomon H Snyder Dept. of Neurosci., [2]Kavli Neurosci. Discovery Inst., [3]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD; [4]Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: With connections to the nucleus accumbens (NAc) and the ventral tegmental area (VTA), the ventral pallidum (VP) is well positioned to contribute to reward-related computations. To characterize value signaling in this circuit, we implemented a behavioral task where rats received on randomly interspersed trials signaled presentations of 110 μl of either 10% sucrose or 10% maltodextrin solutions. We previously reported that the activity of neurons in both regions reflected the rats' preference for sucrose; notably, a greater proportion of neurons in VP were reward selective, and their activity preceded that of NAc neurons, a surprising result given the canonical role of VP as a major output of NAc (Ottenheimer et al., 2018). Despite no requirement that the rats predict the upcoming choice, and no behavioral differences across trial types, we noted a prominent influence of previous outcome on VP reward-evoked activity. To examine this further, here we employed a linear regression approach that previously revealed an exponentially-weighted impact of multiple previous trials on dopamine neuron activity (Bayer and Glimcher, 2005). We similarly found exponential dependence of VP activity on reward history. Prompted by this result, we classified neurons in VP and NAc as RPE-encoding in an unbiased manner using maximum likelihood estimation of a standard reinforcement learning model; this approach confirmed a larger proportion of RPE-encoding cells in VP. We further tested the adherence of VP neuronal activity to RPE in two additional tasks. First, in sessions where sucrose and maltodextrin were presented consecutively in two blocks of 30 trials each, we observed an exponential decay of the sucrose-evoked signal, consistent with an exponential weighting of previous outcomes; moreover, this led to fewer reward-selective neurons and the emergence of predictive anticipatory firing. Next, in sessions with where on some trials the identity of the outcome was indicated by a predictive cue, we found that neuronal signaling integrated both trial history and cued information. Our work emphasizes the robustness of RPE-like value signaling in VP and encourages further consideration of the contributions of VP to reinforcement learning.

Title: Amygdalocortical circuits for the dynamic regulation of conditioned reward-seeking

Authors: *K. M. FRASER, P. H. JANAK;
Johns Hopkins Univ., Baltimore, MD

Abstract: While much is known about the ability of cues in the environment to serve as predictors of reward, the psychological and neurobiological mechanisms that regulate the predictive and motivational significance of reward-paired cues remains unclear. We investigated the regulation of conditioned reward seeking by discrete and phasic sensory events in the environment that inform whether a traditional conditioned stimulus will or will not be followed by reward delivery by making use of an occasion setting procedure. To assess potential neural circuits underlying occasion setting we trained male Long-Evans rats in a task in which a conditioned stimulus was followed by sucrose reward only if preceded in time by the presentation of a different occasion setting cue. Presentation of either the occasion setting cue or the conditioned stimulus on their own was not followed by reward. As a result of this contingency, conditioned responding to the food cup was highest to the conditioned stimulus when preceded by the occasion setting cue. Using reversible inactivation with the GABA agonists baclofen and muscimol, we found that inactivation of either the basolateral amygdala (BLA) or orbitofrontal cortex (OFC) prevented rats from using occasion setters to produce adaptive conditioned reward seeking. We then recorded BLA and OFC neurons in well-trained rats and found that BLA neurons exhibit a greater excitation to the conditioned stimulus when it was preceded by its occasion setter than on trials when it was presented in isolation. We next assessed the contributions of amygdalocortical connections by selectively expressing the inhibitory DREADD in either BLA to OFC or OFC to BLA neurons. Inhibition of OFC to BLA projections, but not BLA to OFC projections, moderately disrupted the ability of rats to use the occasion setter to guide their reward-seeking. These results are consistent with state value encoding theories of the BLA and OFC and suggest activity within this circuit is critical for flexibly updating the motivational significance of cues on a moment-to-moment basis.

Title: Ventral hippocampus, basolateral amygdala, and nucleus accumbens inactivation impairs cue responding in Pavlovian-conditioned contextual discrimination

Authors: *T. KIM[1], P. JANAK[1,2];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: In order to understand the role of environmental contexts in relapse, we and others have used ABA designs to show that exposure to previously rewarded cues in a previously rewarded context can elicit renewal of conditioned responding even in the absence of reward. However, in these experiments, it is not yet clear if renewal is driven by the conditioned properties of cue, the context, or by modulation of cue responding by the context. To address this question, we used a biconditional contextual discrimination task in which male Long Evans rats had to rely on contextual cues in the chambers to determine which of the two cues was paired with reward that day. We examined if the ventral hippocampus (vHPC), dorsal hippocampus (dHPC), basolateral amygdala (BLA), and nucleus accumbens shell (NAcSh) were necessary for this behavior. Rats were trained in context A to discriminate among four auditory cues: a CS^+ that was followed by a 20% sucrose (20S) reward, a CS^- that was followed by nothing, a CSA^+ that was followed by 20S, and a CSA^- followed by nothing. Rats were then placed into context B where the meanings of the CS^+ and CS^- from context A were switched such that the CS^- cue was now rewarded and the CS^+ cue was not. The meaning of the CSA^+ and CSA^- remained constant between the two contexts. The two contexts differed in scent, chamber wall color, and floor texture. Once rats learned the switching CS^+ and CS^- cues in both contexts, they were tested under extinction in both contexts where all four cues were presented but no reward was delivered. Before each test, rats were administered an infusion of either saline or a mixture of muscimol and baclofen into the dHPC, vHPC, NAcSh, or BLA. Inactivation of the vHPC, BLA, and NAcSh reduced responding to all four cues regardless of the context, although the ability to discriminate among rewarded and unrewarded cues remained intact, perhaps suggesting a decrease in motivation.
Decreased responding was specific to cue related behaviors as inactivation of these regions did not cause a locomotor deficit. Inactivation of the dHPC had no effect on responding. These results demonstrate that none of these four brain regions alone is necessary for rats to use these contextual stimuli to determine the currently rewarded cue.

Title: Aggression alters mood-related behavior in adult sexually experienced male CD-1 mice

Authors: *A. THEMANN, O. LIRA, F. J. FLORES-RAMIREZ, S. D. IÑIGUEZ;
Dept. of Psychology, The Univ. of Texas at El Paso, El Paso, TX

Abstract: Maladaptive aggressive behavior has been linked to a wide array of psychiatric disorders including autism, antisocial personality disorder, and schizophrenia. Although the relationship between maladaptive aggression and psychiatric dysfunction is not well understood, recent evidence indicates that aggressive displays towards conspecifics may be perceived as rewarding - and that this hedonic experience may elicit a similar response as other rewarding stimuli, including food, sex, and drugs of abuse. Nevertheless, the relationship between aggression and mood-related illnesses has not been thoroughly investigated using preclinical affect-related models. To address this issue, we examined whether displays of aggressive behavior result in changes in sensitivity to the rewarding properties of sucrose and novel environments, as well as responses to inescapable stress situations. Specifically, male (retired breeder) CD-1 mice were subdivided into aggressive (AGG) and non-aggressive (NON-AGG) groups, based on their latency to attack an intruder mouse into their homecage, during a three-day screening paradigm. Mice were considered AGG if they displayed attack latencies below 10 sec across the three screening days, while animals with attack latencies greater than 30 sec (or not attacking at all) were classified as NON-AGG. One hour after aggression screening (day 3), responsivity to the sucrose (1%) preference, open field, elevated plus maze, and the tail suspension tests were conducted in separate groups of experimental mice. We found that AGG mice display an increased preference for a 1% sucrose solution, as well as increased exploration in novel environments, per the elevated plus-maze and open field tests. In addition, AGG mice showed reduced immobility in the tail suspension test, representative of a resilient-like behavioral response. Collectively, our data suggest that aggression modulates behavioral sensitivity on preclinical models for the study of mood-related illnesses.

Title: Vicarious social defeat stress induces depression-related outcomes in a sex-specific manner in adolescent C57BL/6 mice

Authors: *M. RODRIGUEZ, E. J. FLORES, S. INIGUEZ;
Dept. of Psychology, The Univ. of Texas At El Paso, El Paso, TX

Abstract: Major depression disorder (MDD) is a prevalent illness that negatively affects the adolescent population, with females having a higher likelihood of diagnosis. Stress is a well-recognized risk factor for the development of MDD, in which psychological stress, in particular, plays a role in the etiology of mood-related disorders. Although there has been progress in our understanding of how animal models of psychological stress induce depression-related phenotypes, a prevailing limitation is that most of this work has been conducted mostly in adult males. Thus, to examine this issue at the preclinical level, we adopted the vicarious social defeat stress (VSDS) paradigm to assess whether psychological stress induces depression-related outcomes in adolescent mice. Specifically, postnatal day (PD) 35 male and female C57BL/6 mice vicariously experienced the defeat bout of a male conspecific, by a larger male CD1 aggressor for 10 consecutive days (10 minutes per day). Twenty-four hours after the last day of VSDS exposure (i.e., PD45), separate cohorts of experimental mice were tested on the social interaction, tail suspension, and light/dark box tests. The results indicate that when compared to non-stressed controls, VSDS exposed male mice displayed a depressive-like phenotype per significant increases in avoidance behavior and immobility on the tail suspension test. Furthermore, VSDS male mice displayed an anxiogenic-like phenotype, since they spent less time in the lighted compartment of the light/dark box, along with significant decreases in body weight. Conversely, in adolescent females, VSDS did not influence performance in any of the behavioral tasks assessed. These findings indicate that adolescent VSDS exposure induces depression-related behavior in a sex-specific manner in C57BL/6 mice.

Title: Upregulation of hippocampal extracellular signal-regulated kinase (ERK)-2 induces antidepressant-like behavior in the rat forced swim test

Authors: *I. GARCIA-CARACHURE, F. J. FLORES-RAMIREZ, S. D. IÑIGUEZ; Psychlogy, The Univ. of Texas at El Paso, El Paso, TX

Abstract: The hippocampus mediates responses to affect-related behavior in preclinical models of pharmacological antidepressant efficacy, such as the forced swim test. However, the molecular mechanisms that regulate escape-directed behavior in this preclinical model of despair are not well understood. Here, using viral-mediated gene transfer, we assessed how overexpression of extracellular signal-regulated protein kinase (ERK)-2 within the dorsal hippocampus influenced behavioral reactivity to inescapable swimming stress in adult male Sprague-Dawley rats. When compared to controls, rats overexpressing hippocampal ERK-2 displayed increases in the time to initially adopt a posture of immobility, along with decreases in total time spent immobile, without influencing general locomotor activity. Collectively, the results indicate that hippocampal upregulation of ERK-2 increases escape-directed behavior in the rat forced swim test, thus providing insight into the neurobiological mechanisms that mediate antidepressant efficacy.

Title: The enduring anxiogenic phenotype induced by juvenile antidepressant exposure is ameliorated by fluoxetine re-exposure in adult female C57BL/6 mice

Authors: *F. J. FLORES-RAMIREZ, O. LIRA, F. D. RODRIGUEZ, J. PRECIADO-PIÑA, D. I. PARDO, S. A. CASTILLO, S. D. INIGUEZ;
Psychology, Univ. of Texas at El Paso, El Paso, TX

Abstract: Accumulating preclinical evidence indicates that adolescent exposure to antidepressant medications results in altered behavioral responses to stress in adulthood. However, to date, these preclinical experimental approaches have been conducted primarily using male subjects. This is surprising given that females, when compared to males, are more likely to be diagnosed with mood-related disorders, and thus, be prescribed to antidepressant medications. Therefore, to examine if altered sensitivity to anxiety-inducing situations are exhibited in adulthood, as a result of juvenile exposure to antidepressants, we exposed adolescent female C57BL/6 mice to the selective serotonin reuptake inhibitor (SSRI) fluoxetine (FLX). Specifically, female mice were forced to consume FLX in their drinking water (250 mg/l) from postnatal day [PD]-35 to PD49, and later assessed in adulthood (PD70+) on responsivity to the elevated plus-maze (EPM) and the light-dark box (LDB) tests - behavioral paradigms commonly used to assess anxiety-like responses in rodents. Our results show that adult female mice pretreated with FLX during adolescence spent less time in the open arms of the EPM, when compared to saline-pretreated controls. Similarly, when tested on the LDB, FLX-pretreated mice displayed significantly longer latencies (sec) to enter the light-side compartment of the testing chamber, and spent significantly less time (sec) within it, when compared to controls. To evaluate whether FLX re-exposure would reverse the SSRI-induced anxiogenic phenotype in adulthood, we reinstated SSRI treatment from PD70-84, and evaluated responses on the EPM and LDB. Interestingly, we found that adult re-exposure to FLX reversed the enduring anxiogenic phenotype, per the EPM and LDB paradigms. Collectively, our data suggest that adolescent exposure to FLX mediates behavioral adaptations that endure into adulthood, which are indicative of a generalized anxiogenic-like phenotype, and that this effect is ameliorated by reinstatement of FLX treatment later in life.

Title: Adolescent rats exhibit context-dependent methamphetamine sensitization while adult rats fail to exhibit sensitization using a one-trial procedure

Authors: *B. W. SORTMAN[1], C. MORENO-BARRIGA[1], D. FRANCO[1], E. NUNEZ[1], K. J. THIEL[2], A. R. ZAVALA[1];
[1]Psychology, California State Univ., Long Beach, CA; [2]Psychology, Madonna Univ., Livonia, MI

Abstract: Sensitization is a well-known effect of psychostimulant drugs such as cocaine, amphetamine, and methamphetamine and is characterized as a leftward shift in the dose-response curve. In rodents, sensitization is manifested as an enhanced behavioral response after a single injection (one-trial) or repeated (multi-trial) administration of the drug. One-trial behavioral sensitization is exhibited differently across ontogeny. Specifically, preweanling rats show context-independent one-trial behavioral sensitization to cocaine (i.e., sensitization is evident regardless of where cocaine is given), while adult rodents show context-dependent sensitization (i.e., sensitization is evident only in the context where cocaine was given previously). Interestingly, adolescent rats do not show one-trial sensitization to cocaine or methamphetamine. The present study sought to examine further the development of one-trial methamphetamine sensitization in adolescent (i.e., postnatal day (PD) 39) and adult (PD 69) rats using low doses of methamphetamine, as well as to determine the role of context in moderating a sensitized response. Male and female rats (PD 38 or 68) were injected with either saline or methamphetamine (3.0 mg/kg, IP) in their home cage (home-paired) or an activity chamber (activity-paired). The following day (i.e., PD 39 or 69), rats received a challenge injection of methamphetamine (0.1-1.0 mg/kg, IP) in the activity chamber and their locomotor activity was assessed for 90 min. A separate control group received saline on (PD 38 or 68), and received a saline challenge injection the following day (PD 39 or 69). In contrast to previous findings, adolescent rats showed context-dependent one-trial behavioral sensitization to methamphetamine (0.3 mg/kg). Moreover, adult rats failed to show behavioral sensitization to any dose of methamphetamine. This data suggests that adolescent rats show increased sensitivity to methamphetamine compared to adult rats. This data is consistent with prior studies demonstrating that adolescent rats are more sensitive to the behavioral effects of methamphetamine compared to adult rats (e.g., enhanced conditioned place preference and self-administration of methamphetamine). The ontogenetic differences in behavioral sensitization highlights the need to examine further the mechanisms underlying these developmental differences.

Title: Lateral habenula gabaergic cells: Involvement in anxiety and stress-related behaviors

Authors: *V. MATHIS[1], P. J. KENNY[2];
[1]Neurosciences, Icahn Sch. of Med. At Mt Sinai, New York, NY; [2]Dept. of Pharmacol. and Systems Therapeut., ICAHN Sch. of Med. At Mount Sinai, New York, NY

Abstract: *Rationale:* The lateral habenula (LHb) is thought to play an important role in coordinating behavioral and physiological responses to stress. Until recently, neurons in the LHb were considered exclusively glutamatergic. However, recent evidence suggests that GABA cells are not only expressed in the LHb but that they may participate in stress-related behaviors. Here, we sought to study the connectivity, activity, and functions of GABA neurons in LHb of mice. *Methods:* Using Vgat/TdTomato mice, we described the location of a subset of LHb GABA cells. Then, using VGAT-Cre mice and viral tracers, we mapped the inputs/outputs of these GABA cells. We assessed, using fiber photometry, the activity of these cells in response to aversive (foot-shocks, tail pinch) or rewarding (sucrose) stimuli. Finally, we chemogenetically manipulated the activity of these cells in aversive and conflict-based behavioral tasks. *Results:* We provided strong evidence that functional GABAergic cells are contained within the LHb. These cells receive inputs from a more restricted connectome than LHb glutamatergic cells. For instance, they do not receive inputs from the entopeduncular nucleus, considered one of the major sources of LHb inputs. In regard to their function, chemogenetic manipulation of these LHb GABAergic cells induced anxiety-like behaviors and impacted decision-making processes, suggesting an important role in regulating mood and cognition. *Conclusions:* Small populations of GABAergic neurons in the habenula play an important role in signaling aversive behavioral states. These cells may participate in behavioral adaptation upon stressful situations. Further work on these GABA cells will help to better define the cellular mechanisms by which the habenula regulates behavior. **Keywords:** Lateral habenula, GABA, tracing, fiber photometry, anxiety, stress, decision making

Title: The role of septal enkephalinergic neurons in anxiety

Authors: *M. AN, K. KIM, H.-K. KIM, S.-Y. KIM;
Inst. of Mol. Biol. and Genet., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: The lateral septum (LS), a forebrain region flanked by the lateral ventricles, is a key player in the regulation of anxiety. The LS is anatomically connected to a number of regions implicated in stress, anxiety and depression, and classic studies using lesion, electrical stimulation, pharmacological manipulations and recordings have implicated the LS in anxiety. Furthermore, recent studies have established the roles of several genetically defined septal subpopulations in anxiety using modern cell type-specific circuit dissection techniques (e.g. Anthony et al., 2014; Besnard et al., 2019). Despite the progress, the function of the many of the cell types in the LS remains largely unexplored. Notably, opioid peptides are involved in a variety of negative affective states including anxiety, and numerous studies have linked opioid neurotransmission in the LS to anxiety. However, the role of the LS neurons expressing opioid peptides in anxiety remains unexplored. Therefore, we explored the function of the LS subpopulation defined by the expression of encephalin in anxiety. Using optical recordings in freely-behaving mice, we observed that septal enkephalinergic neurons are activated by anxiogenic or stressful stimuli. We are currently examining the causal role of this population using optogenetic and chemogenetic tools. Our preliminary data suggest that septal enkephalinergic neurons can modulate diverse anxiety-related behaviors. Further experiments in other related behaviors and physiological measurements will reveal the precise role of these neurons in modulating specific anxiety state features.

Title: The amygdala differentially regulates defensive behaviors evoked by CO_2

Authors: *R. J. TAUGHER[1,4], B. J. DLOUHY[2], C. J. KREPLE[3], A. GHOBBEH[1,4], M. M. CONLON[5], Y. WANG[1], J. A. WEMMIE[1,4];

Abstract: CO_2 inhalation provokes panic attacks in patients with panic disorder. Identifying the brain sites involved could provide important mechanistic insight into the illness. In mice, the amygdala has been suggested to promote CO_2-evoked responses; however, recent studies in humans with amygdala damage indicate the amygdala is not required for CO_2-induced fear and panic. To clarify the role of the amygdala, we produced lesions in mice paralleling the lesions in humans. Compared to sham controls, we found that amygdala-lesioned mice froze less to 10% CO_2, and unlike shams they also began to jump frenetically. At 20% CO_2, controls also exhibited jumping suggesting it is a normal response to more extreme CO_2concentrations. The effect of amygdala lesions was specific to CO_2 as amygdala-lesioned mice did not jump in response to a predator odor or to an auditory conditioned stimulus. In amygdala-lesioned mice, jumping evoked by 10% CO_2 was eliminated by co-lesioning the dorsal periaqueductal gray, a structure previously implicated in panic and escape-related behaviors. Together, these observations suggest a dual role for the amygdala in the CO_2 response: promoting CO_2-induced freezing, and opposing CO_2-induced jumping, which may help explain the exaggerated CO_2 responses in humans with amygdala lesions.

Title: Region and cell-type specific contribution of mGlu5 receptors to social behavior and anxiety

Authors: *A. RAMOS PRATS, F. FERRAGUTI;
Pharmacol., Med. Univ. of Innsbruck, Innsbruck, Austria

Abstract: A large body of evidence has implicated an altered signaling or expression of the metabotropic glutamate 5 (mGlu5) receptor in the pathology of several neuropsychiatric disorders, including autism, anxiety disorders and schizophrenia. In particular, enhanced mGlu5 receptor signaling has been suggested to underlie impaired social behavior, a symptom shared by these disorders. Recent research suggests that systemic deviations in any direction of mGlu5 receptor function may lead to social dysfunction. Whereas germ line deletion of the mGlu5 receptor gene leads to a phenotype showing remarkable analogies with Williams syndrome, characterized by a marked prosocial behavior and enhanced anxiety, increased mGlu5 receptor expression and signaling underlies obsessive-compulsive behavioral abnormalities. So far, it remains unclear how mGlu5 receptors contribute to the expression of social preference and anxiety and particularly which neural circuits underlying these behaviors are preferentially affected by activity of these receptors. Our work aims at elucidating whether mGlu5 receptor ablation in a cell-type specific manner can affect social and anxiety-like behavior. To this aim, we performed stereotactic injections of an AAV-CamKIIa-Cre-GFP viral vector in the ventral hippocampus of $mGluR5^{Fl/Fl}$ mice to selectively ablate mGlu5 receptors in that area. We then tested these mice in several classical behavioral paradigms to assess social and anxiety-like behaviors. Our preliminary data suggests that mGlu5 receptors in the ventral hippocampus modulate novelty-induced locomotion and have divergent effects on social recognition and anxiety. Our findings corroborate the view of a complex role played by mGlu5 receptors in social behavior and anxiety and questions systemic pharmacological treatment strategies aimed at alleviating social dysfunction and pathological anxiety e.g. in neurodevelopmental disorders such as autism.

Title: Central inhibition of heme oxygenase carbon monoxide pathway modifies the anxiety-like behavior in endotoxemic rats

Authors: *C. R. A. LEITE-PANISSI, E. O. PRIMINI, M. C. CARVALHO;
Dept. de Psicologia, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Ribeirão Preto, Brazil

Abstract: The carbon monoxide (CO) is a neuromodulator gas that is produced by the action of the enzyme heme-oxygenase (HO), and it may be involved in several biological processes such as nociception and emotional modulation. This mechanism can modulate noradrenergic neurons in locus coeruleus (LC), which makes projections to neural substrates, such as hippocampus, amygdala, and hypothalamus. The presence of bacterial endotoxins (Lipopolysaccharide, LPS) in blood circulation can result in a set of adaptive behavioral changes referred to as sickness behavior, that prepare the body to cope with viral or bacterial infections. Several mechanisms may be related to central nervous system activation by the peripheral production of proinflammatory cytokines. Previous studies showed that the HO-CO pathway is involved in the regulation of anxiety in healthy animals. Thus, the project aims to evaluate if the HO-CO pathway regulates the anxiety in endotoxemic rats. Male Hannover rats (300g, n = 8 per group; CEUA (# 2017. 1.381.58.4) were anesthetized and submitted to surgery to implant a guide cannula toward to the fourth ventricle. Afterward, rats were divided into groups for the administration of LPS (200µg/kg) or sterile saline (SAL 0.9%) via i.p. and HO enzyme inhibitor, tin protoporphyrin IX (SnPP; 0.005M; 2µL) or vehicle (DMSO 10%) via i.c.v. After 2h, the rats were submitted to the emotional behavior tests, elevated plus maze (EPM) during 5 min or ultrasonic vocalization (USV) over 10 min. The fever was evaluated through the tail skin temperature (TsK) by a thermographic camera (Flir One). ANOVA one-way and two-way followed by Tukey and Bonferroni test were applied, with $p < 0.05$. The results showed a reduction of TsK after 120 min and 180 min of the LPS injection (Bonferroni test; $p < 0.001$). In EPM, LPS+VEHI group presented a decrease in the number of entries into the open arms compared to the SAL + VEHI (Tukey test; $p < 0.05$). The treatment with SnPP reversed the anxiety-like behavior partly since the LPS+SnPP group presented a higher number of heading dipping compared to LPS + VEHI (Tukey test; $p < 0.05$). Furthermore, the i.c.v. treatment with

SnPP (LPS+SnPP group) prevents the emission of USVs (Tukey test, $p < 0.05$). The results showed that LPS induced fever and anxiety-like behavior. Moreover, the HO-CO pathway is involved in the modulation of the emotional behavior in endotoxemic rats, since the treatment with an inhibitor of HO enzyme prevents the LPS effects.

Title: Basolateral amygdala projections to the insular cortex mediate social approach to stressed rats

Authors: *A. DJERDJAJ, N. S. RIEGER, J. P. CHRISTIANSON;
Boston Col., Chestnut Hill, MA

Abstract: Social vocalizations, chemosignals, and behavioral expressions of one's internal affective state shape the selection of social behavior responses made by others who detect these cues. A network of interconnected brain structures called the social decision making network (SDMN) integrates these stimuli and network output yields social behaviors that are appropriate for a given interaction. Deficits in SDMN connectivity underlie several psychiatric disorders such as schizophrenia and autism so further understanding the function of the SDMN may grant us new insight into aberrant social behaviors. The basolateral amygdala (BLA) and the insular cortex (IC) are reciprocally connected and each contribute to social and emotional behaviors. We explored the involvement of BLA projections to the IC in a social affective preference (SAP) test in which a test rat is presented with 2 juvenile conspecifics (PN30), 1 naïve to treatment and 1 stressed via 2 footshocks. Test rats prefer interaction with the stressed juvenile in this paradigm. Chemogenetic inactivation of the BLA via bilateral transduction of AAV-hSyn-hM4D(Gi)-mCherry followed by systemic administration of clozapine-N-oxide (3mg/kg) prior to SAP tests prevented test rat preference for the stressed juvenile. Further, inhibition of IC-projecting BLA neurons via CNO injection directly into the IC also prevented preference for the stressed juvenile. Ongoing investigations include retrograde tracing and Fos immunoreactivity and in vivo Ca2+ imaging of BLA-IC neuron activity during encounters with stressed conspecifics to elucidate the pattern of neuronal activity of BLA projections in the IC. The current results identify a new tract by which social emotional information is processed within the SDMN.

Title: A spino-hypothalamo-habenular pathway mediating aversive behaviors

Authors: *S. LEE, Y. FAN, M. KIM, C. YANG, H. KIM;
Col. of Korean Med., Daegu Haany Univ., Daegu, Korea, Republic of

Abstract: Lateral habenula (LHb), an epithalamic region, is sensitive to aversive stimuli and controls aversive responses through projecting its output to ventral tegmental area which in turn reduces the dopamine release. Lateral hypothalamus (LH), the lateral region of hypothalamus, is also known to regulate aversive responses. Although the LHb has been shown to receive nociceptive inputs, it is not known yet how the somatosensory inputs enter the LHb, which receives input from structures. Thus, the present study attempted to elucidate whether the nociceptive inputs are delivered to the LHb via LH and thus leads to aversive behaviors. To prove it, we utilized extracellular recording, fast-scan cyclic voltammetry, and miniaturized fluorescence microscopy in Sprague-Dawley rats. In *in vivo* extracellular recording, nociceptive stimuli of tail pinch excited most LHb neurons (n=51), which was inhibited by chemical lesion of ibotenic acid in the LH, indicating mediation of LH. When responses of LH neurons (n=68) to tail pinch were recorded, 38 of the recorded neurons (38/68=55%) showed increases in firing rates. It was further confirmed by using the head-mounted miniaturized fluorescence microscopy. In the rats given GCaMP calcium indicators into LH, miniaturized fluorescence microscopy showed spontaneous increase of neuronal activity in response to tail pinch. In the fast-scan cyclic voltammetry, sustained decrease of dopamine efflux in the nucleus accumbens was found in the normal rats after pinching tail for 20 sec, which was abolished in the rats with a

chemical lesion of ibotenic acid in the LH. Our findings suggest that nociceptive inputs enter LHb via spino-hypothalamic pathway in order to generate aversive behaviors.

Title: Ventromedial prefrontal parvalbumin neurons signal active avoidance

Authors: *Y.-Y. HO[1], Q. YANG[2], P. BODDU[3], M. R. WARDEN[1,4];
[1]Neurobio. and Behavior, Cornell Univ., Ithaca, NY; [2]Univ. of Massachusetts Med. Sch., Worcester, MA; [3]Icahn Sch. of Med. at Mount Sinai, New York, NY; [4]Cornell Neurotech, Cornell Univ., Ithaca, NY

Abstract: The medial prefrontal cortex (mPFC) plays an essential role in the suppression of passive behaviors and the facilitation of active behaviors in high-threat environments. mPFC parvalbumin (PV) neurons, which innervate the axon initial segment, cell body, and proximal dendrites of pyramidal neurons, gate mPFC signaling and play an important role in reward and fear extinction, working memory, and the allocation of attention. Here, we investigate the role of ventral mPFC (vmPFC) PV neurons in actions to avoid punishment and to obtain reward in freely moving mice. Animals were placed in an operant chamber and trained to cross to the opposite side of the chamber following an auditory cue. In the avoidance task, crossing the chamber within 5 seconds allowed the mouse to avoid receiving a shock. If the mouse failed to cross, the shock was turned on until escape occurred. In the approach task the mouse was required to cross the chamber within 5 seconds to obtain a water reward, and failure led to an aborted trial. We used fiber photometry to monitor the real-time population calcium dynamics of genetically defined vmPFC PV neurons in freely behaving mice. We injected AAV1-CAG-Flex-GCaMP6f into the vmPFC of PV-cre mice to express a genetically-encoded calcium indicator, and implanted an optical fiber over the vmPFC to monitor calcium-dependent fluorescence.

vmPFC PV neurons were strongly activated immediately prior to and during chamber crossing in successful avoidance trials, but were slightly suppressed during chamber crossing in successful approach trials. In addition, vmPFC PV neurons were active during chamber-crossing movements during the inter-trial interval during avoidance sessions, a response that only emerged after animals had experienced shock. No response to locomotion in the open field or during approach behavior was detected, and neural activity was not correlated with speed of movement. Since the auditory tone was turned off the moment the mouse successfully crossed the chamber, we also recorded neural activity during a modified version of the task, in which short auditory cues were used in some trials and auditory cues persisting beyond chamber crossing were used in others. We found that PV neural responses during shock avoidance were better explained by chamber crossing than by tone termination. Our results reveal that vmPFC PV neurons respond during actions to avoid threats.

Title: Norepinephrine inhibits sensory neuron TRPV1 signaling in a sex- and stress-dependent manner

Authors: *L. V. THANG[1], M. K. MADASU[2], S. SINGH[3], J. GARCIA[4], R. AL-HASANI[6], J. G. MCCALL[5];

Abstract: Exposure to stressful stimuli can suppress or enhance pain, a phenomenon known as stress-induced analgesia or hyperalgesia, respectively. The precise mechanisms of how stress affects pain is unclear. Similar to chronic pain, stress-related psychiatric disorders such as depression and anxiety are highly prevalent with poorly understood pathophysiology. Interestingly, females have twice the lifetime risk for depression and anxiety disorders and have greater pain prevalence when compared to her male counterparts. The exact neurophysiological underpinning for these sex differences is unknown. Chronic pain and stress lead to adaptations

that share significant overlapping physiology such that tricyclic and serotonin/norepinephrine reuptake inhibitor antidepressants are effective in treating chronic pain. Therefore, norepinephrine (NE) is likely one of the key neurotransmitters regulating pain processing during stress. Recent studies showed that activation of alpha 2-adrenergic receptors in the dorsal root ganglion (DRG) inhibits the transient receptor potential cation channel subfamily V member 1 (TRPV1), a polymodal molecular integrator in the pain pathway expressed in Aδ and C fiber nociceptors. However, it is unclear whether NE modulation of TRPV1 signaling is altered during chronic stress and whether this is sex-dependent. In this study, we show that social isolation stress, by singly-housing mice, increases paw-withdrawal thresholds to mechanical and thermal stimuli in both male and female mice. Using calcium imaging, we show that NE inhibits TRPV1 activation in the DRG of male group-housed mice, but not in female group-housed, or singly-housed mice of either sex. Furthermore, TRPV1-mediated calcium mobilization is higher in group-housed male mice compared to singly-housed male mice. This reduction in TRPV1-depdent calcium signaling may help explain the mechanism for social isolation stress-induced antinociception in male mice, but suggests this mechanism is NE-independent in female mice. Better understanding of stress-induced analgesia and its sex differences could aid in uncovering new, more targeted therapeutic targets for the treatment of pain and stress-related disorders.

Title: Midbrain glutamatergic neurons drive locus coeruleus-mediated negative affect

Authors: *K. E. PARKER[1,3], A. R. BUCKLEY[1,3,4], S. L. STEWART[1,3], S. C. HUNTER[2,3,5], J. G. MCCALL[1,3];
[1]Anesthesiol., [2]BP-Endure St. Louis Neurosci. Pipeline Program, Washington Univ. In St. Louis, St. Louis, MO; [3]Ctr. for Clin. Pharmacol., St. Louis Col. of Pharm., St. Louis, MO; [4]Psychological and Brain Sci., Washington Univ. in St. Louis, St. Louis, MO; [5]Emory Univ., Atlanta, GA

Abstract: More than 40,000 Americans commit suicide each year. Many of these victims suffered from stress-induced Major Depressive Disorder (MDD) and anxiety disorders. Many individuals of this susceptible population are particularly at risk, as current monoamine treatments for depression do not alleviate symptoms in a third of MDD patients. Further, many MDD patients have increased expression of N-methyl-D-aspartate (NMDA) glutamate receptors

in the locus coeruleus (LC), the main source of norepinephrine (NE) for the mammalian forebrain. Importantly, the LC is known to modulate stress-induced anxiety and resilience to chronic stress and is certainly positioned be an important modulator of stress-induced MDD. While glutamatergic modulation of LC-NE neurons is often associated with behavioral flexibility and attention, data from suicide victims points to an important role of glutamate signaling in the LC-NE system in modulating affective disorders and opiate withdrawal. Since previous studies have shown that blocking NMDA receptors has rapid antidepressant-like effects in humans and animal models, we investigated the neurocircuitry of traditional monoamine pathways and the role glutamate has in coordinating depressive-like phenotypes in mice. Specifically, we hypothesized that excitatory projections to the LC may modulate behaviors related to stress, depression, and anxiety. Using retrograde tracing techniques, we unveiled a prominent glutamatergic LC afferent projection and examined this newly identified projection using slice electrophysiology, *in vivo* optogenetics, and fiber photometry. Implementing behavioral assays including real-time place testing, elevated plus maze, and the open field test, we determined that this pathway plays a prominent role in mediating the LC's coordination of negative affective behaviors.

Title: Chemogenetic inhibition of neurons in the paraventricular nucleus of the thalamus that project to the nucleus accumbens has an anxiolytic effect on stress-induced anxiety

Authors: *X. DONG, S. LI, G. J. KIROUAC;
Rady Fac. of Hlth. Sci., Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: The paraventricular nucleus of the thalamus (PVT) is a member of the midline and intralaminar thalamic nuclei. Following a detailed analysis of fiber projections made by PVT neurons to its output targets, we found that most PVT neurons innervate the shell of the nucleus accumbens (NAcSh) and that these same neurons send collaterals to a wide range of cortical and subcortical targets associated with negative emotion and motivation, including prelimbic, infralimbic, and insular cortices, bed nucleus of the stria terminalis, the central nucleus of the amygdala. The pattern of the output distribution suggests a role of the PVT in the regulation of

aversion and stress-induced behavioral responses. This view is supported by experimental evidence that shows that the PVT mediates footshock induced anxiety-like behaviors and conditioned fear expression. In addition, projection-specific studies focusing on the PVT to NAcSh pathway have shown that this projection may be involved not only in food and drug seeking, but also in avoidance associated with morphine withdrawal and anxiety-like behaviors. The present study explored the role of the PVT to NAcSh pathway in stress-induced anxiety. We expressed Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) in the form of the inhibitory hM4Di in PVT neurons that project to the NAcSh using an intersectional dual-virus approach. One week after surgery, rats were exposed to an episode of moderately intense footshock (1.5 mA × 2 s × 5) and assigned to either high-responder group (HR) or low-responder group (LR) according to their level of fear (freezing time) in a novel context at 24 h after footshock. Stress-induced anxiety was measured at approximately 2 weeks post-footshock after a treatment of the hM4Di agonist clozapine (0.01mg/kg, i.p.) or saline. HRs showed a higher level of anxiety in a social approach and avoidance test compared to non-shocked animals and LRs. The elevated anxiety level was attenuated in clozapine treated HRs. There was no difference in anxiety levels between LRs and non-shocked rats. Clozapine had no effect on anxiety in LRs and non-shocked rats. Both HRs and LRs showed high level of freezing behavior when they were re-exposed to the shock context and clozapine treatment did not affect the expression of conditioned fear. The result suggests that the PVT to NAcSh pathway is involved in stress-induced anxiety-like behavior but not contextual fear. This study provides evidence for a role of a projection from the PVT to the NAcSh in stress-induced anxiety independent of contextual fear mechanisms.

Title: Extensive divergence of projections from neurons in the paraventricular nucleus of the thalamus to widespread regions of the forebrain

Authors: *S. LI, X. DONG, G. J. KIROUAC;
Rady Fac. of Hlth. Sci., Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: The paraventricular nucleus of the thalamus (PVT) is an important component of the forebrain circuits involved in the mediation of appetitive and aversive behaviors. While the PVT

projects to a number of cortical and subcortical regions, work from our research group has established that the PVT projects most heavily to the shell of the nucleus accumbens (NAcSh), dorsolateral bed nucleus of the stria terminalis (BSTDL) and the lateral and capsular subnuclei of the central nucleus of the amygdala (CeL). Recent experimental evidence suggests that the PVT mediates distinctive behavioral responses in a projection specific manner. For example, a PVT projection to the CeL appears to be involved in conditioned fear whereas a projection to the NAcSh may be involved not only in avoidance associated with morphine withdrawal but also the regulation of food seeking. We have also shown with injections of the retrograde tracer cholera toxin B in a combination of NAcSh, BSTDL and CeL in the same animal that many neurons in the PVT provide collateral projections to NAcSh, BSTDL and CeL. However, the extent of these collateral projections is difficult to accurately determine using retrograde tracing alone. The present study used adeno-associated viruses (AAVs) to further evaluate the amount of fiber collateralization throughout the brain produced by PVT neurons. An AAV that transports in the retrograde direction to express the Cre-recombinase enzyme was injected in one of the target areas innervated by the PVT. Another AAV that is transported in the anterograde direction and transduces GFP in a Cre-dependent manner was injected in the PVT of the same animal. This resulted in GFP labeling of all collateral fibers made by PVT neurons associated with a specific projection. The density of fibers was quantified across all the cortical and subcortical projection targets associated with these injections. The global pattern of innervation to various forebrain regions made by different projection specific PVT neurons (NAcSh, BSTDL or CeL) was essentially the same with the NAcSh, BSTDL, and CeL receiving dense projections from these neurons while cortical and hypothalamic regions receiving less dense innervation. It is also clear that PVT neurons that primarily innervate the CeL or BSTDL send equally dense projection to the NAcSh. These results indicate that most PVT neurons innervate the NAcSh and send collaterals to a wide range of cortical and subcortical targets. How coordinated activity between the PVT and all of its cortical and subcortical targets regulates behavioral responses is unknown and will require innovative experimental approaches to resolve.

Title: Treating psychiatric illness through targeted network disruption and electrical biomarker identification

Authors: M. BILGE[1], A. KANABAR[1], I. BASU[1], ***S. T. OLSEN**[3], M. J. BOGGESS[1], A. ROCKHILL[1], A. K. GOSAI[1], E. HAHN[1], C. CUSIN[1], T. DECKERSBACH[1], Z. WILLIAMS[2], D. D. DOUGHERTY[1], A. S. WIDGE[3];
[1]Psychiatry, [2]Neurosurg., Mass Gen. Hospital/Harvard Med. Sch., Boston, MA; [3]Psychiatry, Univ. of Minnesota, Minneapolis, MN

Abstract: Psychiatric disorders are increasingly understood as dysfunctions of hyper- or hypo-connectivity in distributed brain circuits. A prototypical example is Obsessive-Compulsive Disorder (OCD), which has been repeatedly linked to hyper-connectivity of Cortico-Striatal-Thalamo-Cortical (CSTC) loops. Deep brain stimulation (DBS) and lesions of CSTC structures have shown promise for treating both OCD and related disorders involving over-expression of automatic/habitual behaviors. Physiologically, we propose that this CSTC hyper-connectivity may be reflected in high synchrony of neural firing between loop structures, which could be measured as coherent oscillations in the local field potential (LFP). We have designed an Early Feasibility study in which we use the Medtronic PC+S device to simultaneously record and stimulate in the supplementary motor area (SMA) and Ventral Capsule/Ventral Striatum (VC/VS). Simultaneous recording of both structures lets us test the CSTC coherence hypothesis, while frequency-mismatched stimulation should disrupt that coherence and reduce compulsive symptoms. We report results from the first enrolled patient. Intraoperatively, we observed strong peaks in SMA-VCVS coherence in the theta (5-8 Hz) and alpha (8-15 Hz) bands, consistent with the initial hypothesis. We were further able to monitor SMA-VCVS coherence for over a year, with daily recordings that fluctuated as the patient's clinical status changed. Combined SMA-VCVS stimulation dramatically decreased subjective experience of mood and OCD symptoms, with an approximately 5-point drop in clinical rating scales. Further, there was a marked disruption of SMA-VCVS coherence across the theta and alpha bands, specifically with loop-disrupting stimulation and not with DBS alone. Theta coherence correlated with improvement in symptoms, although we observed stronger effects in the gamma (30-55 Hz) band. We will discuss implications of these results for network modulation more broadly, across the psychiatric disorders.

Title: Alteration of brain connectivity and behavior using a precisely timed electrical stimulation paradigm in a fear regulation circuit

Authors: *M.-C. LO, R. L. YOUNK, E. B. BLACKWOOD, A. E. REIMER, A. S. WIDGE; Psychiatry, Univ. of Minnesota, Minneapolis, MN

Abstract: Information flow in brain networks may depend on the oscillatory synchrony of local field potential (LFP) between regions. For fear-related disorders, the connection between the medial prefrontal cortex (mPFC) and basolateral amygdala (BLA) is particularly important. Theta-band (4-8 Hz) PFC-BLA LFP synchrony correlates with the ability to learn and recall safety memories. Clinical exploitation of this knowledge is limited by the lack of established paradigms to alter inter-area synchrony. This work aims to alter PFC-BLA connectives and assess behavioral outcomes in rodents.

Electrodes with 8 recording channels and one stimulating channel were implanted into infralimbic cortex (IL, the rodent homologue of mPFC) and BLA of Long-Evans rats. Rats underwent fear conditioning and extinction, with bar press suppression and freezing as behavioral measures. On the Extinction day, rats received either SHAM (connected without stimulation, N=10) or paired electrical stimulation (N=10), which delivered pulse trains (100 μA and 90 μs pulse width, 6Hz) simultaneously into IL and BLA with 180^{o} phase lags (IL leading), prior to the extinction session. Electrophysiological signals were recorded throughout the entire behavioral experiment. We measured entrainment of the low-frequency LFP (coherence) and synaptic connectivity changes against baseline. For the ERP measurements, 50 single biphasic pulses (100 uA and 90 μs pulse width) were delivered to either IL or BLA and LFPs from the other region were recorded.

Rats that received paired, theta-frequency electrical stimulation exhibit more effective fear regulation compared to the SHAM group with 1) faster fear extinction rate on the Extinction day (decrease in freezing and bar press suppression) and 2) less fear response on the Recall day. We also expect the paired electrical stimulation to enhance both the coherence in the theta band (4-8 Hz) and top-down synaptic connectivity in the IL-to-BLA direction, both post-stimulation and during extinction and recall sessions.

In summary, we have proposed a paired electrical stimulation technique to alter brain oscillatory synchrony and behavior. This may provide a new technique for neuroscientists to study brain networks. It may provide causal evidence for oscillatory synchrony as a key communicative mechanism. The intervention may eventually lead to more effective therapies for treatment-resistant varieties of psychiatric disorders.

Title: Impact of immediate, pre-learning stress on the acquisition, extinction, and generalization of fear in a fear-potentiated startle paradigm

Authors: *P. R. ZOLADZ[1], M. R. RIGGENBACH[1], J. N. WEISER[1], B. E. MOSLEY[1], J. J. HIPSKIND[1], L. E. WIREMAN[1], K. L. HESS[1], T. J. DUFFY[1], J. K. HANDEL[1], M. G. KASCHALK[1], K. E. RENEAU[1], S. J. HELWIG[1], B. R. RORABAUGH[2], S. D. NORRHOLM[3], T. JOVANOVIC[3];

Abstract: Stress time-dependently affects hippocampus-dependent learning and memory. Stress administered immediately before learning enhances long-term hippocampus-dependent memory, while stress that is temporally separated from learning impairs long-term hippocampus-dependent memory. Limited work has addressed the time-dependent effects of stress on learning that is dependent on other brain areas, such as the amygdala. Therefore, in a set of two experiments, we extended previous work examining the time-dependent effects of stress on learning by assessing the impact of immediate, pre-learning stress on fear conditioning and fear generalization. In both experiments, healthy participants underwent a stress (socially evaluated cold pressor test) or control manipulation immediately before completing differential fear conditioning in a fear-potentiated startle paradigm. In Experiment 1, participants completed extinction and extinction memory sessions 24 and 48 h after conditioning, respectively. In Experiment 2, participants completed generalization testing 24 h after conditioning. Results from Experiment 1 revealed that stress administered immediately before acquisition enhanced baseline startle and fear learning, evidenced by greater fear-potentiated startle to the CS+. Although no group differences were observed during extinction training, stressed participants exhibited evidence of impaired extinction memory 48 h after training. Importantly, stressed participants' cortisol responses to the stressor on Day 1 were positively associated with CS discrimination during extinction and extinction memory testing. Results from Experiment 2 are currently being assessed. Thus far, our findings suggest that stress immediately before fear conditioning results in a stronger, more enduring fear memory, perhaps via corticosteroid activity. Such a paradigm could be useful for understanding factors that influence traumatic memory formation.

Title: Stress that is temporally separated from learning sex-dependently affects long-term memory in a forced confabulation paradigm

Authors: ***K. E. RENEAU**[1], M. R. RIGGENBACH[1], J. N. WEISER[1], L. E. WIREMAN[1], M. G. KASCHALK[1], S. J. HELWIG[1], B. R. RORABAUGH[2], K. E. PAYMENT[1], P. R. ZOLADZ[1]; [1]Psychology, Sociology, & Criminal Justice, [2]Pharmaceut. & Biomed. Sci., Ohio Northern Univ., Ada, OH

Abstract: Stress exerts time-dependent effects on learning and memory. Stress administered immediately before learning enhances long-term memory, while stress that is temporally separated from learning impairs long-term memory. Research examining the time-dependent effects of stress on false memory formation is limited. We previously reported that stress administered immediately before learning prevented false memory development in participants who exhibited a blunted cortisol response to the stressor. In the present study, we examined the impact of stress administered 30 min before learning on false memory development in a forced confabulation paradigm. We predicted that stress temporally separated from learning would impair the storage of a witnessed event and increase participants' susceptibility to false memory development. Eighty-six participants underwent a stress (socially evaluated cold pressor test) or control manipulation 30 min before viewing an 8-min excerpt from the Disney movie *Looking for Miracles*. The next day, participants were interviewed and asked questions about the video, some of which forced them to confabulate responses. Three days and three weeks later, respectively, participants completed a recognition test in the lab and a free recall test via email. Results revealed a robust misinformation effect, overall, as participants falsely recognized a significant amount of confabulated information as having occurred in the original video. Stress, overall, did not significantly influence this misinformation effect. However, participants' cortisol responses to the stressor were positively associated with the recall of confabulated information. Moreover, stress impaired the recognition of actual events that occurred in the video in males, while enhancing such recognition in females. These findings suggest that stress-induced increases in cortisol might result in greater recollection of misinformation. They also indicate

that stress temporally separated from learning selectively impairs memory accuracy in males and enhances memory accuracy in females, which is consistent with previous research from our laboratory.

Title: Impact of stress and the timing of misleading questions on false memory formation

Authors: *M. R. RIGGENBACH[1], B. R. RORABAUGH[2], K. E. PAYMENT[1], P. R. ZOLADZ[1];
[1]Psychology, Sociology, & Criminal Justice, [2]Pharmaceut. & Biomed. Sci., Ohio Northern Univ., Ada, OH

Abstract: Stress can enhance, impair, or have no effect on learning and memory. One factor that determines the type of effect that stress exerts on learning and memory is the timing of the stress relative to learning. When stress is administered around the time of learning, long-term memory is generally enhanced; when stress is temporally separated from learning, long-term memory is generally impaired. Research examining the impact of stress on false memory formation has been conflicting. It is possible that the timing of stress relative to the acquisition of misinformation could influence false memory development. Thus, we examined the time-dependent influence of stress on the misinformation effect in a forced confabulation paradigm. Seventy-three participants (31 males, 42 females) submerged their hand in a cold (stress) or lukewarm (no stress) water bath and then watched a 9-min excerpt from *Return of the Pink Panther*. Ten or twenty-five minutes after the water bath manipulation, participants were asked questions about the video, some of which forced participants to confabulate answers. Salivary cortisol levels were assessed before and after the water bath in order to evaluate stress-induced alterations of cortisol levels. Twenty-four hours later, participants were given a memory test that asked them to determine which events actually occurred in the video and which did not. They were also asked to provide a confidence rating for each answer. Three weeks following the memory test, participants were contacted via email to complete a free recall test. Overall, participants exhibited a misinformation effect and recognized a significant amount of false information as having actually occurred in the original video. There was no significant effect of stress on false memory formation. However, participants who were interviewed 25 min after the

water bath manipulation recognized significantly more false information as having occurred in the original video than participants who were interviewed 10 min after the water bath manipulation. These findings suggest that interviewing individuals closer in time to a witnessed event decreases their susceptibility to identifying false information as having occurred in the witnessed event.

Title: The effects of mindfulness-based interventions on sustained attention and inhibitory control

Authors: *E. M. MOHR[1], T. BRANDMEYER[3], R. HECHT[3], R. S. GUPTA[4], P. L. A. SCHOENBERG[1], D. R. VAGO[2];
[1]Physical Med. & Rehabil., [2]Physical Med. & Rehabilitation; Psychiatry & Behavioral Sci., Vanderbilt Univ. Med. Ctr., Nashville, TN; [3]Sch. of Med., Univ. of California, San Francisco, San Francisco, CA; [4]Vanderbilt Univ., Nashville, TN

Abstract: Mindfulness-Based Interventions (MBIs) are a family of standardized cognitive and behavioral therapies that focus on cultivating mindfulness-related skills for improving maladaptive cognitive, emotional, and behavioral processes. MBIs have been developed for a wide range of problems, disorders, and populations and are increasingly available in a variety of health settings. Empirically supported MBIs include acceptance and commitment therapy (ACT), dialectical behavior therapy (DBT), mindfulness-based cognitive therapy (MBCT), and mindfulness-based stress reduction (MBSR). As the empirical evidence for the efficacy of these interventions continues to grow, the importance of investigating the mechanisms or processes by which they lead to beneficial outcomes is increasingly recognized. The purpose of the present study was to investigate the behavioral and cognitive mechanisms by which MBIs may improve health outcomes. Specifically, we sought to examine engagement between MBSR, perceived levels of stress, and performance on an emotional variant of a Go-NoGo task. Individuals with moderate to high levels of stress will be recruited (n=30). Perceived levels of stress, measured by the Perceived Stress Scale (PSS), and performance on an emotional Go-NoGo task will be assessed before and after MBSR. The Go-NoGo task included 600 negative, positive, and neutral

words. Although data is still being collected, preliminary post-MBSR testing showed a decrease in stress levels. Post-testing also showed performance changes in the Go-NoGo task. Preliminary data showed an increase in hit rates for negative, positive, and neutral words, and a decrease in false alarm rates for negative, positive, and neutral words. Results also showed a decrease in reaction times for negative and positive words, and an increase in reaction times for neutral words. These preliminary results suggest MBSR targets self-regulatory mechanisms, leading to changes in perceived stress.

Title: Can EEG explain obesity-related cognition during exercise?

Authors: *J. BENAVIDEZ[1], C. DY[1], H. TRAN[1], M. MIYAKOSHI[2], S. KESLACY[1]; [1]Sch. of Kinesiology & Nutritional Sci., California State University, Los Angeles, Los Angeles, CA; [2]Swartz Ctr. for Computat. Neuroscience, Inc, UCSD, La Jolla, CA

Abstract: Introduction: A developing body of evidence depicts that obesity may induce damaging effects to brain health, decreasing cognitive performance & increasing the risk of dementia. Exercise may be one of few prophylactic strategies against cognitive decline. However, it is still unknown if exercise has a beneficial effect on obesity-related cognition. Additionally, robust measurements of brain activity remain difficult but could give insight to possible mechanisms that are induced by obesity. This study aims to determine if exercise affects cognitive performance and brain activity in healthy-obese (HO) compared to healthy non-obese (HNO). We hypothesize that HO will have a difference cognitive performance during exercise compared to HNO. Methods: 15 healthy male adults, 10 (HNO BMI<30) & 5 (HB BMI>30) with average age 24 ± 3 y.o. have participated in this study. During a 1st visit, participants completed health-questionnaires, anthropometric measures, familiarization with Stroop task, and a VO2max (Cosmed Quark-CPET) to determine peak performance. On the 2nd visit, EEG was recorded during a resting condition (5-min eyes closed), baseline Stroop (Strp1), Stroop during

steady-state exercise (Strp2) at 50% of VO2max on a Lode Sport Excalibur (20 min.) & lastly a post exercise Stroop (Strp3). EEG was measured by Mobita TMSi, sampled at 250Hz using 10-20 international system recorded at 24 sites including 2 EOG artifact electrodes. Data was acquired on Biopac Acqknowledge Software 4.2 & offline analysis will be performed on EEGLAB12.1.2b. Stroop was performed using the Psychtoolbox-3 for 20 trials recording RT (sec) and errors (ER). Results: HNO have a greater VO2max vs HO (47.76 ± 3.84 ml.kg.min-1 vs 33.68 ± 3.05 ml.kg.min-1; $p<0.05$). Error were lower for NO vs HNO before exercise (7.6 vs 1.5ER; p=.01). Results of comparing HNNO showed a faster RT and less ER compared to s HNO during exercise (243.09s vs 323.91s; p=.031 & 4.3 vs 10.6; p=.001). After exercise, HO showed more errors than HNO (5.2 vs 3.0ER; p=.04). Conclusion: This study is the first to demonstrate differences in the effect of exercise on obesity and brain performance. EEG data will provide insight on possible mechanisms. Our preliminary data are promising in dissecting the role of exercise on obesity related brain function.

Title: Disentangling the effects of subjective task load and task performance on neuroendocrine stress response

Authors: *K. LAFOLLETTE[1], B. C. SATTERFIELD[2], M. LAZAR[2], W. D. S. KILLGORE[2]; [1]Psychiatry & Behavioral Sci., Stanford Univ., Stanford, CA; [2]Psychiatry, Univ. of Arizona, Tucson, AZ

Abstract: Introduction: Subjective task load, the perceived demands for resources to engage in a task, are often conflated with stress response and actual task performance. While recent efforts have laid the groundwork for disentangling stress and performance from mental/cognitive load, few studies have considered other variants of task load, such as time and performance pressure. Here we investigated the effects of objective task performance and subjective task load on cortisol stress response. We hypothesized that task load would significantly predict stress response and that task performance relevant to the loading variant would partially mediate this relationship.
Methods: 120 adults (62 F; 21.6±3 yrs) completed three neurocognitive assessments as part of a

prolonged assessment battery (two-stage reinforcement learning, response inhibition, and tapping tasks) and psychosocial stressor. The NASA Task Load Index was administered following the neurocognitive assessment block to assess subjective task load. Saliva samples were collected twice upon arrival and once immediately after task administration to assess changes in cortisol stress response. Multiple regression models were used to predict stress reactivity using task loadings as predictors. Post-hoc mediation analyses included objective performance metrics that were determined to be associated with the loadings.
Results: Linear regressions demonstrated that mental, physical, and performance-based task load significantly predicted stress response ($F>4.1$, $p<0.05$). Subsequent models determined *mental load* significantly predicted model-free strategy and *performance load* predicted both money earned and model-free strategy on the two-stage task ($F>4.28$, $p<0.04$), while *physical load* was found to predict total number of taps and reaction time on the tapping task ($F>5.07$, $p<0.03$). Task loadings were not predictive of performance on the response inhibition task. Post-hoc causal mediation analyses determined that none of the direct effects of task load on stress reactivity were mediated by objective task performance ($abs(b)<0.15$, $p>0.84$).
Conclusions: These findings suggest that stress reactivity during performance can be predicted by a number of subjective task loading variants. Furthermore, the effect of these loads is not explained by standard metrics of objective task performance. Such findings emphasize the importance of subjective experience during task performance beyond the scope of task yields, with implications for a wide array of applications, such as the teaching of new skills or performance assessment.

Title: Environmental pollutants influence stress hormone and memory: Implications to brain health in human aging

Authors: *J. N. SOUZA-TALARICO[1], P. PLUSQUELLEC[3], S. J. LUPIEN[4], F. C. SILVA[2], D. SUCHECKI[5];
[1]Dept. of Medical-Surgical Nursing, Sch. of Nursing, Univ. of São Paulo, Sao Paulo, Brazil; [2]Dept. of Medical-Surgical Nursing, Sch. of Nursing, Univ. of São Paulo, São Paulo, Brazil; [3]École de Psychoéducation, Univ. de Montréal, Montreal, QC, Canada; [4]Dept. of psychiatry, Univ. of Montreal, Montreal, QC, Canada; [5]Univ. Federal de Sao Paulo, Sao Paulo, Brazil

Abstract: Background: Chlorinate pollutants still have wide industrial and commercial applications despite evidence regarding their negative effects on human. For decades the endocrine disruptive effect of the chlorinate pollutants has been demonstrated in the gonadal system. However, endocrine disruptors are capable of interfering on steroids hormones implying that chlorinate pollutants may act on cortisol concentration by disrupting the hypothalamic-pituitary-adrenal (HPA) axis and therefore impairing memory performance through impact on hippocampus, the main neuronal structure responsible for the HPA axis negative feedback. However, there is no evidence to support that. This is a relevant issue since HPA dysfunction is associated with vulnerability to several disorders including those related to brain and cognition. **Objective**: to analyze the influence of chlorinate pollutants on diurnal cortisol concentration and memory performance in older adults. **Methods**: Using a cross-sectional study design, polychlorinated biphenyls (PCB) and organochlorine (OC) pesticide concentrations, known chlorinate pollutants, were determined from blood samples of 128 cognitively healthy older adults (83.6% female; Age: M=65.8, SD±7.9; Years of education: M=9.7, SD±4.4). Salivary cortisol was collected at home over 2 days at awakening, 30 min. after waking, afternoon (~3PM) and evening (~10PM) periods. Declarative memory was assessed using the California Verbal Learning Test (CVLT). **Results**: Multivariate regression (MR) analysis, controlling for gender, age and education, revealed a significant PCB effect on diurnal cortisol concentration (β= -0.241, R^2 = 0.103; p = 0.002). Similarly, PCB (β= -0.205; p = 0.022) and OC compounds were negatively associated with low CVLT scores (β = -0.293; p = 0.001), explaining 9% of the memory performance variability in the MR model (R^2 = 0.09; p = 0.001). **Conclusion**: Environmental chlorinate pollutants may influence cortisol and memory during aging. Our findings may set the stage for longitudinal studies investigating whether cumulative exposure to chlorinate pollutants represent a risk factor for stress-related and cognitive disorders later at life and therefore to sustain public policy strategies to control environmental contaminant exposure aiming the brain health promotion during aging.

Title: Predicting real-life stress reactivity from the effects of acute stress on brain function

Authors: *R. TOUTOUNJI[1], B. KAPTEIJNS[1], M. KRENTZ[1], F. KRAUSE[1], L. D. DE VOOGD[2,1], E. VASSENA[1], E. J. HERMANS[1];
[1]Donders Inst. for Brain, Cognition, and Behaviour, Radboud Univ. Med. Ctr., Nijmegen, Netherlands; [2]Dept. of Psychology & Ctr. for Neurosci., New York Univ., New York, NY

Abstract: Rationale
Acute stress affects the brain on multiple levels, including that of large-scale brain networks. Research has implicated the salience (SN), executive control (ECN), and default mode (DMN) networks in this process. These effects have also been shown to be time dependent, varying across the duration of the stress response, while also resulting in different behavioral changes across the time course. This evidence stems from multiple, cross-species studies, however, the full extent of the effects of stress on these networks in humans has not been investigated. Furthermore, individual stress reactivity can vary greatly from person to person. This inter-individual difference can be seen in reactivity to daily life stressors. Here, we investigate whether the temporal dynamics of the neural response to acute stress can predict stress reactivity in daily life.
Methods
One-hundred medical students will be recruited. Participants undergo two, counter balanced fMRI sessions: a stress session, with acute stress induction implemented with the socially evaluated cold pressor test (SECPT), and a control session. During scanning, 3 tasks are performed, known to elicit activity in the SN (oddball), DMN (associative memory), and ECN (2-back), intermixed with resting state blocks, and physiological monitoring. Participants also undergo experience sampling during an exam (i.e. stress) and a non-exam (i.e. control) weeks. Survey data and physiological measures will be acquired using smartphones and wristbands, allowing for the investigation of real-life stress during both weeks.
Results
Initial results (n=39) show a significant increase in self-reported stress measures during the stress week (event, activity, mood, and social stress; all $P<0.01$; but not physical stress), thus validating an exam week is more stressful than a non-exam week. Preliminary fMRI analyses (n=16) confirm that the employed tasks recruit the SN, DMN, and ECN networks, and confirm increased stress responses to the SECPT, shown by decreased heart rate variability. Further analyses will focus on linking subjective stress with physiological stress measures acquired in real life. Importantly, we will investigate how the effects of stress on brain function predict real-life stress reactivity.
Conclusions
Current results confirm the validity of our real-life stress reactivity measures, including variability in real-life stress reactivity, which is essential to examining inter-individual differences. Analysis of fMRI data show that the tasks are engaging the corresponding networks

This study will yield insight into the biological basis of stress sensitivity and reactivity in real life.

Title: Relationship between academic stress and heart rate variability (HRV) patterns for college athletes

Authors: *N. RAJ[1], M. DITOMMASO[1], A. JOHNSON[2], R. E. JOHNSON[1];
[1]Mechanical Engin. and Bioengineering, [2]Data Sci., Valparaiso Univ., Valparaiso, IN

Abstract: Stress is common in college students, and can cause low academic performance, depression, and anxiety. Student athletes typically experience higher stress levels due to rigorous training, travel schedules, and competition [1]. Some level of stress is healthy: performance peaks at an optimum level of stress called eustress. But as stress increases, performance and health decline and burnout can occur [2]. One strategy for monitoring physiological stress is to measure heart rate variability (HRV). HRV is often used in athletics to monitor training load and recovery; however, for many student athletes, the effects of academic stress may confound these results and is less well studied. To properly interpret HRV patterns and optimize training, we need to better understand the physiological effects of academic stress on student athletes.
In this experiment we studied the relationship between perceived stress and HRV in college athletes. Perceived stress was measured using a daily survey where athletes indicated their stress on a scale from 1 (very stressed) to 5 (not stressed). HRV was measured using a chest belt heart rate monitor from Firstbeat Technology, with which athletes recorded five minutes of data soon after waking up each morning. This data was used to calculate a Recovery Index (ranging from 0 to 100%), which estimates how fully athletes have recovered from training and how well the autonomic nervous system is functioning [3]. 27 players on an NCAA Division I women's soccer team participated in this study, which was approved by the Valparaiso University IRB. Data was collected from Aug. to Oct. in 2017.
We found that perceived stress significantly affected the HRV-based Recovery Index. When athletes rated their stress as a 2, the median Recovery Index was 47.3%. When athletes rated their stress as a 3, the median Recovery Index was 55.3%. Stress levels 4 and 5 had a median Recovery Index of 57.3% and 57.8%, respectively. In summary, higher perceived stress was linked to lower HRV and decreased recovery. These results suggest that academic stress can

have a significant effect on the physiological recovery of college athletes.

Abstract: Dynamic adaptation to stress is essential for coping with daily life challenges and chronic stress. Stress reactivity is regulated in the central nervous system through coordinated activity in limbic and prefrontal brain regions, such as the amygdala, hippocampus, and ventromedial prefrontal cortex (vmPFC). Previous studies have shown changes in functional connectivity (FC) between these regions both after exposure to childhood stress and during acute stress, but it remains unknown whether these two factors interact. In current study, we therefore investigated the interactive effects of childhood stress and acute stress on prefrontal FC during rest. We furthermore explored if such interactions could be mediated by altered HPA-axis function. 120 healthy volunteers underwent resting-state functional MRI (7 min) after a standardized stress induction and control procedure. All participants completed the childhood trauma questionnaire (CTQ), and saliva samples were collected five times to assess HPA-axis function. BOLD-fMRI voxel time courses were extracted and averaged for bilateral amygdala, hippocampus and ventromedial prefrontal cortex (vmPFC). FC was calculated using (Fisher's z transformed) pairwise Pearson's correlations after correction for motion and physiological nuisance variables. FC data were analyzed using repeated-measures ANOVAs with stress as within-subject factor, and non-parametric correlations (for differential FC, CTQ scores and salivary hormone levels) was carried out. The results showed acute stress decreased hippocampus-vmPFC resting-state FC compared to the neutral control session. This decrease

was qualified by an interaction with CTQ score, indicating that the reduction of FC in these circuits was exacerbated in individuals with higher CTQ scores. CTQ scores were furthermore negatively associated with basal cortisol levels. However, we found no evidence that basal cortisol (partially) mediated the interaction between CTQ scores and differential FC between these regions. Our findings show that exposure to stressful life events during childhood alters the neural response to acute stress in neural circuits known to be involved in stress adaptation and emotion regulation in a sample of healthy volunteers recruited from a student population. In line with earlier studies in several patient populations, childhood adversity was also associated with blunted basal HPA-axis function. Although we found no statistical evidence of mediation in this relatively healthy sample, future research should address the question whether blunted HPA-axis during development plays role in altering central response to stressors.

Title: Evaluation of stress-reducing interventions in an undergraduate student population: Perceived stress, blood pressure, frontal EEG asymmetry, and salivary immunoglobulin-alpha

Authors: L. ANDERSEN[1], S. GOWAN[2], B. RONNESTRAND[1], B. TAYLOR[3], *M. WONG[1]; [1]Psychology, [2]Biol., [3]Microbiology, Univ. of Wisconsin-La Crosse, La Crosse, WI

Abstract: High levels of stress are reported by undergraduate students globally, but how do we combat student stress? Mindfulness meditation is commonly used to reduce stress. Here we aim to investigate the relative effectiveness of different forms of stress-reducing interventions compared to mindfulness meditation. In our first study, all participants were undergraduate students at the University of Wisconsin-La Crosse. Participants in our first study either completed a mindfulness meditation exercise (n = 30) or played Flower (n = 29), a simple instruction-free video game, for 20 minutes. There is some suggestion from the literature that an instruction-free game that requires little training may be effective for stress reduction. Before and after each intervention, we recorded participant self-perceived stress (using an abbreviated, modified version of the Psychological Stress Measure-9) and measured participant heart rate and blood pressure. Preliminary data analyses revealed a statistically significant (pre to post) reduction across all measures of stress ($p < 0.05$), but no statistically significant difference between playing Flower and meditating. We next wondered how another type of stress intervention, listening to a stress management audiobook, compares to mindfulness meditation in

reducing student stress. In this second, ongoing study, we wish also to investigate what effects, if any, these two forms of stress interventions have on the nervous and immune systems. To assess the effect stress has on the nervous system, we are using electroencephalography to examine the relative left versus right frontal lobe alpha-wave asymmetry. Greater left than right alpha-wave asymmetry is indicative of a more relaxed state of mind. To assess the effect stress has on the immune system, we are using an enzyme-linked immunosorbent assay to quantify the level of the antibody immunoglobulin-alpha (IgA) present in participants' saliva. Higher levels of IgA are indicative of a stronger immune system. Given the results of the first study, we hope the second follow up study will elucidate the neurophysiological and immunological effects of stress-reducing interventions on undergraduate students.

Title: Silver brain: Forget bingo, start virtual cardio

Authors: *H. TRAN[1], T. ESGUERRA[1], E. PUENTE[1], A. MUNOZ[1], V. GONZALEZ[1], S. KESLACY[2];
[1]California State Univ. of Los Angeles, Los Angeles, CA; [2]Kinesiology, CSULA, Los Angeles, CA

Abstract: Aging is the most important risk factor for cognitive decline, partly due to the attenuation of brain oxygenation. Exercise enhances muscle oxygenation but has not being shown to increase brain oxygenation. The emergence of Virtual Reality (VR) technology could prove to be meaningful and relevant to stimulate the brain. There is a lack of studies on the effect of VR and exercise on cerebral and muscle oxygenation across ages. **Purpose:** to assess the effect of VR on exercise-induced change in cerebral oxygenation in elderly.We hypothesized that there would be a greater augmentation of cerebral oxygenation ($CerO_2$) in the prefrontal cortex (PFC) while cycling with VR compared to the No-VR condition for the elderly. **Methods:** Both young male and female participants (n=4, 23±2 years) and old male and female participants (n=4, 55±25 years) first performed a graded VO_{2max}test on a cycle ergometer (828E, Monark) and returned to the lab to perform the VR paradigm. The VR test was performed on a stationary bicycle made to synchronize with a cycling game (VR bike, ViRzoom). Participants wore a virtual reality headset (Playstation 4, Sony) and cycled at a moderate intensity (60% of Pmax). Near-infrared spectroscopy (NIRS, Artinis Oxymon MkIII) was used to measure O_2Hb,

deoxyhemoglobin (HHb), and total hemoglobin (tHb) from the left and right frontal brain cortices (LFC, RFC) and the right vastus lateralis (RVL) muscle.**Results:** BrainO_2Hb mean values increased with exercise. The right frontal cortex O_2Hb increased with VR, but there was no difference for the left frontal cortex (RFC 6.1 vs 10.4; LFC 9.3 vs 9.4 fold). Muscle O_2Hb decreased (13.1 vs 11.6 fold) with VR. Brain HHb increased with VR in the LFC (RFC -10.6 vs 11.5 and LFC -4.8 vs 1.0) while muscle HHb decreased (-1.3 vs. 27.6 fold). There was a trend for tHB to decrease for both muscle and brain during exercise with VR.We will compare young adults and elderly.**Conclusion**: Our preliminary data are promising, and we hope to provide an alternative approach to increase cerebral stimulation and to contribute additional understanding on the cerebral and muscle hemodynamics of exercise in VR milieu and affect cognitive decline in the aging population.

Abstract: Most people have experienced a stressful period of time during their life, however the way each person reacts to stress is unique for each individual. Some can recover from a stressful period fast without any physical or mental consequences, while others find it difficult to get back to high level functioning or take longer to do so. This study aims to identify biomarkers that can be used to quantity stress-reactivity between resilience, the ability to overcome stress, and vulnerability, the failure to overcome stress, for an individual. In an animal study, candidate blood RNA markers for stress responsiveness were identified from rat less stress-reactive and more stress-reactive rat strains using their memory changes after prolonged stress as indicators of their cognitive stress-reactivity. By aligning these memory changes with transcriptional consequences of stress in these strains, biomarkers that showed parallel significant changes between blood and the hippocampus were selected. The present study applies these findings to human subjects. Serum samples from Air Force trainees were obtained before, during, and after

intensive physical and mental training. This training represents repeated, prolonged stress to the trainees. Serum protein concentration of the candidate blood markers of stress were quantified across the training. Results show that individual variations in response to stress are large and that each subject's individual trends in biomarkers compared to other biological markers measured throughout the period of training can be associated with their overall evaluation in the training.

Abstract: Cardiovascular risk factors in aging populations increase the risk for Alzheimer's disease (AD). Breath and heart rate are linked and influence one another. Breathing exercises, including breathing at 6 breaths per minute (bpm) can calm the autonomic nervous system (ANS) and modulate cardiac function. We investigated whether five minutes of breathing at 6bpm affected cardiac and ANS measures in 23 older women with cardiovascular risk factors (mean age=68.91, SD=10.8). Participants completed the perceived stress scale and underwent respiratory and electrocardiogram (ECG) recording for five minutes at rest and slow breathing each. BioPac equipment and Acqknowledge software 5.0 were used to compute exhale/inhale ratio, R-R intervals, heart rate (HR), sympathetic-vagal balance, respiratory sinus arrhythmia (RSA) and sympathetic and vagal tones. We used non-parametric Spearman's correlation coefficients and paired-samples Wilcoxon ranked tests (rest vs. slow breathing). Perceived stress correlated negatively with resting exhale/inhale ratio (rho=-.53, p=.02). Breath rate significantly slowed with paced breathing (Z=-4.14, p<.001). R-R interval and HR remained stable (ps>.09), while RSA increased (Z=3.33, p=.001) and sympathetic-vagal balance decreased with paced breathing (Z=2.9, p=.004). Sympathetic tone increased (Z=2.98, p=.003) and vagal tone decreased (Z=-2.98, p=.003). The change in exhale/inhale correlated with RSA change, i.e.

participants who showed the largest reduction during slow breathing, increased the most in RSA (rho=.49, p=.047).
In sum, older women with risk factors associated with AD, show larger exhale/inhale ratios with lower perceived stress. Breathing at 6bpm rendered heart rate unchanged but reduced vagal activity, while increasing sympathetic tone. Higher resting exhale/inhale corresponded to increased vagal tone during slow breathing. Slow breathing may not benefit this at risk group. Training and longer interventions, as well as a control group are required to optimize vagal activity in this population.

Title: Investigating technostress from a neurobiological perspective: Results of a neurois research program with a focus on field studies

Authors: R. RIEDL, ***T. FISCHER**;
Univ. of Applied Sci. Upper Austria, Steyr, Austria

Abstract: Neuro-Information-Systems (NeuroIS) relies on neuroscience and neurophysiological knowledge and tools to better understand the development, use, and impact of information and communication technologies (ICT) (Riedl, Fischer, & Léger, 2017; Riedl & Léger, 2016). A major topic in NeuroIS research is *technostress*, defined as stress that results from both the use of ICT and the pervasiveness and expectations of ICT use in society in general (Riedl, 2013). In previous technostress research, a strong focus on self-report measurement (e.g., survey) is observable (Fischer & Riedl, 2017), which is problematic as pointed out by Riedl (2013, p. 19), who writes: “[B]efore humans even begin to consciously perceive negative effects of stress ⋯, about which they could give an introspective account in self-reports, it is often the case that biological systems ⋯ have already started to act in the body...” Against this background, in our research program on technostress we use neurophysiological tools and measures, in particular those related to measurement of autonomic nervous system activity and we concentrate on the investigation of technostress in the field (in organizational environments) as most existing studies were conducted in laboratory settings. In a case study with 16 participants, we tracked individual stress over a period of three weeks based on blood pressure and heart rate variability. While we did not find any significant changes in blood pressure due to stress, we found changes in sympathetic (represented by LF/HF ratio of heart rate) and parasympathetic activity (represented by RMSSD of heart rate). In a recent field experiment, we investigated the effect of technological unreliability (e.g., non-availability of websites) on heart rate. A major result of this preliminary evidence is that we observed time-related changes, in particular habituation to stressors. It will be rewarding to see what insight future neurophysiological research will reveal on technostress. Fischer, T., & Riedl, R. (2017). Abstract: Although useful *in vitro* models of psychiatric disorders such as bipolar disorder (BP) and schizophrenia (SCZ) are required for pathological analysis and drug discovery, it is difficult to establish good *in vitro* models because of the heterogeneity of these disorders. In the present study, in attempt to establish *in vitro* models recapitulating the characteristics of these disorders, we performed the phenotype analysis using patient-derived induced pluripotent stem cells (iPSCs). To overcome the phenotypic variations, we focused on the patients with copy number variations (CNVs) which are expected to be highly contributive factors affecting the onset and treatment resistance. Thus, we established iPSCs from BP and SCZ patients with novel CNVs: two BP patients with *PCDH15* heterozygous exonic deletion and one SCZ patient with *RELN*

heterozygous exonic deletion. We differentiate iPSCs into neurons by two methods: dual-SMAD inhibition and overexpression of transcriptional factors. Immature neurons from patient-derived iPSCs induced by dual-SMAD inhibition showed abnormalities of neurite extension. Then, we differentiated iPSCs into both glutamatergic and GABAergic mature neurons separately and efficiently by overexpressing different set of transcriptional factors. We performed immunocytochemical analysis and found that both types of induced neurons from both patients-derived iPSCs exhibited similar phenotypes in dendrite and synapse formation, which are similar to the previously reported findings observed in the postmortem brains. These results suggest that our *in vitro* model may reflect general phenotypes of these disorders. Now, we are investigating the genotype-phenotype causal relationship using genome-edited isogenic iPSCs.

Title: Emotional control in bipolar disorder type 1: An mvpa analysis of fMRI data

Authors: *F. KONDO[1,3], J. C. WHITEHEAD[1,3], F. CORBALÁN[3], S. BEAULIEU[2,3], J. L. ARMONY[2,3];
[1]Integrated Program in Neurosci., [2]Dept. of Psychiatry, McGill Univ., Montreal, QC, Canada; [3]Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada

Abstract: Background: Bipolar disorder type-I (BD-I) patients are known to show emotion regulation abnormalities. In a previous fMRI study using an explicit emotion regulation paradigm, we compared responses from 19 BD-I patients and 17 matched healthy controls (HC). A standard GLM-based univariate analysis revealed that BD patients showed increased activations in VLPFC when instructed to decrease the emotional response elicited by neutral images indicating BD patients engage this region even when emotion regulation is not necessary. Also, BD patients showed sustained amygdala response to all negative images regardless of instruction. **Methods:**We reanalyzed explicit emotion regulation data using a multivariate pattern recognition approach, as implemented in PRONTO. The original experimental paradigm consisted of a full 2 × 2 factorial design, with valence (*Negative/Neutral*) and instruction (*Look/Decrease*) as within subject factors. **Results:**The multivariate models were able to accurately classify different task conditions when HC and BD were analyzed separately (63.24 % - 75.00 %, p =0.001 to 0.012). In addition, the models were able to correctly classify HC vs BD with significantly above-chance accuracy for "Decrease" conditions (58.61 % - 60.84 %, p =0.003 to 0.014). Also, the results for HC vs BD classification demonstrated an involvement of several frontal and occipital regions, as well as other cortical regions, including inferior parietal lobe, to the classification.**Conclusion:**Our multivariate analysis successfully reproduced some of the results obtained in our previous univariate analysis, confirming that these findings are not dependent on the analysis approach. In particular, both types of analysis suggest that there is a significant neural pattern difference between conditions within each subject group, and also between HC and BD during "Decrease" conditions, indicating that BD shows distinct patterns of neural activity from HC when engaging in cognitive control.

Title: Gamma band auditory steady-state responses in bipolar disorder patients

Authors: *N. ORIBE[1], Y. HIRANO[2], S. HIRANO[3], T. ONITSUKA[3], T. UENO[4];
[1]Hizen Psychiatric Ctr., Saga, Japan; [2]Neuropsychiatry, [3]Kyushu Univ., Fukuoka, Japan; [4]Hizen Psychiatry Ctr., Kanzaki-Gun, Japan

Abstract: Gamma band auditory steady state response (ASSR) especially to 40Hz stimuli have been reported to be consistently abnormal and considered to be a robust biomarker in schizophrenia patients. However, the ASSR deficits in patients with bipolar disorder have not been investigated enough. We previously reported abnormal ASSR to 30, 40 and 80 Hz stimuli in Patients with bipolar disorder using magnetoencephalography. In the current study, we measured ASSR responses in bipolar disorder patients (BP, N=13), as well as in patients with major depressive disorder (DP, N=5) and healthy control subjects (HC, N=41) while presenting click trains varying in rate of stimulation (20, 30, 40 and 80 Hz) using electroencephalography(EEG). EEG-evoked power and phase locking were obtained in response to each stimulation frequency.
BD showed significant reduction in phase locking to the 40Hz stimuli compared with HC while DP showed intact responses both in phase locking and evoked power to the 40Hz stimuli. There were no significant group differences in responses to other frequency bands.Our findings suggest that 40 Hz phase locking are impaired in Bipolar disorder.Patients with major depressive disorder didn't show ASSR deficits in our sample.Further investigation with larger samples will be required to elucidate these results.

Abstract: Background. Bipolar disorder is a psychiatric disease characterized by high genetic heterogeneity. It is believed that there is a genetic component to bipolar disorder, but genomic variations that strongly and directly contribute to bipolar disorder are not still specified, and the pathophysiology of bipolar disorder is also not fully understood. Recently, patient-derived induced pluripotent stem cells (iPSCs) with genetic variations having large effects on the development of neuropsychiatric diseases are expected to be cellular disease models. However, iPSC disease models with specific genomic causes of bipolar disorder remain absent. Here, to establish novel iPSC disease models of bipolar disorder with a strong genetic component, we surveyed pedigrees with multiple patients of bipolar disorder in Okinawa, the southern islands in Japan, and performed comprehensive genomic analysis and generated iPSC lines.
Results. We found a large family with an autosomal dominant inheritance pattern of bipolar disorder and recurrent depressive disorder in an isolated island of Okinawa. We obtained informed consent from participants and collected blood samples of 8 affected and 8 unaffected individuals. Parametric linkage analysis detected a significant linkage peak in a chromosome region which previous studies repeatedly reported link to bipolar disorder and depression. Whole genomic sequencing-based haplotype phasing determined an extremely rare haplotype shared among affected individuals of the pedigree in the chromosomal linkage region. We focused on a candidate gene in the affected haplotype and identified the characterized localization of the gene in the brain. We generated iPSC lines from affected and unaffected individuals of the pedigree and differentiated iPSCs into neurons. We are now investigating the phenotype of the iPSC-derived neurons and the relationship between the genomic variant and the neuronal phenotype.
In summary, we identified the affected haplotype and candidate variants which have the potential to contribute to bipolar disorder and induced iPSC-derived neurons with the genetic component. Our work could be expected to establish the cellular model of bipolar disorder for various applications.
The study was approved by the Research Ethics Committee of the University of the Ryukyus and all participating institutes.

Abstract: Quantitative reverse transcription PCR (qRT-PCR) is frequently used to demonstrate changes in gene expression levels in a wide range of conditions. A normalization step is routinely included, preferably by using multiple stably expressed reference genes, also known as housekeeping genes. Some of those genes, such as beta-actin (ACTB) or ubiquitin (UBC) are universally considered as unvarying and used for the normalization step. However, it is important to acknowledge the inherent biological variability of each set of samples and the possible effect of disease on the genes selected. In this study, we aim to determine what the best set of reference genes would be for the analysis of gene expression in the human Frontopolar cortex in healthy control subjects compared to bipolar disorder (BPD) and schizophrenic subjects (SZ).
Methods: Human brain blocks from the Frontopolar cortex of 23 controls, 24 schizophrenics, and 21 bipolar disorder subjects were obtained from the Brain Donor Program at the University of California, Irvine by agreement with the Pritzker Neuropsychiatric Consortium. The subjects included in the schizophrenic and bipolar disorder groups met diagnostic criteria from the Diagnostics and Statistical Manual of Mental Disorders (DSM-V). In the control group, there was no evidence of psychiatric or neurological disorders. Variables accounted for include gender, age and postmortem interval. All subjects used in the study had tissue pH above 6.5 and

agonal factor scores (AFS) of zero. Fresh frozen blocks of tissue averaging 500 mg were dissected from the frontopolar region of each subject and processed for RNA extraction to be used for gene expression studies. We used TaqMan® microfluidic cards to perform qPCR in a Viia™7 machine for evaluation of the gene expression profiles of a set of 12 commonly used reference genes: 18s, ACBT, B2M, HPRT1, GUSB, HMBS, IPO8, PGK1, RPLP0, TBP, TFRC, UBC. ExpressionSuite® software version 1.1 was used to analyze the results.
Results: ExpressionSuite® software allows the evaluation of different quality control measurements for the endogenous controls and targets run in a microfluidic card. After looking at parameters such as standard deviation, Ct max, and Cq confidence values, our results show that several commonly used reference genes are not ideal for normalization of gene expression in our samples. Of twelve genes tested, only five were a good fit for our study, as the other seven showed high variability, especially in the control samples.
We suggest that a careful selection of housekeeping genes appropriate to the sample being used is a fundamental first step before proceeding with gene expression studies using qPCR.

Title: Differentiating young depressed adults at high risk for developing bipolar disorder from those at low risk: A machine learning approach

Authors: *J. CHA, A. ANAND;
Cleveland Clin., Cleveland, OH

Abstract: Introduction:Identifying major depressive disorder (MDD) patients who are at high risk (HRMDD)(indicated by subthreshold symptoms or family history) for developing bipolar disorder (BD) is a critical diagnostic and treatment issue. This study aims to use brain imaging data from an fMRI activation task to construct a predictive model to classify three groups: BD, HRMDD, and low risk MDD (LRMDD).
Methods:Subjects:This study recruited BD and MDD participants ages 15-30 years who were medication-free for at least 2 weeks from the outpatient psychiatry clinic at the Cleveland Clinic and by advertisement. The final analyses included 94 subjects: 20 BPD (bipolar I and bipolar II), 33 HRMDD, and 41 LRMDD. Imaging:We used an Emotion Go/No-go fMRI activation task

paradigm. We conducted the analysis in AFNI. Beta images (contrast images) were used by computing the difference between NoGo vs. Go condition: Happy face inhibition (Happy NoGo vs. Neutral Go), Fear face inhibition (Fear NoGo vs. Neutral Go), and Emotional Face Inhibition ((Happy NoGo + Fear NoGo) vs. Neutral Go). Machine Learning Analysis: We used the random forest algorithm in R statistical software. Firstly, using the whole-brain beta images, we extracted 116 ROI-wise average values from using the AFNI built-in atlas.For feature selection, we performed Recursive Feature Elimination (RFE) with ten-fold cross validation (CV) for all subjects via random forest approach to identify ROIs which contributed the most to classify the groups. The predictive model was trained based on the training set with the ten-fold CV and applied to the test set for prediction. By comparing the predicted and true labels, we computed the area under the receiver operating characteristics (ROC) curve (AUC).
Results: A. HRMDD vs LRMDD: Happy face inhibition (0.80 AUC and 0.70 accuracy); Fear face inhibition (0.68 AUC and 0.68 accuracy); and Emotional Face Inhibition (0.80 AUC and 0.70 accuracy). B. (BPD+HRMDD) vs LRMDD: Happy face inhibition (0.76 AUC and 0.68 accuracy), Fear face inhibition (0.68 AUC and 0.67 accuracy), and Emotional Face Inhibition (0.72 AUC and 0.68 accuracy). C. BPD vs MDD(HRMDD +LRMDD): Happy face inhibition (0.81 AUC and 0.79 accuracy), Fear face inhibition (0.74 AUC and 0.82 accuracy), and Emotional Face Inhibition (0.74 AUC and 0.79 accuracy).
Conclusions:The classification approach with machine learning techniques applied to fMRI task-induced activation data may provide a method for diagnostic classification of MDD subjects at high and low risk for BPD. This method may also be useful to differentiate BPD from MDD.

Title: Bioenergetic and behavioral impacts of ketamine and lithium combinatorial treatment in a state of antidepressant resistance

Authors: *J. PRICE[1], B. A. MORATH[1], K. BUTTERS[1], M. A. FRYE[3], S. MCGEE[4], S. J. TYE[2];
[2]Psychiatry & Psychology, [1]Mayo Clin., Rochester, MN; [3]Integrative Biol. and Physiol., UCLA, Los Angeles, CA; [4]Deakin Univ., Waurn Ponds, Australia

Abstract: Background: The potential of ketamine's efficacy with adjunctive treatments in treatment-resistant depression is still relatively unexplored. Lithium is a common adjunctive treatment for refractory depression, as well as a mood stabilizer for bipolar disorder. Its

molecular mechanisms overlap with those of ketamine and it has been shown to enhance the duration of ketamine's efficacy in rodents modeling depression, even when both treatments are administered at subclinical doses (Duman, 2014). Here, we investigate ketamine and lithium's synergistic effects in a rodent model of antidepressant treatment resistance.
Methods: To establish an antidepressant-resistant phenotype, male Wistar rats were administered adrenocorticotropic hormone (ACTH; 100ug/day, 14 days). Rats were subsequently treated with ketamine (10mg/kg; 2 days; n=12), lithium (37mg/kg; 2 days; n=12), ketamine+lithium (n=12), or control vehicle saline (0.9%; n=12). Rats were subjected to open field (6 minutes) and forced swim tests (6 minutes). Thirty minutes after behavioral testing, rats were euthanized, and cardiac blood and brain tissue were immediately collected. Enzyme-linked immunosorbent assays (ELISAs) were performed to detect mammalian target of rapamycin (mTOR), glycogen synthase kinase-3ß (GSK3ß), and glutamate ionotropic receptor AMPA 1 (GRIA1) concentrations.
Results: ACTH-pretreated rats receiving ketamine+lithium expressed significantly reduced immobility in the forced swim test compared to ACTH-controls ($p<0.05$), unlike rats receiving ACTH+ketamine or ACTH+lithium. Open field testing did not reveal significant pre-existing differences in locomotor activity between groups. Rats treated with ketamine+lithium had higher expression of peripheral mTOR and central GRIA1 than rats receiving ketamine or lithium alone, as well as higher peripheral insulin than all other groups.
Conclusions: These results suggest a synergistic capability of combinatorial ketamine and lithium treatment mediated by enhanced effects on cellular protein signaling and plasticity. The cumulative impact of ketamine+lithium was effective in promoting greater mTOR, GRIA1, and insulin as compared to rats treated with ketamine or lithium alone. Taken together, the elevation of these factors resulted in a greater antidepressant-like effect as reflected in the forced swim test.

Title: Assessment of rapid antidepressant effects of ketamine in animal model

Authors: R. MEDAPATI, J. TADIPARTHI, N. GANUGA, G. RAMALINGAYYA, P. JAYARAJAN, *K. MUDIGONDA, R. NIROGI;
Suven Life Sci. Ltd, Hyderabad, India

Abstract: Current existing pharmacotherapies for treating major depressive disorders (MDD) generally take several weeks to months to exert their full therapeutic effects. Clinical evidences showed that ketamine, a noncompetitive N-methyl D-aspartate (NMDA) receptor antagonist exert rapid antidepressant effects. The antidepressant effect of ketamine was evaluated in dominant submissive assay. Briefly, animals were food-deprived overnight prior to testing. Habituation of the animal to the apparatus and milk was carried out during the first week (one week). Selection of dominant and submissive pair was carried out during the second week (one week). The animals were randomized based on the dominance levels. Both the dominant and submissive animals of the control group were treated with vehicle. For the remaining groups, submissive animals were treated with ketamine or imipramine or fluoxetine. In the control treatment group, dominance levels remained unchanged during the entire course of the study. In the ketamine treatment group, dominance levels decreased significantly from the 3rd day of the treatment. Significant effects of imipramine or fluoxetine was observed only during the 3rd week of treatment. Based on the results, it can be concluded that ketamine exerts its antidepressant activity rapidly than the current conventional treatments. There is a need of thorough research for finding out the exact mechanism of action of ketamine's antidepressant effects.

Abstract: Postpartum depression is a multifactorial mental disorder that affects 1 in 7 women worldwide and it is an important public health problem since affects both mother and child's health. There are pharmacotherapies available for the treatment of this disease, but many of these medications can affect the child through breastfeeding. Likewise, there are several women that do not respond to those therapies, which make it urgent the development of more effective, faster-acting and with less side effects medications. Recent studies have shown that ketamine has a promising therapeutic potential for treatment of depression, due to its rapidly response, low toxicity, and few side effects. However, there is no established dose and route of administration for ketamine's use as an antidepressant. Thus, the aim of this study was to evaluate the effects of maternal separation as a postpartum depression model and of prolonged exposure to ketamine in lactating rats. Twenty-four dams were divided into three groups: group A - control; group B - maternal separation; and group C - maternal separation + ketamine 10 mg/kg, n=8 animals/group. Groups B and C were induced to postpartum depression through the maternal separation model for 10 days, from lactating day 2 to 12, which was previously validated through the forced swim test. Group C was also treated with 10 mg/kg of ketamine intraperitoneal during all lactation period. On lactating day 5 and 6 it was performed the maternal behavior and the maternal aggressive behavior tests, respectively. The parameters evaluated on the maternal behavior test were: latency to retrieve the first 4 pups, latency to group all pups in the nest, percentage of dams that group all pups in the nest, total time of pup-grooming, total time of self-grooming, latency to full maternal behavior and percentage of dams that displayed the full maternal behavior. The parameters evaluated on the maternal aggressive behavior were: total time of social interaction with the intruder, total time that the intruder spends sniffing the offspring, frequency of boxing, latency to the first fight, number of fights, total time of maternal behavior and total time of self-grooming. The results showed no differences between groups in all parameters evaluated, which indicates that neither the maternal separation model nor the ketamine exposure was able to alter the maternal behavior of these animals

Title: Naltrexone attenuates the antidepressant-like effects of ketamine in C57B/6 mice

Authors: *F. ZHANG, R. RICE, J. H. PORTER, A. ANDRADE, S. MANICKA, J. LANE; Psychology, Virginia Commonwealth Univ., Richmond, VA

Abstract: Ketamine has been shown to produce both rapid and prolonged antidepressant effects in depressed patients; however, the underlying mechanisms mediating these antidepressant effects remains undetermined. Ketamine's antagonism of glutamatergic NMDA receptors has been the focus of much research; however, other mechanisms may be responsible for ketamine's antidepressant effects as ketamine is known to interact with several other neurotransmitter systems, including opioid receptors. Recently, Williams et al. (2018) reported that the opioid receptor antagonist naltrexone attenuated ketamine's low dose (0.5 mg/kg, iv) antidepressant effect in depressed patients. Interestingly, the dissociative effects of ketamine were not blocked by naltrexone. The authors suggested that opioid system activation is necessary for ketamine's acute antidepressant to be evident. The current study explored this possibility by testing C57BL/6 mice in a differential-reinforcement-of-low-rate (DRL) 72 s operant task. In the DRL assay, animals are required to wait for a specified length of time (e.g., 72 s) between lever responses to receive a reinforcer. Drugs with clinical efficacy as antidepressants typically increase the number of reinforcers received and decrease the number of responses emitted. The DRL 72 s task has high predictive validity for screening antidepressant drugs, and is less vulnerable to false positives (e.g. psychostimulants). Ketamine (32 mg/kg) produced a significant increase in the number of reinforcers received as compared to vehicle. Next, the mu opioid receptor antagonist naltrexone (1, 2, and 4 mg/kg doses) was tested alone and in combination with 32 mg/kg ketamine. Naltrexone alone did not produce any significant increases in reinforcers. However, when tested in combination with 32 mg/kg ketamine, naltrexone produced a significant reduction of ketamine's antidepressant-like effects at 2 mg/kg, but not at 1 or 4 mg/kg doses. Thus, naltrexone's effects on ketamine's antidepressant-like effects produced an inverted U-shaped function. Additional testing is being conducted to determine if this inverted U-shaped function can be replicated. These results tentatively support the conclusion by Williams et al. (2018) that opioid system activation may be necessary for ketamine's acute antidepressant effects.

Title: Evaluating the antidepressant-like effects of ketamine, its isomers, and (2R,6R)-hydroxynorketamine (HNK) in C57B/6 mice

Authors: *J. H. PORTER, F. ZHANG, J. E. PRICE, M. K. SHEARER, E. POTTANAT, R. RICE;
Psychology, Virginia Commonwealth Univ., Richmond, VA

Abstract: The monoamine hypothesis inadequately explains the delay of therapeutic effects of currently available antidepressants. Recently, there has been an increased focus on the role of glutamatergic mechanisms underlying depression; following the demonstration that a single, subanesthetic dose of ketamine (0.5 mg/kg iv) produced a rapid and long lasting (3 days) improvement of depressive symptoms (Berman et al 2000; Hillhouse and Porter 2015). Preclinical research also has reported antidepressant-like effects with ketamine treatment in several assays (Maeng et al., 2008; Zhou et al., 2014), but ketamine's abuse liability and psychotomimetic side-effects limit its clinical use. In addition to the (R)-ketamine and (S)-ketamine isomers, it was recently postulated that the ketamine metabolite, (2R,6R)-hydroxynorketamine (HNK) may be important for ketamine's antidepressant effects (Zanos et al., 2016). The observed antidepressant-like actions of HNK were independent of NMDAR antagonism and it lacked ketamine-related side effects. The current study examined the antidepressant-like effects of ketamine, its isomers, and HNK in C57BL/6 mice in a differential-reinforcement-of-low-rate (DRL) 72 s operant task. In the DRL assay, animals are required to wait for a specified length of time (e.g., 72 s) between lever responses to receive a reinforcer. Drugs with clinical efficacy as antidepressants typically increase the number of reinforcers received and decrease the number of responses emitted. The DRL 72 s task has high predictive validity for screening antidepressant drugs, and is less vulnerable to false positives (e.g. psychostimulants). Ketamine (32 mg/kg) and the S-isomer (17.8 and 32 mg/kg)produced a significant increase in the number of reinforcers received as compared to vehicle. The (R) isomer (32 mg/kg) did not increase the number of reinforcers. HNK (56 mg/kg) also failed to increase the number of reinforcers. Thus, while ketamine and (S)-ketamine displayed an antidepressant-like profile in the DRL 72 s assay, (R)-ketamine and HNK did not. These results different from other preclinical assays of antidepressant-like behavior (e.g. forced swim test).

Title: Effects of ketamine and (2R-6R)-hydroxynorketamine (HNK) on cognition: A role for the nucleus reuniens?

Authors: *R. RICE[1], F. ZHANG[1], P. GOSWAMEE[2], R. MCQUISTON[2], J. H. PORTER[1]; [1]Psychology, [2]Dept Anat/Neurobiol, Virginia Commonwealth Univ., Richmond, VA

Abstract: Major depressive disorder is the most common mental disorder worldwide. The U.S. alone has a greater than 16% lifetime prevalence rate for depression. Here, treatment costs and an estimated loss in productivity cause an annual $83 billion socioeconomic burden. More efficacious pharmacological treatments might attenuate this burden. After the demonstration that a single, subanesthetic dose of ketamine (0.5mg/kg i.v.) produced a rapid and relatively long-lasting (3 days) improvement of depressive symptoms, there is increased focus on glutamatergic mechanisms for the treatment of MDD. Animal research also has reported antidepressant-like effects with ketamine, but these promising findings are limited by ketamine's aversive side effects. Fortunately, the antidepressant-like actions of (2*R*,6*R*)-hydroxynorketamine (HNK), a ketamine metabolite, appeared to lack side effects associated with ketamine treatment (e.g. psychomimetic effects). Similar to others, we saw ketamine exert antidepressant-like effects in rodents as measured by the forced-swim test. To assess potential cognitive-effects of these compounds, we measured spontaneous alternation in a T-maze after treatment with racemic ketamine and HNK (both 10 mg/kg and 32 mg/kg; both with 5-minute and 24-hr pretreatments) on adult male C57BL/6 mice. Results indicate that ketamine significantly reduced alternations at both doses 5 minutes after treatment. Furthermore, these effects persisted for 24 hours at the higher ketamine dose of 32 mg/kg. Conversely, HNK (10 mg/kg and 32 mg/kg; 5 minute and 24-hour pretreatment) did not significantly differ from saline treatment. We hypothesize this effect is due in part to reduced neurotransmission in a thalamic nucleus; the midline thalamic nucleus reuniens (RE). RE acts as a structural and functional hub in the flow of information from the medial prefrontal cortex (mPFC) to the hippocampus. To assess whether ketamine reduced neurotransmission in the mPFC-RE pathway, we conducted whole-cell patch clamp electrophysiology in RE neurons in combination with optogenetic stimulation of mPFC afferents in brain slices of mice that received saline, ketamine, or HNK. Pilot electrophysiological data demonstrate that ketamine (32 mg/kg) reduces the strength of neurotransmission in the mPFC-RE pathway. Taken together, these results suggest that ketamine, but not HNK, can result in a cognitive deficiency that may arise due to alteration in the mPFC-RE neurocircuitry.

Title: Evaluation of serotonin 2A receptor involvement in the antidepressant-like and abuse-related effects of ketamine

Authors: *T. M. HILLHOUSE[1], H. S. POPAL[2], C. MERRITT[2], S. E. CARLAN[2], K. A. WEBSTER[2], J. H. PORTER[2];
[1]Psychology & Neurosci., Weber State Univ., Ogden, UT; [2]Psychology, Virginia Commonwealth Univ., Richmond, VA

Abstract: The noncompetitive glutamatergic N-Methyl-D-aspartate (NMDA) receptor antagonist ketamine produces rapid and sustained antidepressant effects in treatment-resistant patients suffering from major depressive disorder (MDD). However, ketamine is considered to have high abuse liability due to dissociative and hallucinogenic effects, which are likely a result of NMDA receptor inhibition. There is some evidence that the abuse-related effects of ketamine are produced by activation of serotonin (5-HT) 2A receptors. Our study used a differential-reinforcement-of-low-rate (DRL) 72 s operant procedure and ketamine drug discrimination to determine the role of 5-HT2A receptors in the antidepressant-like and abuse-related effects of ketamine, respectively. The noncompetitive NMDA antagonists ketamine (5.6-18.0 mg/kg) produced antidepressant-like effects in the DRL 72 s procedure; whereas, the higher affinity noncompetitive NMDA antagonist MK-801 (0.1-0.18 mg/kg) produced a psychostimulant-like effect. The 5-HT2A receptor antagonist ritanserin (1.0 mg/kg) failed to block the antidepressant-like effects produce by 18.0 mg/kg ketamine, but reversed the psychostimulant-like effect of 0.18 mg/kg MK-801. To determine if ketamine was an antagonist at 5-HT2A receptors, as ketamine produced opposing behavioral effects as compared to MK-801 in DRL 72 s procedure and the behavioral effects of MK-801 were blocked by ritanserin, co-administration of the 5-HT2A agonist quipazine was used. Quipazine (5.6 mg/kg) failed to block the antidepressant-like effects of 10.0 mg/kg ketamine. Ketamine (7.5-20 mg/kg) produced full generalization in rats trained to discriminate 10.0 mg/kg ketamine in the drug discrimination paradigm. MK-801 (0.56-0.1 mg/kg) fully substituted for ketamine. The 5-HT2A agonist quipazine (0.32-3.2 mg/kg) and the 5-HT2A antagonist ritanserin (2.5-10.0 mg/kg) did not substitute for ketamine when administered alone and combination testing with ritanserin (10.0 mg/kg) did not block ketamine discrimination. These results suggest that 5-HT2A receptors do not play a significant role in ketamine's antidepressant-like or abuse-related effects.

Title: Evaluation of the antidepressant, anxiolytic, and locomotion effects of the N-methyl-d-aspartate (NMDA) receptor antagonist dextromethorphan in mice

Authors: *J. J. SAAVEDRA, S. C. HONEYCUTT, P. I. GARRETT, A. M. PETERSON, J. W. WHITE, T. M. HILLHOUSE;
Psychology & Neurosci., Weber State Univ., Ogden, UT

Abstract: Major Depressive Disorder (MDD) is among the most common disorders in the United States. The glutamatergic system is currently being evaluated as a novel pathway for treating MDD. For example, the N-methyl-d-aspartate (NMDA) receptor antagonist ketamine has produced rapid and sustained antidepressant effects in clinical trials. Other NMDA receptor antagonists have produced antidepressant-like effects in preclinical models, but have failed to produce similar antidepressant effects in clinical trials. It has become increasingly important to evaluate novel antidepressant drugs in several preclinical models to better understand the therapeutic potential of the drug. Dextromethorphan (DM) is a NMDA receptor antagonist that has produced antidepressant-like effects in the forced swim test (FST) and tail suspension test (TST); however, some studies have shown that DM can increase locomotor activity at a dose (30.0 mg/kg) that produces antidepressant-like effects. The present study sought evaluate the antidepressant-like, anxiolytic-like and behavioral effects of DM. The novelty-induced hypophagia (NIH) test was used to evaluate the rapid antidepressant-like and anxiolytic-like effects of DM. For the NIH test, mice are trained to drink a sweetened solution and then placed in a novel environment, which increases their latency to drink as compared to their home cage. Rapid antidepressants and anxiolytic drugs will decrease the latency to drink after acute administration; whereas, standard antidepressant drugs require repeated administration to reduce latency to drink. Acute administration of 20.0 mg/kg imipramine increased latency to drink. Interestingly, acute administration of 32.0 mg/kg DM significantly increased latency to drink as compared to saline. Neither drug significantly alter the volume of liquid consumed. A standard 60 min open field test was used to assess the effects of DM on locomotor activity. Treatment with 32.0 mg/kg DM did not significantly alter locomotor activity suggesting that the increased latency to drink in the NIH test was not a result of changes in locomotor behavior. These results suggest that while DM produces antidepressant-like effects in standard models of depression (i.e. FST and TST), DM does not produce rapid antidepressant-like effects in the NIH test. One possible explanation for these findings are that the antidepressant-like effects of DM have been attenuated by a sigma receptor antagonist suggesting that the antidepressant-like effects of DM are not produced by NMDA receptor antagonism. The inhibition of NMDA receptors produced by ketamine are thought to be responsible for the rapid antidepressant effects.

Title: Corticosterone as a confounding factor in delineating mechanisms underlying ketamine's rapid antidepressant actions

Authors: *L. J. WEGMAN-POINTS, B. POPE, L. SEMKE, A. M. ZOBEL, E. WAUSON, V. DURIC, L.-L. YUAN;
Physiol. and Pharmacol., Des Moines Univ., Des Moines, IA

Abstract: Despite significant efforts, the mechanisms specific to ketamine's fast-acting antidepressant effects when administered in subanesthetic doses have yet to be identified. In our current study, we focused on the characterization of a previously observed surge in corticosterone (CORT) following a subanesthetic ketamine administration (10mg/ml). Blood and brain tissue collected at 1 hour post-injection of either saline, ketamine or (2R, 6R)-hydroxynorketamine (HNK), an active metabolite of ketamine, was analyzed for levels of circulating CORT. The levels of circulating CORT were ~ 4 fold higher in the ketamine-injected rats, when compared to saline controls and HNK treatment. This translated to an even more robust increase of CORT in the brain cortex. Interestingly, HNK did not elicit the spike in CORT seen with a ketamine injection. It is well established that ketamine, but not HNK, at antidepressant doses, induces side effects including locomotor deficits. To identify whether this increase in CORT was purely biochemical, or a behavioral response to the locomotor deficits, we removed the behavioral component by anesthetizing the rats before administering saline or ketamine. While under isoflurane sedation, the levels of circulating CORT 1 hour post-ketamine injection were consistent with those seen in anesthetized saline controls. This suggests that the increase in CORT levels is likely to reflect the increased stress of rats experiencing the locomotor deficit associated with a subanesthetic dose of ketamine. This increase in CORT release, virtually concurrent with ketamine administration in awake animals, could mask some of the mechanisms relevant to ketamine's rapid antidepressant effects, thus representing a potential confounding factor in this research.

Title: Effect of ketamine on parvabumin interneurons in the prefrontal cortex and hippocampus during depression-like behavior in mice

Authors: *O. LAWLER[1], M. GAMES[1], V. MAGANA NAVAS[1], V. ARMENDARIZ CABRAL[2], K. MATA ARAUZ[3], K. ODELL[1], Q. WANG[1];
[1]Biol., [2]Chem., [3]Biochem., John Brown Univ., Siloam Springs, AR

Abstract: Major depressive disorder (MDD) is an illness characterized by lack of motivation, sadness, apathy, and suicidal thoughts and actions. While MDD is often attributed to a chemical imbalance in the brain, interneuron circuits may be a critical piece to understanding its complexity. MDD has been reported to impair parvalbumin (PV) interneuron activity under chronic stress (Hu, Wen et al. 2010; Czeh, Boldizsar et al. 2018). Previous research also suggests that ketamine has a fast-acting antidepressant effect. In mice, ketamine administration decreases immobility time during the forced swimming test (FST), an animal behavioral model of MDD (Zanos. et al. 2016). However, ketamine's effect on PV interneurons during FST is unclear. To understand ketamine's effects on PV interneurons in brain regions that are closely associated with MDD, we selectively examined the prefrontal cortex (PFC) and the hippocampus (HP). Vehicle (VEH, 0.9% saline) or ketamine (KET, 10 mg/kg) intraperitoneal injections were administered to 6-7-week-old male CD-1 mice one hour prior to FST. All mice were sacrificed by perfusion two hours after the onset of FST. Brain tissue slices were labeled with fluorophore-conjugated antibodies that recognized PV and Fos expression. PV interneurons and Fos puncta were quantified using ImageJ. As predicted, behavioral video analysis indicated a shorter immobility time in KET mice (n=3) compared to VEH (n=3) mice. Patterns of PV and Fos, however, varied between examined brain regions. Interestingly, in the PFC, quantification revealed no significant difference in the total number of PV interneurons in the lateral orbital cortex between groups. However, the percentage of dual-labeled neurons among all PV interneurons was significantly lower in KET mice. In the HP, the ventral CA1 displayed significantly higher numbers of PV- and dual-labeled neurons in KET mice, but no significant difference in the percentages of dual-labeled neurons among all PV interneurons. This region-specific pattern suggests that the antidepressant effect of ketamine may be mediated by differentially activated PV interneurons in these regions. Research is supported by The Arkansas IDeA Network of Biomedical Research Excellence (Faculty Recruitment) to QW.

Title: Unique signaling of ketamine and 2R, 6R HNK in their rapid antidepressant actions

Authors: *R. THAPA[1], C. XU[2], X. CAI[1], S. YAN[3];
[1]Physiol., Southern Illinois Univ., Carbondale, IL; [2]Life Sci., Shaanxi Normal Univ., Xi'an, China; [3]Capital Med. Univ., Beijing, China

Abstract: Traditional antidepressant drugs generally take weeks and even months to ameliorate the conditions of people with depression. Ketamine, a noncompetitive NMDA receptor antagonist, exerts antidepressant actions in hours. However, its use is limited by its dissociative, psychotomimetic and other undesirable side effects. Recent studies have shown that the major metabolite of ketamine, 2R, 6R-HNK, exhibits antidepressant action but lacks unwanted side effects of ketamine. The mechanism of antidepressant action of 2R, 6R-HNK is not fully understood, especially the initial step and upstream signaling mediating the action of 2R, 6R-HNK on synaptic protein synthesis. In the current study, we observed that both ketamine and HNK enhanced fEPSPs and EPSCs at Schaffer collateral-CA1 (SC-CA1) synapses in acutely prepared hippocampal slices. MK-801, a selective NMDA receptor blocker, completely inhibited the action of ketamine but not 2R, 6R-HNK at SC-CA1 synapses. Ketamine but not 2R, 6R-HNK enhanced GluA1 Ser845 phosphorylation, and the action of ketamine but not 2R, 6R-HNK on synaptic transmission was abolished in GluA1 S845A knock-in mice. Using the optogenetic approach, we also explored the initiating signaling of 2R, 6R-HNK on excitatory synaptic transmission and synaptic protein synthesis in hippocampal CA1.

Title: Ketamine produces a long-lasting enhancement of synaptic transmission

Authors: *G. JANG, B. MACIVER;
Anesthesiology, Perioperative and Pain Med., Stanford Univ. Sch. of Med., Stanford, CA

Abstract: Ketamine has recently been shown to improve major depressive disorder (MDD) in patients that are unresponsive to other forms of treatment. The antidepressant effect occurs rapidly, often following a single exposure, and can outlast the presence of the drug, often for several weeks. Current evidence suggests that the mechanism for this effect does not involve NMDA receptor antagonism. Little is known about other molecular targets for ketamine. The present study examined the effects of ketamine on synaptic transmission at glutamate and GABA synapses, to determine whether lasting effects can be produced by this drug. All procedures were approved by the Stanford University Animal Use Committee, male C57BL/6J mice weighing between 25-30 grams were used to prepare 400 µm thick coronal brain slices. We studied the effects of ketamine and its major metabolites (2R, 6R & 2S, 6S)-hydroxynorketamine by stimulating Shaffer-collateral axons while recording evoked responses from CA1 pyramidal neurons and GABA inhibitory interneurons. Ketamine produced three effects: 1) an acute depression of population spike amplitudes, 2) an enhancement of GABA-A fast and/or tonic inhibition, 3) a long-lasting increase in population spike amplitude. The long-lasting increase in amplitude was observed following drug washout and could last for over 8 hours. This effect was unlike other anesthetics that also produce an acute depression of population spike amplitudes, but do not produce long-lasting effects following washout. These effects were mimicked by the primary ketamine metabolite (2R, 6R)-hydroxynorketamine. Our results agree with previous studies showing that ketamine produces an acute depression of population spike amplitudes with an increase in GABA-mediated inhibition. This is the first report to demonstrate a long-lasting increase in excitability following washout of ketamine from the brain slice. We suggest this long-lasting effect could be related to the long-lasting antidepressant effects produced by ketamine and its (2R, 6R) metabolite. The (2R, 6R) metabolite is thought to be the active agent for ketamine-induced antidepressant effects.

Title: Antidepressant effects of s-ketamine through a reduction of functional I_h

Authors: *C. KIM, D. JOHNSTON;
The Univ. of Texas At Austin, Austin, TX

Abstract: Compelling evidence suggests that a single sub-anesthetic dose of ketamine exerts rapid and robust antidepressant effects. However, the cellular mechanisms underlying the antidepressant effects of ketamine remain unclear. We found that s-ketamine reduced dendritic but not somatic functional I_h of dorsal CA1 neurons in normal conditions. This effect was independent of NMDA receptors, barium-sensitive conductances (GIRK and IRK), and cAMP-dependent signaling. In the chronic unpredictable stress (CUS) model of depression, we found that s-ketamine reduced not only dendritic, but also the previously reported (Kim et al., 2018) CUS-induced upregulation of somatic functional I_h. Furthermore, s-ketamine normalized CUS-induced decreases in neuronal excitability and AMPA-mediated synaptic excitation at Shaffer collateral-CA1 synapses. Finally, s-ketamine pretreatment before the onset of depression prevented CUS-induced behavioral phenotypes and neuropathological changes of dorsal CA1 neurons. Our results suggest that s-ketamine reduces or prevents functional I_h from being increased following CUS, which contributes to the rapid antidepressant effects and resiliency to CUS.

Title: Ketamine but not rapastinel increases mPFC pyramidal cell GCaMP fluorescence

Authors: *B. D. HARE, R. S. DUMAN;
Yale Sch. of Med., New Haven, CT

Abstract: Depression is a debilitating disorder that impacts nearly twenty percent of the population and is predicted to be a leading cause of disability worldwide in the near future. Monaminergic antidepressaants are effective in only thirty percent of cases and may take weeks to months of treatment to ease the symptoms of depression. The NMDA receptor antagonist ketamine has been shown to produce an antidepressant response within hours that persists for up to a week. Clinical and pre-clinical studies have pointed to an increase in frontal cortex activity after ketamine as a potentially important component of the mechanism underlying the antidepressant actions of ketamine. The development of genetically encoded calcium indicators (GECI; e.g. GCaMPs) allows in-vivo monitoring of fluorescence associated with calcium activity such as that produced with synaptic activity and action potential generation. Here we sought to determine the effect of rapid acting antidepressants on GCaMP fluorescence in mPFC pyramidal cells immediately following treatment. Male and female C57BL6J mice were implanted with fiber optic cannula over ventral mPFC CaMKII-expressing cells virally transfected with GCaMP6f. Animals were habituated to the fiber photometry apparatus for 30 minutes prior to treatment with saline or a rapid acting antidepressant compound and data was collected for an additional hour. We observed a clear increase of GCaMP fluorescence in the 30 minutes following ketamine administration that was dose dependent (3mg/kg, 10mg/kg, 30mg/kg, 100mg/kg; IP) indicating an increase in ventral mPFC activity immediately after treatment. Rapastinel, another rapid acting antidepressant that is a positive allosteric NMDA receptor modulator without the psychotomimetic side effects and abuse potential of ketamine was also tested. Administration of rapastinel (3mg/kg; IV) did not produce the increase in GCaMP signal that was observed with ketamine. These studies suggest that the mPFC response to rapid acting antidepressant treatment may vary with the mechanistic target, and point to the potential utility of GECIs in delineating population activity that is necessary for rapid antidepressant effects versus that associated with off target effects. Studies are ongoing to examine the effects of ketamine enantiomers and metabolites on GCaMP fluorescence.

Title: Distinct projections of the medial prefrontal cortex underlie the rapid antidepressant actions of ketamine

Authors: *R. SHINOHARA, B. D. HARE, R.-J. LIU, R. S. DUMAN;
Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstract: Ketamine, an N-methyl-D-aspartate (NMDA) receptor antagonist, triggers a rapid antidepressant response, even in patients categorized as treatment-resistant. Preclinical studies indicate that glutamatergic signaling in the medial prefrontal cortex (mPFC) is critical for the therapeutic actions of ketamine. A low-dose ketamine produces a paradoxical burst of glutamate in the mPFC and leads to increased synaptic number and function. We recently identified a key neuronal population in the mPFC that underlies the actions of ketamine; optogenetic activation of dopamine receptor D1 (*Drd1*)-expressing neurons in the mPFC reproduced the rapid and sustained antidepressant responses, and optogenetic or chemogenetic silencing of these neurons blocked the behavioral actions of systemic ketamine in the forced swim test (FST) and novelty suppressed feeding test (NSFT). Optogenetic activation of *Drd1*-expressing neurons in the mPFC increased c-Fos expression in the basolateral amygdala (BLA) and anterior portion of the bed nucleus of the stria terminalis (aBNST). Additionally, bilateral optogenetic activation of mPFC *Drd1* terminals in the BLA resulted in the rapid antidepressant responses in the FST and anxiolytic response in the NSFT 1 day after photostimulation. Although bilateral optogenetic activation of mPFC *Drd1* terminals in the aBNST resulted in no obvious response in the FST, an anxiolytic response in the NSFT was observed 1 day after photostimulation. Here we tested the necessity of these mPFC circuits in the actions of ketamine by pairing Cre-dependent AAV expressing inhibitory DREADD (hM4Di) that was infused into the mPFC with retrograde AAV expressing Cre that was infused into either BLA or aBNST. Behavioral testing was conducted 1 day after administration of a DREADD agonist clozapine-N-oxide (CNO) (1 mg/kg) and ketamine (10 mg/kg). Chemogenetic silencing of the mPFC-BLA pathway prior to ketamine dosing blocked the ketamine response in the FST but had no effect on the ketamine response in the NSFT. By contrast, chemogenetic silencing of the mPFC-aBNST pathway prior to ketamine dosing blocked the ketamine response in the NSFT and female urine sniffing test (FUST) but no effect on the ketamine response in the FST. These findings indicate that ketamine-induced plasticity of the mPFC distributes information to downstream circuit targets (i.e. BLA and aBNST) that produce distinct behavioral responses. Further experiments are being conducted to investigate whether ketamine induces neuroplasticity in the BLA and aBNST and to test the role of neuroplasticity in these regions in the action of ketamine.

Title: Temporal characterization of sex-specific changes in glutamatergic/GABAergic neuron markers expression in a mouse model of stress

Authors: *C. JIANG[1], R. S. DUMAN[2];
[1]Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT; [2]Dept. of Psychiatry, Yale Univ. Sch. Med., New Haven, CT

Abstract: Depression is a highly prevalent mental illness with devastating public health impact. According to the National Center for Health Statistics (NCHS), depression affects 8.1% of U.S. adult population in a given 2-week period and women are nearly twice as likely as men to develop depression. Evidence from clinical and preclinical studies indicates that stress exposure increases vulnerability to depression and depression leads to altered physiological and molecular responses to stress. Dysfunctional glutamatergic and GABAergic neurotransmission systems have been proposed to underlie the link between stress and depression. However, which system is more susceptible to stress and whether sex differences exist in this susceptibility remain incompletely understood. Our current study seeks to address these issues utilizing chronic variable stress (CVS), a stress paradigm that has been demonstrated to trigger the onset of depression-like phenotypes in a sex-specific time course, and biochemical approach to characterize the changes in the expression of various glutamatergic and GABAergic neuron makers in a temporal and sex-specific manner. We subjected 9 - 12-week-old female and male C57BL/6J mice to CVS for different lengths of time (3 days, 6 days, 12 days and 21 days) and used western blot analysis to examine the changes in the expression of AMPA receptor subunit GluR1, postsynaptic density protein 95 (PSD-95), vesicular glutamate transporter 1 (VGLUT1), vesicular GABA transporter (VGAT) and GABA-synthesizing enzyme (GAD2) in synaptosomal preparation of medial prefrontal cortex (mPFC). Our preliminary data reveals a trend of reduction in the levels of these markers in mPFC synaptosomes of both female and male mice stressed for 21 days. In addition, we observed higher expression levels of PSD-95 and GAD2 in males compared to females in the naïve control groups. Interestingly, GluR1 expression was decreased more rapidly in stressed females than males, reaching a significantly lower level at the 6-day stress timepoint compared to naïve female controls. In contrast, males manifested more

pronounced reduction in VGAT expression than females, showing a significant difference at the 6-day stress timepoint compared to naïve male controls. These preliminary results indicate that sex differences in glutamatergic/GABAergic systems potentially exist at baseline and at different stages of stress exposure. Experiments are being conducted to validate these observations in a new cohort of mice and to assess the changes in the expression of these neuronal makers in other brain regions that are implicated in the stress response and depression.

Title: Initial cellular trigger for rapid antidepressant actions of rapastinel: Cell-type specific role of NMDAR and dopamine receptors

Authors: *S. POTHULA[1], T. KATO[1], R.-J. LIU[1], M. WU[1], A.-N. SLIBY[1], R. SHINOHARA[1], P. BANERJEE[2], R. DUMAN[1];
[1]Dept. of Psychiatry, Yale Univ., New Haven, CT; [2]Allergan Inc.,, New Jersey, NJ

Abstract: Rapastinel (Glyx-13) is a novel NMDA receptor (NMDAR) modulator that enhances NMDAR function. It exerts rapid antidepressant effects similar to ketamine but has a lower propensity to induce dissociative and psychotomimetic side effects than ketamine. Although, recent studies demonstrate that the actions of rapastinel require BDNF release, mTORC1 signaling, and synapse formation in the medial prefrontal cortex (mPFC), the initial cellular trigger and molecular target for rapastinel remains unknown. Here, we use a combination of AAV2-viral mediated cell specific knockdown, behavioral, pharmacological, microdialysis and electrophysiological approaches to identify the molecular target, initial cellular trigger, and neuronal cell type involved in the actions of rapastinel. The results demonstrate that knockdown (KD) of the GluN2B subunit of NMDARs on glutamatergic but not GABAergic neurons in mPFC blocks the antidepressant effects of rapastinel. In contrast, the actions of ketamine were blocked by knockdown of GluN2B on GABAergic but not glutamatergic neurons. In support of rapastinel's direct action on principal neurons, microdialysis studies demonstrate that ketamine, but not, rapastinel increases glutamate release in mPFC. Electrophysiological studies conducted in layer V pyramidal neurons in mPFC slices are consistent with these findings, demonstrating

that bath application of rapastinel causes a dose dependent increase in NMDA-induced inward current while ketamine completely blocks the NMDA response. We further examine the role of two major subtypes of mPFC principle neurons in the actions of rapastinel, and demonstrate that GluN2B KD on Drd1, but not Drd2-expressing principal neurons blocks the antidepressant-like effects of rapastinel. We also show that pharmacological inhibition of D1R but not D2Rs in the mPFC blocks the rapid antidepressant behavioral actions of rapastinel. Together, our findings demonstrate that the GluN2B subunit on glutamatergic neurons is the cellular target for rapastinel, and that rapastinel enhances NMDA-induced inward currents on these mPFC principle neurons. These findings are also consistent with in vivo microdialysis studies demonstrating that ketamine, but not rapastinel causes a rapid, transient increase in extracellular glutamate. The results also show that D1Rs are required for the rapid antidepressant actions of rapastinel. Ongoing experiments are evaluating the cell-type specific role of GluN2A and D1Rs in the antidepressant actions of rapastinel.

Title: Cell type specific transcriptome analysis in medial prefrontal cortex and ventral hippocampus after ketamine treatment

Authors: *B. LEE, M. J. GIRGENTI, M. V. FOGACA, R. S. DUMAN;
Dept. of Psychiatry, Yale Univ. Sch. Med., New Haven, CT

Abstract: Ketamine, an anaesthetic and hallucinogenic drug, has received a great deal of attention over the past decade as a rapid-acting antidepressant and recently esketamine, a form of ketamine, has been approved by the Food and Drug Administration (FDA) for depression treatment. Two hypotheses exist to explain the underlying mechanisms of ketamine as an antidepressant. One is the “disinhibition” hypothesis, which suggests that ketamine selectively blocks NMDA receptors on GABA interneurons resulting in decreased inhibitory input to pyramidal neurons. The other is the “direct” hypothesis, which suggests that ketamine blocks NMDA receptors on glutamatergic neurons resulting in homeostatic control of synaptic activity.

Therefore, transcriptional changes within different cell types in response to ketamine treatment may provide further insights of the underlying mechanisms of ketamine as an antidepressant. Given the significant volume reduction in medial prefrontal cortex (mPFC) and hippocampus in depressed patients, and studies showing the important role of ventral hippocampus in controlling depression symptoms, we decided to isolate specific cell populations from fluorescently tagged, rodent mPFC and ventral hippocampus after ketamine treatment. Although ketamine acts rapidly, evidence of the contributions of the spine formation to its sustained antidepressant effect indicates that transcriptomic changes 24 hours after treatment could provide insight into the molecular underpinnings of this effect. Using CaMKII, SST and PV subtype-specific fluorescence activated cell sorting (FACS) from transgenic mice and RNA sequencing, we identified distinct transcriptome profiles from each subtype of neuron. Pathway and network analysis suggest distinct molecules and pathways for each cell type and could explain the mechanisms underlying ketamine's antidepressant effects. We also analyzed mRNA from both male and female mice to allow for identification of gender specific transcriptome changes that could help to elucidate the neurobiology underlying the higher prevalence in women. Ultimately, these findings could lead to identification of novel biomarkers or potential therapeutic targets.

Title: Stress-sensitive antidepressant-like effects of ketamine in the mouse forced swim test

Authors: *P. J. FITZGERALD, J. Y. YEN, B. O. WATSON;
Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: Major depression is a stress-linked disease with significant morbidity worldwide. The anesthetic drug ketamine is of growing interest in depression treatment since in responsive individuals a single dose has rapidly acting (i.e., within hours) antidepressant effects that can be sustained for at least a week. This combination of fast action and a therapeutic effect that lasts far beyond the drug's half-life points to a unique mechanism of action. In this reverse translational study, we investigate how and whether the well-documented effects of ketamine in rodents are

sensitive to the stress state of the animal. Male C57BL/6J mice (n=8 per stress/drug condition) were given a single injection of vehicle (0.9% saline; i.p.), 10 mg/kg ketamine, or 30 mg/kg ketamine, and were tested in the forced swim test (FST) 24 hours and 7 days later, as well as in the open field test on the eighth day. Unstressed mice had normal group housing, environmental enrichment, and experimenter (5 days) pre-handling, whereas stressed animals were subjected to chronic mild stress, including two-week unpredictable chronic stress (UCS). Ketamine (24 hours post-injection) increased immobility and decreased swimming behavior (depression-like effects) in unstressed animals and did the opposite in UCS animals, where these opposing effects are similar to recent human findings. In summary, chronic stress interacts with ketamine to modulate its effects in the C57BL/6J mouse FST, which reinforces the relevance of this test, and this strain of mice, to human, stress-induced depression.

Title: Ketamine modulates spontaneous and miniature excitatory synaptic currents in the medial prefrontal cortex of acutely stressed rats

Authors: *F. SALERNO SCARZELLA[1], E. SCHIAVON[1], L. MUSAZZI[2], M. POPOLI[2], L. FORTI[1];
[1]Dept. of Biotech. and Life Sci., Univ. of Insubria, Busto Arsizio, Italy; [2]Dept. Pharmacol. and Biomolecular Sci., Univ. degli Studi di Milano, Milano, Italy

Abstract: The cellular and functional changes underlying the adaptive or maladaptive behavioral effects of an acute stressor are not well understood. In the medial prefrontal cortex (mPFC) of preclinical animal models, an acute stressor may rapidly change dendritic morphology and synaptic function. In the male rat mPFC, the foot-shock stress protocol (FS) rapidly (~1 hr) increases the number of excitatory synapses, the readily releasable Glu vesicle pool, [K^+]-evoked Glu release from synaptosomes (doi.org/10.3389/fpsyt.2015.00060), and the amplitude of spontaneous excitatory postsynaptic currents (sEPSCs) recorded in L2/3 pyramidal neurons (Pyr). Within 24 hrs, FS induces shrinkage of apical dendrites, while no information exists for sEPSCs. Miniature excitatory synaptic currents (mEPSCs) have been suggested to have a neurotrophic and homeostatic role, but the effects of FS on mEPSCs are unknown.
To understand the sustained effects of FS on Glu transmission in the mPFC and its regulation by

ketamine at antidepressant dosage, synaptic currents were recorded 24 hrs after FS in visually identified layer 2/3 Pyr of prelimbic mPFC in slices from adult male rats. Animals subjected to a 40-min session of inescapable FS (FS group), animals injected with ketamine (10mg/kg) 6 hrs after FS, and controls (CTR) were compared. The amplitude, area, rise, decay, and inter-event intervals of mEPSCs and sEPSCs were analyzed. mEPSCs in the FS group showed minor changes in frequency (small increase) and ampitude (small decrease) vs CTR. Ketamine after FS increased mEPSC frequency and peak amplitude and accelerated rise and decay with no change in area, vs CTR. The above effects were significant with the Kolmogorov-Smirnov test on pooled cumulative unbinned data but not with 2-way ANOVA of binned histograms. sEPSCs frequency in the FS group had a small decrease, with no change in waveform vs CTR. Ketamine after FS produced similar effects on sESPCs as for mEPSCs. Overall, this work indicates that, 24 hrs after FS, minor changes occur in miniature and spontaneous synaptic currents at layer 2/3 Glu synapses of the mPFC of adult male rats. Ketamine effects on Glu synaptic currents of stressed animals suggest changes in synapse morphology and/or dendritic localization.

Title: Midazolam potentiates heroin-induced brain hypoxia, hypothermia, and behavioral inhibition

Authors: *A. AFZAL, E. A. KIYATKIN;
Behavioral Neurosci. Br., Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: Benzodiazepines are important therapeutic drugs, but they are often abused and co-abused with opioids. Clinical evidence suggests that benzodiazepines can inhibit respiration, and when combined with the respiratory-depressive effects of opioids, may increase likelihood of death. In this study we used oxygen sensors coupled with high-speed amperometry and multi-site thermorecording to examine how intravenous (iv) midazolam, a potent benzodiazepine, modulates the brain hypoxic and temperature effects of iv heroin in freely-moving, male Long-Evans rats. Oxygen levels and brain temperature were assessed with high temporal resolution in the nucleus accumbens (NAc), and additional thermorecordings from temporal muscle and subcutaneous space allowed us to assess drug-induced changes in metabolic brain activity and

skin vascular tone. When administered alone, midazolam (2 mg/kg) modestly decreased NAc temperature but had no evident effects on NAc oxygen levels. In contrast, heroin (0.4 mg/kg) induced a strong decrease in oxygen that was followed by a weaker, rebound-like oxygen increase which appears to be caused by cerebral vasodilation and subsequent increases in cerebral blood flow (CBF). Midazolam pretreatment did not affect heroin-induced brain hypoxia but potentiated the initial hypothermia induced by heroin. In contrast, co-administration of these drugs potentiated heroin-induced oxygen decrease and brain hypothermia. This potentiated oxygen decrease appears to be caused by decreases in CBF due to strong peripheral vasodilation, thus opposing increases in CBF normally induced by heroin-alone. Midazolam co-administered with heroin thus appears to "disenable" this latter adaptive mechanism, resulting in more prolonged and sustained brain hypoxia. Co-administration of heroin and midazolam also resulted in enhanced locomotor inhibition and ataxia/loss of behavioral control, which caused some rats to collapse, resulting in nose and mouth occlusion which created a secondary hypoxic phase. Our results thus highlight the exaggerated dangers of the polydrug abuse of benzodiazepines with potent opioid drugs and they could have important implications for human drug users, as combined use not only results in sustained brain hypoxia but creates conditions of loss of motor control which could result in asphyxia and death.

Title: Effect of transporter inhibitors on brain concentration of peripherally injected diphenidine

Authors: *K. OKUDA[1], M. ASARI[1], H. TANAKA[1], C. HOSHINA[1], K. HORIOKA[1], K. MATSUBARA[2], H. SHIONO[1], K. SHIMIZU[1];
[1]Asahikawa Med. Univ., Asahikawa, Japan; [2]Kyoto Univ. Hosp., Kyoto, Japan

Abstract: Background: Diphenidine (DPD) is one of the new psychoactive substances. The chemical structure of DPD is similar to phencyclidine and ketamine. DPD and some of its derivatives are designated as controlled drugs in Japan and many other countries. The mechanisms of the drugs are common and known as the NMDA receptor antagonist. We have reported that DPD increased locomotor activity and stimulated A10 nervous system, which is known as reward system and strongly related with drug addiction, rather than A9 nervous system in rat. In this study we estimated time course of the brain concentration of DPD by using rat

brain microdialysis and evaluated the effect of several transporter inhibitors related to blood-brain barrier.
Method: Male Slc:Wistar/ST rats were anesthetized and stereotaxically implanted a microdialysis probe with a dialysis area of 2 mm length in the nucleus accumbens (NAc, A +2.0 mm, L +1.5 mm from the bregma, V -6.0 mm from the skull). On the next day, perfusion was performed in a plastic cage with free access to food and watery gel. An inhibitor was injected subcutaneously 1 hr before i.p. injection of 10 mg/kg DPD. Dialysate were collected every hour and then analyzed by LC-MS/MS. LC-MS/MS analysis was performed with an API3200 QTRAP System (Applied Biosystems) coupled to a Shimadzu HPLC LC20A system. Reversed-phase L-Column2 ODS (150 mm x 1.5 mm I.D., 5 μm) was used as the separation column. The separation was performed with 70% methanol in 10 mM ammonium formate (flow rate 0.1 ml/min). DPD was detected by ESI-positive mode. The product ion m/z 86 from m/z 235 of DPD was the most suitable ion for quantitative determination using selected reactions monitoring (SRM).
Result and discussion: DPD was detected in the dialysate from rat brain after i.p. injection. The highest concentrations were observed at 30 minutes and the concentrations were decreased time-dependent manner. This result proved that DPD pass through the blood-brain barrier. The DPD concentration in the dialysate was significantly increased by pretreatment of P-glycoprotein inhibitors such as verapamil and quinidine. And also, an organic cation transporter inhibitor, diphenhydramine, significantly increased the DPD concentration in the dialysate. However, no difference was identified between DPD levels in the blood of the inhibitors and saline pretreatment groups. The results indicated that P-glycoprotein and organic cation transporter has an important role in the transportation of DPD across the blood-brain barrier.

Title: Changes in the structure and diversity of the rat gut microbiota induced by volatilized cocaine and adulterants

Authors: *C. SCORZA[1], C. PICCINI[2], M. MARTINEZ BUSI[3], J. ABIN CARRIQUIRY[3], P. ZUNINO[2];

Abstract: A close relationship between the gut microbiota (GM) and neuropsychiatric disorders has been suggested. However, only a few studies have investigated the GM in the context of drug addiction. In addition to the intranasal consumption, cocaine can be smoked (i.e., cocaine base named crack or coca-paste, CP). The consumption of CP or crack is associated with a very high abuse liability and toxicity. We have demonstrated that CP seized samples contained caffeine and phenacetin as main active adulterants, which may potentiate its motivational, reinforcing, and toxic effects. It has been recently reported that rats chronically treated with antibiotics show important changes in GM and also potentiate the sensitization process to cocaine. However, the effect of volatilized cocaine and adulterants on the GM still remains unexplored. We evaluated the effect of volatilized cocaine and two adulterants on the structure, diversity, and functionality of the GM in rats. Male adult rats were chronically exposed to the fume of cocaine, caffeine, and phenacetin during 14 days. At the end of the treatment, feces were collected and the structure, composition, and functional predictions of the gut microbiota were analyzed. Cocaine significantly decreased the community richness and diversity of the GM while both cocaine and phenacetin drastically changed its composition. Phenacetin significantly increased the Firmicutes-Bacteroidetes ratio compared to the control group. When the predicted metagenome functional content of the bacterial communities was analyzed, all the treatments induced a dramatic decrease of the aromatic amino acid decarboxylase gene, suggesting that neurochemical changes can occur. Our results show for the first time that cocaine and adulterants are able to modify the GM. Although further studies are needed, our results support that GM could be a site of action for treatment in drug addiction.

Title: Role of the terminal amine group of alphaPVP derivatives (synthetic cathinones) inducing psychostimulant and rewarding effects

Authors: *R. LÓPEZ-ARNAU[1], L. DUART-CASTELLS[1], N. NADAL-GRATACÓS[2], X. BERZOSA[2], M. MURALTER[1], M. CARBÓ[3], J. CAMARASA[1], D. PUBILL[1], E. ESCUBEDO[1]; [1]Dept. of Pharmacology, Toxicology and Therapeut. Chem., Fac. of Pharm. and Food Science,

Univ. of Barcelona, Barcelona, Spain, Barcelona, Spain; [2]Dept. of Organic and Pharmaceut. Chem., IQS Sch. of Engineering, Univ. Ramon Llull, Barcelona, Spain, Barcelona, Spain; [3]Dept. of Pharmacology, Toxicology and Therapeut. Chem., Univ. of Barcelona, Barcelona, Spain

Abstract: New psychoactive substances is a term describing analogues of classic psychostimulant abused drugs. One of the most prevalent and abused group is synthetic cathinones, whose effects are similar to amphetamine, cocaine or MDMA. Data suggest that, by analogy, other synthetic cathinones will join to the recreational drug market and most of them may have strong rewarding effects and have abuse liability. Thus, the aim of the present research was to study the role of the terminal amine group of pentiophenone derivatives (a class of synthetic cathinones) inhibiting dopamine and noradrenaline uptake as well as their psychostimulant and rewarding effects. N-ethyl-pentedrone (NEP) (1, 3 or 10 mg/kg, i.p.), α-pyrrolidinopentiophenone (α-PVP) (1, 3 or 10 mg/kg, i.p.) or N-piperidyl-pentedrone (NPP) (7.5, 25 or 75 mg/kg, i.p.) were administered to Swiss CD-1 male mice (8 weeks-old) and their locomotor activity was recorded for 60 min. Moreover, conditioned place preference experiments were also performed at the same doses. Synaptosomes from male rat (Sprague-Dawley, 200-250 g) striatum were used for [^{3}H]dopamine (DA) and [^{3}H]noradrenaline (NA) uptake experiments. NEP and α-PVP (3 and 10 mg/kg) induced a dose-dependent increase in locomotor activity while NPP produced only a slight increase in locomotion at the highest doses tested. Once again, both NEP and α-PVP produced similar place preference conditioning at the highest doses tested (3 and 10 mg/kg) although NEP also produced a significant preference score at a dose of 1 mg/kg. Therefore, and based on the ability of producing rewarding effects, NEP may have potential for abuse and addiction comparable to α-PVP. However, NPP only induced rewarding effects at the lowest dose tested (7.5 mg/kg) although the same dose did not produce an increase in the locomotor activity. On the other hand, the three substances were able to inhibit [^{3}H]DA and [^{3}H]NA uptake in rat synaptosomes. The IC_{50} values (nM) of DA and NA uptake for NEP, α-PVP and NPP were 696.4 ± 54.4 and 93.7± 0.4, 129.3 ± 7.3 and 18.8 ± 0.6, 887.9 ± 83.1 and 279.3 ± 48.8, respectively. Therefore, the order of potency inhibiting both DA and NA uptake was α-PVP> NEP≥ NPP. In conclusion, the terminal amine group of these compounds seems to impact in their potential to induce rewarding and psychostimulant effects as well as to inhibit DA and NA uptake. The present results also provide new information about the effects of new synthetic cathinones that may appear soon on the drug market.

Title: Cue-induced reinstatement following chronic intravenous ketamine self-administration in male and female Long-Evans rats

Authors: *D. P. HAGARTY, C. STRONG, K. L. MANN, J. BREEDLOVE, K. SCHOEPFER, S. CAJUSTE, M. KABBAJ;
Florida State Univ., Tallahassee, FL

Abstract: Ketamine's rapid and long-lasting antidepressant effects have shown great promise for helping Major Depressive Disorder (MDD) patients with Treatment Resistant Depression (TRD). However, ketamine itself is addictive and little has been done to examine the abuse potential of repeated exposure treatment regimens for TRD. Additionally, most current research has been done in only male subjects and primarily assessed higher doses of ketamine. Depression is twice as prevalent among women as compared to men and clinical studies suggest that women cycle through the stages of addiction at a faster rate than men. Furthermore, our lab previously demonstrated that female rats were more sensitive to ketamine's antidepressant-like and addictive-like properties, so more research is needed to examine the addictive potential between sexes. Given that men and women receive the same dose of antidepressant ketamine in clinical settings, the aim of this study was to investigate ketamine's addictive properties across a range of doses to better assess the safety of repeated ketamine treatment using a rodent model. Here, we investigated sex differences in the reinforcing properties of repeated ketamine to determine the optimal dose of ketamine for future studies examining both addiction-like behaviors and antidepressant outcomes without eliciting addictive-like behaviors. We examined ketamine's reinforcing properties by using a self-administration (SA) paradigm to assess measures of drug acquisition, maintenance, extinction, and reinstatement in male and female rats. Independent groups of rats were assigned to self-administer various doses of ketamine (0, 0.125-, 0.250-, or 0.500 mg/kg/infusion, i.v.). Male and female rats self-administered under fixed ratio 1, 3, and 5 (FR1, FR3, FR5) schedules of reinforcement during daily 2-hour long sessions. Following SA, animals were exposed to 10 days of extinction followed by cue-induced reinstatement 24-hours after the last extinction session. Preliminary data suggest sex differences in both infusions and active responding during SA, extinction, and cue-induced reinstatement, such that females consistently had more infusions and responses than males at higher doses. Future research should investigate the specific molecular mechanisms and circuitry underlying cue-induced reinstatement of ketamine SA.

Title: Methamphetamine-induced behavioral sensitization: A role for brain CYP2D1

Authors: *M. R. STOCCO[1], S. MIKSYS[1,2], F. B. WADJI[1], B. ZHAO[1,2], A. EL-SHERBENI[1], R. F. TYNDALE[1,2];
[1]Pharmacol. and Toxicology, Univ. of Toronto, Toronto, ON, Canada; [2]Campbell Family Mental Hlth. Res. Institute, CAMH, Toronto, ON, Canada

Abstract: Introduction: Brain CYP2D metabolism of methamphetamine (METH) is a potential source of variation in response, abuse liability, and neurological outcomes. CYP2D is genetically variable and metabolizes many CNS active drugs, including metabolizing METH to metabolites amphetamine (AMP) and 4-OH-METH. Brain CYP2D influences CNS drug levels and response, as has been shown in rats with opioid analgesia. Inhibiting brain CYP2D could increase brain METH and decrease metabolite levels. Increases in stereotypy, ambulation, and rearing would suggest a METH effect, while the reverse would indicate a metabolite effect. We hypothesized that METH, more so than AMP and 4-OH-METH, induces behavioral sensitization, and that inhibiting rat brain CYP2D metabolism would increase sensitization following repeated METH administration. Methods: Male Wistar rats were injected with METH (0.5 mg/kg SC) daily for 7 days and on challenge days 11 and 27. Stereotypy, ambulation, and rearing responses were assessed. Twenty hours prior to each METH injection, rats were given intracerebroventricular pretreatment injections of the CYP2D suicide inhibitor propranolol (80 µg; N=11) to irreversibly inhibit brain CYP2D, or of vehicle (20% cyclodextrin solution; N=12). Two replications were performed, each with N=5-6 rats per pretreatment group. Results: Vehicle pretreated rats exhibited modest sensitization of stereotypy, but no change in ambulation or rearing. Compared to day 1, their stereotypy time was *higher* on challenge day 27 (ANOVA main effect of session, $p<0.0001$; Bonferroni post hoc, $p<0.05$). CYP2D inhibitor pretreated rats exhibited greater sensitization. Compared to day 1, their stereotypy time was *higher* on days 4-7 and challenge days 11 and 27 (Bonferroni post hocs, all $p<0.05$); their ambulatory activity was *lower* on challenge day 27 (main effect of session, $p<0.05$; Bonferroni post hoc, $p<0.05$); and their rearing episodes were *lower* on days 5-7 and challenge days 11 and 27 (main effect of session, $p<0.01$; Bonferroni post hocs, all $p<0.05$). Comparing pretreatments, rats given CYP2D inhibitor (versus vehicle) exhibited *greater* stereotypy sensitization (main effect of pretreatment, $p<0.0001$), as well as a *decrease* in ambulatory activity (main effect of pretreatment, $p<0.0001$) and in rearing

episodes (main effect of pretreatment, $p<0.001$). Conclusions: These data indicate (1) a role for brain CYP2D in METH responses, and (2) a greater contribution of METH than of AMP and 4-OH-METH to METH sensitization. Variation in brain CYP2D metabolism is a potential novel mechanism contributing to differences in response following repeat METH exposure.

Title: Drug addiction and withdrawal induce changes in behavior and epigenetic biomarkers

Authors: *A. ZMAROWSKI, S. REED, B. LEARN, C. BOND, J. CLAYBOURNE, R. LORDO, D. S. B. S. SILVA, R. SPURBECK;
Battelle, West Jefferson, OH

Abstract: Drug abuse, including prescription drug abuse, is an immense problem with huge economic and sociological costs. The present study was designed to assess behavioral and epigenetic changes after inducing drug dependence and during withdrawal using positive controls. Animals (8-9 animals/sex/group) were given subcutaneous injections once daily for 30 days with d-Amphetamine (AMPH, 0.08 or 0.1 mg/kg), Diazepam (DIAZ, 5 or 10 mg/kg) or Morphine (7.5 or 15 mg/kg). Control animals received sterile water for injection. After the last day of dosing, animals underwent a drug-free 7-day withdrawal period. Functional observational battery (FOB) assessments, including behavioral, physiological and reflex tests, were conducted by an examiner blinded to dose groups between 1-3 hours after dosing. Locomotor activity was measured for 4 hours per occasion. Behavioral testing was conducted once prior to dosing, on treatment Day 1, Day 30, and Days 1-7 of the withdrawal period. After 7 days of withdrawal, animals were euthanized and brains dissected. For morphine treated rats and controls, DNA and proteins were extracted from the hypothalamus for analysis of two epigenetic marks: DNA methylation and histone modifications. Reduced representation bisulfite sequencing was conducted to obtain DNA methylation profiles and Mod Spec® was used to measure the abundance of 80 different histone modifications to identify targets effected by morphine addiction and withdrawal. Differences in FOB endpoints and changes in locomotor activity were noted for drug treated groups primarily on Day 1 and Day 30. Most behavioral differences resolved by Day 7 of the withdrawal period. Data from the present study will contribute to the characterization of the neurobiological effects of different drug classes in addiction and

withdrawal. The epigenetic targets will enable development of new diagnostics for opioid addiction/withdrawal and provide the basis for development of alternative treatments for addicted individuals.

Title: Effects of chronic co-administration of modafinil and citalopram on motor activity and the subsequent oral self-administration of modafinil

Authors: *E. YEPEZ[1], L. MOLINA-MARTINEZ[2], J. JUAREZ[3];
[1]Univ. De Guadalajara, Guadalajara, Mexico; [2]Univ. of Guadalajara, Guadalajara, Mexico; [3]Univ. Guadalajara, Guadalajara, Jalisco, Mexico

Abstract: Most drugs of abuse share a common neurobiological substratum; particularly related to an increase in the release of dopamine (DA) in areas of the mesocorticolimbic circuit. There is evidence that besides norepinephrine (NE), serotonine (SER) activity seems to play an important role in addictive behavior. Cocaine, a psychostimulant with high addictive potential, acts enhancing the monoaminergic activity of DA, NE and SER. Modafinil is a week psychostimulant used for sleep disorders acting on DAT and NET but without affinity on SERT, and at the same time, no addictive potential has been described for this drug. On the basis of the differential action on monoamine activity, it is possible that the co-administration of modafinil plus citalopram (a specific inhibitor of SER reuptake) could conferring or increase the incentive value of modafinil and so facilitate its subsequent self-administration. Due to there is no background in the literature, the initial approach was to evaluate different doses of modafinil and citalopram. Seven groups of male rats 60-day old were treated chronically (16 days) with, either modafinil (MOD) in doses of 30 or 60mg/kg alone or co-administered with citalopram (CIT) at doses of 3mg/kg and 5mg/kg, 40 min before evaluating the motor activity. In addition, the behavior of anhedonia was assessed at 48, 72 and 96h after the treatment was interrupted. Oral modafinil self-administration was assessed after 12h of liquid restriction. Motor activity was diminished in 60MOD+3CIT and 60MOD+5CIT groups during the initial phase of pharmacological treatment. The co-administered groups 30MOD+3CIT and 60MOD+3CIT show high values of anhedonia, which were increasing over time in comparison with the other groups in the abstinence phase. At the same time, these groups show higher MOD self-administration than the other groups, and only the 60MOD+3CIT group showed motor activity sensitization

respect of the vehicle group. The co-administration of 30MOD+3CIT and 60MOD+3CIT seem to damp the hyperactivity effect of MOD as a psychostimulant drug; produces more signs of drug-withdrawal and an apparent proclivity to an increased consumption of modafinil.

Title: The effects of inhaled salvinorin A on resting state functional connectivity in humans

Authors: *M. K. DOSS, R. R. GRIFFITHS, D. G. MAY, M. W. JOHNSON, J. M. CLIFTON, F. S. BARRETT;
Psychiatry and Behavioral Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Salvinorin A is a potent κ-opioid receptor agonist and the main psychoactive constituent of *Salvia divinorum*, an atypical dissociative hallucinogen that is used recreationally and remains legal in many countries. Inhaled salvinorin A leads to a rapid onset and short duration of subjective effects that include a sense of depersonalization and derealization, as well as peculiar subjective effects that may mimic some of those of typical dissociative hallucinogens (i.e., NMDA receptor antagonists like ketamine) and classic psychedelics (i.e., 5-HT_{2A} receptor agonists like psilocybin). Additionally, some evidence suggests a rapid antidepressant effect of salvinorin A like ketamine and psilocybin, drugs with noteworthy effects on default mode network (DMN) connectivity. In a single-blind, placebo-controlled design, we conducted the first functional magnetic resonance imaging study with acute administration of inhaled salvinorin A to explore its effects on resting state functional connectivity in 12 healthy participants. Participants inhaled placebo (hot air) or vaporized salvinorin A (15 μg/kg) at the beginning of two separate 20-minute resting state scans. Participants listened to ambient music and wore eyeshades during each scan. Across the whole brain, salvinorin A (compared to placebo) decreased the number of significant static functional connections. This effect was especially robust within the DMN during the first half of the scan, and persisting attenuation of the DMN during the second half of the scan correlated with the duration of subjective drug strength. Salvinorin A was also found to decrease static connectivity within the frontoparietal network and a subcortical network that includes the salience network. An increase in functional connectivity

was found between medial and lateral visual networks during salvinorin A scans, perhaps reflecting visual distortions. Finally, analyses on functional connectivity dynamics revealed that salvinorin A reduced variability in functional connectivity within the DMN and within the medial and lateral visual networks. These findings reflect both similarity and dissimilarity with the neural effects of other hallucinogens, suggesting neural mechanisms that are unique to the altered state produced by salvinorin A.

Title: Acute oral administration of clobenzorex increases rectal temperature without altering motor activity in rat

Authors: *B. GÓMEZ-DE LOS SANTOS[1], D. MARCELO-PÉREZ[1], G. D. APÓSTOL-DEL ROSAL[1], A. PATRICIO-MARTÍNEZ[1,2], I. D. LIMÓN[1];
[1]Lab. de Neurofarmacología, Benemérita Univ. Autónoma De Puebla, Puebla, Mexico; [2]Facultad de Ciencias Biológicas, Benemérita Univ. Autónoma de Puebla, Puebla, Mexico

Abstract: Clobenzorex (Clx) is an amphetamine-like widely used in morbid obesity treatments, due to it is a potent anorexigenic agent as well as being a less potent stimulant agent. Because of this drivers use the Clx to decrease the fatigue and insomnia for long periods. Acute treatment with amphetamine (AMPH) has been evidence to produce hyperthermia, decrease dopamine levels and tyrosine hydroxylase inmunoreactivity in the striatum, which has been associated with locomotor damage. The aim of this study was to evaluate the effect of acute oral administration of Clx on rectal temperature and motor activity in rats. Male Wistar rats were used, which were divided into three experimental groups: a control group (SSI, n=6), an amphetamine group (3 mg/kg, n=6) and a clobenzorex group (60 mg/kg, n=6). The administration of the drugs was carried out orally three times in an interval of three hours, in a single day. Rectal temperature was measured half an hour before starting administration begin administration and every hour after the first administration. Register ended two hours after the last administration. The following day was evaluated the motor activity in the open field model (Columbus Instrumens, Ohio USA). The results show that the acute oral administration of Clx and AMPH increases the rectal temperature two and three hours after the first administration, respect to control group.

However, no significant changes in motor activity shown. These results suggest that acute oral administration of Clx and AMPH produce hyperthermia because of the norepinephrine and glucocorticoids' release at the peripheral level. Nevertheless, in this condition do not produce change in motor activity. Support VIEP-BUAP 2019.

Title: The effects of chronic methamphetamine on LINE-1 activity in rat striatum, hippocampus and prefrontal cortex

Authors: *A. B. MOSZCZYNSKA;
Wayne State Univ., Detroit, MI

Abstract: Methamphetamine (METH) is a widely abused psychostimulant with the potential to cause a broad range of cognitive and psychomotor deficits as well as neurobehavioral abnormalities when abused chronically, particularly at high doses. These deficits are related to METH neurotoxicity in the striatum, prefrontal cortex and hippocampus. Transposable elements are repetitive DNA sequences that can induce epigenetic alterations in the genome. Activation of transposable Long INterspersed Element 1 (LINE-1) is associated with several neurological diseases as well as with drug abuse. However, there is very limited data on the effects of high-dose METH on the activity of LINE-1 in adult brain. Employing 2-month-old male Sprague-Dawley rats, pyrosequencing, and real-time quantitative PCR, we examined a few markers of LINE-1 activity in the striatum, dentate gyrus, and prefrontal cortex of chronic METH-treated rats and saline controls. This study demonstrates that chronic administration of neurotoxic METH doses results in significantly increased expression of LINE-1-encoded ORF-1 (Open Reading Frame 1 mRNA) in rat striatum at 24h after the last dose of the drug and decreased ORF-1 expression on the 7thday of METH withdrawal, with the dentate gyrus developing tolerance to these METH effects and prefrontal cortex showing unaffected LINE-1 activity at both time points (as assessed by multiple unpaired two-tailed *t*-tests followed by the Holm-Sidak method to adjusts for the probability of Type I errors in multiple comparisons). The results

indicate that LINE-1 activation might be a new factor mediating neurotoxic effects of chronic METH in the striatum and, therefore, a new drug target against METH-induced psychomotor impairments in chronic METH users.

Title: Chronic clobenzorex administration decreased motor behaviour without dopaminergic degeneration

Authors: *A. PATRICIO-MARTÍNEZ[1,2], G. D. APOSTOL DEL ROSAL[1], B. GÓMEZ-DE LOS SANTOS[1], F. LUNA MORALES[3], I. D. LIMÓN[1];
[1]Lab. de Neurofarmacología-FCQ-BUAP, Puebla, Mexico; [2]Facultad de Ciencias Biológicas-BUAP, Puebla, Mexico; [3]Lab. de Neuroendocrinología-FCQ-BUAP, Puebla, Mexico

Abstract: Clobenzorex is one of the five drugs most used in Mexico for the treatment of obesity. Clobenzorex´s an amphetamine-like due to the structural and stimulant similarities that they share. Several studies have shown that amphetamines induce dopaminergic neurotoxicity and neuroinflammation in the striatum, associated with motor damage. For this reason, the aim of this study was to evaluate the chronic clobenzorex administration on motor behaviour and nigrostriatal dopaminergic degeneration. Male Wistar rats were used, three experimental groups were formed: control group (n= 8) administered with SSI, amphetamine group (2 mg / kg) (n= 8) and the clobenzorex group (30 mg / kg) (n= 8), all groups were administered orally, every 24 hours, for 31 days. Every 10 days the rats were evaluated motor activity in the open field test and motor coordination in the beam-walking test. Thirty-two days post-lesion were euthanasia performed on animals to extract the brains and assess the tyrosine hydroxylase (TH), even to explore the neurodegeneration in striatum and *substance nigra pars compacta* (SNpc), by the amino-cupric silver stain. The results show that the amphetamine and clobenzorex administration decrease motor activity and increased errors number in the beam-walking test compared to the control group. On the other hand, we not found significant changes in the immunoreactivity for TH and the neurodegeneration in striatum and SNpc. These results suggest that chronic administration of clobenzorex could decrease motor function similar to amphetamine through neuroadaptive and non-neurotoxic changes in the striatum under this administration paradigm.

Title: The effects of voluntary methamphetamine vapor exposure and binge intoxication in adult Wistar rats

Authors: *A. GUTIERREZ[1,2], J. D. NGUYEN[1,2], M. A. TAFFE[1,2];
[1]Psychiatry, Univ. of California San Diego, La Jolla, CA; [2]Neurosci., The Scripps Res. Inst., La Jolla, CA

Abstract: Long-term changes in neuronal signaling and cognitive function result from chronic methamphetamine (MA) abuse. Inhalation is a major route of administration among individuals that abuse MA, yet few pre-clinical studies have examined the effects of inhaled MA. The purpose of this study was to examine the effects of MA vapor inhalation using an electronic cigarette style drug delivery system. The first experiment was designed to examine MA vapor self-administration. Adult female Wistar rats were trained to nose-poke for MA vapor at a fixed drug concentration in the vapor vehicle. Drug concentrations were then substituted across days, and concentration-response assessed. Results of this experiment confirmed modest concentration-dependent responding. The second set of experiments used a binge-like dosing regimen to determine whether repeated exposure to a high concentration of MA vapor produced effects characteristic of those produced by repeated MA injection in prior studies, e.g., neurotoxicity and cognitive deficits. For these experiments, animals were implanted with radiotelemetry devices to assess body temperature and locomotor activity during MA inhalation. Rats underwent three sessions of 30-minute MA vapor exposure, each session separated by a two-hour interval. Brain tissue was collected in one group of animals two weeks after MA dosing. A second group of animals underwent behavioral testing to examine effects of MA vapor on impulsivity in a delayed-discounting task, also starting two weeks after MA inhalation. Tissue was collected from these animals upon completion of behavioral testing. This experiment showed that binge MA exposure by vapor inhalation resulted in elevated locomotor activity and in ambient temperature-dependent changes in body temperature, characteristic of binge MA treatment by injection. Results from the delayed discounting task found MA-induced changes in impulsivity since MA-treated animals preferred a small immediate reward over a larger, delayed reward at the longest delay interval examined. Tissue analyses will provide further information

on the effects MA vapor on tissue monoamine content. The findings reported here validate a method of studying both reinforcement of MA by inhalation and cognitive effects resulting from binge MA vapor intoxication.

Title: Characterization of repeated exposure to ketamine and its metabolite in zebrafish larvae

Authors: *N. N. JACKSON, K. S. JONES;
Pharmacol. Dept., Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstract: Ketamine is a commonly used anesthetic that blocks the ion channel pore of the N-methyl-d-aspartate receptor (NMDAR). Therapeutic interest in NMDAR pore blockers has grown considerably because it can rapidly alleviate symptoms of depression (Zaraet et al., 2006). However, the therapeutic use of ketamine is risky because it can also cause serious side effects like psychotomimesis (Domino, 1992) and repeated exposure can be habit-forming. Sensitization and tolerance are neuroadaptive processes that respectively increase and decreases drug effects during repeated exposure to drugs of abuse. Repeated exposure to ketamine has been shown to cause sensitization to the hyperlocomotor actions of ketamine, but the mechanism is unclear. Zebrafish (*Danio rerio)* is an emerging animal model in drug abuse research whose behavioral response to ketamine and other NMDAR antagonists is highly homologous to mammals. Here we examined how repeated exposure to anesthetic and sub-anesthetic doses of ketamine influences the psychomotor and anesthetic actions of ketamine. Additionally, we examined the effect of repeated exposure to ketamine's neuroactive metabolite hydroxynorketamine (6HNK). We also examined how repeated exposure to ketamine and 6-HNK impact brain-wide neuronal activity in zebrafish larvae. The current experiments were designed to examine the impact of daily exposure to ketamine or 6HNK for 5 days after 24 hpf, when zebrafish are expressing NMDARs. Drug treatment was discontinued on day 6. On day 7, larvae received an acute challenge of respective drug and behavioral data was collected. Groups of fish were fixed and stained for pERK. Preliminary data suggests the IC_{50} for ketamine in zebrafish larvae is 0.139 mM.
This study suggests chronic exposure to ketamine shows sensitization or tolerance of zebrafish locomotor activity. These experiments will potentially lead to a better understanding of the

actions of ketamine and the active metabolite 6HNK and its actions in the brain. Furthermore, these findings may contribute to the development of pharmaceutical treatments of disorders involving NMDA receptor inhibition.

Title: The prefrontal cortex and the caudate nucleus respond conjointly to methylphenidate (Ritalin). Concomitant behavioral and neuronal recording study

Authors: *S. S. VENKATARAMAN[1], C. CLAUSSEN[2], C. REYES-VAZQUEZ[3], N. KHARAS[2], N. DAFNY[2];
[1]Neurobio. and Anat., Wake Forest Univ. Sch. of Med., Houston, TX; [2]Neurobio. and Anat., The Univ. of Texas McGovern Med. Sch. at Houston, Houston, TX; [3]Dept. De Fisiología, Mexico, D.F., Mexico

Abstract: Methylphenidate (MPD) is the most commonly prescribed psychostimulant used in children and adolescents to treat attention deficit hyperactivity disorder (ADHD). Though MPD effectively treats the disorder in patients who are diagnosed with ADHD, it is being abused for its ability to improve cognitive enhancement and for recreational purposes. Thus, there are growing concerns regarding its addictive potential. Further, some use MPD for daily cognitive enhancement (chronic), while others use it just prior to an exam or important task (acute).Additionally, the dose of MPD abused varies from individual to individual with some abusing low dose MPD (0.6mg/kg and 2.5mg/kg) and others abusing high dose MPD (10.0mg/kg). The prefrontal cortex (PFC) and caudate nucleus (CN) are two of the brain areas that are dysfunctional in ADHD and are also involved in the reward pathway. The PFC, in particular, is involved with higher cortical processing, decision-making, impulse control and other features inhibited by ADHD. The PFC makes extensive connections with the CN. These frontostriatal connections play critical roles in procedural learning and inhibitory control.The goals of this study are to investigate acute and chronic, dose-dependent MPD exposure on behavioral activity and the PFC and CN neuronal populations in ordinary, (as opposed to ADHD or hyperactive) freely behaving adult animals implanted previously with electrodes within the PFC and CN. For this experiment, four groups of animals were used: saline (control), 0.6, 2.5, and 10.0 mg/kg MPD. It was observed that the same dose of either: 0.6, 2.5, or 10.0 mg/kg

repetitive (chronic) MPD exposure elicited behavioral sensitization in some animals and behavioral tolerance in others. Moreover, it was demonstrated that the majority of PFC units and CN units responded to MPD in a similar, dose-dependent fashion. The majority of animals expressing behavioral sensitization responded to MPD by increasing their neuronal firing rate, whereas the majority of PFC neurons recorded from animals expressing behavioral tolerance responded to MPD by decreasing their neuronal firing rate. We propose that chronic MPD exposure leads to an increase in the number of post-synaptic D1 dopamine receptors in behaviorally sensitized animals and an increase in the number of post-synaptic D2 dopamine receptors in behaviorally tolerant animals. Further, we suggest that as the PFC and CN fire together and behave similarly upon MPD exposure, they likely wire together, supporting the hypothesis that MPD use and abuse may strengthen these frontostriatal connections, which possibly underlie MPD addiction.

Title: Effects of quercetin pre-treatments and repeated toxic-dose methamphetamine on hyperthermia

Authors: *A. ALMALKI[1], Y. ALTHOBAITI[2];
[1]Dept. of Pharmaceut. Chem., [2]Pharmacol. and Toxicology, Taif Univ., Taif, Saudi Arabia

Abstract: Methamphetamine (METH) is considered one of the abused psychostimulants that has been proven to induce nerve damage due to its neurotoxic effects. High dose of METH was discovered to induce hyperthermia which has been suggested to induce neuronal damage. Finding treatment that can prevent or alleviate hyperthermia in METH abusers is critical. Many reports indicated that oxidative stress has been linked to METH induced hyperthermia. Therefore, we proposed that quercetin, well known antioxidant, can reduce the METH induced hyperthermia. Saline (1ml/kg, i.p. every 2h × 4) or quercetin (200 mg/kg i.p. every 2 hours x 4) were given at 30 min pretreatment paradigm. METH (5 mg/kg i.p. every 2 hours x 4) or Saline (1ml/kg, i.p. every 2h × 4) were given as posttreatment paradigm. Four groups of rats were used in this study; (1) saline-saline group (SS) group, (2) Saline-METH (SM), (3) Quercetin-saline (QS) group, and (4) Quercetin-METH (QM) group. Temperature was recorded at 4 time points

(0, 90, 120, and 220 mins). Temperature was elevated significantly in SM group as compared to control group at 90, 120, and 220 min. Interestingly, quercetin pretreatment was revealed to alleviate METH induced hyperthermia as compared to saline pretreatment at 120 and 220 min. This effect could be attributed to antioxidant effect of quercetin. As conclusion, quercetin could be an effective treatment in METH induced hyperthermia and neurotoxicity.

Title: Using nanoparticles to reduce methamphetamine toxicity

Authors: M. SEVERSON[1], P. JAMPANI[2], Z. WANG[2], *L. M. MCFADDEN[1];
[1]Div. of Basic Biomed. Sci., [2]Dept. of Chem., Univ. of South Dakota, Vermillion, SD

Abstract: Methamphetamine (METH) is a highly addictive psychostimulant with potentially deadly consequences. The neurotoxic effects of METH are due in part to the excessive release of dopamine (DA), serotonin (5HT) and other biogenic amines which may lead to persistent damage to DA and 5HT neurons. Currently, no pharmacological treatments for METH abuse/ overdose exist. Metal-organic supercontainers (MOSCs) are a new class of nanoscale particles featuring diverse nanoporous structures. These structures have tunable features that can be manipulated to allow specific molecules to bind to them. It is hypothesized that MOSCs may provide therapeutic potential in reducing METH-toxicity by binding transmitters released by METH, leading to a mitigation of the long-term effects. Ultraviolet-visible spectroscopy (UV-vis) was used to demonstrate that MOSCs has a binding affinity to DA and 5HT. Further, in exploratory studies, male Sprague-Dawley rats (300-400 grams) were used to assess MOSCs therapeutic potential in reducing METH-induced toxicity. Males were utilized given that previous studies have demonstrated that they have greater METH-induced toxicity compared to females. Our initial findings indicate that following a neurotoxic exposure to METH, rats had higher DA content in the MOSC infused striatum when compared to the vehicle control infused striatum, indicating the ability of MOSCs to attenuate of the neurotoxic consequences of METH (6 animals utilized in two experiments). Follow up studies to assess MOSC distribution and viability *in vivo* will also be performed. Systemic administration will also be utilized to assess MOSCs ability to cross the blood-brain barrier. Overall, these findings suggest that MOSCs may provide therapeutic potential in reducing toxicity caused by METH.

Title: Identification of a novel metabolic-epigenetic interaction network mediating learning-related histone acetylation in the brain

Authors: *D. C. ALEXANDER[1], M. MENDOZA[1], G. EGERVARI[1], P. MEWS[2], B. A. GARCIA[1], S. BERGER[1];
[1]Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA; [2]Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Histone acetylation is an epigenetic activator of many types of learning and memory, including the establishment and maintenance of addiction memory. During memory formation, histone acetylation spikes at the promoters of immediate early genes, which are critical regulators of synaptic plasticity. In neurons, a metabolic protein, Acetyl-CoA synthetase 2 (ACSS2), plays an essential role in activity-dependent gene activation by converting acetate to acetyl-coA directly at the regulatory elements of induced genes. While the level of circulating acetate in the mammalian bloodstream is normally low, the consumption and subsequent metabolism of ethanol increases plasma acetate levels 20-fold. Interestingly, this alcohol-derived acetate is directly incorporated into brain histone acetylation in an ACSS2-dependent manner, providing an additional mechanism for the establishment of alcohol use disorder. This finding is striking, but many aspects of ACSS2's action on neuronal chromatin are unknown, including both its method of recruitment and its interacting partners at the chromatin. To establish ACSS2's interacting partners at the chromatin in an unbiased manner, we immunoprecipitated endogenous ACSS2 from nuclear lysate derived from C57Bl6 adult cortex and identified interacting proteins by nano liquid chromatography-tandem mass spectrometry (nLC-MS/MS). To remove non-specific interactors, we compared these results to identical IPs performed in age-matched $ACSS2^{KO}$ mice we generated by CRISPR-Cas9 on a C57Bl6 background. From these data, we described a high-confidence interactome for nuclear ACSS2, demonstrating that it interacts with known chromatin regulators and chromatin remodeling proteins. To map ACSS2's interacting partners to specific genomic loci, we performed chromatin immunoprecipitation of select factors and compared these results to ACSS2's enrichment across the genome. Finally, we

compared ACSS2's binding occupancy to RNA expression at baseline and in the context of memory formation. All molecular experiments were performed in age-matched adult mice (female and male; n=3-5 per group), and controlled for time-of-day effects. Our findings delineate the molecular components of a novel metabolic-epigenetic regulatory machine that is required for learning-related histone acetylation. In the context of alcohol use, this machinery regulates the incorporation of exogenous acetate into histone acetylation in the brain. By clarifying the protein interactome of ACSS2 in vivo, we further establish this enzyme as an important biochemical contributor to learning and memory in physiological and pathological contexts.

Title: A novel method to study prolonged reward-context associations

Authors: *G. MCKENDRICK, N. GRAZIANE;
Anesthesiol. & Perioperative Med., Pennsylvania State Univ., Hershey, PA

Abstract: Animal models have significantly contributed to the understanding of reward-related behaviors, such as in Substance Use Disorder (SUD) research. Two of the most prominent paradigms to date are operant intravenous drug self-administration (SA) and conditioned place preference (CPP), each of which have distinct advantages and disadvantages. The classic SA model benefits from voluntary drug-taking, yet it is time-consuming, often invasive, and can involve non-translational learning procedures. Traditional CPP models are valued for their emphasis on contexts, ease and quickness of use, and sensitivity to drug effects, however it is non-contingent in nature, as the experimenter controls drug exposure. Our new model integrates these two classical methods by utilizing individual benefits and simultaneously diminishing prior downsides. We used a traditional 3-compartment CPP apparatus, where each chamber differs by both visual and tactile contexts. We reformed the apparatus by adding a new plexiglass top that allows for insertion of a 10 mL drinking bottle into each of the main chambers. The bottles, made of modified serological pipettes with a stainless-steel sipper tube, allow for oral self-administration of drug-containing solutions in a specific context. Wild type C57BL/6J mice

underwent 3 habituation trials to quantify baseline preference. Drug (Sucrose (10% w/v) or Morphine (25 mg/L)) and Water were assigned to the least- and most-preferred side, respectively. Two overnight training sessions were followed by 5 conditioning days (40-60 min sessions, 2x per day), restricted to either chamber with access to respective solutions. Solution consumption was recorded in mL. The next day mice were given open access to all chambers (Preference 1d test), and time in each chamber was recorded. After 21 days of homecage abstinence, mice had another test (Preference 21d test) to examine prolonged retention of preference. We have established a novel technique to assess preference for contexts associated with rewarding stimuli, which accentuates both voluntary drug-taking and environmental conditions. The described model can be further utilized to examine alternative drugs of abuse, apply extinction training or other learning models, or allow for inclusion of neurobiological manipulations.

Title: Modeling drug reward in invertebrates

Authors: A. ROMERO[1], J. F. GOMEZ-MOLINA[2], ***U. M. RICOY**[1];
[1]Dept. of Biology, Chem. and Envrn. Sci., Northern New Mexico Col., Espanola, NM; [2]Intl. Group of Neurosci. (IGN), Medellin, Colombia

Abstract: Conditioned place preference (CPP) continues to be one of the most popular models to study the motivational effects of drugs and non-drug treatments in experimental animals. With the underlying mechanisms strongly conserved in evolution, invertebrates have recently emerged as a powerful new model in addiction research. Indeed, as early as 1990, Huber et al. reported cockroaches as good candidates for neurobiology with relevant applications in biomedical research. Cockroaches represent an excellent model organism for a variety of biological and biomedical studies, including development, behavior, and neural responses. Because we can study behavioral mechanisms in cockroaches, we can study neuromodulation in a variety of different experimental paradigms. Early cockroach work focused on octopamine (OA) and

serotonin response in the nervous system. OA is a neuromodulator, neurotransmitter and neurohormone in insect nervous systems prompting the organism for "dynamic action." We use two species of cockroach (Periplaneta Americana and Blaptica Discoidalis). A total of 20 cockroaches, 10 of each species, were placed one at a time in a single lane of a Plexiglas apparatus with vanilla and peppermint. Each session was recorded from a top and side view for three minutes; video sessions were analyzed at a later time for the amount of time spent on each compartment X of the apparatus (X= Intermediate, Vanilla, or Peppermint). Our results show a strong Vanilla preference and peppermint avoidance for both South American and North American roaches. We also examined grooming behavior and found Vanilla to increase exploration and grooming whereas Peppermint had little effect on behavior. In a separate experiment, we show how OA alone increases exploratory behavior and neural excitability of the giant interneurons in the North American cockroach. The neuropil of the thoracic ganglia contains many catecholamine-histofluorescent processes bearing varicosities, providing a possible anatomical substrate for dopamine release sites. It is proposed that release of these biogenic amines may contribute to the modulation of the cockroach place preference behavior. Collectively, these findings suggest that the cockroach model is a useful approach to examine basic mechanistic questions in drug addiction.

Title: *In vivo* labeling and molecular characterization of active neurons in the infralimbic cortex using a genetically encoded photo-activatable calcium integrator (CaMPARI2)

Authors: *R. MADANGOPAL[1], S. J. WEBER[1], V. LENNON[1], L. E. KOMER[1], F. RUBIO[1], V. MENON[2], E. R. SCHREITER[3], B. T. HOPE[1];
[1]Natl. Inst. on Drug Abuse IRP, Baltimore, MD; [2]Dept. of Neurol., Columbia Univ., New York, NY; [3]Howard Hughes Med. Institute, Janelia Farm Res. Campus, Ashburn, VA

Abstract: Animals learn to associate cues (e.g. lights or tones) with rewards (e.g. food or cocaine). These learned associations are thought to be encoded by specific patterns of sparsely distributed neurons called '*neuronal ensembles*' that are selectively activated by these stimuli. Our lab and others have used the immediate early gene Fos to identify neuronal ensembles in rodent models of reward-related behaviors and have shown that they mediate these learned

behaviors. However, Fos protein expression is too slow to distinguish the active neuron patterns underlying individual stimulus-reward associations during these tasks.
To address this problem, we developed a technique to permanently label active neurons *in vivo* during ongoing behavior with sub-second resolution using an activity-dependent photoconvertible protein named CaMPARI2 (calcium-modulated photo-activatable ratiometric integrator). Using UV light, CaMPARI2 can be rapidly and permanently converted from its native green state to an 'active' red state only in neurons with strong activation (high intracellular calcium) time-locked to light delivery.In this study, we used CaMPARI to identify unique molecular alterations within activated neurons in the infralimbic cortex (IL) of rats during cocaine relapse. We first injected a virus to express CaMPARI2 in the infralimbic cortex, implanted optical fibers for UV light delivery and installed intravenous catheters for drug delivery. We then trained these rats to self-administer cocaine (3 h/d x 14 d, FR1, 0.75 mg/kg/inf) followed by 21 days of abstinence. On test day, we used UV light to permanently label IL neurons activated during the first minute of cue-induced drug-seeking. The control group received the same training and abstinence experience but active neurons were labelled during 1 minute of novel context exposure; based on past experience, we expect that the neurons labelled here will be distinct from the relapse-activated ensemble.
We are currently using fluorescence activated cell sorting (FACS) to isolate the active (red-labeled) neurons and will validate the expression of immediate early genes in active cells from both groups. We will also asess molecular alterations in the active neuron populations of the relapse and novel context groups. This is part of our overall strategy to identify the engram underlying maladaptive memories in addiction.

Title: The iDISCO-SMART pipeline for whole brain activity mapping following incubation of palatable food seeking

Authors: *M. JIN[1], J. NGUYEN[1], S. J. WEBER[1], V. A. LENNON[1], L. E. KOMER[1], C. HEINS[1], C. MEJIAS-APONTE[1], J. M. BOSSERT[1], Y. SHAHAM[1], B. T. HOPE[1], S. A.

GOLDEN[2,1], R. MADANGOPAL[1];
[1]Natl. Inst. on Drug Abuse, NIH, Baltimore, MD; [2]Dept. of Biol. Structure, Univ. of Washington, Seattle, WA

Abstract: We have been using the neuronal activity marker Fos to identify neuronal ensembles that mediate reward seeking and relapse. Here, we optimized the iDISCO+ immunolabeling procedure and developed an open source R package called SMART (Semi-Manual Alignment to Reference Templates) to map Fos-positive ensemble neurons across whole mouse brains. SMART extends the Wholebrain analysis framework by streamlining brain-to-atlas registration, simplifying registration correction, and accounting for non-uniform morphing along the anterior-posterior axis during iDISCO+. We used iDISCO-SMART to map brain-wide activity following incubation of food reward craving.
Methods: We trained CD-1 mice to self-administer palatable food pellets and then tested them for relapse to food seeking after 1,15, or 60 homecage abstinence days. We perfused and extracted their brains 90 min after the relapse tests and labeled 'active' Fos-positive nuclei across the brain. We then imaged Fos-immunofluorescence using light-sheet microscopy and used SMART to map "incubation-associated" neural activity patterns across the whole brain.
Results: The mice showed time-dependent increases in food seeking (non-reinforced lever presses in the presence of the food-associated cues) after homecage abstinence, with peak responding after 60 days (incubation of food craving). Currently, we are using SMART to analyze the Fos-expression data and identify the brain-wide neural correlates of incubation of food craving.
Conclusions: At the meeting, we will present data on the functional connectome underlying incubation of palatable food seeking and introduce SMART, an open-source analytical R-package for whole brain activity mapping using volumetric light sheet fluorescence microscope datasets.

Title: A dopamine-induced coordinated gene expression program regulates neuronal function and cocaine response

Authors: *K. E. SAVELL[1,2], A. J. BAUMAN[1], S. THUKRAL[1], N. A. GOSKA[1], F. A. SULTAN[1], L. IANOV[1], L. WHITAKER[2], J. RUBIO[2], B. T. HOPE[2], J. J. DAY[1];

Abstract: Drugs of abuse increase dopamine concentrations in the nucleus accumbens, a key reward structure that integrates contextual and cue-related information and regulates motivated behavior. This surge of dopamine triggers cell signaling cascades that converge in the nucleus to cause changes in gene expression, which are thought to lead to the observed functional and structural alterations in the reward circuit after exposure to drugs of abuse. Here, we defined a dopamine-regulated gene expression program in cultured striatal neurons and engineered a large-scale multiplexed CRISPR activation strategy to recreate this program. Induction of dopamine-responsive genes generated a secondary synapse-centric transcriptional wave, altered striatal physiological properties *in vitro*, and enhanced cocaine sensitization *in vivo*. These results provide proof of principle evidence that activity-dependent gene programs are sufficient to initiate both physiological and behavioral adaptations. Ongoing work aims to examine and manipulate the transcriptional dynamics of neuronal ensembles, a sparse population of cells activated during learning and reactivation of the associated memory, which are defined by the activity-dependent expression of *Fos*. Fos-expressing ensembles in different brain areas have recently been shown to mediate a number of drug-related behaviors, which implies that transcriptional processes within this small number of sparse neurons could be important for encoding and maintaining associative memories.

Title: Social reward learning in adolescent mice using conditioned place preference

Authors: *C. P. CANN, C. N. MILLER, R. MARINO, M. VENNIRO, B. T. HOPE, L. R. WHITAKER;
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: Social interaction promotes survival by helping animals to form stable and supportive social groups. Additionally, maladaptive social behavior is a hallmark of disorders such as autism and schizophrenia. In many different animal species including humans, social interaction under the right circumstances can be inherently rewarding. Despite its importance, very little is known about the neurobiological substrates that mediate social reward learning. To study the rewarding properties of social interaction, we used a social conditioned place preference (CPP) procedure. We discovered that mice form a significant preference for the social interaction-paired context, spending an average of 230 seconds longer in the paired context after social conditioning. This was only expressed during the adolescent period (P21-P49), in agreement with previous studies. Learned associations between natural rewards, including social interaction, and environmental stimuli are capable of driving goal-directed behavior. These associations are thought to be encoded by functional alterations within neuronal ensembles, or specific patterns of neurons activated by reward-predictive stimuli. Fos, an immediate early gene, can be used to identify strongly activated neurons within ensembles. We used Fos immunohistochemistry to determine which brain regions play a critical role in learning about social rewards. We identified several key brain regions that are strongly active when exposed to the social-paired environment. Our future goal is to characterize and manipulate social reward ensembles to uncover the neurobioloical substrates of social associative learning.

Title: Neurobiological substrates of discriminative stimulus controlled incubation of cocaine craving

Authors: *V. A. LENNON, S. J. WEBER, L. E. KOMER, R. MADANGOPAL, L. R. WHITAKER, B. J. TUNSTALL, J. M. BOSSERT, Y. SHAHAM, B. T. HOPE;
Natl. Inst. On Drug Abuse IRP, Baltimore, MD

Abstract: Animal models of incubation of drug craving have primarily focused on the role of conditioned stimuli (CSs) signaling drug delivery. In a recent study we trained rats to self administer cocaine (or palatable food pellets) under the control of discriminative stimuli (DSs). We then tested them for reward during abstinence and demonstrated incubation of DS controlled cocaine seeking (but not food seeking) in the absence of drug paired CSs for up to 300 days of abstinence. Here, we identify neurobiological substrates underlying this DS controlled incubation.
Using Fos as a marker for recent neuronal activity, we found that several brain regions, including the prelimbic and infralimbic subregions of the prefrontal cortex, had increased activity following cocaine seeking during a relapse test after 21 days of abstinence (relative to no test controls). We then used microinjections of a GABA receptor agonist cocktail (0.3 nmol/side baclofen, 0.03 nmol/side muscimol) to suppress activity in these regions and found that injections into the infralimbic cortex reduced DS controlled drug seeking during the day 21 relapse test session but not DS controlled drug taking during training. In contrast, microinjections of the selective D1 receptor antagonist SCH39166 (1ug/side) into either the prelimbic or infralimbic cortex had no effect during either DS controlled cocaine taking or cocaine seeking.
Our data suggest that incubation of DS controlled drug seeking is mediated in part by infralimbic cortex in a D1 independent manner. We are currently assessing the role of other brain regions identified by our Fos study in this new form of incubation.

Title: Alcohol derived acetate promotes brain histone acetylation and alcohol related learning

Authors: *G. EGERVARI[1], P. MEWS[2], R. NATIVIO[1], S. SIDOLI[1], G. DONAHUE[1], S. I. LOMBROSO[1], D. C. ALEXANDER[1], S. L. RIESCHE[1], E. A. HELLER[1], E. J. NESTLER[2], B. A. GARCIA[1], S. L. BERGER[1];

Abstract: Ethanol binds to various receptors in the brain. It is, however, often overlooked that alcohol metabolites, primarily acetate, also reach and affect the brain. In neurons, histone acetylation and gene expression are dependent on the metabolite acetyl-CoA that is produced from acetate by chromatin-bound ACSS2. Strikingly, using in vivo stable isotope labeling in mice, we found that acetate derived from alcohol metabolism is readily incorporated into brain histone acetylation in an ACSS2-dependent manner. Here, we explore the functional relevance of this novel pathway. We used an array of in vitro and in vivo molecular (LC-MS/MS, RNAseq, ChIPseq) and behavioral (ethanol conditioned place preference) experiments to study the importance of alcohol-derived acetyl group deposition. The contribution of ACSS2 was assessed in ACSS2 KO mice as well as by viral-mediated knock-down of ACSS2 in the dorsal hippocampus. Molecular experiments were performed in three or more biological replicates per group. Behavioral experiments were performed using 10-12 replicates/group, and included both male and female mice of 8-10 weeks of age. Behavioral experiments were scored by two independent and blinded investigators. State of the art statistical methods were applied to ensure scientific rigor and reproducibility. We found that exposure to alcohol and its metabolite acetate led to rapid and transient histone acetylation in the brain in an ACSS2-dependent manner. Using heavy labeled stable isotopes, we showed that this is in part mediated by direct incorporation of injected or alcohol-derived acetate. Furthermore, injection of labeled alcohol into a pregnant mouse resulted in incorporation of labeled acetyl groups into gestating fetal brains, indicating that the acetate passes through the placenta and might play a role in fetal alcohol syndrome. In isolated primary hippocampal neurons, extracellular acetate induced learning and memory-related transcriptional programs that were sensitive to ACSS2 inhibition. In addition, we found that alcohol induces histone acetylation (H3K9ac, H3K27ac ChIPseq) in an ACSS2-dependent manner in vivo, inducing genes implicated in neuronal function, learning, memory and alcohol use. Strikingly, we found that ACSS2-mediated histone acetylation is required for the encoding of alcohol-related environmental cues in vivo. Our findings establish a novel and direct link between alcohol metabolism and ACSS2-dependent histone acetylation in the brain.Importantly, we show that this metabolic-epigenetic pathway plays a critical role in encoding alcohol-associated memories, which drive craving and relapse in human alcohol users.

Title: Altered actin filament dynamics in the *Drosophila* mushroom bodies lead to fast acquisition of alcohol consumption preference

Authors: *A. BUTTS[1], S. OJELADE[3], A. RODAN[1], A. ROTHENFLUH[2];
[2]Psychiatry, [1]Univ. of Utah, Salt Lake City, UT; [3]Baylor Col. of Med., Houston, TX

Abstract: Alcohol use is highly prevalent in the United States and across the world, and every year millions of people suffer from alcohol use disorders (AUDs). While the genetic contribution to developing AUDs is estimated to be 50-60%, many of the underlying molecular mechanisms remain unclear. Previous studies from our lab revealed that *Drosophila* lacking RhoGAP18B and Ras Suppressor 1 (Rsu1) display reduced sensitivity to ethanol-induced sedation. Both Rsu1 and RhoGAP18B are negative regulators of the small Rho-family GTPase, Rac1, a modulator of actin dynamics. Here we investigate the role of Rac1 and its downstream target, the actin-severing protein cofilin, in alcohol consumption preference. We show that these two regulators of action dynamics can alter experience-dependent alcohol preference in a bidirectional manner: expressing either activated Rac1 or dominant-negative cofilin in the mushroom bodies (MB) abolishes experience-dependent alcohol preference. Conversely, dominant-negative Rac1 or activated cofilin MB expression lead to faster acquisition of alcohol preference. Our data show that Rac1 and cofilin activity are key to determining the rate of acquisition of alcohol preference, revealing a critical role of actin-dynamics regulation in the development of voluntary self-administration in male *Drosophila*.

Title: The molecular mechanisms of ethanol neuroadaptation

Authors: *A. ANQUEIRA[1], A. GHEZZI[2];
[1]Univ. of Puerto Rico, Río Piedras, San Juan, Puerto Rico; [2]Dept. of Biol., Univ. of Puerto Rico, Rio Piedras, San Juan, PR

Abstract: Alcohol consumption is known to induce cognitive impairments mainly affecting executive functions, episodic memory, and other capacities related to brain function. Nevertheless, the cellular and molecular mechanisms underlying such interactions is still unknown. Recent evidence has uncovered a similar interaction between ethanol exposure and cognitive function in the fruit fly, Drosophila melanogaster, which opens the way for molecular studies in a genetically tractable model system. Using an olfactory conditioning assay where an odorant is used as a conditioned stimulus (CS) and is paired with a heat shock used as an unconditioned stimulus (US), it was shown that Drosophila larvae can learn to avoid the odor in future exposures. However, when the animals are exposed to a short acute dose of alcohol, they are no longer able to learn this association. Interestingly, larvae that have undergone prolonged chronic ethanol exposure seem to successfully avoid the odorant paired with the heat shock just as well as control ethanol-naive larvae, which is suggestive of ethanol-induced neuroadaptations. Our aim is to understand the genetic and cellular components responsible for this adaptation. For this, we employ RNA Sequencing technology to evaluate differences in gene expression in the brain of larvae chronically exposed to ethanol and in control larvae. With the knowledge obtained from this study we could be able to understand ethanol's effect on learning and memory and gain an insight into how addiction may be contributing to damages in this behavior.

Title: Sex-differences in ethanol conditioned place preference in mice

Authors: *P. KOZAN, E. ALVARADO, P. D. RIVERA;
Dept. of Biol., Hope Col., Holland, MI

Abstract: Addiction is a compulsive behavior that affects ~275 million people worldwide (World Health Organization). Previous studies show the importance of sex-differences in describing pathologies of mental health disorders, such as addiction, between males and females. Moreover, the difference in immunity and inflammatory responses between males and females implicate the impact of sex hormones, namely estrogen, on immune responses in both humans and mice. Research has shown that receptors for estrogen (ERs) and estradiol, a specific type of estrogen produced in the ovaries, play a significant role in the modulation of innate immune cells and thereby innate immune responses. However, little is known about the influence of sex hormones on innate immune system during the process of addiction. One way to determine the innate immune involvement is to focus on microglia, resident immune cells found in the brain,

and their function during the onset of addiction. First, a group of mice were introduced to ethanol conditioned place preference (eCPP). In a parallel group of mice, levels of testosterone and estrogen and presence of Fos were examined in males and females at 4 distinct points during a 3 week eCPP behavioral paradigm. Mice were sacrificed 90 minutes after eCPP pairing, test, week 1 extinction, and week 3 extinction. Next, immunohistochemistry (IHC) was used to examine microglia and Fos (Iba1+) in mice brains of males and females in ethanol treated mice compared to water controls. Blood samples were also analyzed to determine levels of estrogen and testosterone. Finally, the original group of mice was sacrificed and presence of testosterone, estrogen, and Fos were examined. A comparison of sex hormones and rewarding behavior was assessed in a sex-dependent manner. If we can understand the contribution of resident microglia and sex hormones to the onset of addiction in a sex-dependent manner, we may be able to develop sex-specific treatments of addiction. Future experiments will replicate this process using other drugs of abuse, such as morphine.

Title: A longitudinal fMRI resting-state study of reward-circuit plasticity induced by chronic ethanol exposure in rats

Authors: M. ESGUERRA[1], H. M. WIESNER[2], C. E. HUTCHISON[1], W. ZHU[2], Y. ZHANG[2], A. K. ZILVERSTAND[3], J. ZIMMERMANN[1], W. CHEN[2], X. H. ZHU[2], ***M. J. THOMAS**[1]; [1]Neurosci., [2]Radiology, [3]Psychiatry, Univ. of Minnesota, Minneapolis, MN

Abstract: A wealth of neuroimaging research in humans has demonstrated aberrant resting-state brain function after chronic alcohol use. However, it is difficult from these studies to distinguish abnormalities that may pre-date alcohol abuse from those induced by alcohol experience. To address this gap, we collected functional magnetic resonance imaging resting-state data (rs-fMRI) in 10-12 week-old female Wistar rats prior to (t1) and at the end (t2) of 7 weeks of intermittent ethanol vapor (12h on:12h off; target range 150-250 mg/dL); at the start (t3) and end (t4) of the 3-week withdrawal; and after a yohimbine injection (t5, same session as t4)—a model of stress-induced relapse. To characterize changes in rs-fMRI directly induced by chronic alcohol exposure and withdrawal in this translational model, we used the analytical methods employed in human resting-state studies of chronic alcohol abuse. Neuroimaging was performed

at 16.4T (t1-t4) and 9.4T (t4-t5). Rats were anesthetized with 1% isoflurane via inhalation, and vital signs were monitored throughout (~2.5h sessions). As each rat habituated to the scanner, we constructed structural/anatomical brain images using T2-weighted fast-spin-echo mapping sequences. For rs-fMRI analyses, following standard preprocessing, images were co-registered to a down-sized rat brain atlas. Preliminary network analysis of changes in reward circuits revealed that the relative size of nucleus accumbens (NAc)-linked networks decreased from the start (t1) until end (t2) of ethanol exposure, and partially recovered from the start (t3) until the end (t4) of withdrawal. The pharmacological stress challenge (t5) reversed this effect, renewing the reduction in relative size. Similar to the NAc network, hippocampal- and amygdala-connected networks decreased following chronic ethanol (from t1-t2), but in contrast to the NAc network, these two networks did not recover between the start until the end of withdrawal (from t3-t4). Similar to the NAc network, hippocampal- and amygdala connected networks were reduced in size during the pharmacological stress challenge (t5). Our findings establish that chronic ethanol exposure produces widespread, but not uniform, changes in reward circuit dynamics in the mammalian brain. The changes identified here are persistent—far outlasting the period of ethanol exposure itself. Furthermore, stress exposure during late withdrawal exacerbated the decreases in connectivity between specific nodes in reward circuits (NAc and BNST). These data outline specific aspects of neural plasticity that may provide fruitful targets for new therapeutic interventions for those suffering from AUD.

Title: Ventral paired median neurons mediate state-dependent alcohol memory

Authors: *K. M. NUNEZ[1], M. TALAY[2], G. BARNEA[2], K. R. KAUN[2];
[1]Mol. Pharmacol. and Physiol., [2]Neurosci., Brown Univ., Providence, RI

Abstract: Alcohol is a widely abused drug, that imposes substantial social, economic, and global health burdens. Despite recent advances, the neural and molecular mechanisms through which alcohol affects the brain, and the underlying reward circuitry, is poorly understood. Moreover, a changing external and internal environment further complicates factors by shifting the internal state of an animal. However, it is not well understood how an animal's internal state can influence reward processing and alcohol memory circuitry. We sought to investigate the neural substrates necessary for state-dependent alcohol reward memory in *Drosophila melanogaster* by focusing on how food-deprivation influences acquisition and expression of memory for alcohol-associated cues. We found a role for a discrete subset of octopamine neurons specifically in food-deprived flies during both alcohol memory acquisition and retrieval. Tyramine-beta-hydroxylase mutants that lack the enzyme needed to synthesize octopamine, displayed a loss in memory expression in food-deprived animals. These results provide a circuit-specific mechanism through which stressors can modulate reward circuitry, thereby influencing acquisition and expression of alcohol-associated memories. As octopamine is most similar to vertebrate norepinephrine, a monoamine neurotransmitter that is involved in a diverse set of behaviors, physiological processes, we believe our results will inform the function of similar circuit motifs in vertebrate models of memory and alcohol use disorder.

Title: The effect of adolescent delta-9-tetrahydrocannabinol and ethanol exposure on prefrontal cortex reliant behaviors

Authors: *C. E. SMILEY, K. E. NIMCHUK, H. K. SALEH, A. M. MOORE, J. T. MCGONIGAL, J. T. GASS;
Med. Univ. of South Carolina, Charleston, SC

Abstract: Cannabis is the most commonly used illicit drug with rates of use that have steadily increased over the last decade especially in the adolescent population. Chronic abuse can lead to cannabis use disorder (CUD) which has high comorbidity rates with alcohol use disorder (AUD) and post-traumatic stress disorder (PTSD). Abuse of both cannabis and alcohol is occurring during a period of ongoing development in the prefrontal cortex which makes the adolescent brain especially vulnerable to insults from drugs of abuse. This set of studies tested the long term effects of adolescent exposure to THC and ethanol on prefrontal cortex reliant behaviors. Three separate experiments were completed to address different cognitive domains. The first experiment tested susceptibility to stress following THC and ethanol exposure. Animals were exposed to THC vapor and subsequently exposed to chronic intermittent ethanol vapor. Then, fear conditioning was tested with a series of tone-shock pairings to measure the rate at which animals acquired this learned association. Once conditioning was established, animals were tested for extinction learning to see how well they could learn new associations between previously conditioned stimuli. A second set of studies investigated the ability of adolescent THC exposure to alter ethanol seeking behavior. Animals were given five days of THC exposure followed by self-administration training to measure the levels of alcohol seeking and consumption. Once self-administration behavior was established, extinction sessions proceeded where animals were exposed to conditioned ethanol associated cues without the delivery of ethanol to see how long it took for ethanol seeking behavior to be extinguished. A third set of experiments examined the effect of THC and ethanol exposure during adolescence on cognitive flexibility. Animals were put into set-shifting training to establish lever pressing behavior before being tested in a between-session set-shift that measures behavioral flexibly. Preliminary studies have found that when adolescent animals are exposed to a combination of THC and ethanol they are more susceptible to fear conditioning and are resistant to extinction learning. THC exposed animals also showed escalated ethanol seeking in self-administration paradigms. In behavioral testing, THC and ethanol exposed animals showed a deficit in behavioral flexibility when tested in a model of strategy set shifting. These results indicate that adolescent exposure to THC and ethanol is detrimental to cognitive functioning in adulthood. Further studies are being done to elucidate the brain mechanisms that contribute to these behavioral results.

Title: Long-term behavioral effects of nicotine and ethanol exposure in aged rodents

Authors: L. M. FOLTS, *G. M. FERNANDEZ;
St. Mary's Col. of Maryland, St. Mary's City, MD

Abstract: Co-morbid rates of alcohol and nicotine use are rising, especially given the increasing popularity of electronic nicotine delivery systems. Previous literature suggests that drug exposure during later developmental stages can have detrimental effects on learning and memory, as well as emotional regulation. Our current study examines the behavioral effects of nicotine and ethanol exposure in aged rats on spatial memory. Male and female Sprague Dawley rats, post-natal day 80, were exposed to either a subcutaneous injection of 0.4 mg/kg nicotine, intraoral gastric gavage of 20% ethanol at a dose of 4 g/kg, combined nicotine plus ethanol, or combined saline injections and water gavage. All rats received a total of 16 exposures on an intermittent, 3 day on/ 2 day off schedule. Nicotine, ethanol, and combined nicotine plus ethanol group differences were not found in Object-In- Place performance. However, when nicotine, ethanol and combined nicotine plus ethanol groups were collapsed, there was an overall effect of drug exposure on recognition memory. The drug exposed animals spent significantly more time with the displaced objects compared to saline/water controls and non- manipulated animals. There were no sex differences regardless of experimental drug grouping. Our results indicate a potential facilitation of memory as a result of drug exposure during adulthood in later senescence. Upcoming studies will also examine anxiety- like and reward seeking behavior.

Title: The role of baseline anxiety in associative learning and response to acute stress

Authors: *T. E. H. MOSES[1], E. A. WOODCOCK[2], M. K. GREENWALD[1];
[1]Dept. of Psychiatry, Wayne State Univ. Sch. of Med., Detroit, MI; [2]Yale Univ. Sch. of Med., New Haven, CT

Abstract: Introduction: Acute stress impacts multiple behaviors, including learning and memory. Associative learning is the ability to remember relationships between unrelated items (e.g. object and spatial location). Acute stress impacts associative learning, but the direction of this relationship is not clearly understood. One factor that modulates acute stress-reactivity is baseline psychological state. Studies examining 2 primary stress hormones (cortisol, norepinephrine) show that biobehavioral responses to acute stress differ between patient populations. This study explores how baseline anxiety (State-Trait Anxiety Inventory [STAI]) impacts learning during acute pharmacological stress. Methods: 12 regular heroin users were enrolled in a buprenorphine-maintenance, inpatient study. Participants completed a double-blind 3x3 (9-session), placebo-controlled, randomized crossover study comparing oral dose-combinations of yohimbine (YOH 0, 27, 54mg) and hydrocortisone (CORT 0, 20, 40mg). In each dosing condition (4.5 hr post-YOH), participants completed 8 epochs of a computerized associative learning task. Learning rate (k) was modeled using a negatively accelerated function fit to block-wise performance data for each subject. Results: ANCOVA (covarying STAI scores) identified an interaction of anxiety and YOH on total recall accuracy across all 8 epochs ($F(2,20)=11.72$, $p<.001$, $\eta^2=.54$) and learning rate ($F(2,18)=3.93$, $p=.038$, $\eta^2=.30$). In the placebo condition, higher-anxious individuals had higher mean recall accuracy than those with lower anxiety. During YOH exposure, individuals with low anxiety increased their mean recall accuracy to the level of the high-anxiety group (whose learning accuracy and rate was insensitive to YOH dose). There was no significant interaction between CORT dose and anxiety. Discussion: Baseline anxiety levels impact associative learning during acute stress. Levels of norepinephrine play a role in associative learning, but these results suggest a more complex interaction. These findings suggest increased levels of norepinephrine may be advantageous in certain domains.

Title: Stress and drugs of abuse alter GABAergic transmission in the ventral tegmental area via chloride cotransporter KCC2 downregulation

Authors: *A. OSTROUMOV[1], B. A. KIMMEY[1], J. A. DANI[2];
[2]Dept. of Neurosci., [1]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Stress and drugs of abuse trigger or modulate multiple forms of synaptic plasticity within the dopamine (DA) system, leading to maladaptive behaviors. Although glutamatergic synaptic plasticity is most commonly studied, there is a growing appreciation that inhibitory synapses also undergo plasticity and regulate circuit function and adaptability. Our findings indicate that exposure to acute stress or nicotine downregulates neuron-specific anion transporter, KCC2, leading to a depolarized $GABA_A$ reversal potential in ventral tegmental area (VTA) GABA neurons. The depolarized $GABA_A$ reversal potential results in a decreased synaptic inhibition or even paradoxical GABAergic excitation of GABA neurons. Compromised inhibition alters DA signaling in the VTA and the nucleus accumbens, linking synaptic plasticity to circuit-wide modifications. At the behavioral level, decreased KCC2 function and excitatory GABA signaling in the VTA mediate increased stress or nicotine-induced ethanol self-administration. Our most recent, unpublished data demonstrate that acute, *in vivo* injections of cocaine, morphine, and ethanol converge onto the GABAergic circuitry of the VTA. Like stress, these addictive drugs trigger KCC2-dependent depolarizing shift in the $GABA_A$ reversal potential in VTA GABA neurons. In summary, our studies demonstrate that exposure to stress or drugs of abuse trigger a currently understudied form of GABAergic synaptic plasticity in the mesolimbic circuitry.

Title: Chronic toluene exposure produces learning and memory impairment in rats

Authors: *M. Y. GAUTHEREAU-TORRES[1], A. JACOBO-JACOBO[1], J. I. SANDOVAL-MEDINA[2], L. F. ORTEGA-VARELA[3], D. GODINEZ-HERNANDEZ[4];

Abstract: Toluene is the most commonly misused solvent and it can be found as part of multiple products such as thinner, adhesives, gasoline, and cleaning products. The abuse of this solvent is considered a public health problem, mainly between children and adolescents. It has been documented that the deliberate use of toluene impacts on multiple systems in the body and the central nervous system (CNS) is more susceptible to the effects of the solvent. Among the actions on the CNS, cognitive damage, memory impairment and learning deficit can be mentioned; however, the evidence in literature is controversial. Currently, toluene mechanism of action is not completely known, but *in vitro* studies showed that toluene non-competitively inhibits the NMDA receptor (NMDAr), and it is believed that this receptor contributes to many of the effects caused by toluene, since NMDAr plays an important role in the processes of learning and memory. Nevertheless, the mechanism of action by which toluene can produce memory and learning alterations is not clear. The purpose of the present study was to investigate the effect of chronic toluene exposure on learning and long-term memory in rats. Male Wistar rats (200-300 g) were exposed to toluene (6000 ppm) or to air (control) during 30 minutes, twice a day, 4 weeks, in a static exposure chamber. 24 h after the end of exposures, the autoshaping learning task was performed in the conditioning chamber (Skinner box) and novel object recognition test was carried out; in addition, locomotor activity tests were made. The results showed that toluene exposure produced an increase in the number of days needed to learn the task and a decrease in the number of conditioned responses in Skinner box test; on the other hand, a loss of long-term declarative memory in the novel object recognition test was observed. In addition, toluene exposure had no effect on locomotor activity. Taken together, our results suggest that chronic toluene exposure produces impairment in learning and memory in rats; however, additional studies are needed to elucidate the mechanisms involved in these effects.

Title: Repeated exposure to high dose dextromethorphan impairs memory and alters c-Fos expression in adolescent male rats

Authors: E. CARLONI, J. DE CHABOT, J. BOEHLKE, C. HICKS, *L. RAMOS;
Lawrence Univ., Appleton, WI

Abstract: Dextromethorphan (DXM) is a semisynthetic derivative of morphine that acts as a N-methyl-D-aspartate (NMDA) receptor antagonist. It has potent antitussive properties and is the active ingredient in several over-the-counter cough and cold medicines (e.g. Robitussin and NyQuil). Over the last decade, DXM-containing formulations have been abused in conjunction with alcohol, particularly by adolescents, for their psychedelic and out-of-body dissociative effects (colloquially referred to as “robotripping”). Despite numerous anecdotal reports of severe adverse side-effects following high doses of DXM, there is a lack of research examining the neurobiological and behavioral effects of the drug. Therefore, the aim of this study was to investigate the neuronal and behavioral effects of repeated exposure to DXM in rats. Adolescent male Sprague-Dawley rats were administered saline, a 3.5% ethanol vehicle, or one of three doses of DXM (5, 20 or 50 mg/kg) dissolved in 3.5% ethanol. Drugs were administered by intraperitoneal injection during 3 weekend “binges” that consisted of two consecutive days of twice daily injections (separated by 1 h) followed by a 5-day washout period. One week following the last binge, rats underwent a battery of behavioral tests to determine drug-induced changes in social behavior, memory and depression-like behavior. At the end of behavioral testing, rats were challenged with their respective drug treatment and assessed for locomotor activity. Brains and plasma were collected and processed for c-Fos immunoreactivity and corticosterone levels, respectively. Somewhat surprisingly, our results showed no significant effects of DXM on social preference or depression-like behavior. However, rats repeatedly exposed to the highest dose of DXM (50 mg/kg) had significantly impaired memory on both the novel object recognition and novel object location tests. These rats also exhibited significant locomotor hyperactivity in response to a challenge injection of DXM, and reduced corticosterone levels. Examination of regional c-Fos expression showed that repeated administration of DXM significantly altered neuronal activation in several brain regions. The current findings demonstrate that repeated exposure to high doses of DXM can produce memory impairments and regional changes in brain activation, which may be related to deficits in NMDA receptor function.

Title: Sex differences in meta-learning in a dynamic bandit task in mice

Authors: *C. S. CHEN[1], B. A. EBITZ[2], S. R. BINDAS[3], N. M. GRISSOM[4];
[1]Psychology, [2]Neurosci., [4]Dept. of Psychology, [3]Univ. of Minnesota, Minneapolis, MN

Abstract: There are substantial differences in the risk for multiple neuropsychiatric disorders across genders. Gender and sex differences in most performance outcome in behavioral and cognitive testings are small, but there is substantial neural evidence for sex differences in the mechanisms that are implicated in executive function and reward. This raises the possibility that disease vulnerability and resilience is conferred by differences in the cognitive strategies and neural circuits that are preferentially employed across sexes in solving behavioral tasks. Indeed, we have previously observed that female mice show modestly accelerated reinforcement learning in a test of decision making, the two-armed visual bandit task. Critically, we were able to identify strongly divergent strategies in the use of spatial versus visual information by males and females. However, how strategy selection is affected by history of choices and reward separately and how this differs between sexes both remain unclear. One hypothesis is the fundamental difference in the dynamics of reinforcement learning between sexes. To test this, we examined thirty-two 129/b6j F1 mice (16 male and 16 female) in a restless spatial two-arm bandit task that allowed us to examine reward as a dynamically changing system. The reward probabilities of two arms changed independently and stochastically over trials so that the animals could only infer values through constant sampling and integration of reward history. The result suggested similar baseline performance between sexes in the percentage of choosing the correct choice in blocks of 300 trials, but males tended to switch after wins more frequently than females. Fitting reinforcement learning models revealed that the reward prediction error (RPE) updating rate of females was higher than males overall and, unexpectedly, increased over time, indicating that females "learned to learn" faster. These results suggest that the differences in reinforcement learning and strategy selection between females and males may lie in their ability to meta-learn. This is consistent with our findings in the visual bandit task that females used a more systematic approach to learn, employing a global strategy.

Title: Multifocal transcranial direct current stimulation over the left dorsolateral prefrontal cortex and left ventrolateral prefrontal cortex reduced risk-taking behavior depending on personality traits

Authors: *D. REDOLAR-RIPOLL[1], O. MARTIN DE LA TORRE[2], A. CUEVAS-GONZÁLEZ[3], D. GALLARDO-PUJOL[2];
[1]Hlth. Sci., Open Univ. of Catalonia (UOC), Barcelona, Spain; [2]Individual Diferences, Univ. de Barcelona (UB), Barcelona, Spain; [3]Biomed. Sci., Univ. Autònoma de Barcelona (UAB), Barcelona, Spain

Abstract: Background: Transcranial direct current stimulation (tDCS) with right anodal and left cathodal dorsolateral prefrontal cortex (DLPFC) montage has shown to reduce risk-taking behavior. Further evidence show that the activity in left ventrolateral prefrontal cortex (VLPFC) during uncertain reward expectancy is associated with risky decision-making. The aim of this experiment was to investigate the effect of multifocal transcranial direct current stimulation (MtDCS) over the left DLPFC and VLPFC separately on risk-taking behavior during Balloon Analogue Risk Task (BART) and the Bomb Risk Elicitation Task (BRET), taking into account individual differences in personality measured through the Big Five and the Dirty Dozen inventories. We hypothesized that cathodal MtDCS over the left DLPFC and left VLPFC would modify risk propensity according to previous studies. We also hypothesized that individual differences will have an effect on how stimulation affects risk-decision making.Methods: A mixed design was used to test for differences between independent groups (Personality and Stimulation intensity) whilst participants (34 healthy volunteers) were subjected to repeated measures (Stimulation location). The order within conditions was counterbalance [DLPFC (F3 cathodal, AF3, FC1, FC3, FC5, F5, return), VLPFC (F7 cathodal, FP1, F3, FC5, FT7, F9, return) and sham]. MtDCS (1.5 mA or 2 mA, randomly assigned) was applied for 20 minutes: 10 min before starting the BART and BRET and 10 during task performance. Personality data was collected a priori.Results: Via a latent profile analysis (LPA) we obtained three personality profiles: profile 1 (n=9) tended to be more narcissistic and Machiavellian, profile 2 (n=18) showed an average type and profile 3 (n=7) who tended to be introverts. There were no differences in pumps and parcels collected due to MtDCS intensity. During BART in the sham condition,profile 1 participants were more impulsive and showed higher pump values. When the stimulation was applied over VLPFC, profile 3 participants showed a cumulative impulsive trend. In BRET, the total parcels recollected decreased when the stimulation was applied over DLPFC for participants from profiles 2 and 3. Conclusions: These results show that MtDCS over the left DLPFC and VLPFC reduced risk-taking behavior. In addition, personality traits may have had a modulating effect on how non-invasive brain stimulation affects risk-taking decision.

Title: Neural correlates of risk and reward evidence accumulation during decision-making

Authors: J. PURCELL[1], A. JAHN[2], ***J. W. BROWN**[1];
[1]Psychological & Brian Sci., Indiana Univ., Bloomington, IN; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Several brain regions have been implicated in the evaluation of prospective outcomes during risky decision-making. However, the role of evidence accumulation indexed by attention to potential rewards with accompanying risk remains underexplored. Existing theories purport that the anterior insula (AI) and anterior cingulate cortex (ACC) are sensitive to risk, driving risk avoidance, yet other theories posit that the ACC drives approach or foraging behaviors despite potential risk. The current experiment aimed to explore these theories and discern how attention to potential rewards and penalties (i.e. lesser reward, null outcome, or loss) corresponds with activation in brain regions associated with value-based decisions.
During concurrent fMRI scanning and eye-tracking, 18 subjects were presented with a 2AFC decision between a sure-win reward or a 50/50 gamble consisting of a larger reward or penalty. Options were displayed for 7s while foveations on the prospective GambleWin, GamblePenalty, and SureWin amounts were recorded. Subjects then chose between the sure-win and gamble. For imaging analyses, individual boxcar regressors separately modeled distinct foveations of the three prospects, and data were analyzed using a GLM with random effects.
Behaviorally, within-trial preference for the gamble option was predicted by GambleReward foveations relative to GamblePenalty, and combined foveations to GambleReward and GamblePenalty, relative to SureWin. However across trials, only total time spent foveating GambleWin and GambleLoss relative to SureWin predicted a greater percentage of gambles chosen. Imaging results showed effects consistent with some regions of posterior dorsal ACC accumulating evidence in favor of the chosen option, as greater activation when subjects foveated the GambleWin was associated with choosing the gamble option. Other regions of mid-dorsal ACC apparently signaled after-the-fact that a riskier choice is likely to be made, as choosing the gamble was associated with more activation when subjects foveated the

GamblePenalty. This is consistent with a suggested ACC role in performance monitoring. Results in the AI also showed effects consistent with accumulating evidence in favor of avoiding risk, as greater activation while foveating the GamblePenalty was observed on trails when the SureWin was chosen.

Title: Neural dynamics of value-based action selection: Effect of reward and risk on alpha and beta oscillation

Authors: *X. CHEN, Y. KWAK;
Univ. of Massachusetts, Amherst, Amherst, MA

Abstract: Neural oscillations in alpha (8-14 Hz) and beta (15-30 Hz) frequency bands are known to reflect active states of cortical processing related with motor planning and selection. The current study investigated the contribution of the alpha and beta oscillations during value-based action selection based on the associated reward and risk level. Forty-one healthy participants (17 males, 20.68 $\pm$ 1.97 yrs) performed a direction judgement task, while EEG was continuously recorded. They were asked to judge the direction of the stimulus by pressing the left or right button with left or right hand. Prior to the target stimulus, a cue which consists of the rewards associated with the two responses and the probability of the left vs. right stimulus (probability left vs. probability right: 25% vs. 75%, 50% vs. 50%, 75% vs. 25%) is presented (trial information period). The left and right responses are always assigned different magnitudes of reward (6 vs. 120). Faster and accurate responses gave larger proportion of the assigned rewards, whereas incorrect responses led to losing of the total rewards at stake. We compared the magnitude of beta and alpha oscillations during the trial information period across different cue conditions in brain regions involved in motor planning and execution, including SMA (Cz and Fcz), bilateral premotor (left: FC3, FC5; right: FC4, FC6) and M1 (left: C3, C5, CP3, CP5; right: C4, C6, CP4, CP6). We found a significant reward by probability interaction in alpha oscillations from the premotor regions. Alpha power was greater in the contralateral hemisphere assigned with lower than higher reward when the probability favored the response associated with higher reward. However, alpha power was greater in the contralateral hemisphere assigned with higher than lower reward in 50% vs. 50% probability assignment and when the probability favored the response associated with lower reward. No such pattern was found in M1. For SMA, in which no laterality is defined, we compared the neural oscillations across the three cue conditions which

differed in conflict levels. Conflict level was low when the reward and probability assignments both favored one side over the other, and high when the reward and probability assignments favored different sides. We found a main effect of conflict in alpha and beta oscillations with opposite patterns. The beta oscillations decreased while the alpha oscillations increased as the conflict level decreased.Taken together, our data suggests involvement of higher-level motor planning regions, but not the primary sensorimotor regions, in integrating reward and probability information during value-based action selection.

Title: Neural correlates of risky decision-making and relations with risk- and reward-related behavior among individuals with low SES

Authors: *R. POUDEL[1], M. J. TOBIA[2], M. C. RIEDEL[2], T. SALO[1], J. S. FLANNERY[1], L. D. HILL-BOWEN[1], A. R. LAIRD[2], A. S. DICK[1], C. M. PARRA[3], M. T. SUTHERLAND[1]; [1]Psychology, [2]Physics, [3]Information Systems and Bussiness Analytics, Florida Intl. Univ., Miami, FL

Abstract: Brain activation during risky decision-making has been associated with aspects of self-reported risk- and reward-related personality metrics. However, the associations between risk-related brain activity, personality traits, and real-world behaviors remains poorly understood. To identify neural correlates of risky decision-making we employed a variant of the Balloon Analogue Risk Task (BART) and collected fMRI data from individuals (*n*=27) with low SES (income<$19,000/yr). To characterize relationships with personality traits and real-world financial behavior, participants also completed self-report surveys assessing aspects of risk (Attitude Towards Risk: ATR) and reward sensitivity (Behavioral Approach System: BAS) and participated in a financial savings program where their saving behaviors were tracked over a 6-month period. We expected differential activation in reward-related regions during BART and expected such activation to correlate with ATR scores, BAS scores, and financial saving outcomes. Regarding BART task effects, we observed increased activity during the decision-making phase of the task in the left medial frontal gyrus, bilateral thalamus, right putamen, and bilateral insula (Fig. 1). Furthermore, right thalamus activity was negatively correlated with ATR and BAS scores and left insula activity was negatively correlated with BAS scores (Fig. 2). This

indicated that lower activity in the right thalamus was associated with higher risk attitudes and reward sensitivity, and lower activity in the left insula was associated with higher reward sensitivity. Importantly, saving outcomes were negatively correlated with frequency of explosion, a metric of risk-taking behavior during the BART (Fig. 3). This indicated that more frequent balloon explosions were related to lower savings outcomes. Overall, these findings provide insight into the neural correlates of risky decision-making and their relationship with risk-related personality measures and demonstrate an association between laboratory and real-world behaviors.

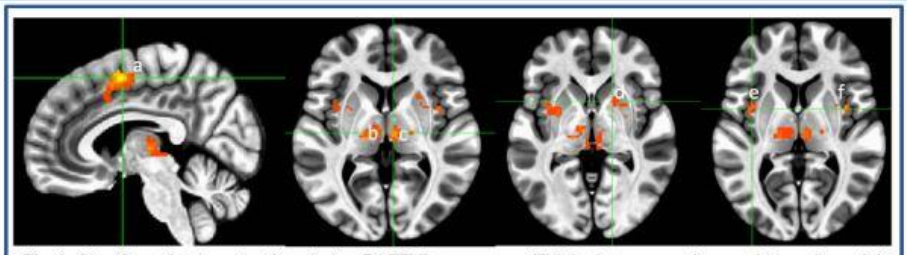

Fig 1. Significant brain activation during BART Pump versus Think phase was observed in regions: (a) medial frontal gyrus, (b) left thalamus, (c) right thalamus, (d) right putamen, (e) left insula and (f) right insula (clusters represent activation during Pump > Think; $P_{corrected} < 0.01$).

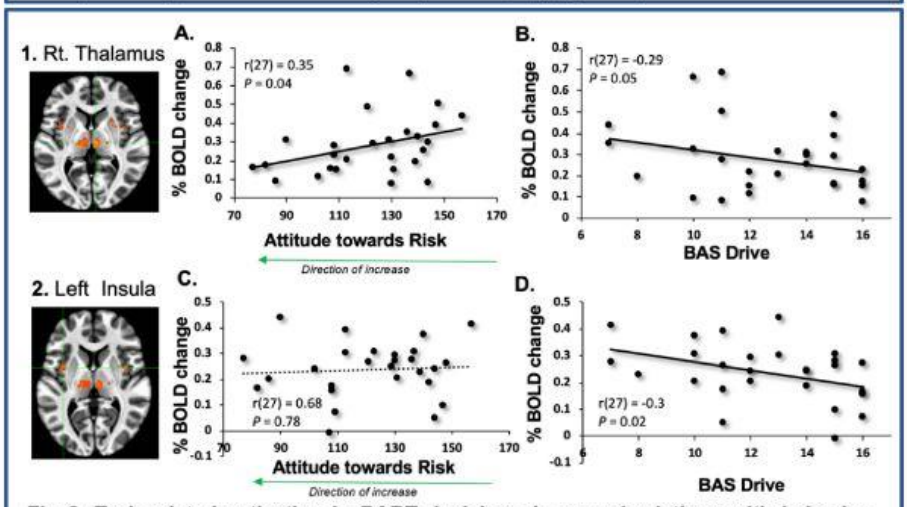

Fig 2. Task related activation in BART decision phase and relations with behavior measures. Decision related activation in right thalamus [1] is correlated with Attitude towards risk [A] and BAS drive [B]. Brain Activation in left insula [2] is correlated with BAS drive [C] but not Attitude towards risk [D].

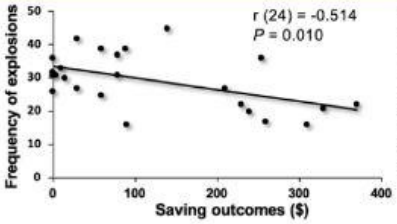

Fig 3. Significant correlation of laboratory performance and real-world behavior. The frequency of explosions (measure or risk) in Balloon Analogue Risk Task significantly correlated with total amount of money saved over the course of 6 months (saving outcomes).

Title: Regulation of risky decision making via activity in dopaminergic neurons in the ventral tegmental area

Authors: *S. L. BLAES[1], C. A. ORSINI[1], H. M. HOLIK[1], S. M. BETZHOLD[1], S. M. SINGHAL[2], C. J. FRAZIER[3], J. L. BIZON[5], B. SETLOW[4];
[2]Dept. of Pharmacodynamics, Col. of Pharm., [3]Pharmacodynamics, [4]Dept. of Psychiatry, [1]Univ. of Florida, Gainesville, FL; [5]Neurosci., Univ. of Florida McKnight Brain Inst., Gainesville, FL

Abstract: The ability to decide adaptively between options associated with different rewards and risks is critical for well-being and quality of life, and impairments in this form of decision making are associated with a range of psychiatric disorders. Dopamine signaling plays a critical role in such "risky" decision making, but the contributions of dopaminergic activity to temporally-discrete components of the decision process is not well understood. To address this issue, an optogenetic approach was used to inactivate dopaminergic neuron cell bodies in the ventral tegmental area (VTA) in rats during performance of a risky decision-making task. Male and female tyrosine hydroxylase-cre rats underwent surgery to inject AAV- EF1a-DIO-eNpHR3.0-mcherry (which carries the gene for halorhodopsin) into the VTA. Initial verification experiments indicate robust selectivity of transgene (mCherry) expression for TH+ neurons, and further indicate that light-induced activation of eNpHR3.0 is effective at silencing transduced VTA neurons in a midbrain slice preparation. For behavioral experiments, an optic fiber was implanted during surgery to target the VTA. Rats were then trained in a task in which they made discrete trial choices between a small, "safe" food reward and a large, "risky" food reward accompanied by varying probabilities of footshock punishment as in Orsini et al. (2017). Once stable task performance was achieved, the VTA was optogenetically inactivated during discrete task epochs, including deliberation (the time window between trial initiation and a choice) and during delivery of the various possible choice outcomes. Initial data suggest that inactivating VTA dopaminergic neurons during receipt of the large reward when it was not accompanied by footshock reduces rats' preference for the risky option (i.e., decreased risky choice). These results are consistent with the idea that brief reductions in tonic dopaminergic neuron activity

signal negative reward prediction errors regarding the outcomes of behavior, rendering the actions that led to those outcomes less attractive during subsequent choices. Ongoing experiments are testing effects of VTA inactivation in other task epochs, as well as effects of VTA activation via channelrhodopsin.

Abstract: Previous work shows that the nucleus accumbens shell (NAcSh) mediates cost/benefit decision making, but its role in decision making involving risk of explicit punishment is unclear. The current experiments addressed this question using both circuit- and cell type-specific optogenetic approaches in rats during a decision-making task involving risk of explicit punishment. In Experiment 1, we tested the hypothesis that input from the basolateral amygdala (BLA) to the NAcSh is necessary to guide choice away from risky options. Rats received intra-BLA infusions of an AAV vector encoding halorhodopsin and optic fiber implants in the NAcSh. Rats were then trained in a risky decision-making task wherein they made discrete trial choices between a small, “safe” reward and a large reward accompanied by varying probabilities of footshock punishment. Using a within-subjects design, BLA projections to the NAc (BLA-NAcSh) were optogenetically inhibited during deliberation (the time between trial initiation and reward choice) and during delivery of the large reward when it was punished (LP). Results show that BLA-NAcSh inhibition during either deliberation or the LP outcome increased choice of the

large, risky reward (increased risk taking), indicating that, during both deliberation and evaluation of the LP outcome, BLA input to the NAcSh is required to bias subsequent choices away from risky options. Experiment 2 used a cell type-specific optogenetic approach to test the hypothesis that neurons expressing dopamine D2 receptors (D2R) in the NAcSh also contribute to choice of safer options. Transgenic rats expressing Cre-recombinase selectively in D2R-containing neurons received intra-NAcSh infusions of an AAV vector encoding floxed halorhodopsin, followed by optic fiber implants in the NAcSh. Optogenetic procedures were identical to those in Experiment 1. Inhibition during deliberation increased risk taking, but inhibition during the LP outcome had no effect on choice behavior. These data provide novel information about the contribution of NAcSh activity to risky decision making. First, the NAcSh receives risk- and reward-related information from the BLA to bias choices toward safer options during deliberation, and to provide negative feedback about choices resulting in punishment. Further, within the NAcSh, activity of D2R-expressing neurons may signal this information during the deliberative process, the integration of which biases choices toward safer options. Future experiments will investigate whether BLA inputs onto D2R-expressing neurons are critical for this latter process.

Title: High gamma activity in the human prefrontal and insular cortices represent monetary gains and losses during decision making

Authors: *S.-J. WU, S.-W. WU;
Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: Many decisions we face involve choosing between options that carry potential gains and losses. Decades of research from psychology show that people are loss averse — the agony incurred by a loss outweighs the pleasure of the same-sized gain. Human fMRI studies showed that many brain regions, including the ventromedial prefrontal cortex (VMPFC), orbitofrontal cortex (OFC) and ventral striatum, represent information about monetary gains and losses during

decision making. It remains controversial, however, whether these regions simultaneously represent gains and losses. In this study, we attempted to address this issue using human intracranial electrophysiology. ***Method.*** In a mixed-gamble task, human subjects (n=13) on each trial faced a 50/50 lottery of a potential monetary gain or loss and had to decide whether to play the lottery. As part of a treatment plan attempting to identify epileptogenic zone, multi-contact depth electrodes were implanted in different brain regions including the OFC, dorsal-to-mid cingulate cortex, amygdala and insula. These four brain regions, with a total of 141 contacts across subjects, were the focus of this study. ***Results.*** We replicated previous findings on loss aversion. Lambda, the ratio of sensitivity to changes in losses to gains inferred from choice behavior was 1.93 (median), close to previous studies (lambda=2). Overall, high-gamma activity in 90% of the contacts in these regions showed gain-only, loss-only, or gain-and-loss representations. However, there were more contacts representing either gain or loss than representing both gain and loss. The proportion of contacts representing only gains was identical to that representing only losses (~ 40%), while a significantly smaller proportion (15%) represented both gains and losses. When examining each region separately, these two statements remain true in amygdala and insula. Dorsal-to-mid cingulate cortex, compared with OFC, amygdala and insula, showed less response to both gains and losses: the ratio of gain-representing contacts in dorsal-to-mid cingulate to all gain-representing contacts was significantly smaller than the ratio of contacts in dorsal-to-mid cingulate to all contacts. The same is true for losses. Together, these results provide more support to the separate encoding hypothesis — that gains and losses are represented by different populations of neurons in these regions than by the same neurons.

Title: Influence of dopamine on perception of effort

Authors: *P. PADMANABHAN[1], R. T. ROEMMICH[2], V. S. CHIB[3];
[1]Dept. of Neurosci., [2]Dept. of Physical Med. and Rehabil., [3]Dept. of Biomed. Engin., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: The depletion of dopaminergic neurons in Parkinson's disease has been thought to give rise to motivational deficits that result in a reduced willingness to exert effort to obtain reward. Dopamine signaling is generally considered to mediate these deficits via its influence on reward processing. However, there is little known about the role of dopamine in processing of effort costs and the perceptions of effort. In this study, we investigated the influence of dopamine on the perception of effort by testing persons with Parkinson's, ON and OFF-dopaminergic medication. Participants performed an effort perception task in which they were cued to exert unknown amounts of effort by gripping a hand-held dynamometer, and subsequently rating their perceived exertion on a numerical scale. We found that participants reported exertions to be more effortful in the dopamine depleted condition, as compared to supplemented condition. Moreover, in a trial-wise analysis we found that variability in force production during exertion explained deviations in subsequent effort ratings in the dopamine depleted condition, but not the supplemented condition. A total of 11 participants have been assessed with this paradigm, and subsequent analyses will investigate the role of dopamine in mediating the influence of exertion variability on ratings of perceived exertion.

Title: Motor cortical thickness and the subjective valuation of physical effort in humans

Authors: A. UMESH[1], K. KUTTEN[2], P. S. HOGAN[3], J. T. RATNANATHER[1], *V. S. CHIB[4]; [2]Whiting Sch. of Engin., [1]Johns Hopkins Univ., Baltimore, MD; [3]Biomed. Engin., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [4]Biomed. Engin., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: The subjective nature of effort critically shapes our decisions to engage in physical activity. For example, if a workout routine feels overly effortful we may decide not to participate, regardless of its potential benefits. One factor that might critically influence subjective perceptions of effort is the inherent anatomy an individual's motor cortex. In this experiment, we investigated the relationship between behavioral preferences for prospective effort and the anatomical properties of motor cortex. We hypothesized that the thickness of a specific region of motor cortex, the hand knob, a region responsible for motor output during

effortful exertions of the hand, would be predictive of an individual's subjective valuations of hand-grip effort. This hypothesis was motived by previous studies that have shown greater cortical thickness is associated with a higher resting motor threshold, suggestive of a diminished capacity to initiate motor action. To study the relationship between motor anatomy and subjective effort preferences, we acquired structural MRI scans of participants brains and had them perform an effort-based decision-making task. To estimate subjective preferences for prospective effort, participants performed a series of risky forced-choices involving two potential options - a low amount of effort, required with certainty, or a risky option that could result in even more effort exertion or none at all (with equal probability). From these choices, we were able to acquire a mathematical parameter which captured individual participants' subjective valuations of prospective effort. Using the structural MRI scans, we traced each participants' hand knob and determined the average cortical thickness of this brain region. We found that the mean thickness of the hand knob was positively correlated with individuals' subjective valuations of effort - those individuals that found effort to be more costly exhibited thicker hand knobs. Critically, subjective effort preferences were not correlated with other dimensions of hand knob anatomy or other brain regions, and hand knob thickness was not related to subjective preferences for reward. These results suggest that the inherent properties of an individual's motor cortical anatomy play a significant role in representations of feelings of effort and decisions to exert.

Title: Brain-behavior correlates of intertemporal choice in healthy aging

Authors: H. ROMERO-KORNBLUM, A. J. BEAGLE, J. KRAMER, *W. CHIONG;
Univ. of California San Francisco Dept. of Neurol., San Francisco, CA

Abstract: Older adults often face important real-world choices between present and future value. Population-level data indicate that compared with middle-aged adults, older adults use credit disadvantageously; e.g., paying higher interest rates on loans and more frequently incurring fees (Agarwal, Driscoll, Gabaix, & Laibson, 2009). Many previous studies of intertemporal choice in aging have focused on group differences between young and old cohorts (often recruited in

different ways), with conflicting results. In a preregistered study (https://osf.io/hxwvm), we examined cognitive and neural correlates of intertemporal choice within a cohort of 158 healthy adults aged 45-84 (*M*=76). Participants made 92 choices between a smaller immediate and larger delayed reward, in which the absolute magnitude of the delayed reward, delay length, and the relative difference in reward magnitude were orthogonally varied. Subject-level sensitivities to these features, as well as participants' baseline tendency to choose a smaller immediate or larger delayed reward, were estimated using mixed-effects logistic regression (see also de Water et al., 2017). Individual discount rates (k, assuming a hyperbolic function) were also separately estimated via maximum likelihood. In preregistered behavioral analyses, individual discount rates and feature sensitivities were not significantly associated with age or standard measures of executive function. In preregistered VBM (voxel-based morphometry) analyses in 118 subjects with linked T1 MRI images, we found suggestive associations between sensitivity to relative differences in reward magnitude and grey matter volumes in the left (p=0.064, based on cluster extent using a Monte Carlo simulation in 1000 permutations at voxelwise p<0.001) and right (p=0.087) mid-caudate. In an exploratory VBM analysis, individual discount rates (k values) were associated with grey matter volumes in the right frontal operculum (p=0.042; left frontal operculum p=0.130). Our findings suggest that in a rigorously-screened healthy older adult population, age itself and executive function are not associated with disadvantageous intertemporal choice; while atrophy in the caudate and frontal operculum may be associated with such choices.

Title: Optogenetic inactivation of prefrontal cortex during intertemporal choice reveals unique roles for this structure in young and aged rat decision making

Authors: *C. M. HERNANDEZ, III[1,3], A.-R. WHEELER[1], T. W. TEN EYCK[1], C. C. LABISTE[1], B. SETLOW[2,1], J. L. BIZON[1,3];

[1]Neurosci., [2]Psychiatry, Univ. of Florida, Gainesville, FL; [3]McKnight Brain Inst., Gainesville, FL

Abstract: The medial prefrontal cortex (mPFC) is the rodent homologue of human dorsolateral prefrontal cortex and is critical for mediating executive functions such as working memory and cognitive flexibility. These executive functions are important for supporting cost-benefit decision making such as whether to choose an option that yields a small reward delivered immediately versus an option that yields a larger reward that isn't delivered until sometime in the future (intertemporal choice). Previous work from both rats and humans indicates that older subjects reliably prefer large, delayed rewards in comparison to young and these preferences correlate with age-associated impairments in cognitive flexibility. The current study used an optogenetic approach to better define the exact contributions of mPFC to intertemporal choice, and to determine if these contributions change with age. Young adult (6 mo.) and aged (24 mo.) Fischer 344 x Brown Norway F1 hybrid rats were surgically implanted with guide cannulae targeting mPFC, through which pAAV-CaMKIIa-eNpHR3.0-mCherry (halorhodopsin) was delivered and optic fibers were implanted. Rats were subsequently trained on an adjusting-delay intertemporal choice task in which preference for small vs. large rewards was evaluated in the presence of ascending delays to large rewards. Upon reaching stable performance, a within-subjects design was used to inactivate mPFC during discrete phases of choice behavior. In young rats, multiple roles for mPFC in intertemporal choice were identified. mPFC inactivation prior to choices *increased* young rats' preference for the large, delayed reward (made rats less impulsive). In contrast, mPFC inactivation after choices were made (during evaluation of the large, delayed reward) *decreased* rats' preference for the large, delayed reward (made rats more impulsive). In contrast to the effects in young rats, mPFC inactivation during the delay period prior to large reward delivery *increased* aged rats' preference for the large, delayed reward but had no effects during other choice phases. The data suggest that differential engagement of mPFC during intertemporal decision making may help explain robust age differences in intertemporal choice behavior.

Title: Contributions of gonadal hormones to intertemporal choice in male rats

Authors: *A.-R. WHEELER[1], C. M. HERNANDEZ[1], C. A. ORSINI[1], T. W. TEN EYCK[1], C. C. LABISTE[1], B. SETLOW[2], J. L. BIZON[3];

Abstract: Intertemporal choice involves decisions among options that differ in both reward magnitude and delay to reward delivery. All other things being equal, individuals prefer large over small rewards; however, individuals tend to more readily choose small over large rewards the longer they must wait for the large reward (i.e., the value of the large reward is "discounted" by the delay to its delivery). There are marked individual differences in intertemporal choice across the population. Extreme preferences for either small, immediate rewards (greater "impulsive choice") or large, delayed rewards (reduced impulsive choice) are associated with multiple psychiatric disorders. Even outside of pathological contexts, however, variation in intertemporal choice predicts life outcomes such as educational attainment and socioeconomic status.

Gonadal hormones have been proposed to contribute to variation in intertemporal choice both within and between sexes, but there have been relatively few direct tests of this hypothesis. The current study evaluated the contributions of gonadal hormones to intertemporal choice in male rats. Young adult (4 mo.) male Fischer 344 × Brown Norway F1 hybrid (FBN) rats were trained in an intertemporal choice (delay discounting) task in which they made discrete trial choices between levers that yielded a small, immediate reward (1 food pellet) vs. a large reward (3 food pellets) delivered after a delay period. The delays to large reward delivery increased in blocks of trials across each session (0, 10, 20, 40, 60 s delays). Rats were initially trained on the task, then divided into two groups matched for choice behavior that received castration or sham surgery. After recovery, rats were re-tested on the task, and data compared both between groups and before/after surgery. Castration caused an increase in choice of the small, immediate reward (increased impulsive choice) compared to both sham controls and pre-surgical baseline performance. Surprisingly, however, 5 days of subcutaneous injections of a physiological dose of testosterone (125 µg) in castrated rats did not reverse this phenotype, suggesting that the effects of castration on impulsive choice are not mediated solely by reductions in circulating testosterone. Considered together, these data demonstrate a role for testicular hormones in maintaining preference for large, delayed rewards, but that testosterone alone (at least under the conditions tested here) is not sufficient to reproduce this effect.

Title: The neuroeconomics of narratives and asset-price bubbles: Power-law dynamics of asset markets may arise from switching between valuation and control networks

Authors: *J. L. HARACZ;
Dept. of Psychological and Brain Sci., Indiana Univ., Bloomington, IN

Abstract: Objective: Narratives (e.g., "housing prices will keep rising", "dot-com stocks are a great investment in a new era", and variations on "this time is different") may drive asset-price bubbles by persuading investors to focus attention on supposedly positive characteristics of assets (Shiller, 2017). Furthermore, narratives may elicit bubble-related herding (Baddeley, 2010; Stiglitz, 2011) by activating an evolutionary predisposition to group behavior seen also in non-human species (Haracz, 2013). Therefore, this review seeks neuroeconomic mechanisms potentially involved in the spread of bubble-related narratives.
Methods: A systematic literature review focused on neuroimaging studies of herding (i.e., social conformity), persuasion, and narrative-influenced attention.
Results: Components of the valuation network (i.e., nucleus accumbens [NA] and ventromedial prefrontal cortex [vmPFC] or nearby orbitofrontal cortex [OFC]) were activated in subjects showing a herding-like change in opinion or behavior (Zaki et al., 2011; Wei et al., 2019). Exposure to persuasive health-related messages was associated with increased connectivity between the NA and vmPFC (Cooper et al., 2017, 2018a; Falk and Scholz, 2018), as well as decreased connectivity in the frontoparietal control network (Cooper et al., 2018b). This connectivity pattern, increased in the valuation network and decreased in the control network, was found relative to healthy controls in individuals with heroin addiction (Xie et al., 2014; Zhai et al., 2015) or internet gaming disorder (Dong et al., 2015), suggesting a tendency for these networks to function alternatively or in opposition. An fMRI study of lab markets indicates that asset-price bubbles and crashes may involve an oppositional relationship between these networks. Lab bubbles were driven by asset buying based on NA activity, whereas crashes were triggered by selling related to anterior insula (AI) activity (Smith et al., 2014). A meta-analysis (Chang et al., 2013) as well as simultaneous fMRI and EEG recordings suggest that the AI may signal the need for deliberation and frontoparietal activity (Hinault et al., 2018). Roles for the NA and AI in mediating asset buying and selling, respectively (Smith et al., 2014), may arise from an involvement of these areas in attention focusing. The NA and AI were activated when subjects were instructed to focus, respectively, on positive or negative aspects of stimuli (Kruschwitz et al., 2018).

Conclusion: Narratives that drive asset buyers and sellers may generate power-law dynamics of bubbles (Preis et al., 2011) by eliciting switches between valuation and control network activity.

Title: Decoding the time-evolving neural valuation of gain and loss using MEG

Authors: *S. NIE[1], M. WANG[1], H. ZHANG[1,2,3];
[1]Sch. of Psychological and Cognitive Sci. and Beijing Key Lab. of Behavior and Mental Hlth., [2]PKU-IDG/McGovern Inst. for Brain Res., [3]Peking-Tsinghua Ctr. for Life Sci., Peking Univ., Beijing, China

Abstract: In human decision-making under risk, loss is typically valued more than the same amount of gain, a behavioral phenomenon known as loss aversion, which suggests that gain and loss are valuated differently in the brain. Functional MRI studies have identified different brain pathways for the processing of gain and loss but leave the temporal course of valuation unresolved, due to their limited temporal resolution. Here we used magnetoencephalography (MEG) to investigate how the neural valuation of gain and loss in decision-making under risk evolves over time from milliseconds to seconds. On each trial, participants (N = 8) were presented first with a sure amount of monetary payoff and then a sequence of two-outcome gambles (1250 ms per gamble) that might end unexpectedly. Their task was to evaluate each gamble, choosing between the gamble and the sure payoff, but only report their choice for the last gamble in the sequence. Each gamble had a 50-50 chance to yield a gain or a loss, with the values of gain and loss varying independently across gambles. We found loss aversion in participants' behavioral choices: A logistic regression analysis showed that one unit of loss had a larger influence on participants' choices compared to one unit of gain ($t(7) = 2.38$, $p = .049$). For each participant, 306-channel MEG recordings were available for approximately 1250 gambles, from which we extracted 2-16 Hz power spectrum for single time points using time-frequency analysis. We then applied dimension-reduction and regression analysis to the spectrum at each specific delay after gamble onset (in the range of 0 to 1250 ms) to decode the values of gain and loss in the gamble. We found that the cross-validated decoding performance was significantly above chance (two-tailed paired *t*-test $p < .01$, uncorrected) first at 59 ms and 310 ms after gamble onset, respectively for gain and loss. Decoding was on average better for gain before 222

ms and better for loss between 283 and 1156 ms. Our preliminary results suggest that the neural valuation occurs earlier for gain but lasts longer for loss.

Title: Testing neural representations of value and task space

Authors: *A. R. VAIDYA[1], H. JONES[1], D. BADRE[2];
[1]Dept. of Cognitive, Linguistic and Psychological Sci., [2]Dept. of Cognitive, Linguistic and Psychological Sciences, Carney Inst. for Brain Sci., Brown Univ., Providence, RI

Abstract: Adaptive decision-making depends on knowing the value of a choice given current circumstances — i.e. contextual state information. The orbitofrontal cortex (OFC) has long been implicated in the flexible representation of option values. However, recent work has argued that this region may instead represent a 'cognitive map of task space' — that is, information about a latent contextual state that conditionalizes the value of different options. Other work has argued that contextual state information of this kind may be signaled by the hippocampus (HPC), or depends on both of these regions. To test these hypotheses, we crossed hidden contextual state information and expected value in a functional magnetic resonance imaging (fMRI) experiment. Human participants learnt the value of three different image categories (leaves, hands and foods) via feedback in three different context states with distinct category-value associations. Each of these latent contextual states was cued by three different pictures of natural scenes. Participants were then trained on the value of three new image categories (faces, animals and objects) in the presence of one natural scene cue from each state. Finally, in a test phase in the scanner, participants had to transfer information about the value of these new categories to the other two held-out natural scene cues based on their previously established associations with the trained cue, without any new information provided by feedback. Participants' choices showed they were able to leverage abstract information about the latent contextual states to transfer new value associations to these held-out cues. Using representational similarity analysis (RSA), we tested whether OFC and HPC pattern activity carried information about the state-dependent values of options, latent state information needed to infer option values, or both. This experiment contrasts

two major hypotheses regarding the function of the OFC, giving critical insight into the function of this region in guiding flexible behavior.

Title: Kibra modulates learning and memory via binding to dendrin

Authors: Y. LU[1], *S. MA[2];
[1]Sch. of Basic Med., Huazhong Univ. of Sci. and Technol., Hubei, China; [2]The Inst. for Brain Research, Collaborative in, Wuhan, China

Abstract: Kibra is a synaptic scaffold protein regulating learning and memory. Alterations of Kibra-encoding gene WWC1 cause various neuronal disorders, including Alzheimer's disease and Tourette syndrome. However, the molecular mechanism underlying Kibra's function in neurons is poorly understood. Here we discover that Kibra, via its N-terminal WW12 tandem domains, binds to a postsynaptic density enriched protein, Dendrin, with a nanomolar dissociation constant. On the basis of the structure of Kibra WW12 in complex with Dendrin PY motifs, we developed a potent peptide inhibitor capable of specifically blocking the binding between Kibra and Dendrin in neurons. Systematic administration of the inhibitory peptide attenuated excitatory synaptic transmission, completely blocked long-term potentiation induction, and impaired spatial learning and memory. A Kibra mutation found in Tourette syndrome patients causes defects in binding to Dendrin. Thus, Kibra can modulate spatial learning and memory via binding to Dendrin.

Title: The mechanism study of histone demethylation gene Utx in mouse cognitive function

Authors: *L. CHEN[1], M. LIU[2], X. YANG[1], W. LI[1];
[1]Bio-X Institutes,Shanghai Jiao Tong Univ., Shanghai, China; [2]Shanghai Jiao Tong Univ. Sch. of Medcine, Shanghai, China

Abstract: Epigenetic abnormalities caused by genetic mutation in epigenetic regulators can result in neurodevelopmental disorders, deficiency in neural plasticity and intellectual disability. *Utx* (Ubiquitously transcribed tetratricopeptide repeat, X chromosome, also known as lysine-specific demethylase 6A, KDM6A) is candidate gene for X-chromosome-linked intellectual disability (XLID) which coding histone demethylase.
We focus on the function of *Utx* on the pathogenic mechanism in one specific type XLID-Kabuki syndrome using the *Utx* conditional knockout mice. Previous genetic studies showed that *Utx* is one of the main pathogenic genes in Kabuki syndrome. However, the mechanism about how *Utx* gene causes cognitive dysfunction in Kabuki syndrome remains unclear. We found that *Utx* knockout mice showed the learning and memory deficits in water maze test and contextual fear conditioning. The KO mice also displayed long term potential (LTP) deficits and neuron morphological defects. Mechanistically, we found that the dysfunction of *Utx* caused the downregulation of calmodulin.
Keywords: *Utx*, learning and memory, calmodulin

Title: Calcineurin modulation of conditioned taste aversion extinction

Authors: *S. E. REYES-GARCÍA[1], M. L. ESCOBAR[2];
[1]UNAM, Facultad de Psicología, Mexico City, Mexico; [2]UNAM, Fac Psicologia, Mexico City, Mexico

Abstract: Nowadays, it is widely accepted that memory extinction involves the formation of a new associative memory that inhibits a previously conditioned association rather than unlearning of acquisition. Nevertheless, the cellular and molecular mechanisms that underlie this process are still unclear. In this regard, it has been suggested that kinases and phosphatases modulate the processes of conditioning and extinction, respectively. A body of evidence suggests that protein phosphatase calcineurin (CaN) is involved in the extinction of some behavioral tasks. Indeed, our previous studies showed that conditioned taste aversion (CTA) extinction increases the CaN expression in the insular cortex (IC). CTA is a well-established learning and memory paradigm in which an animal associates a novel taste with nausea. Meanwhile, the IC is a region of the brain that lies in the temporal neocortex and is known for its role in processing aversively motivated learning tasks, like CTA. The aim of the present study was to evaluate the participation of CaN in the extinction of the conditioned taste aversion. To do so, we infused bilaterally in the IC of adult male Wistar rats, the calcineurin specific inhibitor FK506, 30 minutes before the second extinction session. Our results show that infusion of FK506 elicits an impairment of CTA extinction. That is, CaN inhibition slows down the extinction of CTA, thus revealing that this phosphatase plays an important role on extinction learning, and therefore on the maintenance of CTA.

Neurodegenerative Dis., Göttingen, Germany; [4]Med. Br., The Univ. of Texas, Galveston, TX; [5]Univ. Goettingen/Dzne, Goettingen, Germany

Abstract: Overwhelming stressful experiences can lead to mental illnesses known as dissociative disorders. They are thought to arise when normally integrated functions of consciousness, such as memory, perception, and identity awareness become disrupted. Dissociative symptoms are often debilitating, and persist for a long time after the initial stress has ended. While many dissociative symptoms are intrinsic to human sufferers, and therefore cannot be studied in rodents, this is not the case with dissociative amnesia, which can be modeled in rodents using state-dependent learning. Fear-inducing memories can be state-dependent, meaning that the retrieval of a memory is most efficient when occurring under the same state of consciousness as when the memory was encoded. State-dependent memories are long lasting, and they retain their state-dependence, suggesting that distinct mechanisms initiated at encoding are maintained during consolidation and transition from recent to remote. The cytoskeletal system plays a crucial role in neuronal plasticity, learning and memory, early after encoding. Interestingly, the most over-represented genes differentially expressed under normal and state-dependent conditions at this early stage are those with known function in cytoskeletal architecture. However, changes in the expression of cytoskeletal and cytoskeleton-associated (CCA) genes, and their function during the transition of fear-inducing memories from recent to remote in different states, remains largely unknown. Here we analyzed the global changes in the expression of CCA genes using proteomic and high throughput RNA analyses to identify individual genes which contribute to the transition of fear-inducing memories from recent to remote under normal and state-dependent conditions. Our results show that the consolidation of memories and their transition from recent to remote in different states is accompanied by diverging alterations in the expression of CCA genes belonging to distinct cytoskeleton-mediated cellular processes.

Title: Imaging endogenous AMPA receptor dynamics underlying fear learning

Authors: *A. R. GRAVES[1], D. J. TWARD[2], M. I. MILLER[2], J. T. VOGELSTEIN[2], R. L. HUGANIR[1];

Abstract: Synapses are the fundamental unit of the nervous system. They enable rapid communication between neurons and provide a substrate for plasticity that drives adaptive behavior. Synaptic plasticity, the bidirectional control of synapse strength via dynamic regulation of AMPA receptors, is the leading cellular mechanism underlying many cognitive functions, including learning and memory. However, the distribution of memory encoding, storage, and retrieval within vast networks of millions of synapses remains almost completely unknown. Here, we employ in vivo imaging of fluorescently tagged AMPA receptors to directly observe the dynamics of endogenous synaptic networks in retrosplenial cortex during fear learning and recall. These unprecedentedly detailed neural maps reveal that memories are stably stored by complex synaptic networks within retrosplenial cortex.

Title: Tracking metabolic changes associated with retrieval in the hippocampus

Authors: *M. MARUI, K. ADACHI, T. HAYASHI, M. NAGASAWA;
Meijo Univ., Nagoya-shi, Japan

Abstract: Background: Dementia is one of major diseases in the world today. World Health Organization reported that it is estimated that its subjects exceed 100 million in 2050. Especially, memory impairment, one of the characteristic symptoms of dementia, is an issue and induce the reduction of ‘‘Quality of Life’’. Thus, it needs to be established the therapeutic treatment and prophylaxis of memory impairment. Memory function is consisted of three processes, “encoding’’, “storage’’ and “retrieval’’, and many dementia subjects are impaired their retrieval processes. However, the retrieval mechanism in memory function remains unclear. The present study aimed to elucidate the mechanism for retrieval process using a retrieval-induced model , especially it was focused on the transition of metabolites levels in the brain depending on the time course from the onset of retrieval. Material and Method: Object recognition test (ORT) with some modifications was performed for a retrieval-induced model. Male 8-week-old ICR mice

were allowed to explore in the black square arena with two identical objects for 5 min. This trial was performed once a day for 3 days. On 4th day, control (CON) mice explored the familiar objects, while ‘‘memory retrieval’’ (MR) mice explored an identical object and a novel object. The duration for exploration in these trials were 1 min, 3min or 5min. Mice have an interest in a novel object. Accordingly, a ratio of duration for exploring a novel object on 4th day, an index of retrieval-based behavior of MR mice was calculated form the following formula; 100 × duration for exploring a novel object /duration for exploring both objects. In CON mice, the expediential index was estimated by a similar method. After these trials, mice were sacrificed under anesthesia and their hippocampi were immediately dissected from their whole brain. Metabolites in the hippocampus were determined by GC-MS, and those levels were compared with each time point for exploration. Result: A ratio of duration to explore a novel object of MR mice was significantly higher than those of CON mice in all time points, approximately MR mice showed 70% and CON mice showed 50%. This result indicates that MR mice recalled a familiar object at any time point. In metabolome analysis, glutamate showed different levels in each time point. Additionally, it suggested that glycine production was accelerated. Glutamate and glycine regulate the function of N-methyl-D-aspartate (NMDA) receptor which related to memory function. Present study demonstrated that the metabolites which regulate NMDA receptor function altered depending on the duration for retrieval and partial mechanism of retrieval was revealed.

Title: Developmental deltamethrin exposure to Sprague-Dawley rats alters dopaminergic and glutamatergic systems and long-term potentiation when tested as adults

Authors: *E. M. PITZER[1], C. SUGIMOTO[2], G. A. GUDELSKY[3], M. T. WILLIAMS[1], C. V. VORHEES[1];

Abstract: Pyrethroids are a prevalent class of synthetic insecticides that act through voltage gated sodium channels to prolong channel opening leading to depolarization. Pyrethroids are

used in many settings where children are present, such as schools and parks, as well as for treating head lice. Epidemiological studies find that developmental exposure to pyrethroids is associated with neurological and behavioral abnormalities. The effects of Type II pyrethroids, such as deltamethrin (DLM), on development have received relatively little attention. We showed that Sprague-Dawley rats exposed to DLM from postnatal day (P)3-20 had deficits in egocentric and allocentric learning and memory as adults. We also observed increased hippocampal long term-potentiation (LTP) at P28-35 in DLM-treated rats. Here we exposed Sprague-Dawley rats to 0 or 1.0 mg/kg/day DLM by gavage from P3-20. LTP was assessed at P60-90 in brain slices in CA1. Males treated with DLM had increased LTP in the CA1 region compared with controls ($p < 0.0001$). Females treated with DLM had slightly decreased LTP compared with controls ($p < 0.05$). Amphetamine-stimulated dopamine release was assessed via microdialysis. DLM-treated rats exhibited decreased dopamine release in the nucleus accumbens ($p < 0.05$). Currently potassium stimulated glutamate release is being tested in the hippocampus. Western blots revealed that DLM-treated rats did not differ in dopamine receptor D1 (DRD1) protein in the n. accumbens or hippocampus, but was increased in the neostriatum of male but not female rats ($p < 0.05$). No differences were observed for DRD2 levels or for NMDA-NR1. However, NMDA-NR2B protein was decreased in the neostriatum of male DLM-treated rats ($p < 0.05$). A trend was observed for increased NMDA-NR2A protein in the hippocampus of male DLM-treated rats ($p < 0.10$) compared with controls. No dopamine or NMDA receptor related changes were observed in female DLM-treated rats. The results indicate that rats developmentally exposed to DLM have altered CA1 LTP, decreased extracellular n. accumbens dopamine release, increased DRD1 and decreased NR2B protein in neostriatum. These DLM effects are consistently male-specific. Experiments testing the effects of developmental DLM exposure on dopamine and glutamate release in other regions and expression of apoptotic markers are in progress.

Title: Characterization of behavioral deficits in activity-regulated cytoskeleton-associated protein knock-in (ArcKR) mice

Authors: *D. W. YAKOUT[1], Z. D. ALLEN[1], A. J. GEORGE[1], F. P. TALLARD[1], J. SEXTON[1], S. S. MOY[2], A. M. MABB[1];

Abstract: The induction of activity-regulated cytoskeleton-associated protein (Arc) is correlated with neural activity, which is critical for learning and memory consolidation. Upon induction, Arc is rapidly degraded by the ubiquitin-proteasome pathway. However, the significance of Arc degradation on memory processes has been poorly characterized. The endosomal-associated E3 ubiquitin ligase, TRIAD3/RNF216 ubiquitinates Arc at Lysines 268 and 269, which is necessary for its proteasome-dependent degradation. To test the role of TRIAD3/RNF216-dependent effects on Arc degradation, we previously generated a transgenic mouse-line (ArcKR). In ArcKR mice, TRIAD3/RNF216-dependent Arc ubiquitination sites are mutated to Arginine, thus interfering with Arc degradation. Although memory acquisition was intact, ArcKR mice have specific deficits during reversal learning in a Barnes Maze spatial memory task. Here, we continue to characterize behavioral deficits in ArcKR mice, elucidating the role of TRIAD3/RNF216-dependent Arc removal in sensorimotor integration, associative learning, social memory, attention, and depression-like behaviors. Additionally, we examine Arc patterning in ArcKR mice in brain regions associated with the tested behaviors such as the hippocampus, orbitofrontal cortex and medial prefrontal cortex.

Title: Overexpression of purinergic P2X4 receptors in hippocampus rescues memory impairment of rats with type 2 diabetes

Authors: P.-A. ZHANG[1], Q. SUN[1], R.-X. WENG[1], H.-H. ZHANG[1], S. YU[2], ***G.-Y. XU**[1];
[1]Soochow Univ., Suzhou, China; [2]Anesthesiol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Aims: More and more cognitive dysfunction has seriously affected the life quality of patients with diabetic mellitus (DM). The pathogenesis of the diabetic cognition impairment remains largely unknown. Purinergic receptors have been reported to be involved in brain high function and related disorders. The present study aims to explore roles of purinergic receptors and mechanisms underlying the diabetic memory impairment in rats with type 2 diabetes mellitus (T2DM). **Methods:** T2DM model was induced in rats fed with high fat diet for 2 weeks followed by intraperitoneal injection of streptozotocin and confirmed by fasting blood glucose and insensitivity to insulin treatment. T-maze and Morris water maze (MWM) tests were used to detect learning and memory. Immunofluorescence and Western blot were used to determine the location and expression purinergic receptors. DNA damage was detected by Long Amplicon Polymerase Chain Reaction (LA-PCR). **Results:** T2DM rats exhibited a significantly lower correct choice rate, higher win-shift failure and Lose-shift failure in the T-maze test, and the less passing times, less time in the quadrant, more mean distance in MWM test than in the age-matched control rats. P2X4Rs were dramatically reduced in the hippocampus of T2DM rats. LA-PCR showed that DNA amplification of *p2x4r* gene in the hippocampus was significantly less in T2DM rats than in control rats. P2X4Rs positive microglia in hippocampus was reduced and the number of activated microglia was significantly increased in T2DM rats compared to controls. Intraperitoneal injection of minocycline significantly reduced the number of activated microglia in the hippocampus and the mean distance in MWM test. Most importantly, overexpression of P2X4Rs markedly suppressed the activated microglia, reduced the expression of TNF-α and IL-1β and reinstated the memory impairment of T2DM rats. **Conclusions:** T2DM leads to excessive activation of microglial cells in the hippocampus, which is most likely mediated by the downregulation of P2X4Rs due to the DNA damage, thus contributing to memory impairment. Overexpression of P2X4Rs might be a potential strategy to rescue memory impairment.

Title: The role of vitamin D in the adult brain

Authors: M. M. AL-AMIN, R. K. P. SULLIVAN, Y. YU, J. LUI, X. CUI, ***T. H. BURNE**; Queensland Brain Inst., Brisbane, Australia

Abstract: Vitamin D deficiency is a global public health burden, affecting millions of people worldwide. Low serum vitamin D levels are associated with many neuropsychiatric diseases, such as schizophrenia, autism and depression. In these diseases, impaired hippocampal function has been reported as a central issue. The hippocampus is an important brain region contributing to spatial learning and memory, partly by consolidating short to long term memory. Vitamin D may have a specific role in the hippocampus, since neurons in the hippocampus and its various subfields express the vitamin D receptor (VDR). In this study we examined spatial memory impairment in adult vitamin D-deficient BALB/c mice and its underlying mechanism by measuring spine density, perineuronal nets and GABAergic interneuron density in the hippocampus. We also examined the molecular changes in gene expression. Adult male BALB/c mice were fed a control or vitamin D deficient diet for 20 weeks. We showed that AVD-deficient BALB/c mice took significantly longer to learn to avoid the shock zone than control mice over 5 days. All mice performed similarly on the last day of training, demonstrating that AVD deficiency produced a delay in learning. We found a reduction in the spine density in the CA1 region of the hippocampus of AVD-deficient mice. However, there was a significant reduction in the number of cells that immunostained positive for perineuronal nets and neural nitric oxide synthase in all subfields of the hippocampus. The molecular changes were restricted to reductions in the expression of VDR and tyrosine hydroxylase mRNA. Therefore, we can show that adult vitamin D deficiency is associated with impaired spatial learning and altered hippocampal function in mice. We were able to show that chronic vitamin D supplementation prevented the decline in spatial learning, showing that vitamin D supplementation for a prolonged duration may be required to restore hippocampal-dependent function. This research has important public health implications because vitamin D deficiency can be treated.

Title: The role of epigenetics in regulation of promoter competition of Prkcz gene

Authors: *A. BORODINOVA[1], P. M. BALABAN[2];
[1]Inst. of Higher Nervous Activity, Moscow, Russian Federation; [2]Inst. Higher Nervous Activity & Neurophysiol. RAS, Moscow, Russian Federation

Abstract: Memory mechanisms require synergic functioning of many intracellular molecular systems, but until recently neither of them was shown to be selectively involved in the learning process. However, in the last decades the neuron-specific product of *Prkcz* gene (protein kinase Mz) was characterized as the necessary and sufficient molecule for memory formation and maintenance. Multi-promoter organization of the *Prkcz* gene enables to selectively transcribe either a short (PKMz) or a long (PKCz) isoform in a tissue-specific manner. However, the molecular mechanism of the region-specific *Prkcz* expression is still uncharacterized. The main idea of this study was to uncover and extend the principles and mechanisms of tissue-specific expression of *Prkcz* transcripts. In the recent article (Borodinova et. al., 2019) we have demonstrated that chromatin rearrangements, induced by histone deacetylase inhibitors (trichostatin A, TSA; sodium butyrate), can influence transcription of the Prkcz gene and shift the natural balance of expression of different Prkcz isoforms in neurons. Analysis of the promoter regions of Prkcz gene demonstrated significant increase in histone acetylation levels in both upstream and downstream promoters that was detected 4 h after the application of TSA, and persisted up to 19 h. Remarkably, we revealed a significant enrichment of H3K4me3 mark of the transcriptionally active regions specifically in the upstream Prkcz promoter that is responsible for synthesis of the PKCz. We showed previously that TSA-induced changes in expression of PKMz and PKCz, were abolished in the presence of protein synthesis inhibitor anisomycin, applied 1 hour before TSA administration, which means that the epigenetically regulated patterns of expression of PKMz and PKCz, reflecting activity of alternative promoters of the Prkcz gene, were controlled by protein synthesis-dependent mechanisms. To find the critical time window during which the specific proteins are necessary for regulation of the PKMz/PKCz transcription, we performed the series of experiments, where anisomycin was applied at different time points after the TSA administration (30 min, 4 h, 6 h). We found that the epigenetic regulation of PKMz/PKCz expression was abolished in the presence of anisomycin applied at all indicated time points, suggesting that synthesis of the specific proteins can be a necessary and limiting step in the epigenetically-triggered competition of Prkcz promoters. Therefore, the identification of genes encoding the described protein regulators that participate in the Prkcz promoter competition requires additional experiments.

Title: TET1 is expressed as two distinct isoforms in the mouse brain with differing effects on physiology and cognitive function

Authors: C. B. GREER[1], S. P. MORAN[1], J. WRIGHT[1], J. D. WEISS[1], P. J. KINGSLEY[2], K. S. CHRONISTER[1], J. ZHU[1], A. Y. JIN[1], L. J. MARNETT[3], A. J. KENNEDY[4], ***G. A. KAAS**[1]; [1]Pharmacol., [2]Biochem., [3]Biochemistry, Chemistry, Pharmacol., Vanderbilt Univ., Nashville, TN; [4]Chem., Bates Col., Lewiston, ME

Abstract: Recently, using a number of different experimental techniques, we have discovered that the *Tet1* gene locus is actually expressed as two distinct mRNA transcripts within the mouse brain. The first, *Tet1 Long* (*Tet1L*), encodes for the previously-annotated canonical *Tet1* enzyme which contains a CXXC, Cysteine-rich and DSBH domain, while the second, *Tet1 Short (Tet1S)* is expressed from an intronic region located ~0.5 kb upstream of *Tet1L* exon 3 and encodes for a truncated enzyme lacking the N-terminal coding region. Using both *in situ* hybridization and qRT-PCR, we detected each transcript throughout the mouse brain and found *Tet1S* mRNA levels to be ~10-20 times greater than *Tet1L.* In addition, the two isoforms both show substantial differences in regards to their transcriptional responses to neuronal activity, sub-cellular protein localization and enzymatic activities. Similarly, RNA and Genome Wide Bisulfite seq (GWBS) data generated from primary hippocampal cultures either overexpressing or repressing these *Tet1* isoforms further support the notion that the function of these enzymes is not redundant. In fact, a large portion of the differentially expressed genes and differentially methylated regions were unique to each *Tet1* isoform. Behaviorally, we found that viral-mediated manipulations of the long isoform led to memory impairment, whereas loss of *Tet1S* did the opposite. Electrophysiological recordings from *Tet1* isoform-altered hippocampal slices revealed significant changes in Long-term potentiation (LTP), which correlated strongly with experimental groups that also exhibited cognitive changes. Overall, our data strongly indicate that these two TET1 enzymes provide important functions in the adult brain, through their unique attributes, gene targets and effects on physiology and cognition. Given that many of the early TET1 studies were done using tools that disrupted both isoforms, it will be important going forward to untangle which of the previous observations result from *Tet1L*, *Tet1S* or both.

Title: Convergent roles of beta-catenin and APC in regulating mRNA translation, plasticity and learning

Authors: *J. M. ALEXANDER, S.-X. JIN, L. A. FEIG, M. H. JACOB;
Neurosci., Tufts Univ. Sch. Med., Boston, MA

Abstract: Intellectual disabilities (ID, IQ<70) are a prevalent brain disorder, affecting 2-3% of the population. Although there are numerous human ID risk genes, the malfunction of convergent processes essential to synaptic plasticity and function, such as local protein synthesis, are thought to underlie the disorder. Our findings identify a new mechanism regulating neuronal mRNA translation, centered on β-cat (β-catenin) and its primary negative regulator in the canonical Wnt signaling pathway, APC (adenomatous polyposis coli protein). APC is also an RNA-binding protein (RNP) (several of its targets are ID-linked genes), and it localizes to RNA-granules with other RNPs such as Fragile-X Mental Retardation Protein (FMRP). We propose novel convergent roles for β-cat and APC in regulating translation with major impact on cognitive function. To test this hypothesis, we generated a mouse that conditionally (CamKIIα-Cre) expresses an N-terminally truncated β-cat in forebrain neurons; this construct closely resembles that produced endogenously by NMDA-mediated Ca^{++} influx stimulating calpain cleavage of β-cat. We used multi-disciplinary approaches (biochemical,n=3-6 per genotype [p.g.], behavioral, n=10-14 p.g. and electrophysiological, n=6-8 p.g. techniques, adult mice [2-4 months old] of both sexes in equal amounts, with Cre-negative littermates as controls). We show that truncated β-cat strongly associates with APC (by co-immunoprecipitation), causes APC hyperphosphorylation, and alters APC binding to and translation of its target mRNAs (altered levels of new protein synthesis). Compared with control littermates, these mice exhibit severe intellectual disabilities and reduced synaptic plasticity consistent with their decreased surface membrane levels of several glutamate receptor subunit subtypes. Intriguingly, we show that truncated β-cat also associates with FMRP (an RNA-binding protein critical for cognition) and this interaction is dependent on the presence of APC.
We propose a new mechanism whereby modification of the Wnt/APC destruction complex and calpain cleavage of endogenous β-cat regulate the mRNA binding and translational functions of APC and potentially other associated RNPs such as FMRP. Our findings identify novel convergent roles of β-cat and APC in regulating translation of synapse associated proteins, and suggest that dynamic, tight regulation of truncated β-cat levels is essential for normal plasticity and learning.

Title: Targeting Tet2 enhances spatial memory

Authors: *A. REDA[1], A. E. PRATT[1], S. RAUF[1], K. E. ZENGELER[1], H. C. SMITH[1], C. P. GETTENS[2], B. G. MALACHOWSKY[2], A. J. KENNEDY[1];

Abstract: Active and dynamic DNA methylation in the hippocampus is required for the formation, maintenance, and recall of memories. Here, we demonstrate that enhancing the fidelity of DNA methylation in the CA1 of the hippocampus enhances the strength and lifetime of object location memory in mice. Specifically, DNA demethylation in the CA1 of the hippocampus is mediated by ten-eleven translocation 2 (*Tet2*), which appears to negatively regulate spatial memory function. Conversely, a *Tet2* knockdown or knockout enhances long-term and remote object location memory, and results in the hypermethylation of learning-associated genes. Taken together, these data suggest that *Tet2* negatively regulates hippocampal long-term memory by active demethylation of the genome.

Title: Enhanced response learning with intrastriatal infusions of a BDNF mimic, 7,8-dihydroxyflavone

Authors: M. T. AMBALAVANAR, ***R. S. GARDNER**, P. E. GOLD, D. L. KOROL;
Biol., Syracuse Univ., Syracuse, NY

Abstract: Mature brain-derived neurotrophic factor (BDNF) is a secretory neurotrophin known to activate signaling cascades through phosphorylation of the tropomyosin receptor kinase B (TrkB). Activation of TrkB by BDNF is implicated in synaptic plasticity and hippocampus-sensitive learning and memory. However, the role of BDNF and its downstream signaling in modulating other forms of learning and memory has received less attention. We previously found that exercise, either cognitive or physical, enhanced not only hippocampus-sensitive learning but also striatum-sensitive learning. Enhancement of both types of learning relied on BDNF signaling. Here, we tested the effects of pre-training striatal infusions of the TrkB agonist, 7,8-dihydroxyflavone (7,8-DHF) on striatum-sensitive learning in 3-mo-old male rats. Specifically, we infused several doses of 7,8-DHF (1, 5, or 10 µg / hemisphere) or dimethyl sulfoxide (vehicle) into the dorsolateral striatum 20 min prior to 75 training trials on a response maze that is sensitive to striatal manipulations. During response training, rats learn to use a body turn (right or left) to reach a food reward. The results showed that 7,8-DHF at all doses significantly reduced the number of trials to reach a learning criterion of 9/10 correct consecutive trials from 50±4 (mean±sem) trials in controls to 23-30±~3 trials in 7,8-DHF-treated rats. 7,8-DHF at all doses also significantly increased choice accuracy across the 75 trials of training. These findings add the striatum to those memory systems for which activation of TrkB receptors enhances learning and memory and support the hypothesis that TrkB activation at the time of a learning experience contributes to cognitive performance. The results also reveal a rapid effect on learning of activation of the TrkB receptor, suggesting that neurogenesis associated with BDNF may not be necessary for cognitive enhancements.

Title: Myosin IIB as a key player in memory maintenance

Authors: *L. DE OLIVEIRA ALVARES[1], M. SILVA[2];
[1]Biophysics, Federal Univ. Rio Grande do Sul, Porto Alegre, Brazil; [2]Univ. Federal do Rio Grande do Sul, Porto Alegre, Brazil

Abstract: Synaptic plasticity events are intrinsically linked to dendritic spines and both are substrates for the formation, storage and expression. Myosin IIB is a main component for the morphophysiology of the dendritic spines and synaptic regulation. Here, we used blebbistatin (Blebb) to pharmacologically block myosin IIB activity to assess the effects of its inhibition on distinct memory processes. We first found that immediate post-training infusion of blebb in the hippocampus impaired long-term fear memory consolidation, but not short-term memory. Next, we showed that pre-test infusion of the drug hindered memory retrieval. Surprisingly, we also found that blebb was able to suppress memory retention when applied after the consolidation window, even without reactivation. We then replicated those results in a number of other behavioral protocols involving different brain structures and memory tasks. Thus, our results show that Myosin IIB plays an essential role not only in memory formation and expression, but also memory maintenance through its crucial dynamics with actin filaments in the dendritic spines.

Title: Phosphorylation of 4EBP2 affects hippocampus-dependent memory

Authors: *I. K. SUCCI, N. A. BURKERT, T. JENKINS, J. C. TUDOR;
Dept. of Biol., St. Joseph's Univ., Philadelphia, PA

Abstract: The hippocampus is a region of the brain critical for memory and cognition. Hippocampal neurons require protein synthesis for memory formation. Lack of sufficient protein synthesis impairs hippocampal-dependent memory consolidation. The mammalian target of rapamycin (mTOR) signaling pathway is a key pathway in protein synthesis. We developed a mutant phosphodefective 4EBP2 adeno-associated virus (AAV) with a CamKII alpha promoter

fragment to selectively express it in excitatory neurons in the hippocampus. Point mutations to alanine residues at the phosphorylation sites of 4EBP2 were to prevent phosphorylation. Mice exposed to the phosphodefective AAV experienced memory deficits compared to control mice. This indicates that phosphorylation of 4EBP2 is necessary in hippocampal-dependent memory consolidation. To further this investigation, we developed a mutant phosphomimetic 4EBP2 adeno-associated virus (AAV) with mutations to the aspartate residues at the phosphorylation site to mimic phosphorylation. Expression of the phosphomimetic AAV did not enhance memory in comparison to control animals. Our findings further support the importance of protein synthesis and mTOR signaling in memory consolidation.

Title: Poly I:C has sex-specific effects on learning and memory systems

Authors: *C. K. POSILLICO, R. E. GARCIA-HERNANDEZ, J. AHMED, S. JACOB, N. C. TRONSON;
Univ. of Michigan, Ann Arbor, MI

Abstract: The neuroimmune system is critical for normal neural processes, including synaptic plasticity and memory formation, and in the regulation of these processes during illness. For example, neuroimmune activation and cytokine signaling impair hippocampal-dependent memory. Here, we used intracerebroventricular (ICV) administration of polyinosinic:polycytidylic acid (poly I:C) to determine the modulation of circuit and molecular mechanisms of memory across multiple memory systems in both males and females. We first examined the activation of the hippocampus during context fear conditioning memory consolidation. Counter to expectations that poly I:C administration would result in decreased activation of context-fear related brain regions, correlating with diminished fear memory, females treated with poly I:C showed exaggerated cFos levels in dorsal hippocampus after context fear conditioning. This suggests that memory deficits as a consequence of neuroimmune activation is not due to suppression of neuronal activity, but rather a shift in the molecular mechanisms, learning strategies, or memory systems engaged. To identify specific effects of neuroimmune activation across multiple memory systems, we used a place-vs-response T-maze task, with a dark escape box as the goal to eliminate confounding effects of immune and

hormonal signaling on food-motivated behavior. Thus, this escape-motivated task is an effective tool for studying simultaneous modulation of hippocampal and striatal learning and memory processes after neuroimmune challenge. Sex differences in poly I:C-modulation of memory may be due to sex-specific neuroimmune response to this immune stimulant. We found that, as expected, ICV poly I:C increased levels of hippocampal cytokines in both sexes, but with stronger activation of CXCL10 in females and CCL2 in males. Neuroimmune function is strongly implicated in disorders of memory such as post-traumatic stress disorder and Alzheimer's disease, and women are twice as likely to develop these disorders compared to men. Uncovering the underlying mechanisms of immune modulation of memory processes in both sexes is thus essential for the development of novel prevention and treatment strategies for memory disorders in both sexes.

Title: Duration of aromatase inhibition differentially affects levels of a postsynaptic scaffolding protein in highly estrogenic female and male hippocampal tissue

Authors: T. COURT[1], C. GUSHO[1], ***D. BAILEY**[2,1];
[1]Med. Col. of Wisconsin-Green Bay, De Pere, WI; [2]St. Norbert Col., De Pere, WI

Abstract: The estrogen (estradiol, E2)-synthesizing enzyme aromatase is abundant in the hippocampus (HP) of vertebrates, including humans. Brain-derived E2 is important to memory function, and given pronounced sex differences in aromatase expression, this is especially of interest in regard to memory decline following drug treatment in clinical settings. For example, aromatase inhibitors, used to treat estrogen receptor-positive breast cancer, may produce cognitive impairment like forgetfulness. A unique model to examine the direct effects of aromatase inhibition on sexually dimorphic cognitive function and synaptic structure is avian HP tissue. The HP in birds is located on the dorsal surface, so manipulation of neuronal aromatase can be done *in vivo* without the confound of upregulation of the enzyme in glia. Aromatase is localized primarily in axon terminals in the HP, in higher concentration in males than females, and inhibition in males impairs spatial memory acquisition and performance consistent with lesions of the structure. The local E2 synthesized presynaptically can act postsynaptically via G protein-coupled estrogen receptors (GPER). Antagonism results in failure of spatial memory acquisition, and together aromatase inhibition with GPER agonism result in behaviors similar to

controls. Moreover, levels of a postsynaptic scaffolding protein, PSD95, are low in HP tissue treated with an aromatase inhibitor, suggesting a means whereby locally-synthesized E2 and GPERs modify receptor activity or transduction pathways to increase synaptic strength. The current study examined varying durations of aromatase inhibition in adult male and female zebra finch HP tissue. Bilateral craniotomies were made over the HP, and pellets containing the lipophilic aromatase inhibitor 1,4,6-androstatriene-3,17-dione (ATD) were placed and affixed to rest on the brain's surface. Animals were euthanized at 3, 7, and 14 days (d) post-implant, the HP was microdissected, and PSD95 levels were analyzed by Western blot. Levels of PSD95 were significantly ($p < 0.05$) lower in females than in males at 3 d and 14 d but not 7 d. Protein levels were low at 3 d in females but increased at 7 d and were maintained. In males, expression at 3 d did not differ from the 7 d treatment, but there was a significantly higher concentration at 14 d than 7 d. Thus, aromatase inhibition affects PSD95 levels to a greater extent in the female HP initially, perhaps due to a greater aromatase availability in male tissue. Additional work is examining other postsynaptic proteins as well as those promoted by the genomic actions of E2.

Title: Targeting DNA methylation to improve long-term memory in a model for intellectual disability

Authors: L. GALE, J. SERRANO, A. REDA, K. ZENGELER, H. C. SMITH, *A. J. KENNEDY;
Bates Col., Lewiston, ME

Abstract: Active DNA methylation is necessary for some forms of long-term memory function, including spatial and episodic memory. Here we demonstrate that inhibiting the de-methylation of DNA prolongs long-term memory maintenance and is a potential therapeutic target to treat memory deficits associated with intellectual disability. We knocked out Tet genes (Tet1 or Tet2), that encode for cytosine demethylases, from the neural tissue of both neurotypical mice and a mouse model for Pitt-Hopkins Syndrome, an ultra-rare intellectual disability on the autism

spectrum. Tet knockout enhanced long-term memory function, extended memory recall capacity, and rescued memory deficits in Pitt-Hopkins mice at long-term time points. These data suggest Tet enzyme inhibitors might be therapeutically useful in the treatment of Pitt-Hopkins Syndrome and other like intellectual disabilities.

Title: Monkeys with orbitofrontal cortex lesions show normal pupil responses and eye movement patterns when viewing valuable images

Authors: *J. HWANG, P. L. NOBLE, E. GONZALEZ-ARAYA, E. A. MURRAY;
Section on Neurobio. of Learning and Memory, Lab. of Neuropsychology, NIMH/NIH, Bethesda, MD

Abstract: Evidence from neurophysiological studies in macaques indicates that neurons in the orbitofrontal cortex (OFC) encode the values of anticipated foods and fluids associated with visual stimuli, and these value signals are modulated by gaze and attention. It is not well understood yet how gaze and/or attentional modulation of neuronal activity in OFC guides behavior, and in what circumstances OFC neuronal activity is necessary. To investigate the causal contribution of OFC to visual exploration of valuable objects, we trained rhesus monkeys with bilateral excitotoxic OFC lesions (N = 3) and unoperated controls (N = 4) on a preferential viewing task. The lesions were intended to include OFC areas 11, 13 and 14, and placement of injections of ibotenic acid was verified using T2-weighted MR scans. The experiment occurred in two stages: stimulus-reward association training and preferential viewing test. We first showed the monkeys 60 images, one at a time. The monkey's job was to look at each image for 2 s, at which time a fluid reward was delivered. Thirty images were followed by a large reward (high-value images) and the other thirty, by a small reward (low-value images). This stimulus-reward association training was given at the rate of 480 trials per day for 5 days. When the training stage was completed, we administered a preferential viewing test. On each trial, two images—one high-value image and one low-value image—were presented simultaneously and the monkeys were allowed to freely view them for 4 s. The only requirement was that the monkey's gaze stay within the boundaries of the two images for the full 4 s. In this stage, an

intermediate amount of fluid was delivered at the end of every trial. All possible pairings of high- vs. low-value images were presented. We collected several behavioral measures, including pupil response, the category of image that captured the 'first look', proportion of viewing time, and the total number of fixations. Both groups showed a consistent preference for the high-value images. During the training stage, the monkeys aborted fewer trials and exhibited greater pupil dilation for high-value relative to low-value images. During the preferential viewing test, when both a high- and a low-value image were available, monkeys looked at the high-value image first on 80% of trials. In addition, monkeys viewed the high-value images 3.7 times longer and made 3.5 times more fixations relative to the low-value images. There was no group difference on any of these measures. Our findings indicate that, at least when stimulus-value associations are acquired postoperatively, OFC is not necessary for guiding the eyes to valuable images.

Title: Contribution of the orbitofrontal cortex to inference based on specific stimulus-reward relationships

Authors: *M. OGAWA[1], S. ISHINO[1], K. TOKUOKA[2], T. ISA[2], B. D. ALLEN[3], A. S. CHUONG[3], E. S. BOYDEN[3], N. OISHI[1], I. SANGHUN[4], T. YAMADA[1];

Abstract: In classical appetitive conditioning, a neutral stimulus that initially has no effect on a subject is repeatedly followed by reward (or no reward). The subject is then able to predict an outcome during the presentation of the stimulus (i.e., conditioned stimulus: CS). Furthermore,

the subject often needs to use acquired CS-reward (or no reward) relationships to facilitate subsequent adaptive behaviors. Previous studies have shown that neurons in the orbitofrontal cortex (OFC) develop firing in response to both CS and reward outcomes. OFC is hypothesized to be critical in inference based on acquired associative relationships between multiple CS and outcomes. However, precise roles of OFC in such inference and the contribution of specific subtypes of projection neurons are unknown.
To address these questions, food-restricted mice were trained to learn CS1-reward (a food pellet) and CS2-no reward associations in a blocked manner, and the stimulus-outcome relationships were then reversed. Conditioned responding (CR) was defined as the time in front of a food cup in anticipation of reward following CS presentation. Here we show that optogenetic inhibition of OFC at the time of omission of expected reward following CS1 in the reversal phase, using a red-light sensitive chloride pump Jaws expressed in all layers of OFC, delayed extinction of the CR during CS1. Notably, this inhibition also delayed subsequent CS2-reward association, despite no inhibition during the association. By contrast, optogenetic inhibition of Jaws-expressing superficial layers 2/3 of OFC at the time of omission of expected reward following CS1 induced an increase of CR during CS2. These distinct behavioral effects were not evident when new CS3 was introduced instead of CS2 or CS1, or the optogenetic inhibition was from the beginning of CS1. These results pinpoint temporally, context-, and layer- specific bidirectional causal roles of OFC in the derivation of inference of the relationship between specific CS and reward outcome, based on acquired associative relationships between multiple conditioned stimuli and reward outcomes.

Title: Establishing causal links between the orbitofrontal cortex and economic decisions

Authors: *S. N. BALLESTA[1,2], W. SHI[2], K. E. CONEN[2], C. PADOA-SCHIOPPA[2];
[1]LNCA, Primatology Ctr., Univ. of Strasbourg, Strasbourg, France; [2]Neurosci., Washington Univ., St Louis, MO

Abstract: Multiple lines of evidence link economic choice behavior to the orbitofrontal cortex (OFC). Most notably, studies in which monkeys chose between different juices showed that neurons in OFC encode the identities and subjective values of offered and chosen goods. Furthermore, the population dynamics in OFC reflects an internal deliberation, and activity fluctuations in different groups of neurons correlate with choice variability. There results suggest that economic decisions are generated within this area. However, causal links between neural activity in OFC and economic choices have not yet been established. In principle, such links are demonstrated if electrical stimulation predictably biases choices. Building on this concept, classic work in area MT found that low-current stimulation facilitates, while high-current stimulation disrupts perceptual decisions. One challenge in applying this concept to economic choices is the lack of columnar organization in OFC. In other words, neurons associated with two goods available for choice are physically intermixed in cortex. To circumvent this challenge, we developed two experimental paradigms. In Exp.1, monkeys chose between two juices offered sequentially (pseudo-random order). High-current stimulation (≥100 μA) delivered during offer1 or during offer2 consistently biased choices against the juice offered during stimulation. Moreover, high-current stimulation during offer2 (when values were compared) increased choice variability (i.e., disrupted decisions). In Exp.2, we took advantage of the fact that *offer value* cells in OFC undergo range adaptation. Because of adaptation, for any given juice, the increase in offer value induced by low-current stimulation should be proportional to the value range. If two juices are offered, low-current stimulation should increase both values, but ultimately bias choices in favor of the juice with the larger value range. In the experiments, monkeys chose between two juices offered simultaneously, and we delivered electric current (50 μA). Confirming predictions, the stimulation induced a choice bias strongly correlated with the difference in value ranges. These results demonstrate that economic decisions are causally related to neural activity in OFC.

Title: Stimulation of serotonergic terminals in the orbitofrontal and medial prefrontal cortices differentially affects waiting for the future rewards

Authors: K. W. MIYAZAKI[1], ***K. MIYAZAKI**[1], A. YAMANAKA[2], K. F. TANAKA[3], K. DOYA[1];

[1]Okinawa Inst. Sci. and Tech. (OIST), Okinawa, Japan; [2]Res. Inst. of Envrn. Medicine, Nagoya Univ., Nagoya, Japan; [3]Keio Univ. Sch. of Med. Dept. of Neuropsychiatry, Tokyo, Japan

Abstract: Optogenetic activation of serotonin neurons in the dorsal raphe nucleus (DRN) enhances patience in waiting for future rewards (Miyazaki et al., 2014) and the effect is maximized when the probability of reward delivery is high and the timing of delivery is uncertain (Miyazaki et al., 2018). Here we explored which serotonin neuron projecting areas contribute to these effect by optogenetic terminal stimulation in orbitofrontal cortex (OFC), medial prefrontal cortex (mPFC), and nucleus accumbens (NAc). Tph2-ChR2 transgenic Mice (n = 15) were trained to perform a sequential tone-food waiting task (Miyazaki et al., 2014, 2018) with two reward delay conditions with 75% reward probability: (i) fixed 6 s (D6 test, low timing uncertainty) and (ii) randomly set to 2, 6, or 10 s (D2-6-10 test, high timing uncertainty). Each mouse was implanted optic fibers into both the DRN and one of the serotonin projecting areas. In OFC-DRN group (n = 5), optogenetic stimulation of serotonergic terminals in the OFC during waiting for delayed rewards significantly increased waiting time in reward omission trials compared to that without optogenetic stimulation (D6 test, 11.97 ± 0.28 vs. 10.72 ± 0.30 s; D2-6-10 test, 16.67 ± 0.29 s, vs. 13.76 ± 0.30 s). In mPFC-DRN group (n = 5), the waiting time with serotonin activation in mPFC was significantly longer than without serotonin activation in D2-6-10 test but not in D6 test (D6 test, 11.16 ± 0.28 s vs. 11.02 ± 0.23 s; D2-6-10 test, 16.50 ± 0.43 s, vs. 14.75 ± 0.31 s). In NAc-DRN group (n = 5), there was no significant difference of waiting time with and without optogenetic stimulation in the NAc (D6 test, 10.97 ± 0.22 vs. 10.97 ± 0.24 s; D2-6-10 test, 14.08 ± 0.33 s, vs. 14.07 ± 0.38 s). In each group (n = 15), the waiting time with serotonin activation in the DRN was significantly longer than without serotonin activation (D6 test, 12.17 ± 0.14 s vs. 10.83 ± 0.11 s; D2-6-10 test, 18.92 ± 0.26 s, vs. 14.08 ± 0.18 s). In summary, serotonergic stimulation in the OFC promotes waiting similar as affectively as the DRN optogenetic stimulation, while serotonergic stimulation in the mPFC promotes waiting only when timing uncertainty of future rewards is high. These results suggest that serotonin in mPFC affects evaluation of time committed, while serotonin in OFC in responsible for overall evaluation of delayed reward.

Title: Causal role of monkey orbitofrontal cortex on reward value computation and decision-making

Authors: *T. SETOGAWA[1], T. MIZUHIKI[1], N. MATSUMOTO[2], B. J. RICHMOND[3], M. SHIDARA[1];
[1]Fac. of Med., Univ. of Tsukuba, Tsukuba, Ibaraki, Japan; [2]AIST, Tsukuba, Japan; [3]NIMH, Bethesda, MD

Abstract: When we choose one item from several alternatives, we consider their values from amount of reward and the amount of work needed to obtain them. One of a candidate brain region related to such a reward value computation is orbitofrontal cortex (OFC). Here we studied whether 1) neurons in OFC are related to the value difference between offered options, and 2) there is a causal link between OFC and choice. We developed a decision-making schedule task and recorded single neuron activity from monkey OFC during this task. Two monkeys were initially trained to perform a reward schedule task. In this task, the monkey had to complete the schedule composed of 1, 2 or 4 trials of visual discriminations to earn 1, 2 or 4 drops of liquid reward. After learning this task, the decision-making schedule task was introduced. This task had a decision-making part and a reward schedule part. In the decision-making part, two choice targets (CT) were presented sequentially. Brightness and length of the CT were proportional to the amount of liquid reward (1, 2, or 4 drops) and the number of the visual-discrimination trials (1, 2, or 4 trials) needed to obtain reward, respectively. After both first and second CTs had been presented, the same two CTs simultaneously reappeared side by side of the fixation point. The monkey was required to choose one of the two CTs by touching the corresponding bar in the chair. Then, the chosen reward schedule task was started. We recorded 256 neurons in the monkey OFC (137 and 119 neurons from each monkey). The values of each CT were estimated from the monkey's choice behavior using an exponential discounting model. To analyze the relation between the firing rate in the second CT period and the presented CT values, we introduced seven analytic models and carried out a model selection by comparing AIC. 21.9% (56/256) of the neurons showed a significant correlation with value difference between two offered CTs. Inactivating a small regions of OFC rich in neurons coding for choice-related values using muscimol caused both slower to choose and more likely to choose the less valuable alternative, when the value difference was small. Thus, OFC neurons code for value information that could be used to guide choices, and these signals have a direct influence on the choice.

Title: Interaction between basal forebrain orbitofrontal cortex and secondary visual cortex during a visual discrimination task

Authors: *P. GOMBKOTO, P. VARSANYI, C. M. CHAVEZ, P. ZIOBRO, L. ZABORSZKY; Ctr. for Mol. and Behavioral Neurosci., Rutgers The State Univ. of New Jersey, Newark, NJ

Abstract: Basal forebrain (BF) cholinergic neurons provide the cerebral cortex with acetylcholine. Despite the long-established involvement of these cells in sensory processing, attention, and memory, the mechanisms by which cholinergic signaling regulates cognitive processes remains elusive. In a visual discrimination task, we examined cholinergic and non-cholinergic firing in basal forebrain (BF) which modulates cortico-cortical interaction between orbito frontal cortex (OFC) and secondary visual cortex (V2) (Gombkoto et al. 2019). Our overall goal was to understand how neural firing and detection of short timescale interactions of neuronal pairs correlate with behavioral epochs and how cholinergic and non-cholinergic neuronal activity in the BF influence cortico-cortical information processing. We hypothesized, that cholinergic activity increases during tasks that require cognitive flexibility (during reversal learning) versus well-trained tasks. In order to test this hypothesis, we introduced a touch-screen based task that contains visual feature recognition, discrimination based on the two distinct visual cues, and decision making in which the location of the reward delivery was associated to the visual cue. We found that unit firing responded heterogeneously to the visual cues, discrimination presentation, reward, or punishment, in the three brain regions indicating that these units code specific aspects of the task. Single unit activity from OFC coded outcome of expectation and error signal. In V2, single units responded to complex visual features which was associated with only one type of cue. BF neurons increased their firing at the initiation of correct choices and during reward but were inhibited during punishment when the animals were well trained. However, during reversal learning sessions, we found sustained activity by putative cholinergic cells specifically during correct trials but not incorrect trials. This sustained cholinergic activity may have influenced cortical processing allowing improved behavioral performance during reversal learning, since we did not observe this firing pattern when the animal was well trained. Our study defines how identified cholinergic and non-cholinergic firing in the BF modulate cortical network during learning.

Title: Distinct local and long-range cortical dynamics in an adaptive decision-making task

Authors: *A. BANERJEE, G. PARENTE, J. TEUTSCH, C. LEWIS, F. VOIGT, F. HELMCHEN;
Brain Res. Inst., Univ. of Zürich, Zürich, Switzerland

Abstract: Adaptive decision-making is a key component of flexible behavior, which enables animals to select appropriate goal-directed strategies based on the evaluation of recent stimulus/action-outcomes. The prefrontal areas of the mammalian neocortex, especially the orbitofrontal cortex (OFC), play an important role in invoking rule-based strategies to enable flexible learning. However, the neural circuit mechanisms in OFC and its interactions with different hierarchical cortical areas underlying such processes remain elusive. To study neural circuits of flexible decision-making, we developed a tactile-discrimination-based reversal learning task for head-fixed mice. We trained mice in a ‘Go/No-go’ texture discrimination task and then enforced them to relearn the task after a ‘Go/No-go’ rule-switch. Mice exhibited high performance during learning and re-learned the task upon reinforcer devaluation. Upon silencing lateral OFC, mice showed impaired reversal learning but intact acquisition of a new task-rule. To investigate how altered reward contingency is encoded and retrieved in distinct neuronal subpopulations in OFC, we employed 2-photon imaging through a rod-like GRIN lens to measure learning-induced changes in specific neural circuits. Longitudinal imaging of trial-by-trial Ca2+ responses from the same subsets of OFC neurons in mice expressing GCaMP6 in L2/3 neurons, revealed that OFC neurons are a key substrate assigning value to the sensory context. We also imaged neuronal responses in primary somatosensory cortex (S1). In S1, distinct neuronal subpopulations showed 'stimulus-selective' as well as ‘outcome-selective’ responses. The ‘outcome-selective’ neurons were differentially modulated by reward-history and altered response selectivity upon reversal. Silencing OFC-to-S1 projections following rule-switch impaired these plastic changes in S1 neurons. Taken together, our experiments shed light on the

circuit mechanisms underlying behavioural flexibility, indicating a crucial role of mouse OFC neurons in encoding predictive 'teaching signals' that drive adaptive changes in sensory cortices and in behavior.

Title: Decision-making in the context of multi-attribute options

Authors: *Z. S. GILLIS, A. Q. PERKINS, E. L. RICH;
Dept. of Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Optimal decision-making often requires evaluating multiple attributes of available options. When deciding between two cars to purchase, one might take into account the vehicles' gas mileage, reliability, safety, and general aesthetics among other aspects, complicating the decision-making process. It is currently unclear how multiple attributes are instantiated in neural activity during a decision and how such attributes are combined into a general value signal and represented and evaluated separately in neural activity. The OFC is known to play a critical role in representing stimulus values, and may simultaneously or sequentially represent the overall value of the stimulus and the value of individual stimulus attributes. In order to better understand the mechanisms through which multi-attribute stimuli are represented in neural activity, we trained two monkeys on a choice task in which composite stimuli were predictive of both the probability of reward and the level of sweetness. A trial consisted of two options, each represented by two bars of differing colors indicating the probability and sweetness of the reward. In order to make a choice, subjects had to fixate on the option and release a touch sensitive bar. Both subjects formed clear preferences for options with higher probability of reward and higher sweetness. We found that the subjects' decisions were differentially influenced by each attribute, and that their decision-making strategies changed over the course of a session, with the probability attribute more predictive of choice at the beginning and sweetness becoming more predictive toward the end. We will record from the OFC using multi-contact

arrays to determine how complex stimuli are represented in neural activity, and how such neural representations may change as discrete attributes become more or less predictive of choice behavior.

Title: Orbitofrontal-to-striatal projection drives confidence-dependent choice bias

Authors: *J. HIROKAWA[1], A. LAK[2], T. OTT[3], T. OHNUKI[1], Y. OSAKO[1], H. MANABE[1], Y. SAKURAI[1], A. KEPECS[3];

Abstract: In the face of environmental uncertainty adaptive behavior requires continuous changes in decision strategy. Theoretical considerations suggest that changes in choice strategy should reflect both decision outcome and confidence in obtaining the outcome. Orbitofrontal cortex (OFC) and striatum (STR) have been implicated in the computation of decision confidence and reward value, and their manipulation is known to produce choice biases. Therefore, we set out to examine the role of the OFC to striatum (OFC-STR) projecting neurons in shaping trial-by-trial choice strategy under perceptual uncertainty.
We designed a perceptual decision making task in which rats were encouraged to attend to the past outcomes of their choices. We trained rats in a 2-alternative odor-guided decision task, and varied perceptual uncertainty by changing the odor mixture ratio across trials. Rats received water reward after correct choices, while incorrect choices were not rewarded and led to a repeat of the stimulus in 50% of trials. We observed that their choices showed systematic biases depending on the outcome and difficulty of past choices. The influence of past outcomes on perceptual decisions was strongest when the previous sensory stimulus was difficult to judge, and thus the confidence in obtaining the reward was low. This choice bias was explained by reinforcement learning models that incorporate decision confidence into their teaching signals and hence adjust learning according to decision confidence (Lak et al, 2017).
Next, we monitored the activity of OFC-STR projecting neurons during the task. To target OFC-

STR neurons, we used a retrograde viral strategy to express ChR2 and optogenetically identify them based on short-latency spikes to brief light pulses delivered through a fiber next to the recording tetrodes. We found that 23/24 of OFC-STR neurons significantly encoded the outcome of the trial with sustained activity extending beyond the feedback period and until the next trial. To evaluate the behavioral function of OFC-STR neurons, we optogenetically activated or suppressed them using ChR2 or Jaws. Optogenetic activation (1s, 10Hz) during the outcome period increased choice bias in the following trial whereas optogenetic suppression (10s, continuous) had the opposite effect, reducing the choice bias. These behavioral effects can be mimicked in our model by manipulating the post-decision decision value, the reward expectation associated with a perceptually ambiguous decision (Lak et al, 2017). These results reveal that the OFC-STR pathway is important for signaling the decision value, and hence for regulating confidence-dependent choice biases.

Title: The role of the orbitofrontal cortex in updating value expectations

Authors: *E. L. RICH[1], Z. S. GILLIS[2];
[2]Dept. of Neurosci., [1]Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Expectations inform decision-making and can alter our perceptions. Aberrant expectations are a feature of psychiatric disorders, such as major depressive disorder, yet the neural mechanisms through which expectations are formed, maintained, and overridden are still unclear. The OFC is known to encode the value of reward-predictive stimuli, and distinct regions of OFC may serve disparate roles in updating stimulus-value associations. To understand the neural mechanisms through which expectations are instantiated and updated, we trained two monkeys on a reward expectation task in which pictures served as stimuli predicting rewards with varying levels of sweetness and bitterness. During forced choice trials, only one reward-predictive stimulus was offered. During free choice trials, the subject was presented with two

options, and chose between them. To receive an initial reward, the subject fixated on a stimulus and simultaneously released a touch sensitive bar. Initial reward delivery was followed by a 4 second response interval, during which the subject could freely tap the bar for small amounts of additional reward. Both subjects formed clear and stable reward preferences, selecting sweeter or less bitter rewards on free-choice trials. During the response interval, subjects tapped the bar more frequently for more preferred rewards, providing a time-varying behavioral measure of motivation to earn each reward. To determine whether bar tapping was motivated by expectations or actual rewards received, mismatch trials were included in which the reward delivered was not the expected reward. We found that subjects were initially motivated by expectations, and gradually adjusted their response rates, so behavior was better predicted by the actual rewards. Additionally, we found that subjects adapted their tapping behavior based on the mean and variance of available reward sweetness levels within an individual session. Preliminary neural data from OFC show modulation of beta frequencies that changes with expectation updating on mismatch trials. Using multi-contact arrays we will record simultaneously from OFC and gustatory cortex to determine how expected values and taste perception dynamically motivate behavior.

Title: Activity of single neurons in the macaque orbitofrontal cortex complies with the continuity axiom of expected utility theory

Authors: *S. FERRARI-TONIOLO, W. SCHULTZ;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: A possible mechanism for decision making under risk involves the computation and comparison of the subjective values (SV) of all available options. Expected utility theory (EUT) was the first rigorous axiomatic theory able to describe choices in this framework. The continuity axiom of EUT demonstrates the possibility of representing SV on a finite, numerical scale. We tested the continuity axiom in monkeys to verify that their choice behavior could be described in terms of numerical SV, a necessary step for comparison with the inherently cardinal neuronal

responses. Two rhesus monkeys were trained to choose between gambles with different reward magnitude-probability combinations. The continuity axiom was tested by verifying the existence of choice indifference between a certain reward and a gamble with a specific probability. Behavioral results (presented at the 2017 SfN meeting) confirmed the compliance with the continuity axiom. We recorded the activity of single orbitofrontal neurons while monkeys were presented with the same gambles used in the continuity tests. The activity of neurons coding the numerical SV predicted by EUT should be consistent with the pattern of choice indifferences observed in the continuity tests: the responses of such neurons should be modulated by the reward probability and be equal at the indifference point. We found that different classes of neurons were differently modulated by combinations of reward magnitude and probability. A first group of neurons was modulated by both magnitude and probability, a general necessary requirement for value coding. A subset of these neurons responded according to the continuity axiom, a more stringent condition for the coding of numerical SV. Two further neuronal classes were found to encode only the reward magnitude or the reward probability, while another group responded differentially to the presentation of probabilistic or certain rewards. These activity classes are compatible with the mechanism for computing SV delineated by EUT: different computational units could encode the subjective weight assigned to magnitudes (utility) and to probabilities (probability weighting), and these "partial" values could be combined into the signal observed in neurons complying with the continuity axiom. These neurons would represent the final step in encoding the SV, making them suitable candidates for driving (subjectively) optimal decisions.

Title: Structured representations in orbitofrontal neurons during time investment decisions

Authors: *T. OTT[1], P. MASSET[1], J. HIROKAWA[2], A. KEPECS[1];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Lab. of Neural Information, Doshisha Univ., Kyoto, Japan

Abstract: Every decision we make is accompanied by a sense of confidence about its likely outcome. This sense informs subsequent behavior, such as investing more ―whether time, effort, or money― when reward is more certain. We previously showed that using decision confidence to guide time investment relies on the orbitofrontal cortex (OFC) in rats. However, it is unknown how the activity of OFC neurons supports confidence-guided time investment behavior. Here we show that the activity of OFC neurons is highly structured: distinct groups of neurons show unique temporal response profiles and represent distinct task variables that enable confidence-guided time investment. We trained rats to make choices based on evidence from two different sensory modalities (auditory clicks or olfactory mixtures). After making a choice, rats had to wait in a choice port to obtain an uncertain, randomly delayed reward. The time rats were willing to invest in waiting for a potential reward reflected their decision confidence. We found that individual OFC neurons showed rich and complex response patterns; different neurons were active during different task epochs and encoded different aspects of the task, such as choice, decision confidence, or elapsed time. However, these dynamic activity patterns were not randomly distributed but clustered into a small set of typical response profiles that spanned the entire duration of a trial. Many neurons encoded decision confidence immediately after making a choice, irrespective of the sensory modality used to make a choice. Another group of neurons showed ramping activity during the time investment period, predicting the rats' time investment, while different neurons sharply increased their activity just before leaving decisions. OFC thus links information about decision confidence with subsequent time investment behavior and leaving decisions and could thereby mediate confidence-guided economic decisions.

Title: Interactions between the medial orbitofrontal cortex and nucleus accumbens facilitate risk assessment behaviors

Authors: *M. K. LOH, N. C. FERRARA, J. A. ROSENKRANZ;
Cell. and Mol. Pharmacol., Rosalind Franklin Univ., North Chicago, IL

Abstract: The ability to assess risk and predict potential negative consequences heavily biases the decision-making process and is evolutionarily important for survival. The nucleus accumbens (NAc) supports reward-directed actions and its activity is reflective of risky behavior. These

behaviors are influenced by input from several brain regions to the NAc. Namely, the medial orbitofrontal cortex (MO) contributes to behavior guided by reward probability and sends direct projections to the NAc, suggesting that MO-NAc efferents may permit risk evaluation. Therefore, a clearer understanding of MO-NAc interactions is crucial to elucidate the neural mechanisms underlying risk assessment. Here, we investigated MO-NAc interactions in gating risk assessment behaviors. Using a disconnection approach, we found that MO-NAc interactions may be necessary for risk assessment behaviors in rats, observed as stretch and attend postures (SAP) on the elevated plus maze (EPM). In line with these findings, we found that adolescent subjects, who characteristically have delayed frontal lobe maturation and potentially less cortical input influence, also exhibited less EPM risk assessment behaviors than adults. A balance between reward versus risk elements is weighed during decision-making, perhaps reflected by the interactive nature of cortical and limbic inputs into the NAc. Therefore, we investigated if MO-NAc interactions influence circuits that underlie reward-seeking. Using *in vivo* extracellular single-unit electrophysiology, we isolated NAc neurons responsive to basolateral amygdala (BLA) stimulation, as BLA-NAc projections facilitate reward-seeking behaviors and attenuate cortical-NAc interactions. We hypothesized that MO stimulation will diminish BLA-evoked NAc spiking. Single pulses at increasing interstimulus intervals and frequency-varying trains were delivered to the MO to assess its effects on BLA-evoked NAc spiking. We found that MO single-pulse stimulation enhanced BLA-evoked NAc spiking in a time-dependent manner, optimal at the 11-ms ISI. Shifts to BLA-evoked NAc spike probability by MO train stimulation were also frequency-dependent. Further, MO train stimulations resulted in a bimodal distribution of NAc activity; half of BLA-evoked NAc neurons showed diminished spike probability to MO train stimulation while the remainder showed an increase. This suggests that MO activity timing and frequency are important NAc activity modulators. Due to the behavioral role of MO and BLA-NAc projections, these interactions may contribute to the neurobiological mechanism in the incorporation of risk information to influence reward-directed actions.

Title: Distinct roles of the pACC and cOFC in cost-benefit decision-making

Authors: *G. K. PAPAGEORGIOU[1], K.-I. AMEMORI[3], H. N. SCHWERDT[1], D. J. GIBSON[2], A. M. GRAYBIEL[1];
[2]McGovern Inst. for Brain Res., [1]MIT, Cambridge, MA; [3]Primate Res. Inst., Kyoto Univ., Inuyama, Japan

Abstract: The pregenual anterior cingulate cortex (pACC) has been implicated in learning, decision-making and mood-related disorders, but very little is known about a relatively adjacent region, the caudal parts of the orbitofrontal cortex (cOFC). Although the orbitofrontal cortex (OFC) has been actively investigated, surprisingly, most electrophysiological OFC studies have focused on more rostro-medial or lateral parts of this region. Therefore there is overall uncertainty about the role of the more caudal parts of the OFC in decision-making and learning processes. Here we concurrently investigated the role of each brain region during a cost-benefit approach-avoidance (Ap-Av) task, a task well-established for use in non-human primates and humans. We have trained two adult macaque monkeys (one male, one female) on a visually guided Ap-Av task. During the task, monkeys had to look and fixate at targets displayed on a screen to choose offers comprising of certain amounts of reward (water or juice) and punishment (airpuff), signaled by the length of red and yellow bars, respectively. For the purpose of electrophysiological monitoring during the task performance, moveable platinum-iridium electrodes were chronically and bilaterally implanted in the pACC and the cOFC. In addition, physiological parameters including pupil diameter, licking and pulse oximetry were recorded for estimate the behavioral states. Both animals exhibited a stable decision boundary between Ap and Av choices during the experiment, often accepting an offer when a reward was higher than punishment and rejecting it when the punishment was greater than reward. A further analysis of the neural data revealed differential firing during the various task events in pACC and cOFC. Specifically, neurons in the pACC exhibited higher firing rates during the presentation of the compound offer, whereas neurons in the cOFC were more active during the outcome delivery period, especially during the delivery of the negative outcome (i.e., airpuff). These results show that both of these regions play a significant role during cost-benefit decision-making but that they may influence differentially the decision-making process.

Title: Effect of orbitofrontal cortex DREADDs inhibition on probabilistic discrimination reversal learning and win-stay, lose-shift strategies in male and female rats

Authors: *S. KOLLI[1], C. G. AGUIRRE[1], E. NGUYEN[1], A. STOLYAROVA[1], M. SPITMAAN[2], A. SOLTANI[2], A. IZQUIERDO[1];
[1]Psychology, UCLA, Los Angeles, CA; [2]Dartmouth Col., Hanover, NH

Abstract: The orbitofrontal cortex (OFC) supports functions related to reward learning and decision making and exhibits functional heterogeneity, even in rats (Izquierdo, 2017). Most sectors of rat OFC have been shown to support reversal learning, but less is known about its role in supporting learning under different schedules of reinforcement during probabilistic reversal learning (PRL). For most PRL studies, OFC has also mostly been manipulated using classic techniques like pharmacological inactivations and lesions, with past work predominantly reporting effects only in male rodents. Here we tested both male (n=8) and female Long-Evans rats (n=8) on PRL following expression of inhibitory hM4Di DREADDs on a CaMKIIα promoter in ventrolateral OFC and compared them to rats receiving eGFP null virus, or systemic vehicle injections to control for behavioral effects of virus exposure or hM4Di ligand, clozapine-n-oxide (CNO). After discrimination, rats were injected with either CNO (3.0 mg/kg s.c.) or vehicle daily, prior to testing on PRL via touchscreen response where they could select between two visual stimuli, assigned as the Better (B) or Worse (W) options, rewarded with probability pR(B)=0.90 or pR(W)=0.10, respectively. The control groups were not significantly different, so their data were collapsed. Analyses were focused on the first 10 sessions of each phase for mean probability correct, initiation omissions, and the number of no rewards per session. A repeated-measures ANOVA revealed no main effect of sex or treatment group differences, or sex x treatment group interaction for these measures on initial discrimination learning, when rats initially learned probabilities of reward. There was, however, a significant session x active virus group interaction for probability correct during PRL, with the most pronounced deficits in early PRL following OFC inhibition. Rats could either select the same stimulus after a reward (i.e. Win-Stay) or switch to a different stimulus following a loss (i.e. Lose-shift). Trial-by-trial analyses were conducted to assess win-stay/lose-shift strategies during early learning. Following OFC inhibition, rats adopted significantly more of a win-stay strategy and less of a lose-shift strategy. Also following OFC inhibition, rats were more likely to choose the same stimulus on the subsequent trial, regardless of the outcome. Collectively, the data suggest reduced negative but enhanced positive feedback sensitivity, and enhanced perseverative choice behavior following OFC inhibition. Ongoing work is aimed at comparing learning under other probability schedules, and probing more precise timing of OFC involvement in PRL.

Title: Overtraining of avoidance in rodents as a model for OCD-like compulsions

Authors: *C. I. HUERTAS PÉREZ, Jr.[1], F. J. MARTINEZ-RIVERA[3], M. J. SANCHEZ-NAVARRO[3], J. E. PEREZ-TORRES[3], *G. J. QUIRK[2];
[1]Psychiatry, Univ. Puerto Rico Sch. of Med., San Juan, Puerto Rico; [2]Psych, Anat & Neurobiol, Univ. Puerto Rico Sch. of Med., San Juan, PR; [3]Psychiatry, Univ. of Puerto Rico Med. Sci., San Juan, Puerto Rico

Abstract: Obsessive-compulsive disorder (OCD) is characterized by a persistent urge to avoid perceived threats in the absence of danger. It can be treated with exposure-with-response-prevention (ERP) therapy, in which patients are prevented from carrying out compulsions in response to triggers. We previously used platform-mediated active avoidance to model ERP (Rodriguez-Romaguera et al., 2016), but we now examine overtraining of avoidance to capture the long-term negative reinforcement feature of compulsive behaviors. Food-deprived rats were conditioned for either 8 days or 20 days (9 trials per day) to step onto a platform to avoid a tone-signaled footshock. Mounting the platform prevented access to a bar that delivered sucrose pellets. Following conditioning, rats underwent 4 days of extinction with response prevention training (Ext-RP), where tones were presented without shocks in the presence of a barrier blocking access to the platform. This was followed by a single test session where the tone was presented with the barrier removed. Rats in 8d and 20d groups showed equivalent avoidance conditioning, but 20d rats were severely impaired in extinction of freezing during Ext-RP. When the barrier was removed, 20d rats spent significantly more tone-time on the platform ($p<0.001$), with 75% showing persistent avoidance compared to 37% in the 8d group. 20d rats also displayed heightened anxiety in an elevated plus maze (open arm time (s): 8d: 72.3±14.3; 20d: 32.9±8.5). cFos analysis revealed that the minority of rats exhibiting persistent avoidance in the 8d group had elevated activity in the expected avoidance structures (prelimbic (PL) cortex, nucleus accumbens). However, 20d rats exhibiting persistent avoidance did not have elevated activity in these structures. Instead, the minority of 20d rats not exhibiting persistent avoidance showed elevated activity in lateral orbital/insular cortex, dorsolateral striatum and paraventricular thalamus. Thus, overtraining induced a pre-potent avoidance response not driven by the known avoidance circuit. We next attempted to reverse the effects of overtraining by

lengthening Ext-RP from 4 to 10 days. Preliminary data indicates that the 20d rats given 10d of Ext-RP training continued to show elevated avoidance when the barrier was removed. Furthermore, cFos was not elevated in PL, resembling the impaired pattern of overtraining followed by 4 days of Ext-RP. Taken together, our results suggest that prolonged expression of avoidance-type compulsions alters neural circuits and drives pre-potent responses that may be resistant to extinction based therapies.

Title: An automated arena for *in vivo* recordings of freely behaving lizards

Authors: *S. WEISS, G. J. LAURENT;
Max-Planck Inst. For Brain Res., Frankfurt am Main, Germany

Abstract: Reptiles occupy a critical limb of the evolutionary neuro-developmental tree, sharing a layered cortical architecture with mammals and a dorsal-ventricular ridge (DVR) with birds (or avian reptiles). Recent studies of the reptilian brain in this laboratory have focused on electrophysiological recordings from brain slices, ex vivo brain-explants or anaesthetized animals (Fournier et al., 2018), and on single cell transcriptomics approaches (Tosches et al., 2018). Data collected in vivo are rare, with the exception of sleep-related brain activity in lizards (Shein-Idelson et al., 2016). While behavioral studies have established learning abilities in several lizard species, current tests of lizard cognition lack standardized testing methods and provide no data on brain activity during behavioral tasks. It is thus difficult to generalize results across lizard species or between reptiles and other amniotes. In the current study we developed and used an automated test arena, inspired by the design of a “plus-maze” commonly used to induce different behavioral strategies in rodents. Bearded dragon lizards (Pogona vitticeps) were trained to perform behavioral tasks in the arena, while local filed potential (LFP) and single-unit data were recorded from dorsomedial cortex (a molecular homolog of the CA fields in mammalian hippocampus) and DVR (a homolog, among others, of parts of the mammalian amygdala). We hope that this research can help standardize behavioral neuroscience research in

reptiles and enables a comparative analysis of brain activity across mammals, birds and reptiles, in order to characterize the core and shared anatomical and functional features of memory systems in amniotes.

Title: Neurons in the orbitofrontal cortex encode the same decision variables in different choice tasks

Authors: *W. SHI[1], S. BALLESTA[2,1], C. PADOA-SCHIOPPA[1];
[1]Dept. of Neurosci., Washington Univ. in St. Louis, St. Louis, MO; [2]Lab. de Neurosciences Cognitives et Adaptatives, UMR 7364, CNRS et Univ. de Strasbourg, Niederhausbergen, France

Abstract: Economic choices involve two mental stages - values are assigned to the available options and a decision is made by comparing values. Experiments where monkeys chose between two juices have identified different groups of cells in the orbitofrontal cortex (OFC) encoding the value of individual options (*offer value*), the binary choice outcome (*chosen juice*) and the *chosen value*. These variables capture both the input and the output of the choice process, suggesting that these groups of neurons constitute the building blocks of a decision circuit. This and other results provide a basic understanding for the neural underpinnings of economic decisions. However, current notions emerged mostly from studies where two offers were presented simultaneously. Other authors suggested that decisions under sequential offers might rely on different mechanisms. In a recent study, we examined economic choices under sequential offers (Ballesta & Padoa-Schioppa, *biorxiv*). Individual neurons in OFC encoded different variables in different times windows. However, an analysis across time windows still revealed three groups of neurons: *group1* cells encoded the value of one particular juice whenever that juice was offered; *group2* cells encoded in a binary way the juice type present on the monitor and, subsequently, the chosen juice; *group3* cells encoded the value of the juice currently offered and, subsequently, the chosen value. In the present study, we directly examined the relation between the cell groups identified under sequential offers and those identified under simultaneous offers.
In each session, a monkey chose between two juices offered in variable amounts. Trials with the

two choice tasks- simultaneous or sequential - were pseudo-randomly interleaved. We recorded the activity of 702 cells in OFC. Trials with the two choice tasks were analyzed separately. Thus each cell was classified for its activity under simultaneous offers and under sequential offers. In most cases, neurons tuned in either choice task were tuned in both choice tasks. Furthermore, at population level, an analysis of the contingency table of cell groups revealed a close correspondence between the two classifications. Specifically, [*group1*, *group2*, *group3*] closely corresponded to [*offer value*, *chosen juice*, *chosen value*] ($p<0.01$, Fisher's exact test). These results support the hypothesis that economic decisions under simultaneous and under sequential offers are generated in the same neural circuit, rather than based on two different mechanisms.

Abstract: Combining evidence from lesions, imaging, modeling and neurophysiology, previous results established a clear link between economic choice and subjective values represented in the OFC. Subjective value computation implies a trade-off among multiple attributes and it has been proposed that the central OFC (areas 13m/l and 11l) makes a unique contribution to economic decisions by computing subjective values through integrating multiple attributes of goods. An outstanding question that follows is whether central OFC is dedicated to multi-attribute economic decisions or subserves reward-based decisions in general. Here, we sought to investigate this question by training monkeys to perform alternately in a multi-attribute choice (MAC) and a single-attribute choice (SAC) task. In the MAC task, the animal chose between two

juices of variable amounts while in the SAC task, the animal chose between the *same* juice of different amounts. In the the MAC task, two offers were represented by two sets of symbols in different color displayed to the left and right of the central fixation point. In the SAC task, the two sets of symbols have the same color, indicating the same juice of different quantity. Behaviorally, the animal showed typical trade-off between juice quantity and taste in the MAC task and always chose the offer of larger quantity in the SAC task. In each recording session, we simultaneously recorded an ensemble of neurons (10 on average) under both tasks. We achieved stable recordings from over 200 neurons across two tasks from one animal. We hypothesized that if OFC subserves reward-based decisions in general, when the animal transitions from the MAC to the SAC task, OFC neurons would adapt to the decision context by switching from representing the decision process in juice-based reference frame to that in spatial reference frame. However, we discovered that 1) There are significantly more task-related neurons in the MAC task than that in the SAC task. 2) In the MAC task, OFC neurons primarily encode task-related variables associated with the choice process in a good-based representation, including offer value, chosen value and chosen juice, while In the SAC task, the same population of neurons primarily encode chosen quantity only. 3) In the MAC task, a substantial proportion of neurons encode chosen juice while few neurons in the SAC task encode chosen side (choice outcome in spatial reference frame). These preliminary results based the regression analysis of single unit activity suggest that central OFC subserves the multi-attribute decision in good-based reference but not single-attribute decision in spatial reference frame.

Title: Neural correlates of absolute and relative predictive validity in lateral orbitofrontal cortex during learning

Authors: S. VOLZ[1], M. KANG[1,2], I. REVERTE[1], F. ALHAZMI[1,2], M. IORDANOVA[3], ***G. ESBER**[1,2];
[1]Psychology, Brooklyn College, City Univ. of New York, New York, NY; [2]The Grad. Center, City Univ. of New York, New York, NY; [3]Concordia Univ., Montreal, QC, Canada

Abstract: A vast behavioral literature shows that the value of reward-predictive cues is not merely a function of how well they predict reward by themselves, but by comparison with other

cues, suggesting predictive validity is set in relative rather than absolute terms. This is evident in cue-competition phenomena, in which the presence of other predictors can curtail or drain the value that a cue would otherwise acquire given its statistical correlation with reward, or *absolute validity*. These phenomena are problematic for early models that viewed learning as being driven by a *local* prediction error (PE), or difference between the reward observed and the reward predicted by the cue, since those models predict that each cue will acquire value in proportion to its absolute validity. Instead, they fostered the prevailing notion that learning is driven by a common or *global* PE—the difference between the reward observed and a pooled or aggregate reward prediction based on all cues present. Models that subscribe to the latter notion view cues as competing for value during learning, such that only those that have high *relative validity* will ultimately acquire substantial value. Critically, despite the explanatory power of global PEs, emerging evidence indicates that local PEs also play a role in learning, and that the extent to which they do so is subject to individual differences. This suggests the existence of a learning-style axis, at one end of which individuals track the absolute validity of cues, while at the other end they track the cues' relative validity. To investigate the neural bases of the absolute-relative validity axis, we developed a novel cue-competition task in rats which is first to set absolute and relative validity in conflict, thus affording the starkest possible contrast between both learning styles and their neural underpinnings. Using this task, we recorded single-unit activity in the lateral orbitofrontal cortex (lOFC), a brain region known to encode the reward-signaling properties of cues. Interestingly, our results suggest that lOFC neurons track both the absolute and relative validity of cues, with a greater proportion of neurons representing the latter.

Title: Optimization of a risky decision-making task for electrophysiology in male and female rats

Authors: *D. B. K. GABRIEL[1], A. E. LILEY[2], W. B. CAUGHRON[1], N. W. SIMON[1]; [2]Psychology, [1]Univ. of Memphis, Memphis, TN

Abstract: Risky decision-making is characterized by reward-seeking despite the possibility of punishment. The rat risky decision-making task (RDT) measures this behavior by presenting a

choice between a small, safe reward (one pellet) and a large reward (three pellets) accompanied by the risk of an increasingly likely punishing foot shock (Simon et al., 2009, Neuropsychopharmacology). Understanding the neurobiological mechanisms that drive risky decision-making is necessary for the development of interventions for disorders characterized by excessive risk-taking. Single unit electrophysiology allows synchronization of functional neuronal activity with behavior at exquisite temporal resolution, and is thus ideally suited to determine how neurons encode specific salient events during risky decision-making. Here, we developed an optimized, electrophysiology compatible version of the RDT for use in male and female rats. The RDT was altered to include only two risk blocks (0% and 50% risk of foot shock), with 8 forced choice (only one option available) and 40 free choice trials (both options available) in each block. To parse apart distinct epochs of the decision-making process, rats were trained to perform one-second sustained nose pokes into a lit trough 1) prior to each choice, and 2) prior to each outcome. While male rats were able to acquire these contingencies, females were inconsistent in ability to achieve trial criterion even after extensive training. Accordingly, the task was altered to include only the pre-decision nose poke hold, with outcomes delivered .5 seconds after reward choice. Both male and female rats acquired this iteration of the task, and demonstrated a comparable shift away from the large reward in the second block (50% risk of punishment). This task will facilitate ongoing investigation of the functional neuronal activity underlying individual differences in risk-taking across both males and females. Subjects are currently being implanted with microwire arrays for single unit recording in the orbitofrontal cortex, a brain region shown to contribute to risk-based decision-making.

Title: A computational model for the modulation of learning by the common and separate prediction error

Authors: *F. ALHAZMI[1,2], A. KRISHNAN[1,2], G. R. ESBER[1,2];
[1]Brooklyn College, City Univ. of New York, Brooklyn, NY; [2]The Grad. Center, City Univ. of New York, New York, NY

Abstract: Prediction error (PE) is a fundamental concept in associative and reinforcement-learning models, where it is viewed as the signal that drives learning. Current mainstream models assume that cues concurrently presented share a common PE, or difference between the observed and expected outcome, by virtue of which they compete for learning. However, mounting behavioral evidence from both rat and human studies suggests that learning is also modulated by a separate PE signal, or difference between the observed outcome and that expected on the basis of each cue considered in isolation, in keeping with earlier learning models. Crucially, how the two types of PE combine to modulate learning is not yet understood. Here, we aim to provide a computational account of PE integration specifically aimed at capturing the results of experiments attempting to disentangle the contribution of separate PE and common PEs to learning. Succinctly, our solution consists of combining separate and common PEs in a weighted sum fashion. In this Weighted Sum Model (WSM), the relative weight of each type of PE gives rise to learning-style continuum, at one end of which learning relies on common PEs while at the other end learning relies on separate PEs. This theoretical account explains widely reported individual differences in cue competition as well as variability across cues in their susceptibility to engage in cue competition. Performance and unique prediction of WSM are discussed in the context of other potential PE-integration mechanisms.

Title: Prefrontal mechanisms of economic decisions with sequential offers

Authors: *K. NI[1], Y. LIU[1], X. CAI[1,2];
[1]NYU-ECNU Inst. of Brain and Cognitive Sci., NYU Shanghai, Shanghai, China; [2]Shanghai Key Lab. of Brain Functional Genomics (Ministry of Education), Sch. of Psychology, East China Normal Univ., Shanghai, China

Abstract: A majority of studies in value-based decisions focus on decisions based on an available menu. However, in many real-life decisions, offers appear sequentially. Early studies

discovered that neurons in the OFC encode the value of offers available for choice. However, such studies failed to identify persistent value selective activity in the OFC. Therefore, it is unknown whether and how OFC supports economic choice of sequential offers. Anatomically, central OFC is interconnected with the lateral prefrontal cortex, which has pervasively been demonstrated to encode working memory through sustained activity. In current study, we sought to investigate how the prefrontal network may process value information in working memory for choice. To this end, we developed an economic choice task with sequential offer presentations. In the experiments, the animal chose between two juices offered in variable amounts. The animal maintained center fixation while two offers were presented sequentially on the left or right side. For each pair combination of juice quantities, the sequential order and the left/right configuration of offers were pseudorandomized and counterbalanced within each trial block. Terms "offer1" and "offer2" refer to the first and second offer appearing sequentially. In each trial, offer1 appeared for 500 ms followed by a delay of 1000 ms, after which offer2 appeared for 500 ms, then two saccade targets appeared on each side of the fixation point, and the monkey indicated its choice with a saccade. The combinations of the two offers were designed such that the animal had to wait for offer2 before making a decision. We recorded the activity of multiple prefrontal regions, including the central region of the orbitofrontal cortex (area 11 and 13) and the dorsal and ventral bank of the principal sulcus (LPFCd and LPFCv). We analyzed the activity of around 200 neurons in each of the 3 areas. The task design allowed the representation of goods and values in multiple reference frames (i.e., juice-based, order-based and (left/right) space-based reference frames). We examined neural representations of decision-related variables in all three reference frames in OFC, LPFCd and LPFCv. We discovered that when offer1 or offer2 was on, neurons in the OFC and LPFCv encode the value of the offers in multiple reference frames, however, representations of offer1 value did not persist throughout the delay period. Furthermore, binary choice signals emerge in order-based reference frame first, followed by those in space-based and juice-based reference frames. These activity patterns might reflect the decision through coordinated neural processes in multiple reference frames.

Title: Sex differences in the discounting of delayed punishment

Authors: *A. E. LILEY, D. B. GABRIEL, M. E. UDELL, H. J. SABLE, N. W. SIMON; Psychology, Univ. of Memphis, Memphis, TN

Abstract: Sex differences in sensitivity to punishment during decision-making have been observed in both humans and animal models. However, these studies are limited to designs in which punishment occurs immediately after a decision. To model consequences that occur later in time, we developed the Delayed Punishment Decision-making Task (DPDT). In this task, rats increased choice of rewards associated with punishment (shock) as delay preceding the punishment lengthened, demonstrating that subjects underestimate the negative value of delayed consequences. Males and females showed comparable avoidance of a large, punished reward when punishment occurred immediately. However, when delay was added between the reward and punishment, males showed a greater preference for this outcome than females. This indicates that females discount delayed punishment less than males. Estrous samples were collected from female rats via vaginal lavage, viewed under light microscope, and categorized by the presence of cornified epithelial cells, nucleated epithelial cells, or leukocytes. The four stages of the estrous cycle (proestrus, estrus, metestrus, and diestrus) were then compared to behavioral performance during the task. There were no significant changes in behavior during any stage of estrous during DPDT. Addition of a cue light bridging the delay between the reward and punishment produced a decrease in selection of rewards associated with delayed consequences that was not influenced by sex. Finally, neither male nor female rats demonstrated a correlation between DPDT and delay discounting, which measures preference for delayed rewards.
A region that likely plays a regulatory role in sensitivity to delayed punishment is the orbitofrontal cortex (OFC). We are currently implanting bilateral cannulae into the orbitofrontal cortex of male and female Long Evans rats to measure effects of OFC inactivation on sensitivity to delayed-punishment during DPDT. Ongoing studies will provide insight as to how the OFC affects the undervaluation of delayed consequences, and how this differs between males and females. Collectively, these experiments demonstrate novel sex differences in an understudied form of addiction-relevant punishment-based decision-making.

Title: Effects of a high fat diet on working memory and metabolism in rats

Authors: *H. M. MURPHY, C. H. WIDEMAN;
Neurosci., John Carroll Univ., University Heights, OH

Abstract: The nutritional status of an organism is paramount to optimal brain function. Research has provided evidence that chronic ingestion of a high fat diet is associated with cognitive

decline. The current study evaluated the effects that a high fat diet has on working memory and metabolism of rats. It was hypothesized that, compared to controls, a high fat group would display negative effects in both variables. The T-maze was used to assess working memory. A moveable door was employed to prevent access to one arm during forced (access to only one arm) runs. Rats were shaped for one week. At the beginning of the dark cycle on the first and second days, 250 µL of condensed milk, in a small glass container, was placed in each cage to familiarize the rat to the "treat" incentive. On day 3, 250 µL of treat was put at the beginning of the T-maze and the rat was placed into the maze to find it. For succeeding days, the treat was gradually restricted to the arms of the maze. Following the shaping period, habituation began on week 2 and continued for seven days. Every day during week 2, all rats were individually placed into the maze to complete both a forced run and a choice run. The forced run directed the rat down one of the arms with the incentive of the treat at the end, while the other arm was blocked. Time taken to find the treat was recorded. For the choice run, the rat was placed onto the stem of the T-maze and the block on the other arm as well as the treat were removed. The rat was then allowed to run down the stem and freely choose one of the arms. If the rat entered the same arm as the forced run, a correct response was recorded. If the opposite arm was chosen, an incorrect response was recorded and the rat was returned to its cage. Responses were recorded when the rat moved more than 10 cm down one arm. Forced runs lasted for 2 min, or until the rat found the treat. Choice runs lasted 2 min, or until the rat entered an arm. Body weight, food intake and water intake were recorded daily. Following habituation, each rat was randomly assigned to either the standard rat diet used during habituation or a high fat diet D12492 (Research Diets, Inc., New Brunswick, NJ). The experimental period lasted for 3 weeks and the paradigm utilized in habituation was employed. At the conclusion of the experimental period, rats were sacrificed and blood glucose and adiposity were determined. Working memory was significantly impaired in the high fat group, characterized by a 60% decrease in retention. Furthermore, there were marked increases in body weight, caloric intake, blood glucose, and adiposity in the high fat group. This study provides evidence that a high fat diet has a deleterious effect on working memory and negatively affects some metabolic processes.

Title: Maternal high-fat diet during pregnancy effects on working memory performance and glutathione levels in the rat offspring at young age

Authors: *N. Y. CORTÉS[1], C. R. VUELVAS-OLMOS[1], R. PEDRAZA-MEDINA[2], M. F. PINTO-GONZALEZ[1], N. Y. PEÑA-GARCIA[2], J. L. COLLAS-AGUILAR[2], J. GUZMÁN-MUÑIZ[2], L. M. BALTAZAR-RODRIGUEZ[1], N. A. MOY-LOPEZ[2];
[1]Sch. of Med., [2]Sch. of Psychology, Univ. of Colima, Colima, Mexico

Abstract: Introduction: The environment that a developing offspring experiences during the perinatal period is markedly influenced by maternal health and diet composition. The quantity and quality of dietary fats consumed during pregnancy have critical role in programming the neural circuitry that regulates cognitive processes. Cognitive processes, such as working memory, allows organisms to interact with the environment and to acquire knowledge/information. **Aim:** To analyze the effects of a high-fat diet (HFD) during gestation on working memory and glutathione (GSH) levels in the Wistar rat pups at young age. **Study design:** We used 30 pups: 15 pups from a mother fed balanced diet (BD) (6.2% fat energy) and 15 pups from a mother fed an HFD (42% fat energy) during pregnancy. Since postnatal day 3 (PND3) body weight was measured daily. Posteriorly, since PND 28 to 42, using the Eight-Arm Radial Water Maze, was assessed working memory (indicators: correct/incorrect working memory and reference memory errors). After the behavioral evaluation, a blood sample was collected and blood serum was obtained. Subsequently, the ELISA technique was performed to identify the serum GSH levels. The experiments and treatments were conducted in compliance with the Norma Oficial Mexicana-062-ZOO-1999 and the Ethics Committee of School of psychology of the University of Colima approved the study protocol. **Results:** About weight gain were no significant differences between groups ($p>0.05$), but HFD pups showed a tendency to a higher increase in body weight on last weeks. About the working memory assessment, there was significant difference in all parameters evaluated ($p<0.05$). Also, HFD pups showed significantly lower serum GSH levels at PND42 ($p=0.001$). A correlation was found between the GSH serum levels and the correct working memory errors ($r=0.81$, $p<0.05$). **Conclusion**: Exposure to a maternal HFD during pregnancy cause working memory deficits and decrease the GSH levels. An imbalance between the production of pro-oxidants as a result of cellular metabolism and antioxidants, oxidative stress results. Therefore, GSH decrease may indicate an increase in oxidative stress. The mechanisms by which maternal diet and metabolic profile shape the perinatal environment remain largely unknown, but due to correlation between the alterations, we could hypothesize that this is one mechanisms causative that affect the environment of the developing offspring. Given the high rates of obesity and high fat diet consumption in pregnant women, it is vital continue to examine the influence that maternal nutrition and metabolic profile have on the developing offspring.

Title: Frontal eye field inactivation modulates beta rhythms within V4 cortex

Authors: *M. PARTO DEZFOULI[1], M. ZAREI[2], M. I. VANEGAS[3], M. DALIRI[1], Z. BAHMANI[4], B. NOUDOOST[3];
[1]Dept. of Biomed. Engin., Iran Univ. of Sci. and Technol., Tehran, Iran, Islamic Republic of; [2]Dept. of Electrical Engineering, Sharif Univ. of Technol., Tehran, Iran, Islamic Republic of; [3]Dept. of Ophthalmology and Visual Sciences, Univ. of Utah, Salt Lake City, UT; [4]Sch. of Cognitive Sci., Inst. for Res. In Fundamental Sci., Tehran, Iran, Islamic Republic of

Abstract: Spatial working memory (WM) modulates alpha-beta oscillations of local field potentials (LFPs) within extrastriate visual areas. These areas receive a strong signal from the Frontal Eye Field (FEF) carrying the content of WM. In order to examine the necessity of FEF in driving these WM-induced oscillatory changes, we pharmacologically inactivated FEF and simultaneously recorded the spiking activity and LFPs in the V4 cortex of macaque monkeys using linear array electrodes. The animals performed a modified version of the memory-guided saccade task. In this task, the animal needs to remember the location of a cue throughout the delay period. In order to drive V4 neurons and assess the interaction between spatial WM and sensory processing, we added an oriented grating, with different contrasts and orientations, as a task-irrelevant background. We focused on V4 neurons with visual receptive fields overlapping with the FEF's motor field (defined as the endpoint of saccades evoked by FEF electrical stimulation). After finding overlapping FEF-V4 sites, a portion of FEF was inactivated by local injection of 0.5-1.0 μL of the GABA-a agonist muscimol. The FEF inactivation impaired the behavioral performance: it increased the saccade errors and reaction times of monkeys for the location corresponding to the part of space represented at the injection site. FEF inactivation reduced the strength of visual signals, in terms of orientation and contrast discrimination, within the overlapping V4 area. Moreover, within V4, the Beta power and amplitude of LFPs were reduced by FEF inactivation. The locking of spike times to the phase of LFPs, in the Beta range, was also diminished. Together, these findings show that WM-driven oscillations in V4 depend upon the FEF, and demonstrate how a spatially specific WM signal from prefrontal cortex is capable of changing visual representation within extrastriate cortex.

Title: Thalamic amplification of cortical connectivity supports short-term maintenance of sensory history

Authors: *L. I. SCHMITT, M. M. HALASSA;
MIT, Cambridge, MA

Abstract: The thalamus is the major input to the cortex and interactions between these structures are critical for cognition. While the thalamus is often thought of as a simple relay carrying information to or between cortical regions, a view derived from early studies of sensory thalamic nuclei, recent anatomical and functional data suggest that such an oversimplified model is unlikely to capture the involvement of the thalamus in many cognitive functions. This is particularly true in the case of "higher-order" thalamic nuclei such as the mediodorsal (MD) and Lateral Posterior (LP) which are primarily connected to cortical circuits and receive little input from the sensory periphery. While lesion studies suggest these nuclei are critical for cognition, incomplete understanding of their function makes it difficult to determine whether this is a cause or consequence of dysfunctions seen in complex neurodevelopmental disorders. Previous investigations of into how the MD influences representations of rules used to guide attention in the mouse prefrontal cortex (PFC) showed that the MD sustains rule representations by stabilizing ensemble dynamics among a subset of task-engaged neurons via amplification of effective connectivity. These findings suggest that selective stabilization of cortical networks by thalamic input might be a property of thalamocotical interactions that could enable short-term storage of information, a function that is essential for tasks ranging from understanding language to making inferences about visual scenes. The current study investigates whether this type of interaction supports other types of short-term storage by examining representation of recent sensory inputs in the posterior parietal cortex (PPC). The PPC is a key player in sensory decision-making and recent evidence suggests that one of its roles is to influence responses to current inputs based on sensory history. Using a newly devised feature-based sensory decision-making task we show that behavioral biases from previous trials depended on both the LP and PPC. Both circuits were also necessary for animals to make decisions on trials with ambiguous evidence based on sensory history. Importantly, activation of the LP produced an enhancement

in effective connectivity like that produced by MD activation suggesting that it plays an analogous role in stabilizing cortical representations. Overall, these findings identify a potentially general circuit feature in the mammalian brain, thalamic control of functional cortical connectivity, and suggest that it is essential for cognitive abilities that rely on short term storage of information.

Title: Reversal of an MK-801 induced working memory deficit by the D1 agonist SKF-81297 in a rodent touchscreen test

Authors: R. WYLER[1], M. HAMAN[1], B. KUENNECKE[2], ***E. C. O'CONNOR**[1];
[1]Neurosci. and Rare Dis., [2]Biomarkers and Translational Technologies, F. Hoffmann-La Roche, Basel, Switzerland

Abstract: Working memory impairments feature in many neuropsychiatric and neurological conditions. Disruption of NMDA receptor signaling may represent a common neural substrate for this deficit, while stimulation of dopamine D1 receptors is proposed as a potential pro-cognitive therapy. Here we explored this topic using a rodent touchscreen-based task of spatial working memory, namely trial-unique delayed nonmatching-to-location (TUNL). Male Lister Hooded rats were trained in TUNL until reaching stable performance criteria. Probe sessions were conducted in which the delay between sample and choice stages of individual trials varied from 2 to 6 seconds, leading to a delay-dependent decrement in choice performance. The NMDA receptor antagonist MK-801 (0.025-0.1 mg/kg) induced a dose-dependent impairment of choice performance during probe sessions, while ketamine (2.5-7.5 mg/kg) dose-dependently suppressed trial initiation without impairing choice performance. The D1 agonist SKF-81287 reversed the MK-801 induced working memory deficit in TUNL, but only at doses approximately 10-fold lower than those giving rise to typical D1-dependent locomotor hyperactivity. Pharmacological Magnetic Resonance Imaging (phMRI) revealed that SKF-81297 induced distinct circuit activation patterns at pro-cognitive vs. pro-motor dose levels, providing circuit insight to the observed behavioral effects. We discuss TUNL as a paradigm with translational relevance for assessing mechanisms underlying working memory, and which may facilitate the identification of future therapies for brain disorders where cognition impairment remains of high unmet medical need.

Title: Spatial encoding of mPFC neurons during working memory

Authors: *X. MA, H. ZHU, Z. LI;
NIH, Bethesda, MD

Abstract: Working memory is a cognitive system which temporarily maintains and manipulates information to guide behavior. It provides the functional backbone to high-level cognition. Studies in primates have well demonstrated that the dorsolateral prefrontal cortex (dlPFC) is a critical cortical area for working memory. In rodents, lesion or inactivation of the medial prefrontal cortex (mPFC), which has similarities with the primate dlPFC in anatomical connections and function, leads to working memory impairment. Some mPFC neurons fire in response to the events occurring in the working task, such as cues, and choices or have sustained firing during the delay period. In spatial working memory tasks, some neural activities are tuned by spatial information. However, what information is encoded by these activities and how they contribute to working memory remain unknown. To address these questions, we recorded the spiking activity of mPFC neurons during a spatial working memory task and analyzed the correlation between neural activities and space, time and animal behavior. To this end, we implanted tetrodes controlled by a microdrive into the mouse mPFC. After recovery from surgery, the mice were subjected to water restriction and trained for a delayed alternation working memory task in a T-maze. Each trial of the task consists three phases: sample phase, delay phase and test phase. In the sample phase, one of the two arms with a water spout at the end is randomly selected to open and the animal receives water reward if it reaches the spout. In the delay phase, the animal is restrained in a holding area for 10 seconds. In the test phase, both arms containing water spouts are open, and the animal will receive water rewards only if it runs into the arm that it has not been to during the sample phase. Animals made correct choices in 85% of the trials in three consecutive days were recorded for local field potentials and spiking actives during the task. Single unit activities were isolated manually using the Offline Sorter software. A total of 110 single units, including 95 putative glutamatergic neurons and 15 putative

GABAergic neurons, were obtained from 6 mice. 66.4% of recorded single units change firing rates within a 5-second time window before and after reward delivery. Most of these cells were excited before and suppressed after reward delivery, while only a few of them increased activities after reward delivery. Moreover, 29.8% of these cells responded differently to left and right rewards, suggesting that mPFC neurons encode the location of rewards.

Title: Large-scale non-human primate local field potential dynamics during visual short-term memory

Authors: *S. J. HOFFMAN[1], N. M. DOTSON[2], C. M. GRAY[1];
[1]Cell Biol. and Neurosci., Montana State Univ. Bozeman, Bozeman, MT; [2]Bioengineering, Univ. of California Berkeley, Berkeley, CA

Abstract: Short-term memory is an essential process in cognition. It provides an essential link between sensory input and behavioral output. In object based visual short-term memory a number of operations must unfold rapidly over a widely distributed network of brain areas. Despite much research in this area, little is known about the wide-spread dynamics of the local field potential (LFP) during such cognitive tasks. In order to investigate this process we recorded broadband neural activity in macaque monkeys while they performed an object based delayed match-to-sample task. The recording device enabled the simultaneous recording of neural activity from over 100 intracortical micro-electrodes, across tens of cortical areas, roughly spanning a cortical hemisphere. This allowed the investigation of task dependent LFP spectral power fluctuations, as well as the investigation of task dependent synchronization of multiple narrowband oscillations. Initial findings indicate wide-spread decreases in the beta band power in frontal regions during the memory task. The other frequency ranges investigated (i.e. theta, alpha, and gamma) showed a more heterogeneous and complex activity profile. In parietal areas we found evidence of a decrease in low frequency power coupled with a simultaneous increase in alpha band power. This "sharpening" of the alpha signal is suggestive of a gating-like dynamic

between the low frequencies and the alpha band. These findings will help elucidate the large-scale spatio-temporal dynamics involved in short-term visual memory.

Title: Optogenetic inhibition of secondary motor cortex disrupts olfactory working memory in behaving mice

Authors: *A. BELLAFARD, G. NAMVAR, P. GOLSHANI;
UCLA Dept. of Neurol., Los Angeles, CA

Abstract: Working memory is the ability to store information for short periods of time (seconds) in the absence of ongoing sensory input. While a number of brain regions vital for working memory have been identified, and persistent activity in these regions has been recorded during working memory tasks, we still do not understand the mechanisms by which an ensemble of neurons generate these ongoing activity patterns. To gain more insight into this problem, we have trained head-fixed mice to perform an olfactory working-memory task, in which head-fixed mice compare the identity of two discrete odors separated by a five second delay period. To interrogate the functionality of neuronal population in secondary motor cortex, we have utilized highly efficient soma-targeted Guillardia theta anion-conducting channelrhodopsins (GtACRs) expressing virus to conduct time-resolved optogenetic silencing at different time intervals while the animal was performing the task. We have shown that the stimulation during the delay and reward periods greatly worsens task performance, while stimulation at other time intervals has no effect. Our results suggest that the secondary motor cortex is both important for maintaining the working memory during the delay period, as well as comparing the memory of the first stimulus with the second stimulus to drive decision making.

Title: Impact of spatial working memory on visual processing within V4

Authors: *M. I. VANEGAS[1], W. H. NESSE[1,2], B. NOUDOOST[1];
[1]Ophthalmology and Visual Sci., [2]Mathematics, Univ. of Utah, Salt Lake City, UT

Abstract: Recent studies have shown that extrastriate areas receive the content of working memory (WM) via direct projections from prefrontal cortex (Merrikhi et al. Nat Commun 2017). Extrastriate areas exhibit changes in their oscillations in response to the deployment of WM: the power of alpha-beta oscillations in their local field potentials (LFPs) increases and the spiking activity of neurons in these areas becomes locked to these LFP oscillations (Bahmani et al. Neuron 2018). In spite of receiving the WM signal and exhibiting oscillations in response to it, neurons within extrastriate areas do not reflect the content of WM in their average spiking activity in the absence of visual input. In order to understand how the WM signal affects the extrastriate representation, we examined the influence of WM on these areas in the presence of visual signals. We trained the animal (rhesus macaque) to perform a memory guided saccade task in the presence of a visual stimulus background. In this task, the monkey fixates and a peripheral visual target is presented. The monkey maintains fixation while remembering the target location, and after the fixation point disappears, executes a saccadic eye movement to the remembered location to receive a reward. We recorded the LFP and neuronal activity of extrastriate area V4 using linear array electrodes. The background visual stimulus was an oriented grating covering the full span of the monitor, driving simultaneously recorded V4 neurons irrespective of their receptive field (RF) locations. The orientation (0, 45, 90, 135 degrees) and contrast (0%, 4%, 8%, 16%, 32%, 64%) of the background grating, as well as the locus of WM (toward the V4 RFs or 180 degrees away), were pseudorandomly varied across trials. Preliminary findings show that WM alters the orientation tuning and contrast response function at the level of single neurons, and the representation of visual information at the level of the population. These results indicate that although WM does not alter the average spiking activity of neurons within extrastriate areas in the absence of sensory information, in the presence of sensory input these areas can benefit from the WM signal both at the level of single neurons and the neuronal population.

Title: Low-dose olanzapine and clozapine effects on spatial working memory performance in rhesus monkeys

Authors: ***N. A. UPRIGHT**, M. G. BAXTER;
Nash Family Dept. of Neurosci. and Friedman Brain Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Chemogenetic techniques allow for the precise and reversible manipulation of specific cell populations or neuronal circuitry in awake, behaving animals. Designer receptors exclusively activated by designer drugs (DREADDs) are a popular form of this technology utilizing a non-endogenous actuator ligand to activate a modified muscarinic acetylcholine receptor which is no longer sensitive to acetylcholine as an agonist. The first employed DREADD ligand, clozapine-*N*-oxide (CNO), lacks sufficient brain penetrance and is metabolically converted to clozapine making it potentially unsuitable for future translational applications of chemogenetic systems. It is crucial in studies using chemogenetic systems to test the potential effects of DREADD actuators prior to any DREADD transduction, so that effects of DREADDs can be attributed to the chemogenetic system and not the actuator drug itself. We investigated working memory performance after preoperative injections of two DREADD agonists, clozapine and olanzapine, in male rhesus monkeys tested in a spatial delayed response task. Both agonists are FDA-approved antipsychotics, which could facilitate their use in translating DREADD technology to a clinical setting. Also, both drugs have high affinity for muscarinic-based DREADD receptors, so that each may be administered at low doses to activate DREADD receptors while minimizing off-target effects. Monkeys received intramuscular injections at two doses for clozapine, 0.1 and 0.2 mg/kg, and two doses for olanzapine, 0.1 and 0.05 mg/kg. We found that mean performance at 0.1 mg/kg clozapine did not differ from mean performance after vehicle in all four subjects. Administration of 0.2 mg/kg clozapine impaired performance in 2 of the 4 monkeys, with decreased correct trials at higher delay periods. We also found deficits in two monkeys after administration of olanzapine; both were impaired compared to vehicle after the 0.1 mg/kg dose and one also showed deficits at 0.05 mg/kg. DREADDs remain a powerful tool to remotely manipulate neuronal activity *in vivo*. These data demonstrate

the importance of including preoperative actuator drug injections in experimental studies with DREADDs, to confirm in each subject that the actuator drugs are without effect on their own. Additionally, it remains important to ensure that all ligands are administered at appropriate doses to minimize potential effects at endogenous receptors. We speculate that the unique neuropharmacology of prefrontal cortex function makes the primate prefrontal cortex especially vulnerable to off-target effects of DREADD actuator drugs with affinity for endogenous monoaminergic receptor systems.

Title: Anxiety induced working memory disruption was mediated by amygdala-ventral hippocampal circuit

Authors: *J. CHOI, Y. JEONG;
KAIST, Daejeon, Korea, Republic of

Abstract: Cognitive functions can be impacted by anxiety. In particular, anxiety is regarded to restrict a capacity of working memory by competing with task-relevant processes. Previous studies have shown that when people feel anxiety, working memory problem appears. However, it is still elusive that how anxiety-related brain circuits affect working memory dysfunction. In this study, mice were allowed to conduct working memory task when they felt anxiety which was induced by an anxiogenic drug or optogenetic stimulation. Simultaneous electrophysiological recordings were also performed to verify neural underpinnings of working memory dysfunction in anxious period. During the nonmatch-to-place T-maze task, one of the typical behavior tasks for measuring working memory function, mice showed significantly reduced performance when the anxiogenic drug (picrotoxin) was injected intraperitoneally. Optogenetic inhibition of the circuit from basolateral amygdala to the ventral hippocampus, which was previously reported as an anxiogenic circuit, restored the working memory disfunction by the drug. In the same vein, optogenetic excitation of the circuit also significantly reduced the working memory function during the task. Moreover, delay period-specific

excitation also significantly reduced working memory function and the impairments depended on a delay time (the longer delay time, the more impariments), suggesting that anxiety might be a disturbance factor for maintaining the working memory ability. Results of local field potentials and single unit recordings in medial prefrontal cortex (mPFC), basolateral amygdala (BLA), and ventral hippocampus (vHPC) was showed that coherence between mPFC and vHPC was weakened during the maintaining period of working memory in anxious situations. In addition, pattern of the mPFC units was diminished when the mice showed working memory deficit in anxious status. Thus, this study suggests that, when mice feel anxiety, BLA to vHPC circuit mediates working memory disruption, which involved mPFC dysfunction.

Title: Putative roles of inhibitory interneuron subtypes in working memory

Authors: *P. PATIL, M. KATKOV, O. YIZHAR, M. V. TSODYKS;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Working memory is an essential human cognitive process required for all cognitive activities. Recent studies from our group (Mi et. al. 2017, Mongillo et. al. 2008) have proposed a mechanism of working memory based on short-term synaptic plasticity. A critical component of this model is a central inhibition which prevents multiple item representations from being active at the same time. We know from experimental studies that multiple genetically-defined interneuron subtypes [predominantly parvalbumin (PV), vasoactive intestinal peptide (VIP) and somatostatin (SOM) expressing neurons], each with unique excitability and connectivity properties, mediate inhibition in the cortex. However, the specific role these populations play in working memory is poorly understood. Previous models of working memory lack specific mechanisms for regulating the load of working memory. We addressed this by including interneuron subtypes in the model and exploring the resultant dynamics to probe the functional roles of these subtypes in working memory. We used a simplified model of connectivity and

synaptic parameters based on the literature. Our simulations suggest that incorporation of these three distinct inhibitory motifs in the model allows for the active control of working memory. Specifically, we suggest that the PV expressing interneurons are responsible for one-at-a-time activation of items by implementing “winner-take-all” dynamics of working memory. We propose that SOM expressing interneurons and their facilitating excitatory inputs are responsible for the short lifetime of an item in working memory. We further propose that VIP expressing interneurons prolong the maintenance of items in working memory by inhibiting SOM neurons. We predict that external excitatory input to VIP should increase task performance. We therefore postulate that a diversity of interneuron subtypes, matching the properties of the three major interneuron populations in cortex, is an integral component of the active control of working memory. The presented model makes concrete, experimentally testable predictions for manipulation of inputs to these interneuron subtypes, consistent with the known literature.

Sch. Med., New Haven, CT; [9]Neurosci., Yale Univ. Sch. of Med., New Haven, CT

Abstract: The dorsolateral prefrontal cortex (dlPFC) is critical for working memory, and electrophysiology studies have found neurons in this region that exhibit persistent activity over delay periods in working memory tasks in the absence of continued sensory input. This persistent activity arises from recurrent excitation within microcircuits of pyramidal cells in deep layer III of primate dlPFC. These excitatory glutamatergic connections require NMDA receptor activation, and previous work has shown acetylcholine (ACh) plays a critical role in NMDA receptor activation via actions at nicotinic a7 receptors concentrated within the postsynaptic density (PSD) on dendritic spines. This follow-up study investigated the role of metabotropic

muscarinic M1 receptors (M1Rs), which are also highly expressed in cortex and found postsynaptically within or immediately proximal to the PSD on dendritic spines in layer III of primate dlPFC. These receptors are known to regulate KCNQ potassium channels, or "M" channels, which are also expressed at the synapse in dlPFC. As such, closure of these "M" channels following M1R activation may contribute to the permissive role of ACh in these circuits. Our data show M1R and KCNQ channels also play a critical role in persistent activity in primate dlPFC, as activation of M1R enhances delay-related firing, and this can be reversed by opening KCNQ channels. Additionally, blockade of M1R erodes delay-related activity, and this reduction is reversed by closure of KCNQ channels. As ACh release and cholinergic receptor expression can be reduced or altered in patients with various psychiatric disorders, we also tested the effects of systemic delivery of an M1R positive allosteric modulator (PAM) to determine if targeting M1R my be a useful therapeutic strategy. Our study finds that low doses of M1R PAM consistently improves working memory performance in primates, and support continued pursuit of this receptor as a potential treatment for PFC dysfunction.

Title: Model of temporal integration through recurrent feedback and synaptic facilitation

Authors: *R. A. BAARDA[1], D. L. COX[1], E. R. F. AKSAY[3], M. S. GOLDMAN[2];
[1]Dept. of Physics, [2]Ctr. for Neurosci. and Depts. of Neurobiology, Physio., & Behavior, and Ophthalmology & Visual Sci., UC Davis, Davis, CA; [3]Inst. for Computat. Biomedicine and Dept. of Physio. and Biophysics, Weill Med. Col. of Cornell Univ., New York, NY

Abstract: The oculomotor integrator network is a convenient model system for investigating the circuit mechanisms of working memory. This network receives eye velocity commands as inputs and integrates these to yield eye position commands. The eye position is represented by the collective activity of two opposing neural populations, which exhibit a threshold-linear increase in their firing rates as the eye is held at more ipsilateral positions and decrease their firing when the eye is more contralateral. These firing rates are maintained until the animal makes a saccade

to a new position, yielding a persistence time of ~10 seconds in the dark that far exceeds any known synaptic or intrinsic time constants in the system. This study focuses on how short-term synaptic plasticity may help to both coordinate the neural populations and extend the duration of persistent firing. Previous work (Fisher et al., Neuron 2013), which modeled the effects of inactivating part of the integrator network, suggested the presence of a slow cellular or synaptic process that increases superlinearly with firing rate. Motivated by the observation that synaptic facilitation has prominent slow kinetics in other working memory systems (Wang et al., Nature Neuroscience 2006) and leads to a superlinear response as firing rates are increased, we constructed a model in which synaptic connections exhibit predominantly facilitating dynamics. This model has a bilateral architecture in which each population excites itself and inhibits the opposing population. Due to the superlinearity of the synaptic facilitation, each population primarily controls the eye position in the portion of the ocular range corresponding to its own high firing rates. This feature leads to approximately independent control of each half of the animal's eye movement range, consistent with pharmacological inactivation studies of the effects of silencing one side of the integrator circuit. In addition, a de-tuned version of the model produced slower drift rates compared to the equivalent model with no synaptic facilitation, suggesting that synaptic facilitation may provide an intrinsic synaptic contribution to the long integration time scales seen in this system.

Abstract: Though working memory has long been associated with sustained firing in prefrontal and parietal cortex, attention has recently been focused on dynamic coding, with neurons

showing stable encoding of spatial information for only brief periods. Here we studied stable vs dynamic encoding in both spike rate and local field potential (LFP) signals. We obtained data from two adult male rhesus monkeys (Macaca mulatta) performing a spatial working memory task. On each trial, the animal was shown an array of five locations, awaited a go signal, then reached out to touch one location. A feedback signal and reward indicated whether or not this location was correct. In a first set of trials (cycle 1), the animal explored different locations until the target was discovered. In a subsequent three cycles (exploit phase), the monkey chose the location previously learned to be correct. Animals were extensively trained, with close to perfect performance. In each animal, neuronal activity was recorded from two chambers located over lateral frontal and inferior parietal cortex.
Both the firing rate of single neurons and the voltage recorded on single LFP channels differed across locations, thus encoding spatial information. To examine stability, we performed a cross-temporal generalization analysis, asking how patterns of activity at one trial time correlated with patterns at other times. For spike rate, activity patterns changed rapidly over time and phase of the trial (pretrial, choice array, go signal and movement, feedback). For LFPs, in contrast, a strong signal of target location remained largely constant across time. This target information arose post positive feedback in the explore phase and remained stable throughout the exploit phase. LFPs are influenced by multiple sources of voltage fluctuation in the extra-cellular matrix, integrated over a local region of tissue. Though the firing of individual neurons may be closely locked to specific time-points and/or trial events, the LFP signal is more stable, reflecting integration of multiple signals over a local cell population.

Title: A task-irrelevant visual perturbation reveals hidden information from a spatial working memory network

Authors: *D. Y. JUNG[1], J. ROZOWSKY[2], A. C. SNYDER[3,1,4];
[1]Neurosci., [2]Computat. Biol. and Chem., [3]Brain and Cognitive Sci., [4]Ctr. for Visual Sci., Univ. of Rochester, Rochester, NY

Abstract: Working memory (WM) relies on a network distributed across multiple cortical regions, especially involving the prefrontal and posterior parietal cortices. This network is differentially activated while a memory item is maintained**.** This maintenance activity was conventionally described as elevated and sustained neuronal spiking activity reflecting the quantity of items in WM. Recent studies question this view, however, because this activity can be hidden and often selective to external cues (e.g., reward). Such hidden states are particularly difficult to assay at the network level, where tools such as single neuron recording are prohibitive. Electroencephalography (EEG) can measure large-scale network activity, but measuring hidden neural states with EEG is even more challenging. Previous work has demonstrated that a task-irrelevant, but strongly effective, visual stimulus during the maintenance period of a WM task perturbs the hidden state of WM, evoking a response that can improve decoding of remembered information. We employed this method to noninvasively perturb the hidden neural state of WM of a rhesus monkey performing an oculomotor delayed response (ODR) task while we recorded 32 channels of EEG at its scalp. We hypothesized that this strong noninvasive perturbation would improve our ability to decode spatial features of the memory item from EEG signals during the maintenance period of the ODR task. We indeed found that the irrelevant stimulus improved decoding of remembered spatial information. This shows that spatial features of memory items are maintained in the hidden neural state of WM beyond the information provided by maintenance period spiking activity. Combining this network-level analysis of WM mechanisms via non-human primate EEG with multi-area population-level analysis of neuronal spiking activity will improve our understanding of the function of the brain networks underlying working memory performance.

Title: Automated touchscreen test battery for group-housed mice: TUNL, 5CSRTT and the use of moving visual stimuli

Authors: D. ATTALLA, K. STUMPENHORST, ***Y. WINTER**;
Humboldt Univ. - Inst. fuer Biologie, Berlin, Germany

Abstract: Existing rodents behavioural testing protocols that measure aspects of cognitive decline incorporate food deprivation and animal handling, which can induce stress, anxiety and impulsive behaviour. This in turn may affect the variability and reproducibility of the data. The present study developed a free-feeding, self-motivated, automated touch screen test battery for group housed mice, in which most of the food is collected during task performance throughout the day. C57BL/6J ID-chipped mice, about 15 weeks old, were tested in a 24/7 automated system consisting of a touch screen equipped operant chamber connected to the home cage through a RFID-based sorting system (Fig.1a, ID-Sorter, PhenoSys). Different cognitive domains were examined in the automated system: working memory was assessed using a spatial location task (TUNL), and sustained attention and response inhibition were assessed using the five-choice-serial-reaction-time-task (5CSRTT). Moreover, both visual discrimination and reversal learning were tested. For visual discrimination, we compared performance on signals differing in one feature (2 static images) versus two features (two images, moving in different directions). Mice successfully learned the different behavioural tasks and were sensitive to increasing difficulties (Fig.1b-1d). Importantly, self-motivated mice acquired the tasks in time frames comparable to previous protocols. Mice needed on average 8 days to learn the TUNL, 16 days for the 5CSRTT, and a week for the visual discrimination learning. Furthermore, in our automated experimental setup mice acquired the tasks with performance levels comparable to previous protocols, while avoiding handling and food deprivation.

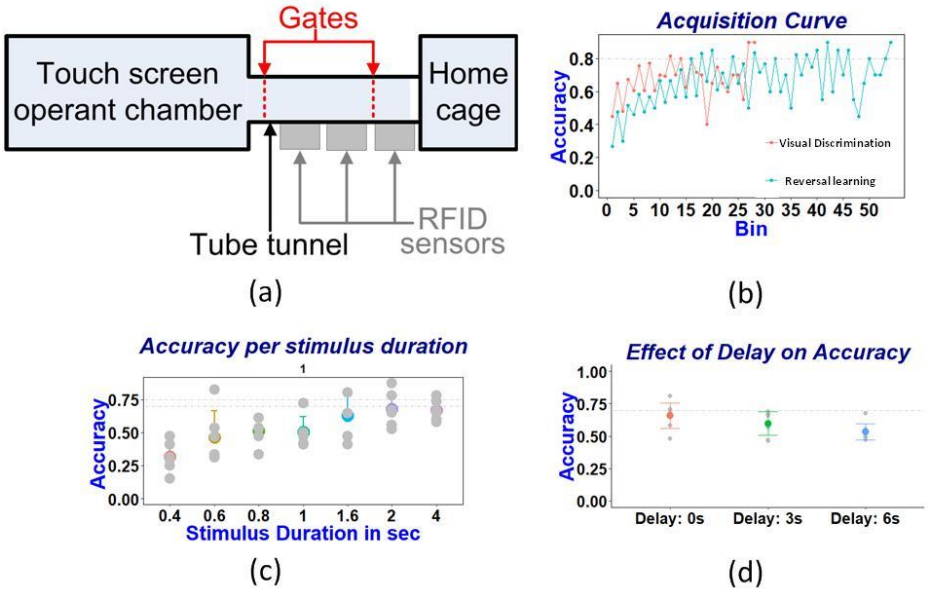

Figure 1: a) Automated touchscreen experimental setup, b) Visual discrimination and reversal learning acquisition, c) 5CSRTT: Data show better performance during long stimuli durations compared to shorter ones, d) TUNL task: Effect of delay (mixed spatial separation).

Data presented as mean ± SD. Data from n=6-7 mice.

Authors: *A. E. PAHUA, B. OLIVER, M. EMERY, A. GUTIERREZ, Y. VALENZUELA, D. AMODEO;
California State Univ., San Bernardino, CA

Abstract: Obsessive-compulsive disorder (OCD) is the fourth most prominent neuropsychiatric condition with an estimated lifetime prevalence of 2.5% of the US population. The core symptoms of OCD include obsessive thoughts, repetitive and compulsive behaviors, uncontrollable urges and impulses, ultimately restricting daily functioning. Previous animal studies have found that serotonin 1A and 1B receptor (5-$HT_{1A/1B}$) activation in the brain exacerbates repetitive behaviors, and enhance behavior flexibility and spatial working memory as well. The current studies examined the effects of repeated systemic 5-HT1A/1B receptor activation on the expression of repetitive behaviors in C57BL/6J mice. Mice received repeated injections of 0, 0.1 or 1.0 mg/kg RU24969 during a delayed alternation task (DAT). For DAT, mice were tested in a three arm radial maze. To obtain food rewards, mice learned to enter the last arm they visited such that peak performance would lead alternations amongst all three arms. Mice received 16 trials with a 60 sec delay inter trial interval. Mice were tested daily until reaching a learning criterion of 80% correct choices for two consecutive days. Results demonstrate that higher dose of 1.0 mg/kg RU24969, significantly impaired performance on the DAT task. As predicted, the higher dose of RU24969 significantly increased the days needed to reach learning criterion. This increase was not due to an overall sedative affect as evidenced by comparable rates of locomotor activity. These findings demonstrate that increased 5-HT1A/1B receptor activation led to impaired working memory performance in C57BL/6J mice. In sum, this highlights how specific serotonin modulation be the underlying alteration that impairs working memory in OCD individuals.

Title: Consolidation of long-term object memory in C57BL/6J mice is enhanced by systemic administration of a dopamine D1 agonist, or post-training exposure to a novel context

Authors: *B. L. HINDMAN[1], J. V. BARAN[2], R. W. STACKMAN, JR[1];
[1]Dept. of Psychology, [2]Max Planck Honors Program, Florida Atlantic Univ., Jupiter, FL

Abstract: Memories of a particular event or experience are often more vividly remembered if the event included a novel or surprising feature. Previous research has indicated that this memory-enhancing effect is thought to depend on novelty-induced dopamine neurotransmission in the hippocampus. Further, dopamine or stimulation of D1-like receptors are thought to enhance the consolidation of short-term memory into long-term memory via plasticity related events known as long-term potentiation. To further investigate dopamine related memory enhancements in C57BL/6J male mice, we first examined the influence of the dopamine D1 receptor agonist, SKF81297, on the consolidation of object memory. A modified version of the novel object recognition task was used to test the D1 agonist's differential effects on strong and weak forms of object memory, defined by the amount of time the mice were permitted to explore two novel objects during the sample session; the more time the mice explored, the stronger the memory, as inferred from the preference mice exhibited for a novel object during the test session presented 24 h later. Regardless of the strength of the object memory, systemic administration of SKF81297 prior to the sample session significantly enhanced object memory. These results suggest that D1 receptor activation enhanced the encoding and or consolidation of object memory in mice. Next, we examined the effects of post-sample session exposure to a novel context on the consolidation of object memory. Mice completed a weak or strong sample session and 30 min later, explored a novel context (clear Plexiglas arena containing 160 decorative fillers, and 1% acetic acid) or the empty Plexiglas arena (control condition) for 5 min. The test session was presented 23.5 hr later. Mice that explored the novel context following the sample session exhibited significantly enhanced object memory 23.5 hrs later, regardless of whether the mice received a weak or strong training protocol. Future studies will examine the effects of local D1 receptor activation in the dorsal hippocampus as the site of memory-enhancing effect of SKF81297, and seek to identify whether the novelty-induced memory enhancement is dependent upon dopamine innervation of the hippocampus from the locus coeruleus or the ventral tegmental area.

Title: Left hippocampal CA3 not right CA3 dominate spatial working memory

Authors: *H. QING[1], **D. SONG**[1], Q. YANG[1], D. WANG[2], Z. XIE[1], Y. YAN[1], Z. QUAN[1]; [1]Beijing Inst. of Technol., Beijing, China; [2]Shanghai University of Traditional Chinese Med., Shanghai, China

Abstract: Hippocampal CA3 is known to contribute to spatial working memory, but which stage of spatial working memory the CA3 neurons act on is still obscure. And whether lateralization of CA3 function affect spatial working memory is elusive. Here, through using fiber photometry, we found that increased activity of hippocampal CA3 in both sample and choice phases of T maze working memory task, while left CA3 region, not right CA3, showed different activities in choice phases between correct and error trials. Single unite recoding also suggested that proportion of responsive-to-choice-phase neurons in left CA3 was higher than that in right CA3 and left CA3 neurons tended to fire earlier than right CA3 neurons. Optogenetic inhibition of left CA3 neurons during choice phases disrupted spatial working memory, but inhibition of right CA3 neurons had no such effect. The behavioral performance can transfer from T-maze to delay-match-to-place water maze and delayed nonmatching-to-location (TUNL) task in touchscreen-equipped operant conditioning chambers. The findings suggested that the asymmetry of hippocampal CA3 in spatial working memory and left CA3 plays a dominant role in retrieval phase of spatial working memory.

Title: The magic number of 7: A novel paradigm for assessing capacity of olfactory working memory in mice

Authors: *G. HUANG;
Clin. Res. Div., Peking Univ. Sixth Hosp., Beijing, China

Abstract: Short term memory is famously limited in capacity to Miller's (1956) magic number 7 ± 2.
Declined working memory capacity are suggested to be the earliest symptoms observed in mild cognitive impairment, Alzheimer's disease and schizophrenia. Although the capacity of working memory is widely studied in healthy subjects and neuropsychiatric patients, there remains lack of tasks to examine capacity of working memory in rodents. The present studies describe a novel olfactory task of working memory capacity, which assesses the ability to remember the numbers of odors in mice. The task was divided into 4 phase, context adaptation phase, no-match rule learning phase, platform training phase, capacity test phase. We found the correction rate was gradually increased from 50% to 90% during the no-match rule learning phase and platform training phase, indicating that mice learn to recall the which odor is the new odor to get food pellets. During the capacity test phase, we found the number that the mice could remember was 7±2, which is similar to the Miller's magic number in humans. Then using the 5×FAD transgenic mice, a widely used animal model of Alzheimer's disease, we found the capacity of transgenic mice is significantly reduced compared that of wildtype mice. Lastly, we found that Fos is significantly decrease in PFC of 5×FAD mice after capacity test, and the number of Fos protein was correlated with the span length during the test. In conclusion, we developed a novel paradigm to assess the capacity of olfactory working memory in mice. We found a "magic 7" rule of span length in mice which indicates mice may shared similar neural basis of capacity of working memory with humans.

Title: The effects of maternal electronic cigarette exposure on offspring behavior and epigenetics

Authors: *T. NGUYEN[1], G. E. LI[1], H. CHEN[1], C. G. CRANFIELD[2], K. C. MCGRATH[1], C. A. GORRIE[1];
[1]Fac. of Science, Sch. of Life Sci., [2]Univ. of Technol. Sydney, Sydney, Australia

Abstract: Electronic cigarettes (e-cigs) are battery-powered devices that convert an oily flavored liquid into an aerosol, and they may or may not contain nicotine. E-cigs are increasingly being used as tobacco cigarette substitutes and there is a growing perception in pregnant women that using e-cigs is safe. However there is little evidence to support this perception. Here we have trialled a maternal model of e-cig exposure and compared the neurological effects on the offspring at different ages. Firstly, Balb/C female mice (n=8/group) were exposed to either ambient air (Sham), e-cigs with nicotine (Ecig+nic) or e-cigs without nicotine (Ecig-nic) to determine whether e-cigs alone had an effect. Then, mimicking a common scenario, mice were switched from tobacco exposure to e-cig exposure during pregnancy: Balb/C female mice (n=8/group) were exposed to either ambient air (Sham), tobacco cigarette smoke (TCS) or exposed to TCS before gestation followed by e-cigs with nicotine (Switch). The period of exposure was 6 weeks prior to gestation, during gestation and lactation. Offspring at 12 weeks old underwent behavioral assessments; Novel Object Recognition (NOR) to study short-term memory and the Elevated Plus Maze (EPM) to study activity and anxiety. Brain tissue (collected at postnatal day (P)1, P20 and Week 13) was processed to analyse global DNA methylation, epigenetic gene changes, and the number of neurons in the dorsal hippocampus and the lateral amygdala nucleus. The behavioral data revealed that offspring from the Ecig+nic and Ecig-nic group showed changes in short-term memory, activity and anxiety. Compared to the sham group, there was an increase in global DNA methylation in the Ecig+nic and Ecig-nic group, an increase in the TCS group and a mild increase in the Switch group. Epigenetic genes such as AurkA, AurkB, AurkC, Kdm5c, Kdm6b, Dnmt3a, Dnmt3b and Atf2 were altered in the Ecig+nic and Ecig-nic group and changes were highest in the TCS group. No significant changes were observed in neuronal cell counts in the Ecig+nic and Ecig-nic group. However, there was a significant reduction in neuronal cell counts in the TCS group and this was somewhat alleviated in the Switch group. Our findings in this mouse model show that 1) E-cig exposure during pregnancy results in neurological changes in the offspring. 2) Tobacco smoking during pregnancy resulted in more marked neurological effects and some of these were alleviated by switching to e-cigs during pregnancy, but not all, and not to normal levels. We conclude that e-cigs are not safe to use during pregnancy.

Title: Collaborative cross and diversity outbred populations as a tool to understand the effect of aging and genetics on cognitive decline

Authors: *A. R. OUELLETTE, G. CHRUCHILL, C. C. KACZOROWSKI;
The Jackson Lab., Bar Harbor, ME

Abstract: Cognitive performance varies greatly within an aging population, as the genetic makeup of individuals affects susceptibility to cognitive declines [1]. Uncovering the complex genetic mechanism underlying age and genetic interactions require equally complex tools. One such tool is the Collaborative Cross (CC) mouse Genetic Reference Panel (GRP), consisting of genetically unique inbred stains derived from 8 founder strains, 3 of which are wild derived, resulting in 42.2 million genetic variants segregating across the panel [2]. This diverse GRP provides a tool to infer the presence of genetic modifiers of cognitive decline, which can justify and inform the study design of large-scale mapping studies using Diversity Outbred (DO) mice. Here, we performed Contextual Fear Conditioning (CFC) on a set of ten CC strains at 6, 12 and 18 months of age to assess variation in long-term memory as a function of genetic background strain and age. We hypothesized that both genetic background strain and age would have a significant effect on contextual fear memory (CFM). Consistent with our hypothesis, we found a significant effect of Strain ($p=5.49x10^{-7}$) and Age ($p=1.02x10^{-14}$) on CFM performance across the CC strains. This phenotype was highly heritable ($h^2<0.8$), providing strong evidence for the presence of genetic modifiers that would likely be revealed through genetic mapping studies. To identify those possible genetic modifiers, we performed CFM tests in a large group of DO mice, which are genetically unique and ideal for fine mapping of QTLs. Using a 24 month old cohort of DO mice, we did not detect significant QTLs associated with long-term memory performance. However, ongoing studies are underway to assess cognitive performance of DOs at 6, 12 and 18 months of age in order to better match the CC study design. Lastly, we will perform RNAseq analyses on memory relevant brain regions from each of the CC strains tested in order to identify gene co-expression networks that correlate with cognitive outcomes. These may reveal novel targets to delay or prevent cognitive decline in the aging mice. [1] Buckner RL, et al. (2004) [2] Srivastava A, et al. (2017)

Title: Chronic sleep fragmentation accelerates age-dependent cognitive decline in human apolipoprotein E4 transgenic mice

Authors: *D. V. NAIR[1], R. VIJAY[2], D. GOZAL[3];
[1]Atlantic Hlth. Systems, Morristown, NJ and Biomed. Res. Inst. of New, Cedar Knolls, NJ; [2]Pediatrics, Univ. of Chicago, CHICAGO, IL; [3]Dept. of Child Hlth., The Univ. of Missouri Sch. of Med., Columbia, MO

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder in which there is a progressive decline in cognitive function. A great deal of evidence supports the idea that Apolipoprotein E4 (ApoE4) is an important genetic risk factor for Alzheimer's disease (AD). Previous studies from our lab on ApoE-deficient (ApoE-/-) mice showed increased cognitive impairments following chronic intermittent hypoxia during sleep (IH), a characteristic of sleep apnea, a condition that occurs frequently among AD patients. However, the effect of chronic sleep fragmentation (SF), another hallmark of sleep apnea on cognition is not known. Spatial reference and working memory under chronic SF conditions were assessed in transgenic mice expressing human ApoE4 (hApoE4) at 3 age points (3, 11, and 18 months) and their age-matched controls (C57BL/6NTac). After acquisition of the Morris water maze-based spatial task, all mice were exposed to 15 days of chronic SF (7am to 7pm for 3 weeks) or control sleep, and then re-assessed using Morris water maze, forced swim, sucrose preference test and novel object recognition tests. Both chronic SF and advancing age independently increased behavioral deficits in hApoE4 mice. Further studies are being carried out to evaluate the role of oxidative stress. Understanding the neural basis of ApoE4 on learning and memory paradigms, and its deleterious effects during SF can lead to the development of new therapeutic strategies in the treatment of AD patients afflicted with sleep apnea.

Title: Sex differences shape memory capacity declining during aging: Rescue effects of voluntary exercise

Authors: *V. LOFFREDO[1,2], G. TORROMINO[2], F. ESPOSITO[3], M. DE RISI[4], E. DE LEONIBUS[2,4];
[1]PhD Program in Behavioral Neurosci., Sapienza Univ. of Rome, Rome, Italy; [2]Inst. of Cell. Biol. and Neurobio. - IBCN-CNR, Monterotondo Scalo, Italy; [3]IGB - Inst. of Genet. and Biophysics, Naples, Italy; [4]TIGEM - Telethon Inst. of Genet. and Med., Pozzuoli (NA), Italy

Abstract: Alzheimer's disease (AD) has higher incidence in women compared to men, but the biological bases of this increased vulnerability are still unknown. The aim of this study is to identify early markers of aging in female subjects to discover early disease's mechanisms that make them more prone to develop dementia.
Memory Capacity (MC) is the amount of information that can be hold in memory for a specific time interval. MC declines with aging and its decline is a form of mild cognitive impairment with high predictive value for conversion to dementia.
Using the Different/Identical Object Recognition Task (DOT/IOT) that we have developed to study MC in rodents, we found that in conditions of high load female mice do not consolidate information into long-term memory.
Here we report that this early highly specific deficit in memory consolidation predisposes female mice to an accelerated aging in memory performance; furthermore, we show that this MC deficit is related to estrogen-dependent impairment in GluA1 trafficking in the hippocampus, which we have previously shown to be important for MC in male mice (Sannino et al 2012, Olivito et al 2014). One-month voluntary exercise training, which is known to stimulate hippocampal function (Colcombe et al 2003), strikingly rescued the performance of aging female mice.
In conclusion, we identified a cognitive marker of early aging in females, whose mechanisms may be at the base of their major vulnerability to AD. Furthermore, we show that this deficit is sensitive to exercise training, which makes it a valid model to study the molecular pathway underlying its therapeutic efficacy.

Title: Online pattern extraction during spatial navigation

Authors: *K. N. GRAVES[1], J. W. ANTONY[2], N. B. TURK-BROWNE[1];
[1]Psychology, Yale Univ., New Haven, CT; [2]Psychology, Princeton Univ., Princeton, NJ

Abstract: When navigating a novel environment, memories are formed about the specific locations visited. This ubiquitous capacity has been demonstrated across species, from rodents to humans. Although such episodic encoding is important for revisiting old locations, it is not sufficient for optimally searching new locations. Rather, it may be more efficient to aggregate across previously experienced locations and make predictions based on their underlying spatial distribution. Previous rodent work has shown that this distributional learning occurs over many days, consistent with the complementary learning systems theory that episodic memories in the hippocampus are gradually consolidated and integrated in the cortex. However, recent computational modeling suggests that the human hippocampus not only encodes episodes but also extracts regularities across these episodes. Thus, the representation of an underlying spatial distribution may become immediately accessible over the course of learning in the hippocampus, prior to offline consolidation. In the current study, participants navigated a virtual water maze, in which, unbeknownst to them, the platform location on each trial was drawn from a Gaussian distribution. While participants demonstrated an increase across trials in navigation through previously learned platform locations, the most significant increase was toward the mean of these locations, which, crucially, was never a platform location itself. To ensure that this apparent distribution-based navigation was not merely incidental to searching for previously learned platforms, we simulated task performance as one of two Gaussian random walks: one with memory for only individual platform locations and one with a representation of the distribution mean. Navigation behavior data matched the outputs of both models equally well in the first half of the task, but the distribution-mean model fit better in the second half of the task. This suggests that participants extracted and updated an internal distribution online and used this knowledge to guide future navigation. We are now running a simplified version of the task in epileptic patients with implanted electrodes, testing whether these online summaries reflect initial work within the hippocampus to support later offline consolidation into cortex.

Title: A modality-independent network underlies the retrieval of large-scale spatial environments in the human brain

Authors: *D. J. HUFFMAN[1], A. D. EKSTROM[2];
[1]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA; [2]Psychology, Univ. of Arizona, Tucson, AZ

Abstract: Previous research has suggested that body-based cues (e.g., translations, body and head rotations) play a critical role in establishing spatial representations in the rodent brain. These results have led some researchers to question the validity of human neuroimaging experiments, which are typically conducted in the absence of body-based cues, other than those provided by visual information (e.g., Taube et al., 2013 JOCN). We refer to the hypothesis that body-based cues fundamentally influence neural spatial representations as "the modality-dependent spatial coding hypothesis." Alternatively, "the modality-independent spatial coding hypothesis" predicts that spatial representations will be similar between spatial modalities (e.g., Bryant, 1997 Mind Lang). Due to technological limitations, little is known about the influence of body-based cues on neural representations of space in humans. We used novel immersive virtual reality technology (e.g., an omnidirectional treadmill, head-mounted display) to test these competing hypotheses by having participants navigate three cities under differing levels of body-based cues. Our behavioral and fMRI results support the modality-independent spatial coding hypothesis. First, a Bayes factor analysis revealed evidence in favor of the null hypothesis of no difference in the rate of spatial learning between body-based cues conditions. Second, a classification analysis based on putative neural interactions revealed significant classification accuracy between spatial memory retrieval, an active baseline task, and the resting state; however, network interactions were similar for spatial memory retrieval across body-based cues conditions. Third, we observed task-based activations for spatial memory retrieval compared to the active baseline task in brain regions known to play a role in spatial memory (e.g., hippocampus, parahippocampal cortex, retrosplenial cortex); however, a novel whole-brain Bayes factor analysis revealed widespread evidence in favor of the null hypothesis of no difference in task-based activations as a function of body-based cues throughout the brain.

Finally, analyses of single trial patterns of activity (e.g., classification analysis, representational similarity analysis [RSA]) revealed differences between task conditions but not between body-based cues conditions. Together, these findings suggest that vision, rather than differences in body-based cues, plays a primary determinant in how we encode and retrieve spatial information about large-scale environments.

Title: Theta power and phase-amplitude coupling in the human hippocampus during spatial memory retrieval

Authors: *U. VIVEKANANDA[1], D. BUSH[2], J. A. BISBY[2], B. DIEHL[3], A. MISEROCCHI[3], A. MCEVOY[3], R. RODIONOV[3], M. C. WALKER[4], N. BURGESS[5];

Abstract: Theta oscillations have been well documented in the rodent and human hippocampal network during translational movement and mnemonic function. In addition, the modulation of high-frequency activity - namely, the amplitude of gamma oscillations - by the phase of low-frequency oscillations such as theta, termed phase amplitude coupling (PAC), may provide a mechanism for encoding information and coordinating activity within and between brain regions. Here, we used intracranial EEG recordings to examine the role of theta power and phase-amplitude coupling in the medial temporal lobe during spatial memory retrieval. Twelve patients with refractory epilepsy undergoing intracranial EEG monitoring for clinical purposes were asked to perform a self-paced spatial memory task in a desktop virtual reality environment. Patients first navigated toward and memorized the location of four objects that sequentially appeared in the environment (‘encoding’). Patients were then cued with an image of one object (‘cue’), placed back in the environment and asked to navigate toward the remembered location of

that object and make a button-press response. The distance error (patient response location versus true location of object) was used as a metric of mnemonic performance.
We find that task performance correlates well with clinical measures of memory function across patients. In addition, we report an increase in low (2-5Hz) and high (6-9Hz) theta power in both hippocampus and lateral temporal lobe during cue periods compared to baseline, while task performance was associated with increased high theta power only. Finally, we find that task performance is also associated with increased theta-gamma PAC within the temporal lobe. These results imply distinct roles for low and high frequency theta oscillations in human spatial memory function, and point to a role for temporal lobe theta-gamma PAC in accurate memory retrieval.

Title: Distinct cerebral structures are involved in landmark- vs. geometry-based spatial navigation

Authors: *S. RAMANOËL[1], M. DURTESTE[1], A. BIZEUL[1], A. OZIER-LAFONTAINE[1], M. BÉCU[1], N. ROSSIGNOL[1], C. HABAS[2], A. ARLEO[1];
[1]Sorbonne Univ. - Vision Inst., Paris, France; [2]CHNO des Quinze-Vingts, Paris, France

Abstract: Orienting in space requires active visual exploration and the processing of environmental cues. Visual spatial cues can either be geometric, such as the global shape of the environment, or correspond to local landmarks, such as objects or features independent of the environment's layout. Although the cortical and subcortical structures implicated in spatial coding are well characterized, the neural networks involved in geometry vs. landmark visual cue reliance remain elusive. To address this issue, this study used functional magnetic resonance imaging (fMRI) to differentiate the brain activities that are specifically associated with landmark- and geometry-based navigation. Twenty-five young participants (μ=25.4 years, σ=42.7; 7F) performed a virtual navigation task in the scanner. Participants explored a Y-maze and had to learn the location of a hidden goal. Subjects then had to navigate to the goal from different starting positions throughout the maze in two separate conditions: a landmark

condition, in which reorientation required the processing of three differently-shaped objects; and a geometry condition, in which reorientation required the processing of the environment's shape. Participants performed similarly in both conditions in terms of escape latency, trajectory accuracy, and rate of correct responses. At the cortical level, two distinct cerebral networks were observed. Reorienting based on landmark information was associated with a greater occipital, hippocampal (posterior and anterior parts), and cerebellar involvement as well as with a specific activation of the perirhinal cortex. In contrast, reliance on the geometric shape of the environment elicited a specific activity in the anterior cingulate and frontal cortices. ROI analyses revealed that the dorsal striatal structures were activated in the geometric condition only, whereas the hippocampus had similar activations in the two conditions. The pattern of activity associated with landmark-based reorientation is congruent with the processing of fine-grained spatial information, while the increased frontal and cingulate activities in geometry-based reorientation reflect the task's greater cognitive control requirements. Moreover, in the geometry condition, the co-activation of hippocampal and striatal regions seems to indicate a flexible use of several navigational strategies mediated by frontal regions. These findings show that the type of visual spatial cue available in the environment influences the behavioral strategy and the underlying brain dynamics during spatial navigation.

Title: Improving individuals' spatial orientation skills

Authors: *M. A. R. MCLAREN-GRADINARU[1], F. BURLES[2], I. DHILLON[2], A. RETSINAS[2], A. UMILTÀ[1], G. IARIA[1];
[1]Neurosci., [2]Psychology, Univ. of Calgary, Calgary, AB, Canada

Abstract: Healthy individuals vary widely in their ability to find their way around, with some people finding it extremely difficult or nearly impossible to orient in a new surrounding without getting lost. Such difficulty in spatial orientation and navigation seems to be related to the inability of the individuals to efficiently form and make use of a cognitive map, i.e. a mental representation of the environment in which environmental landmarks and their spatial relationships are represented. In this study, we designed a training program in a virtual

environment with the aim of improving the ability of the individuals to orient and navigate by using environmental landmarks. Throughout the training program, we asked participants to travel back and forth between key environmental landmarks until they had built an understanding of where those landmarks resided with respect to one another. This process repeated until they had visited every landmark and learned where each landmark was located with respect to the others. The program consisted of a daily training session of 45 minutes for a total duration of 10 days. Before and after the training program, we measured participants' subjective orientation experience in daily life, and their ability to perform a series of computerized behavioural tasks assessing a variety of spatial orientation skills. We found that following the training program participants improved their ability to form cognitive maps, as well as their subjective experience in their daily life orientation. These preliminary findings could have significant implications for improving orientation skills in individuals affected by topographical disorientation and the elderly population in general.

Title: Structural properties of the brain in developmental topographical disorientation

Authors: *J. A. HANNAH, F. BURLES, J. KOHL, K. JELINKOVA, J. PARMAR, G. IARIA; Dept. of Psychology, Univ. of Calgary, Calgary, AB, Canada

Abstract: Developmental Topographical Disorientation (DTD) refers to a lifelong condition in which individuals are unable to orient and navigate in familiar surroundings, despite well preserved general cognitive functioning. Behaviourally, this condition stems from an inability to form a mental representation of the environment (i.e. a cognitive map) that is known to be critical for effective orientation and navigation. To date, however, its structural neurological basis remains largely unknown. In the present study we investigated the volumes and structural integrity of the caudate nucleus (head and body) and the hippocampus (head, body and tail) as these two regions are particularly involved in procedural and non-procedural mechanisms of spatial orientation in humans. We recruited 20 individuals with DTD and 17 control subjects matched for age, gender, handedness and education. The participants were scanned using a 3T

MRI protocol including T1 anatomical imaging and diffusion weighted imaging. Subregions of the hippocampus and caudate nucleus were manually traced using MRIcron. We compared the mean voxel count, fractional anisotropy (FA), and mean diffusivity (MD) of each subregion between DTD and control participants. The results revealed that individuals with DTD tend to have larger hippocampus tails in both hemispheres as compared to controls. We did not detect any other volumetric differences between groups. In terms of structural integrity, the DTD group revealed significantly higher MD in the right caudate nucleus head and significantly higher FA in the right hippocampus head. These findings represent the very first group-based brain structural differences between individuals with DTD and healthy controls and provide a unique opportunity to understand the neurological effects of this developmental condition in the context of neuroplasticity and compensatory cognitive mechanisms adopted in daily life.

Title: The functional contribution of anterolateral entorhinal cortex to intra-item configural processing

Authors: *J. C. LIANG[1], R. K. OLSEN[2], N. G. Y. SHING[2], N. LADYKA-WOJCIK[1], J. D. RYAN[2], M. D. BARENSE[1];

Abstract: There is mounting evidence from studies with humans and rodents that subregions of entorhinal cortex (ERC) are functionally distinct. However, there are disparities in the methodologies used, in the anatomical correspondence across species, and even in the operations these ERC subregions are thought to support. Recent work with humans using MRI found that the volume of anterolateral entorhinal cortex (alERC) predicted intra-item configural processing (i.e., the degree to which one processes the spatial arrangement between an object's features, as measured by eyetracking) across individuals. Having established the importance of alERC volume to intra-item configural processing, we conducted a follow-up fMRI study within the

same cohort of older adult men and women to establish whether the activity of alERC tracked intra-item configural processing on an object-to-object basis. Moreover, we asked whether alERC responded uniquely to different forms of intra-item configural novelty. Finally, we examined how decreases in alERC volume over time impaired general configural processing as well as configural novelty detection. We found above chance multivariate decoding of eye position consistent with sensitivity to spatial configurations.

Title: Learning and categorization of objects through haptic exploration

Authors: *K. GAUDER[1], D. GOLDREICH[2];
[2]Psychol, Neurosci & Behaviour, [1]McMaster Univ., Hamilton, ON, Canada

Abstract: With haptic exploration—the active manipulation of objects to gather information through touch—the brain can seamlessly integrate features into whole percepts, learning the categorical and statistical structures of the world. The processing that underlies this ability is poorly understood. One way to understand this process is through Bayesian inference—a probability framework for comparing hypotheses as information is gathered. This approach has seen success in vision and audition but has rarely been extended into haptics. Here we compare human performance against that of an optimal Bayesian observer. Participants attempted to categorize a set of 3D-printed polygons from which we defined two novel categories with overlapping feature distributions. These features were the number of sides and the spacing of raised dots on one of the surfaces. In Experiment 1, 45 participants completed 9 blocks of 40 trials in one of three training regimens: 1) single-category exposure followed by testing with corrective feedback, 2) single-category exposure followed by testing without feedback, and 3) no prior exposure, testing with corrective feedback. Each trial, participants gave their best guess for object category and their confidence. All participants demonstrated category learning. Group (3) achieved the best performance. Intriguingly, performance did not asymptote, suggesting that further improvement with additional training is possible. To test this hypothesis, in Experiment 2 we conducted 5 sequential days of testing (45 blocks) using regimen 3. We additionally performed Bayesian statistical analysis to determine which of 4 models best predicted the data from each participant: categorization based on both features (expert), a single feature (raised dot spacing or number of sides), and pure guessing. Preliminary results with 7 participants reveal

that 1) performance does not improve noticeably after the first day of testing, and 2) the number of participants whose behaviour fell consistently (majority of the blocks) into each category were: expert (1), single feature (5), guessing (1). Among the single feature participants, dot spacing was the predominantly attended feature. Three of these participants achieved expert performance on at least 5 blocks. We conclude that most individuals can learn statistical categories serving haptic object classification, but only a minority are able to combine cues at an expert level. Furthermore, performance saturates after just one day of training.

Title: Exploring emotion-related changes in spatial memory with virtual reality

Authors: C. BUHLER, **E. NYAM-OCHIR**, M. DIAMOND, M. CLAYTON, *J. O. TAYLOR; Behavioral Sci., Utah Valley Univ., Orem, UT

Abstract: Virtual reality (VR) is an increasingly popular and affordable tool used in clinical and research settings. The presentation of aversive visual and auditory stimuli within a virtual environment can elicit changes in autonomic activity and self-reported indices of emotion, a fact that has made VR a popular platform for the gaming industry as well as therapeutic intervention for emotional disorders such as phobia. Despite limitations of using VR as a true real-world analog, it can serve as a valuable tool in research settings. VR environments have good internal validity by controlling for situational noise and nuanced exposure to stimuli. VR also helps to ameliorate some practical and ethical constraints associated with human research such as allowing for exposure to potentially dangerous situations/stimuli, creating large experimental contexts, and the presentation of complex stimuli that would be difficult to create in a typical laboratory setting. As a result, immersive VR environments are used to explore a variety of clinically relevant research questions. In this study, a VR program was developed with two primary goals: (1) modulate anxious and fearful states in participants while navigating a maze, (2) evaluate emotion-related changes in spatial learning and memory. To accomplish these goals, a virtual hedge maze was designed so that participants would first explore the maze with one of three sets of auditory and visual stimuli. The stimulus sets were designed to elicit emotional states along a gradient from anxious to fearful: diffuse, low intensity aversive stimuli were intended to evoke anxiety, whereas discrete, higher intensity aversive stimuli to evoke fear. Subsequent exploration could be conducted in one of the initial conditions, or in the absence of aversive stimuli. A virtual Corsi block test was delivered prior to, between, and after maze trials

as an additional control for stability of spatial memory within the experiment. Stimulus or context related changes in emotional state were assessed via measures of autonomic activity and self-report. Maze spatial memory was assessed via changes in various movement-related factors (e.g., total time, number of errors, time spent at decision points). This design provides a frame work for exploring the interaction between emotional state and memory with easily manipulated contextual and discrete variables.

Title: Individual differences in gray matter of posterior medial structures predict source memory accuracy

Authors: *J. SNYTTE[1], A. ELSHIEKH[4], S. SUBRAMANIAPILLAI[2], S. PASVANIS[5], M. D. BARENSE[6], R. K. OLSEN[7], M. N. RAJAH[3];

Inst., North York, ON, Canada

Abstract: A recent model integrating evidence from the dual-process theory of recognition memory (Yonelinas, 2002) and the hierarchical-representational perspective (Murray, Bussey, & Saksida, 2007) has suggested that two anatomically distinct networks support distinct memory and perceptual processes (Ranganath & Ritchey, 2012). According to this model, an anterior-temporal (AT) network supports cognitive processes related to “entities” - this includes memory and perception of words and objects, whereas a posterior-medial (PM) network is critical in establishing and recollecting relational links between items and external contextual information. While there is strong support for this model from functional imaging studies, there is a lack of support and consistency from structural MRI studies. To assess this model from a structural perspective, we tested 25 healthy young individuals on an object-location associative memory task and a feature conjunctive perception task (mean age = 22.00 , SD = 3.64). We obtained gray matter (GM) volume estimates of medial temporal lobe (MTL) regions of interest (ROIs) using a

semi-automated segmentation technique (Olsen et al., 2013; Pipitone et al., 2014). We obtained cortical thickness measurements for the non-MTL ROIs using an automated pipeline (Ad-Dab'bagh et al., 2006; Lerch & Evans, 2005). We then used partial-least-squares regressions to determine which regions were significantly related to latent variables (LV) predicting either associative memory, object recognition, or feature conjunctive perception. Based on the AT-PM model we hypothesized that: (1) GM of PM ROIs, but not AT ROIs, would significantly be correlated to the LV predicting associative memory accuracy and (2) GM of AT ROIs, but not PM ROIs, would be significantly related to the LVs predicting object recognition memory and feature conjunctive perception. Our analyses revealed one LV which significantly predicted 52.38% of the variance in associative memory accuracy. We found that GM in a subset PM regions - medial prefrontal cortex ($p = .0053$, $\beta = .0093$), angular gyrus ($p = .0166$, $\beta = .0112$), precuneus ($p = .0232$, $\beta = .0092$), and posterior hippocampus ($p = .0115$, $\beta = .015$), and GM in a subset of AT regions - temporopolar cortex ($p = .0033$, $\beta = .0142$), and orbitofrontal cortex ($p = .0095$, $\beta = .0127$), were significantly positively correlated with this LV. We did not find an LV that significantly predicted object recognition or feature conjunctive perception. This study provides structural evidence which complements and elaborates on the AT-PM model and further demonstrates how individual differences in GM of specific structures relate to specific memory processes.

Title: Low frequency EEG phase synchronization of cortico-hippocampal communication in human spatial navigation

Authors: *W. WANG[1], L. WANG[2], W. WANG[1];
[1]Beijing Normal Univ., Beijing, China; [2]Inst. of Psychology, Chinese Acad. of Sci., Beijing, China

Abstract: In addition to the hippocampus (HC) and entorhinal cortex (EC) that are the key brain regions of spatial navigation system, prefrontal cortex (PFC) also plays a significant role in episodic memory related to spatial navigation. Although explicit evidence indicates that these brain areas communicate via oscillatory synchrony, how interbrain communication precisely transmits information and controls the timing of information interaction is still outstanding questions. Here we recruit preoperative epilepsy patients as subjects and allow them to

participate in tabletop navigation task of virtual reality. Meanwhile, we recorded iEEG signals of the deep electrode of the patients during the virtual navigation experiment. By analysing the neural oscillatory signals of local field potential (LFP) in hippocampus, entorhinal cortex and prefrontal cortex, we found that in the coding and retrieval phases of episodic memory in spatial navigation, there was a significant phase synchronization in low-theta (1-3 hz) and theta (4-8 hz) between either hippocampus and entorhinal, and between hippocampus and prefrontal cortex. Such phase synchronization is absent in other frequencies. In addition, we found that the phase synchronization is related to the merits of episodic memory retrieval and navigation ability. Our results reveal the communication mechanism based on neural oscillations in low theta and theta frequency band among hippocampus, entorhinal cortex and prefrontal cortex. The phase synchronization of low frequency (1-8hz) can serve a biological marker of coding and retrieval information in human episodic memory.

Title: Functional connectivity measured with resting state functional magnetic resonance imaging as a biomarker of spatial neglect during recovery rehabilitation period of stroke

Authors: ***T. EBISU**[1], M. FUKUNAGA[2], T. MURASE[3], M. UMEDA[3];
[1]Devision of Rehabil. Medicine, Kansai Electric Power Med. Res. Inst., Kansai Electric Power Hosp., Osaka, Japan; [2]Div. of Cerebral Integration, Natl. Inst. for Physiological Sci., Okazaki, Japan; [3]Med. Educ. and Res. Ctr., Meiji Univ. of Integrative Med., Kyoto, Japan

Abstract: *Background:* Spatial neglect, which prevents stroke patients from acquiring ability of independent daily living, has been reported to be related with change in the network interactions in the brain. However, it is still unknown whether functional connectivity observed with resting state functional MRI (rs-fMRI) can be a useful imaging tool for evaluation of spatial neglect in clinical practice. The goal of this study was to determine if functional connectivity measured with rs-fMRI could be used as a biomarker of spatial neglect during the recovery rehabilitation period after a stroke.*Methods:* The rs-fMRI data of 8 stroke patients and 31 healthy subjects were analyzed by the seed-based method with the Anatomical Automatic Labeling (AAL) template and Data Processing Assistant for Resting-State fMRI (DPARSF). The functional connectivity score (FCS) was defined as the correlation z score of each AAL region with right inferior and

superior parietal lobules (AAL 60, 62, 64, and 66). The neglect measure was determined with the behavioral inattention test (BIT). The relationship between FCS and BIT of stroke patients was examined in the selected regions, where a high absolute value of FCS was revealed in healthy subjects, during the recovery rehabilitation period. *Results:* The FCS between the right inferior parietal lobule (AAL 62) and the pars triangularis of the right inferior frontal gyrus (AAL 14) was significantly correlated with BIT. In addition, the FCSs of these regions in stroke patients with spatial neglect was significantly decreased, compared with those without spatial neglect. Secondly, negative correlation was detected between the right inferior parietal lobule (AAL 62) and the regions related with the default mode network such as the bilateral medial superior frontal gyri (AAL 23, 24, 25, and 26), posterior cingulate gyri (AAL 35 and 36), and hippocampus (AAL 37 and 38) in stroke patients without spatial neglect in contrast to a loss of negative correlation with spatial neglect. Furthermore, positive correlation was detected between the right superior parietal lobule (AAL 60) and the right caudate (AAL 72) in stroke patients with spatial neglect, in contrast to negative correlation without spatial neglect.*Conclusion:* These findings may support the hypothesis that functional connectivity measured with rs-fMRI is a useful tool for evaluation of spatial neglect during the recovery rehabilitation period after stroke.

Title: Visual perception of joint stiffness from multi-joint limb motion

Authors: *M. E. HUBER[1], A. M. WEST, Jr.[1], C. FOLINUS[1], N. HOGAN[1,2];
[1]Mechanical Engin., [2]Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Humans have an astonishing ability to extract hidden information from the movements of others. For example, even with only limited kinematic information, humans can distinguish between biological and non-biological motion, identify the age and gender of a human demonstrator, and recognize what action a human demonstrator is performing. It is unknown, however, whether they can also estimate hidden mechanical properties of another's limbs simply by observing their motions. Strictly speaking, identifying an object's mechanical

properties, such as stiffness, requires contact. With only motion information, unambiguous measurements of stiffness are fundamentally impossible as the same limb motion can be generated with an infinite number of stiffness values. However, we found that humans can readily estimate the stiffness of a simulated limb from its motion. In a set of three experiments, we observed that participants linearly increased their rating of arm stiffness as joint stiffness parameters in the arm controller increased. This was remarkable as there was no physical contact with the simulated limb. Moreover, participants had no explicit knowledge of how the simulated arm was controlled. An additional set of three experiments tested whether participants could still estimate joint stiffness if the simulated arm followed the same endpoint paths as in the prior experiments but moved with a non-biological velocity profile. In these experiments, we found no relationship between participants' stiffness rating and simulated joint stiffness. Together, these results suggest that participants likely drew upon prior knowledge of human neuromotor control to successfully map non-trivial changes in multi-joint motion to changes in arm stiffness. Having an internal representation consistent with the behavior of the controller used to drive the simulated arm implies that this control policy competently captures key features of veridical biological control. Finding that humans can extract latent features of neuromotor control from kinematics also provides new insight into how humans interpret the motor actions of others.

Title: Bayesian surprise precedes successful memory encoding

Authors: *Y. SHIKAUCHI[1], K. KITAJO[1,2,3];
[1]Ctr. for Brain Sci., Riken, Wako, Saitama, Japan; [2]Natl. Inst. of Natural Sci., Okazaki, Aichi, Japan; [3]The Grad. Univ. for Advanced Studies (SOKENDAI), Okazaki, Aichi, Japan

Abstract: Although learning and memory are always one of the biggest research fields in neuroscience, it is obscure how these are different and how these are common. In the framework of the Bayesian brain hypothesis, learning is equivalent to an update of an internal generative model. A Bayesian observer summarizes observations as the internal model, and thereby it does not keep the memory of each observation. To relate the Bayesian viewpoint to real information processing involved in memory, we examined the contributions of Bayesian model during

incidental memory encoding to subsequent memory recognition using an auditory recognition task with electroencephalographic (EEG) recordings. We presented twenty-two participants with multiple trains of four tones. Participants were required to respond to each train whether it is an upward tendency or a downward tendency. There were no explicit motivation or instructions to remember any of the tone sets. Immediate after the encoding sessions, an unannounced recognition test was administered. Assuming the Bayesian optimal observer, we computed single-trial information processing that reflects the order of appearance during the encoding sessions. Two model variables, the difference between a prior and a posterior (update) and a negative logarithm of model prediction (surprise), were examined with respect to the relations with memory performance. We found that both variables strongly affected the confidence of the trend judgment in encoding. Moreover, higher surprise during encoding precedes higher recognition performance in recognition test. Additionally, frequency analysis of EEG data from encoding sessions showed that the trials with larger update led to the enhancement of preceding theta power in fronto-parietal regions, compared to those with a smaller update. Our results provide new insight into the relationship between learning and memory; a possible explanation is that the Bayesian perceptual learning partly overlaps with successful memory encoding.

Title: Identifying distinct functional subdivisions of the anterior temporal lobes

Authors: *S. J. GOTTS, A. S. PERSICHETTI, A. MARTIN;
Lab. of Brain and Cognition, NIMH/NIH, Bethesda, MD

Abstract: The functional role of the anterior aspects of the temporal lobes (ATL) is a contentious issue in cognitive neuroscience. A wide range of functions have been posited in object recognition, language processing, and social cognition. Given the anatomical heterogeneity of this brain region, the ATL almost certainly supports a wide array of cognitive functions. Our goal is to identify functionally distinct regions within the anterior temporal lobes and understand the extent to which each region is involved in specific cognitive functions. We used resting-state fMRI from 88 participants (24 female) and a novel clustering method to identify subdivisions within the ATL, as well as medial temporal lobe structures (amygdala and

hippocampus). Specifically, we calculated the functional connectivity (Pearson correlation of the resting-state time series) between voxels within the ATL (defined as any temporal lobe voxels anterior to y=-35 in Talairach space) and all voxels outside of the temporal lobes. We then thresholded the resultant correlation matrices across a wide range of correlation values, and clustered the group-average matrices using both Infomap and Louvain Modularity. Finally, the identified parcels were required to replicate across halves of the data (44 participants in each half) and across 10 randomized split-half samples. We identified 5 neocortical and 3 medial temporal networks, corresponding to at least 10 functionally distinct parcels in each hemisphere. Hierarchical and K-means clustering revealed that these networks were organized into 4 larger parent networks with specific target profiles outside of the temporal lobe (2 which divided the larger "default-mode" network into language-related versus more executive function regions, 1 related to visual, auditory, and somatosensory processing, and 1 related to high-level visual and memory processing). This information will be used in the next phase of the project to design experimental task manipulations to more precisely dissociate these parcels based on their unique contributions to specific cognitive tasks.

Title: V1 BOLD signal changes associated with orientation learning and transfer at different visual hemispheres

Authors: *D. HU[1], X. XIE[1], C. YU[1], P. ZHANG[2];
[1]Peking Univ., Beijing, China; [2]Inst. of Biophysics, Beijing, China

Abstract: Functional neuroimaging of perceptual learning often ignores the transfer issue and focuses on specificity to seek low-level learning mechanisms. However, recent psychophysical evidence shows that not only location and feature specificity can be completely abolished with new training methods like double training, but learning of some basic features such as orientation transfers mostly to new locations. Therefore, perceptual learning involves high-level processing and is in principle transferrable. Here we purposely selected a peripheral orientation discrimination task whose learning is known to show great transfer, and used fMRI to investigate the brain mechanisms underlying both learning and transfer.
23 participants practiced orientation discrimination with a noise grating formed by pixelated

stripes of various widths and spacing at the lower-left or -right quadrant. The reference orientation was tangential to fixation. Five sessions of training improved orientation discrimination at the trained quadrant by 43.2±2.5%, as well as at an untrained contralateral quadrant and orthogonal orientation by 32.5±3.4%. The mean transfer index was 0.76±0.07, indicating great learning transfer.
Two fMRI tests were performed before and after training, following the behavioral tests. Participants performed orientation discrimination in the scanner with stimuli presented at the thresholds of pre- and post-tests, respectively. Independent functional localizers were used to identify the retinotopic ROIs of early visual cortex. The BOLD signals with the trained orientation discrimination task increased by 14.19% in V1 (p=0.00001), 17.78% in V2 (p=0.0006), and 10.64% in V3 (p=0.017) at the trained hemisphere. The BOLD signals with the same task also increased by 11.12% in V1 (p=0.011), 13.23% in V2 (p=0.0095), and 5.70% in V3 (p=0.018) at the untrained hemisphere. Across individuals, the transfer index of V1 BOLD signals was positively correlated with the behavioral transfer index (r=0.46, p=0.031). These learning-associated brain activity changes were not observed when participants performed an untrained frequency discrimination task with the same stimulus.
The cross-hemisphere transfer of orientation learning and the task dependent BOLD signal increases suggest the intrinsic involvement of high-level brain areas in perceptual learning and modulation effects on V1 activities as a consequence. Further analysis will elucidate response changes associated with learning and transfer in high-level and possibly subcortical regions, and the causal connectivity changes between brain areas.

Abstract: Spatial navigation is a complex cognitive process based on proprioception, vestibular, and visual cues that are integrated and processed by a wide network of brain areas. The retrosplenial complex (RSC) is an integral part to coordinate and translate between egocentric and allocentric reference frames. Previous works using electroencephalography (EEG) revealed navigation related modulations in different frequency bands in the RSC. However, these studies were based on stationary setups which might not be comparable to the cognitive processes during spatial navigation while naturally walking.

We applied the Mobile Brain/Body Imaging (MoBI) approach to study the human brain dynamics in an ambulatory Virtual Reality (VR) setup. In each trial, the participant was first prompted with one landmark and was instructed to remember the location of the landmark which then disappeared. They then physically navigated paths including two or three turning points. After first navigation phase, participants had to point to the non-visible landmark and subsequently had to memorize a series of letters to indicate, after a short rehearsal interval, whether a target letter was part of the learned set or not. Then, participants navigated a second path including two or three turns while memorizing the positive set and the landmark location. At the end of the second navigation phase, participant again pointed to the landmark.

Seventeen participants (two females) participated in the experiment. The neurophysiological data was collected with a wireless 64-channels EEG system (LiveAmps, Brain Products). EEG data was analyzed using Independent Component Analysis (AMICA) with subsequent source reconstruction of brain components using equivalent dipole modelling. The closest brain region of interest (ROI) to the RSC Talairach location (x=0, y = -45, z = 10) was found by using repeated k-means methods (n = 10000 repeated times) using Independent Components (ICs) properties.

In this study, the results of event-related spectral permutation (ERSP) at RSC showed an upper alpha band (10-12Hz) decrease when the participant actively explored the virtual environment, which concurred with previous stationary experiment using a 2D display. Moreover, there was a delta (1-4 Hz) and theta (4-7 Hz) band ERSP increase after each turning points where participant changed their orientation, which indicates RSC may coordinate with other brain areas like hippocampus to update position of landmarks. In addition, we found that there was a significant decrease in upper alpha and low beta (12.5-15 Hz) bands at RSC in second walk condition, reflecting an influence of the workload to RSC activity.

Title: Visual perceptual learning does not enhance metacognitive efficiency

Authors: *D. KWON, Y. SHIN, D.-J. YI;
YONSEI UNIVERSITY, SEOUL, Korea, Republic of

Abstract: Metacognition is knowing about what we know and what we don't know. In an experimental setting, metacognition is measured through participants' self-reported ratings on how confident they are about their responses in a task. Quantitative levels of metacognition is calculated through metacognitive sensitivity (meta-d' or type 2 d'), which is derived from the sensitivity (d', type 1 d', or first-order performance) representing a participant's performance in a task (Maniscalco & Lau, 2012). Metacognitive efficiency is defined as each individual's metacognitive ability (measured as a ratio of meta-d' to d') under a level of task difficulty controlled across all participants. Metacognitive efficiency is known to vary across different individuals and develops almost exclusively throughout adolescence but rarely changes throughout adulthood (Weil et al., 2013). Generally during visual perceptual learning, enhancement of participants' task performance (first-order performance) shows a specificity that heavily skews towards a trained direction or location. Our current study investigated changes in metacognitive efficiency during visual perceptual learning. Participants were asked to rate confidence levels on their responses on a 4-point scale after identifying the visual field with dots in a coherent motion, as opposed to the visual field containing dots in random motion—each of which was presented randomly in either the left or right visual field. In the test sessions conducted on the first and last days of the five-day-long study, motion of dots were presented in two different directions. However, in the training sessions on the second, third and fourth days of the study, motion of dots were presented in only one direction. We analyzed the data collected across all five days to conduct a side-by-side comparison between the changes in performance and metacognitive efficiency for the trained direction and untrained direction. Not unlike the findings of previous studies, performance increased for the trained direction but not for the untrained direction. More importantly, our results showed that metacognitive efficiency remained constant regardless of training. Our results suggest that metacognitive efficiency is unaffected by visual perceptual learning unlike first-order performance. * This work was supported by the Ministry of Education of the Republic of Korea and the National Research Foundation of Korea(NRF-2017S1A5A2A01024313)

Title: Event similarity biases perceived spatial distance

Authors: ***X. XING**, J. SAUNDERS;
The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: The hippocampus is known to be involved in both episodic memory and spatial navigation. If representing space is part of the more general function of encoding episodic memory of events, the encoding of places and events might be intermixed. Non-spatial properties that determine the association between events might therefore influence spatial judgments. We attempted to manipulate distance in mental representation of places though similarity of events at the places. In virtual reality, subjects learned a map constructed with pairs of houses at same distance in space but with either the same event or different events. The events were either standing on a stone to trigger presentation of name of a blue house, or bypassing a wall blocking the view of name of a red house. Distance in mental representation was measured by priming in a recognition task. When a house name was preceded by name of a similar house, it was expected to be primed and therefore recognized faster than when preceded by name of a different house. Distance in space was measured by estimating distances between houses, and by reconstructing the map. The estimated spatial distance between similar houses was expected to be shorter than for different houses. We observed an overall tendency toward judging houses with the same events as closer in space, with some individual differences in the direction of bias. We further found that distance in mental representation, as measured by recognition priming, was a predictor of judged spatial distances. Our results demonstrate that similarity of events at places can cause places to appear closer in space. This is consistent with the idea that common mechanisms underlie the representation of space and episodic memory.

Title: EEG-derived changes in brain activation and network connectivity in corporate employees due to brain training

Authors: *S. CHELIAN, S. L. MILLER, W. MCBURNETT, A. A. KRUSE;
Platypus Inst., San Diego, CA

Abstract: Employee volunteers (n=21) underwent a neurocognitive training program - which consisted of an initial assessment, a six week “boost” or intervention period, and then a re-assessment to track the progress of each participant. Assessments consisted of the DANA Standard battery along with synchronized EEG recording. For brain training, subjects were given the goal of completing twenty 30-minute training sessions over a 6-week period using BrainHQ. A median split of the group created two training groups: a long-training group that averaged 30 hours of total training during the training period; and a short-training group that averaged 7 hours of training. Whereas previous work focused on changes in behavioral data, here we report on EEG-derived changes in brain activation and network connectivity. EEG analysis included measurements of band power at electrodes and brain sources as well as information flow between brain sources. Results show the task-specific recruitment of brain regions as well as providing observations into mechanisms of neuroplasticity. Insights from this study could lead to new tools and approaches to enhance the neurocognitive performance of elite performers in a variety of domains.

Title: Dynamics and maintenance of cognitive training effects: Analysis of a massive observational dataset

Authors: *R. J. SCHAFER, N. F. NG, A. M. OSMAN;
Lumos Labs, San Francisco, CA

Abstract: Computerized cognitive training, including programs offered via online "brain training" websites and apps, has been the focus of numerous studies over the past decade. While randomized controlled trials have begun to shed light on the efficacy of such training programs, many open questions remain, such as the form of the "dose-response" relationship between brain training and cognitive outcomes, and the extent to which training effects are maintained over time. To address these questions, we analyzed a large, observational dataset of nearly 750,000 individuals who underwent Lumosity online brain training and were assessed with the NeuroCognitive Performance Test (NCPT) at one or more time points separated by several months. Individuals spanned a wide range of ages (13 to 90, median of 46) and educational levels. For all demographic groups examined, we found a consistent, positive relationship between the amount of Lumosity training and improvements on the NCPT from the 1st to 2nd time point. The form of this dose-response function - both the rate of improvement and maximal (asymptotic) improvement - differed across cognitive domains assessed by the NCPT. Examination of the NCPT at the third time point found that improvements in cognitive performance were maintained for months after training with only modest decay. Moreover, additional training between the 2nd and 3rd assessments was associated with small but significant improvement beyond the original training effects.

Title: The effect of stimulus predictability on cerebro-cerebellar verbal working memory processing: An fMRI study

Authors: *Y.-S. SHEU, Y. LIANG, J. E. DESMOND;
Dept. of Neurol., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Anticipating forthcoming situations supports efficient and appropriate goal-directed behavior. In the cognitive domain, performance can be boosted by providing valid cues in advance (e.g. pre-cueing task set), or by incidental learning of the statistical regularities that specify the upcoming characteristics of a task (e.g. sequence learning task). In the literature of motor control, an influential theory of cerebellar function posits that the cerebellum makes prediction of the sensory consequences of a movement through an internal forward model. More recently, some investigators have argued that prediction may be a unifying cerebellar function that can be extended to non-motor domains, such as working memory and language. Therefore, in the current study, we used functional magnetic resonance imaging (fMRI) and a modified version of Sternberg verbal working memory task to investigate the cerebellar contributions of self-generated prediction to verbal working memory processing. Seventeen healthy participants were asked to encode a 6-letter sequence, and to covertly rehearse the letters in sync with the guided symbol on the screen. Because the rehearsal is guided, participants can easily predict the identity of the next correct letter in the sequence. We found participants responded faster to the probe letter by about 133 msec when the probe appeared as a match (i.e. predicted stimulus) compared to a non-match (i.e. unpredicted stimulus). Furthermore, the neuroimaging data showed both the match and non-match trails activated a similar fronto-parietal network subserving the neuronal substrates of working memory. Most critically, less activity was found in this fronto-parietal network as well as in right cerebellum for the match trials compared to the non-match trials. Therefore, our results demonstrate that the human brain spontaneously anticipates forthcoming sensory stimulus which allows predictable stimuli to be processed faster and require less neural activation. We also provide additional evidence that the cerebellum plays a function role in prediction by facilitating verbal working memory processing.

Title: Decoding the temporal dynamics of working memory with recurrent neural networks

Authors: *S. GOLDSTEIN[1], Z. HU[1], M. DING[2];
[1]Univ. of Florida, Gainesville, FL; [2]Univ. Florida, Gainesville, FL

Abstract: Information encoding, retention and retrieval are distinct stages of working memory (WM). Within each stage neural representations of WM undergo dynamic transformation.

Previous applications of machine learning to EEG data recorded during WM have focused on decoding spatial patterns at each instant of time. To what extent information is represented in both spatial and temporal patterns of neural activity remains to be understood. In this study, we decoded working memory load by focusing on spatiotemporal EEG dynamics using recurrent neural networks incorporating long short term memory (LSTM). High density EEG (128-channel) were recorded from twenty subjects performing a Sternberg verbal working memory task. On each trial, a memory array containing either 2, 4 or 6 letters (load 2, load 4 and load 6) was presented for 2000 ms (encoding period). A time period of 3000 ms (retention period) followed the offset of the cue memory array. At the end of the retention period, a probe letter was displayed for 1000 ms (retrieval period), and subjects responded with a button press to indicate whether this letter was contained in the memory array. Following EEG preprocessing, LSTM networks were trained to decode between load 2 and load 6 during retention. There were three findings. First, during the retention period, the decoding accuracy increased with increase in the length of the 128 EEG time series that were inputted into the LSTM, reaching a plateaued decoding accuracy of ~66% when the length of the time series reached ~800ms. Second, the plateaued decoding accuracy in individuals with higher working memory capacity (WMC) is higher than that in individuals with low WMC. Third, after randomly shuffling the time index of the EEG time series, the plateaued decoding accuracy is lower than that of the originally ordered time series, but remains higher than the decoding accuracy from spatial patterns alone. These results suggest that during WM retention, WM information is encoded in both the spatial and temporal dynamics of neural activity, and this is particularly so in individuals with stronger working memory function.

Title: Single-trial contralateral delay activity also reflects item encoding precision

Authors: *C. MERKEL[1], J.-M. HOPF[1,2], M. A. SCHOENFELD[1,2,3];
[1]Otto-von-Guericke Univ., Magdeburg, Germany; [2]Leibniz Inst. for Neurobio., Magdeburg, Germany; [3]Kliniken Schmieder, Heidelberg, Germany

Abstract: The classical slotmodel of visual working memory (VMW) predicts that a global resource is distributed equally amongst the relevant encoded items. Currently it is debated whether items can be prioritized by assignment to bigger chunks of VWM. Previous work has shown, that enhanced encoding of relevant items translates to a better subsequent recall

precision. The current study uses the contralateral delay activity (CDA) as a continuous measure for single item encoding and quantifies the CDA amplitude associated with VWM resources assigned to individual encoded items. In a delayed precision estimation task, subjects are required to remember the orientation of two bar stimuli, presented in succession (in each encoding phase two bars are presented bilaterally, while subjects attend to either the left or the right hemifield). Subsequently, the orientation of either the first or second orientation has to be recalled using a dial. Consistent with previous reports general CDA amplitude increases were observed for the second item subsequently stored in VWM. Interestingly, the single-trial CDA amplitudes related to the first and second item correlated with the precision of recall for that individual item. The CDA amplitude therefore not only seems to reflect the encoding of an item but also the accuracy of encoding of the representation. Furthermore, the data suggests at least a partial independence of the precision of recall of the first item from the CDA amplitude associated with the second item and vice versa. These results provide support to a variable resource model of VWM.

Title: The temporal dynamics of working memory: Persistent interactions with perception

Authors: *C. TENG, S. KAPLAN, D. KRAVITZ;
George Washington Univ., Washington, DC

Abstract: The ability to briefly maintain information in working memory (WM) is crucial for a variety of complex cognitive functions, but its neural substrate remains under debate. The classic view is that information is encoded within the posterior sensory cortices but then recoded and maintained in the fronto-parietal network (e.g. Goldman-Rakic, 1995; Xu, 2017). Alternatively, the sensory recruitment model (e.g. D'Esposito & Postle, 2015) posits that WM content is maintained within the sensory regions themselves. To address the controversy, we tested two contrastive hypotheses. First, if WM is maintained in the sensory cortices, there should be bidirectional interference between WM and perception defined by the known tuning curves in these areas for the maintained features. Second, if the WM representation is held in the sensory cortices, its strength should decay across time causing less interference on perception but being more strongly interfered with by perception. If information is being recoded outside of the sensory cortices then both forms of interference should reduce with time.
In Experiment 1 participants (N = 120) performed a color or orientation discrimination task

while holding a color or orientation in mind. The relationship between the WM and the discrimination stimuli were manipulated such that the maintained item was either between the two discrimination stimuli (middle) or to one side (side). As predicted, the item in WM interfered with perception, drawing the discrimination stimuli towards itself and creating worse discrimination thresholds in the middle than the side condition. In turn, the WM report was distorted by perceiving the discrimination stimuli, resulting in a strong bias in the side condition. This effect held for both orientation and color when the same feature was relevant for both the WM and discrimination tasks, but not when the features were different across the tasks despite identical stimulus displays. Thus, the contents of WM both alter and are altered by ongoing perception.
Experiment 2 (N = 150) used the same design but varied the interval between the WM encoding and the discrimination task between 100ms to 4s to map out the temporal dynamics of WM. We found that WM significantly impacted the discrimination thresholds even at the longest delays. Further, while the strength of WM interference on perception decayed across time, the impact from perception on WM increased, contrary to the predictions of the recoding account. Overall, these results demonstrate that WM content is represented in the sensory cortices even for delays of up to 4s and directly interacts with concurrent perception at fundamental stages of visual processing.

Title: Pupillary signatures of attention and working memory fluctuations

Authors: *P. A. KEENE, M. T. DEBETTENCOURT, E. AWH, E. K. VOGEL;
Univ. of Chicago, Chicago, IL

Abstract: Attention and working memory performance constantly fluctuate. Attention fluctuations have been measured behaviorally using response time (RT) in sustained attention tasks. In these tasks, attention fluctuates as does general task engagement, but attention fluctuations are specifically correlated with the number of items held in working memory. We were interested in how, pupil diameter, a putative signal of arousal, related to attention and

working memory performance. In a series of experiments, we sought to investigate whether attention and working memory fluctuations elicited corresponding and concurrent fluctuations in pupil diameter. We designed an experiment that interleaved two established tasks: a sustained attention to response task and a whole-report working memory task. Participants viewed a stream of multi-item shape displays. The attention task was to monitor the shapes of the displays (circles or squares). The working memory task was to occasionally report the color of each shape from the preceding display, after a blank delay screen. We examined how RT and pupil diameter related to the fluctuations of performance on the hybrid attention and working memory task. In Experiment 1, RT (our operationalization of attentional state) covaried with both pupil diameter and working memory performance. In Experiment 2, we modified our attention task to investigate whether pupil diameter could track covert cognitive fluctuations, even without concurrent response demands. Participants completed a modified sustained attention task where they responded only to infrequent target trials. We found that RT to those targets covaried with pupil diameter and working memory performance. In both of these studies we also observed critical differences between RT and pupil diameter, suggesting they were not redundant indices. These results provide further insight into the relationship between cognitive processes and their concurrent fluctuations.

Title: Threat of shock influences parietal bold responses during a visual short-term memory task

Authors: *N. L. B. BALDERSTON, M. GOODWIN, A. BEALE, M. ERNST, C. GRILLON; NIH, Bethesda, MD

Abstract: Hypervigilance, abnormal orienting to environmental stimuli, is shared across anxiety disorders. This symptom is reflected in the attention biases seen in both clinical anxiety and healthy volunteer models of high state anxiety. Our previous work has shown increased cortical excitability and global brain connectivity in regions of the parietal cortex important for orienting. Based on these results, we hypothesized that threat would also impact orienting and memory performance during a visual short-term memory (VSTM) task. On each trial of the VSTM task, subjects saw an arrow pointing either left or right. Then, an array of squares flashed for 150 ms

on both sides of the screen. Squares differed in terms of color, location, and orientation. Participants were instructed to attend to the squares signaled by the arrow direction, and to ignore the contralateral squares. Next a target square was shown, and subjects made a forced-choice (match vs. mismatch) button press. To manipulate load, we varied the number of ipsilateral squares (2 vs. 4). To manipulate distractor salience, we varied the number of contralateral squares (2 vs. 4). Trials took place during periods of safety and threat of unpredictable shock, BOLD responses were recorded throughout. We extracted BOLD responses to the cue and the square array, and performed ANOVAs on the cue/array-evoked BOLD responses. For the cue-evoked responses, we found a bilateral parietal cluster that responded more toward right-pointing cues during threat. For the array-evoked responses, we found a similar left parietal cluster that responded more during threat when attention was focused to the right, but only when target load and distractor load were congruent. These results suggest that threat impacts attention orienting, and that this effect can influence the neural processing mediating visual short-term memory. These results are consistent with our previous work showing enhanced parietal excitability during threat of shock and offer a mechanistic explanation for the attentional biases and hypervigilance observed in anxiety patients. These results also support the idea that noninvasive neuromodulation targeting the parietal cortex may be a fruitful avenue to treat these symptoms.

Title: Brain networks communicate through theta oscillations to encode high load in a visuospatial working memory task: An EEG connectivity study

Authors: *S. MUTHUKRISHNAN, S. SONI, R. SHARMA;
Physiol., All India Inst. of Med. Sci., New Delhi, India

Abstract: The encoding of visuospatial information is the foremost and indispensable step which determines the outcome in visuospatial working memory (VSWM) task. It is considered to play a crucial role in limiting our ability to attend and process only 3-5 integrated items of information. Despite its importance in determining VSWM performance, the neural mechanisms underlying VSWM encoding have not been clearly differentiated from those involved during VSWM retention, manipulation and/or retrieval. The high temporal resolution of electroencephalography (EEG) and improved spatial resolution with dense array data acquisition makes it an ideal tool to

study the dynamics in the functional brain connectivity during a cognitive task. In the present study, the changes in the functional brain connectivity due to memory load during VSWM encoding were studied using 128-channel EEG. Lagged linear coherence (LagR) was computed between 84 regions of interest (ROIs) defined according to the Brodmann areas for seven EEG frequency bands: delta (2-4 Hz), theta (4-8 Hz), alpha 1 (8-10.5 Hz), alpha 2 (10.5-13 Hz), beta 1 (13-20 Hz), beta 2 (20-30 Hz), and gamma (30-45 Hz). Interestingly, out of seven EEG frequency bands investigated in the current study, LagR of only theta band varied significantly in thirteen brain connections due to memory load during VSWM encoding. LagR of theta band increased significantly at high memory load when compared to low memory load in twelve brain connections with the maximum change observed between right cuneus and right middle temporal gyrus (Cohen's $d = 0.836$), indicating the integration of brain processes to confront the increase in memory demands. Theta LagR decreased significantly between left postcentral gyrus and right precentral gyrus at high memory load as compared to low memory load, which might have a role for sustaining attention during encoding. Change in the LagR values due to memory load between fusiform gyrus and lingual gyrus in the right hemisphere had a positive correlation ($r = 0.464$, $p = 0.003$) with the error rate, signifying the crucial role played by these two regions in predicting the performance. The current study has not only identified the neural connections that are responsible for the formation of working memory traces during VSWM encoding, but also support the notion that encoding is a rate-limiting process underlying our memory capacity limit.

Title: Reconstructing working memory swap errors with fMRI data

Authors: *R. MALLETT, J. A. LEWIS-PEACOCK;
Psychology, The Univ. of Texas At Austin, Austin, TX

Abstract: Maintenance and manipulation of information in working memory is essential to completing short-term behavioral goals. Working memory performance begins to decline systematically as set size (retention demand) increases beyond capacity limitations. While it is clear that working memory failures occur, the mechanisms by which these failures occur is still under debate. For years, behavioral modeling has proposed two distinct types of response errors that underlie most working memory failures: random guesses and item swap errors. Guesses can

occur when memory information is degraded or inaccessible at the time of test. Swaps (responding as if a different memory item was being probed) likely arise from a contextual binding error that manifests at some point during encoding, retention, or at test. While response modeling can identify potential swap errors, this approach alone cannot explain why they occur. Here, we combined fMRI pattern analysis and response modeling to evaluate the source of swap errors. We designed a visual working memory task to induce a high proportion of swap errors ($\geq$20% of trials). After the encoding of six colored circles at different spatial locations ($\geq$45° apart along a circumference), a centrally presented retrospective cue indicated the color of the item whose location would be tested after a 12-sec delay period using delayed estimation. Participants were prescreened for high swap rates with a single behavioral session. We then collected fMRI data while high-swap participants (N=3) repeated the experiment in the scanner. Trials were binned post-hoc into correct, swap, and guess trials using single-trial mixture model estimates (Schneegans & Bays, 2016). Using an inverted encoding model to project fMRI data back into stimulus space (here, spatial location), we attempted to reconstruct representations of the cued memory location and also non-cued locations on each trial. Corroborating recent fMRI work with smaller working memory set sizes (Sprague et al., 2014, 2016), we show that on correct trials, delay-period activity in early visual areas contains information about the memory target. Notably, we extend this work by showing that on swap error trials, delay-period activity contains information about the swapped non-target location, rather than the memory target. These preliminary results provide neuroimaging support that swap errors in visual working memory arise from early binding failures that perpetuate throughout the retention interval.

Abstract: Training with working memory (WM) tasks yields major improvement. Surprisingly, the question of what is actually learned has not been studied yet. We examined it using two WM tasks: spatial N-back and a novel, extremely challenging task. Since N-back training does not improve performance in other tasks (Jakoby et al., 2019), we hypothesized that participants do not increase their general WM capacity, but instead develop a task-specific strategy that boosts their performance. We derived an effective strategy which relies on minimal changes in the order of items to be remembered, as opposed to the naïve strategy, which requires re-ordering all items in memory. We explicitly taught this strategy to 14 participants and compared their performance before and after instructions to other 14 participants, who trained on the task for 40 sessions with no strategy instruction. With instruction, participants achieved within 2 sessions the same amount of improvement observed after 25-40 training sessions. Importantly, questions presented to the trained group suggested that they used the same strategy, but it took them longer to find.To test the generality of this result we designed a new auditory WM task, where the required manipulation for a trial is given only after the stimuli (sequences of pure tones). 14 participants were trained on this task, and an active control group of 14 participants was trained on a complex perceptual task. Both groups were scanned before and after training while performing each task, using fMRI. Following 40 training sessions, most participants in both groups achieved major improvement in the trained task with no transfer to other tasks. Using a combination of self-reports and data analysis, we discovered that in the WM group, successful learners implicitly developed a surprising strategy. Rather than performing the required manipulation, they learned to efficiently detect one salient tone and assess the expected outcome of the whole sequence. fMRI data revealed a shift in activation patterns: pre-training scans showed activations in dorsal fronto-parietal circuits (for manipulation vs. retention-only contrast), while post-training scans showed an increase in activations in ventral regions along the temporal lobe, associated with domain-specific pitch sequence processing. We propose a novel explanation for the improvement found in WM training studies: during training, efficient learners do not increase their WM capacity as previously claimed. Instead, they develop a strategy that requires fewer manipulations (implemented by fronto-parietal networks) based on the perceptual features of the task (processed in ventral-temporal regions).

Title: Connectome-based predictive modeling of working memory from resting-state functional connectivity in people with multiple sclerosis

Authors: *A. J. R. SHANKAR, H. R. MANGLANI, S. FOUNTAIN-ZARAGOZA, D. G. EVANS, R. S. PRAKASH;
Clin. Psychology, The Ohio State Univ., Columbus, OH

Abstract: Previous work associating functional connectivity with behavior has described the consequences of neuronal damage in people with multiple sclerosis (PwMS), including the impairment of working memory systems that underlie complex cognitive functions and are critical for preserved quality of life. Methods to date have been largely correlative in nature, and as such, resting-state functional connectivity (Rs-FC) has yet to be used to accurately predict working memory in PwMS, limiting its potential use as a clinical tool. Connectome-based predictive modeling (CPM; Rosenberg et al., 2016; Shen et al., 2017) is a data-driven technique capable of identifying brain-behavior relationships as well as creating predictive models of behavioral performance from whole-brain functional connectivity. Here, we built two distinct CPMs of working memory using Rs-FC patterns from 27 PwMS (mean age 45.81 ±7.36) to predict performance on the Paced Visual Serial Addition Task (PVSAT) and the WAIS-IV Working Memory Index (WMI), respectively. Using a leave-one-out cross validation procedure, both CPMs successfully predicted working memory performance (correlation between predicted and observed scores: PVSAT: r=.56, p=.003; WMI: r =.51, p=.007), which indicates that the CPM methodology is both sensitive to brain-behavior relationships in PwMS and can create predictive models of working memory solely from Rs-FC. Additionally, we differentiated between the functional connections positively correlated with performance scores (a high-WM network) and those negatively correlated with performance scores (a low-WM network). We found the low-WM networks of both models to be particularly important for predictive power (correlation between predicted/observed scores: PVSAT_low: r=.65, p< .001; WMI_low:r=.51, p=.007), suggesting that certain increases in functional connectivity at rest may be detrimental to working memory performance or indicative of maladaptive firing. As a sanity check for the potential influence of head motion, we also trained a CPM on mean framewise displacement from Rs-FC, which yielded no prediction of head motion (r=.02,p=.936), indicating that our models appear to be unconfounded by such motion.Therefore, our current results support the use of the CPM method as a powerful technique for the prediction of working memory ability in PwMS and suggest the functional connections found in rest are promising indicators of higher-order cognitive function in this population.

Title: Distractor suppression in visual working memory

Authors: *L. L. CHAI[1], N. HAKIM[1], T. FELDMANN-WUSTEFELD[2], E. K. VOGEL[1];
[1]Univ. of Chicago, Chicago, IL; [2]Univ. of Southampton, Southampton, United Kingdom

Abstract: Working memory (WM) is a limited capacity system that actively maintains information. Due to its limited capacity, efficient processing of incoming information is necessary. This process relies on filtering and enhancing relevant information and suppressing irrelevant information. Here, we used event-related potentials to investigate suppression of irrelevant information during a WM task. We used the Distractor Positivity (Pd) to track the suppression of irrelevant information in WM. In the first experiment (n=20), participants performed a change detection task for color square arrays presented along the vertical midline. On 50% of trials, we presented task-irrelevant distractors at lateral positions after three different intervals relative to the onset of the memoranda that reflect different moments at which distractors may impact the processing of the targets: initial selection and perceptual encoding (0 ms); WM consolidation (325 ms); and WM maintenance (650 ms). We observed a significant Pd to the lateral distractors presented during each of these periods that was comparable in amplitude for each condition. Thus, these finding suggest that the suppression reflected by the Pd can be deployed during the encoding and maintenance periods of WM. Notably, these results provide initial evidence that the Pd can be observed under conditions in which the targets and distractors are presented separately in time. In the second experiment (n=20), we manipulated the probability of distractor onsets (33% vs 66%) to examine whether top-down expectations modulate the amount of suppression observed to the distractors. This experiment was identical to the 650ms condition of experiment 1, but with separate blocks of either low probability distractors (33%) or high probability distractors (66%). Both conditions generated a significant Pd component. However, when participants did not expect distractors (33% condition), the Pd was significantly larger than when distractors were expected (66% condition). This suggests that when participants expect to be distracted, less suppression may be needed to minimize the impact of distractors on performance; a pattern supported by our behavioral results in which less interruption cost in accuracy was observed for the high probability condition. Together, the results from these experiments show that active suppression of distractors can occur even after

WM representations have been stored and maintained, and that observer expectations can modulate the amount of suppression applied to irrelevant information.

Title: Representing location versus temporal context in visual working memory

Authors: *J. M. FULVIO, B. R. POSTLE;
Psychology & Psychiatry, Univ. of Wisconsin - Madison, Madison, WI

Abstract: Successful performance on working memory tasks often requires encoding of an item's context (e.g., where or when it was presented) in addition to its identity. Recent work from our lab suggests that elevated delay-period activity in parietal cortex may be more sensitive to demands on context-binding than on stimulus representation per se. The present study investigated the effects of varying context-binding demands along two dimensions: high vs. low, and location vs. ordinal position. Healthy young adult humans (male and female) were scanned with fMRI during trials that began with the sequential presentation (500 ms, 250 ms ISI) of three oriented-grating samples at different locations, followed by an 8-second delay, followed by a recognition probe that appeared at one of the three sample locations with a superimposed digit ("1", "2", or "3"). A pretrial instruction cue indicated whether subjects were to respond to the probed location, the probed ordinal position, or to ignore context (i.e., "does probed orientation correspond to any of the three samples?"). Multivariate pattern analysis (MVPA) of context-binding requirements ("high" (location-cued + order-cued) versus "low" (ignore context)) revealed strong sensitivity to context binding at sample and at probe - but not during the delay - in occipital and parietal areas. Additionally, delay-period signal in parietal cortex was higher during high context-binding trials. Within occipital and parietal cortex, MVPA could not discriminate location-cued from order-cued trials during delay and probe. Next, inverted encoding modeling (IEM) was used to assess the neural representation of sample and probe location at response as a function of context. In occipital cortex, the neural representation of the probed location was stronger on location than on order and ignore-context trials, suggesting sensitivity of contextual information to attentional control. However, the neural representation of the location of the invalidly probed sample (i.e., of the digit-cued item on location trials and of

the location-cued item on order trials) was also active.Thus, although the strength of the representation of context is sensitive to strategic factors, context-binding may nevertheless be an obligatory component of working memory.

Title: Prior knowledge shapes the neural dynamics of mnemonic and response-related representations in visual working memory

Authors: *Q. YU, B. POSTLE;
Univ. of Wisconsin-Madison, Madison, WI

Abstract: Although humans can maintain mental representations of visual information with relatively high precision, their memory performance is not perfect. Previous behavioral studies have demonstrated that responses on tests of working memory for orientations or colors can be strongly biased toward several stable attractors (or priors) in people's long-term representation of orientation/color space, even if memory samples were drawn from a uniform distribution. The neural bases of these biases, however, remain poorly understood. We explored this question by acquiring fMRI while participants performed a delayed recall task of visual orientations. Samples were oriented gratings embedded in noise with different levels of contrast: high-contrast (60%), low-contrast (10%), and 0%-contrast (i.e., a noise patch without visible orientation). On each trial, participants viewed one memory sample, presented centrally for 0.5 s, and after a delay of 8.5 s, they rotated a needle on an orientation wheel to match that of the remembered orientation as precisely as possible. The orientations in the samples were drawn equally from the orientation space (0-180°) across trials. Behaviorally, the distribution of participants' responses was non-uniform, consistent with previous findings. To investigate how this bias was implemented neurally, for each condition and each time point we trained inverted encoding models (IEMs) using participants' behavioral responses. Plotting the distribution of the peak response orientations revealed that, in both early visual and parietal cortex, the distribution of these neural representations of response bias closely tracked the landscape of the subjects' prior distributions of orientation space, even during the earliest time points of a trial. This brain-behavior correlation was highest in the 0%-contrast trials, where neural activity was uninfluenced by sensory signals. The trial-specific neural representation of the impending

response, in contrast, did not emerge until several seconds into the trial. These results suggest that prior knowledge is a stable attribute that is represented within the neural network, which could help to adjust and stabilize mnemonic representations on a trial-by-trial basis.

Title: Neural dynamics of interrupting active working memory

Authors: *N. HAKIM[1], T. FELDMANN-WUSTEFELD[2], E. AWH[3], E. K. VOGEL[1]; [1]Univ. of Chicago, Chicago, IL; [2]Univ. of Southampton, Chicago, IL; [3]Psychology, Univ. of Chicago Dept. of Radiology, Chicago, IL

Abstract: We rely on working memory (WM) to keep information in mind. Recent research that we have conducted has shown that there are two neurally dissociable sub-component processes, item-based storage and spatial attention, that support the maintenance of information in active WM (Hakim, et al., 2019). In this series of experiments, we recorded electroencephalography (EEG) activity while participants performed tasks where we manipulated the demands for item-based storage independently of sustained spatial attention. We found that the Contralateral Delay Activity (CDA), which is a difference in amplitude between contralateral and ipsilateral electrodes, tracked item-based storage. On the other hand, lateralized alpha power (8-12 Hz), which is a difference in power between contralateral and ipsilateral electrodes, tracked spatial attention. Here, we use these two "online" measures of active WM to more finely delineate how task-relevant and task-irrelevant interruption influence item-based storage and spatial attention. In Experiment 1 (n=20), we had participants perform a color change detection task during which task-irrelevant interrupters appeared on a subset (25%) of trials. Following interruption, item-based representations, as indexed by the CDA, sustained for several hundred milliseconds, but were lost by the end of the trial. On the other hand, spatial attention, as indexed by lateralized alpha power, immediately shifted away from the memory locations, but re-oriented back towards these locations by the end of the trial. These results suggest that item-based representations can persist outside the focus of attention. Additionally, spatial attention and item-based storage are distinct, but work together to protect information in active working memory. In Experiment 2 (n=20) and 3 (n=20), we manipulated the relevance of the interrupters. In the task-irrelevant

block, participants had to ignore the interrupters, and in the task-relevant block they had to discriminate the shape of the interrupters. In Experiment 2, we found that memory items, as indexed by the CDA, were dropped more quickly when interrupters were relevant than when they were irrelevant. Additionally, spatial attention, as indexed by lateralized alpha power, more quickly shifted away from the locations of the memory items when interrupters were relevant than when they were irrelevant. In Experiment 3, we extended these findings by showing that relevant interrupters were encoded, but irrelevant interrupters were suppressed. Overall, this series of experiments illustrates that dissociable neural indices of active WM distinctly and dynamically respond to varying task demands.

Title: Multivariate decoding of visual working memory load from the human EEG signal

Authors: ***W. S. THYER**[1], K. C. ADAM[2], E. VOGEL[1], E. AWH[1];
[1]Psychology, Univ. of Chicago, Chicago, IL; [2]Psychology, UCSD, La Jolla, CA

Abstract: Neural signals that can track information stored in visual working memory (WM) provide a powerful tool for tracking the contents of this online memory system. Although univariate signals from human EEG such as contralateral delay activity (CDA) (Vogel and Machizawa 2004) and alpha power suppression (Fukuda et al. 2015) have proven to be robust indices of WM storage, differentiating WM load using these univariate signals requires averaging across dozens or even hundreds of trials per condition. We propose that multivariate analysis of EEG voltage topography may provide higher sensitivity, enabling tracking of WM storage loads even at the level of single trials. First, we tested feasibility of decoding methods using published datasets with CDA (Unsworth et al. 2015; n = 183) and alpha power (Fukuda et al. 2015; n = 30). We found robust decoding of memory load, even when training and testing on single trials. However, in both of these experiments, visual stimulation increased linearly with memory load, potentially confounding our ability to classify memory load. In a new experiment (n = 25), we controlled for this confound by manipulating the number of stored items (1-4) while holding visual stimulation constant. To visually match displays, we presented luminance-

matched filler stimuli along with the memoranda (i.e., participants always saw 5 luminance-matched objects, but encoded only a subset into WM). Using logistic regression, we observed robust decoding of the number of targets in the sample display. Cross training analyses suggested that this multivariate load signal evolved dynamically just after sample onset, but achieved a temporally-generalizable pattern during the final 750 ms of a 1000 ms delay period. Thus, scalp topography of EEG voltage contains robust information regarding online storage loads in visual WM in the absence of confounds in stimulus-evoked activity.

Title: Distinct encoding characteristics in occipital and parietal areas during human sequence memory

Authors: *Q. HUANG, H. LUO;
Sch. of Psychological and Cognitive Sciences, Peking Univ., Beijing, China

Abstract: Temporarily maintaining a sequences of items is important in many cognitive functions, yet the underlying dynamic neural mechanisms and the functions of different brain regions in the process remain unclear. In the present study, we recorded magnetoencephalography (MEG) signals from 24 subjects when they held a two-orientation sequence in working memory. We employed a time-resolved multivariate decoding approach to assess the representation tuning curves for the two sequentially memorized orientations respectively. First, significant recency effect were found in memory behavior (i.e., $2^{nd} > 1^{st}$). Interestingly, during the memory maintaining period, occipital and parietal areas showed distinct encoding characteristics for the two-orientation sequence. Specifically, occipital cortex seemed to employ a type of "power encoding" approach, such that the 2^{nd} item showed stronger decoding strength than the 1^{st} item, whereas their decoding latencies were not different. In contrast, the parietal area displayed a "temporal encoding" profile, during which the 2^{nd} item had earlier latency in the decoding time course compared to the 1^{st} item, whereas their overall decoding strength were similar. Finally, the power- and time-based encoding in the occipital and parietal

areas continued in the recalling period and was strongly associated with recency effect in behavioral performance. Taken together, our results demonstrate distinct and dissociated encoding characteristics of occipital and parietal areas in sequence memory, through which a list of items as well as their relationship would be rapidly represented and organized in working memory.

Title: The temporal dynamics of working memory maintenance in a category-based N-Back

Authors: *O. J. RATCLIFFE, B. STARESINA, K. SHAPIRO;
Sch. of Psychology & Ctr. for Human Brain Hlth., Univ. of Birmingham, Birmingham, United Kingdom

Abstract: A popular theoretical framework suggests that theta-gamma coupling facilitate the short-term retention of several serial items in working memory (WM). According to this model, temporal order is maintained through theta phase coordination and individual items are represented by gamma bursts occurring sequentially during the upstate of the ongoing theta wave. Several lines of evidence point to these two frequency bands being involved: e.g. frontal gamma increases with item load and theta:gamma ratios predict individual WM capacity. However this evidence does not directly show specific content being maintained in slots, as the model would predict. In this study we used multivariate pattern analyses (MVPA) to track reactivation of category-specific working memory representations over the course of an N-Back task.
33 subjects (aged 18-35) participated in two tasks. The first task was a delayed-match-to-sample (DMS) task using three categories of stimuli: faces, objects, and scenes. This task was completed twice, before and after the N-Back. Stimulus timings remained the same in the N-Back as in the DMS. The N-Back task consisted of 12 blocks: 8 2-back, 4 1-back. The N-Back task used two of the previous categories, objects and scenes, so that faces could serve as a neutral stimulus category for subsequent multivariate analyses.
Behavioural accuracy was high in all three tasks: 94% on the DMS, 93% on 1-back trials, and 92% on 2-back trials. Time-frequency analyses demonstrated increases in frontal theta power during the delay period that scaled with working memory load. Conversely, fronto-central beta

power decreased in the delay period of 2-back trials as compared to the 1-back. Classifiers were then trained on EEG data and cross-validated in a leave-one-out procedure. Overall, classification was highest when the stimulus was on screen. Accuracy then reduced before a second peak was observed during the response portion of the task, suggesting neural reactivation of the WM representation. Decoding during the delay period appeared to show some rhythmic reactivation. Frequency transformation of the classifier decision values of individual trials was performed to examine whether category reinstatement oscillated in any of the canonical frequency bands.

Title: Congruent context features enhance integration and attenuate separation of working memory representations across and within memory episodes

Authors: *C. FISCHER[1], S. CZOSCHKE[1], B. PETERS[1], B. RAHM[2], J. KAISER[1], C. BLEDOWSKI[1];
[1]Inst. of Med. Psychology, Goethe Univ., Frankfurt am Main, Germany; [2]Med. Psychology and Med. Sociology, Albert-Ludwigs-University Freiburg, Freiburg, Germany

Abstract: Working memory (WM) provides a direct access to a limited number of object representations that are often conceptualized as bundles of integrated content and context features. Those object representations need to be maintained in a stable but distinguishable manner over time, which requires integrating corresponding inputs as well as reducing interference between concurrently maintained objects by separation. In line with this notion, recent studies showed that WM representations are not maintained independently, but interact across and within memory episodes, in particular when their task-relevant contents are similar to each other. Those interactions can be repulsive or attractive, pointing towards a separating or integrative mechanism, respectively. We hypothesized that integration should be enhanced whereas separation should be attenuated in situations where two representations are likely to represent the same object, i.e. share similar context in addition to their content features. We asked participants to remember the motion directions (content feature) of two sequentially presented colored dot fields (S1 and S2) per trial. One item per trial was retro-cued for continuous report via a context feature, i.e. either by its color (Experiment 1) or serial position

(Experiment 2). We manipulated the congruence of context features of S1 and S2 within and between trials to examine their interactions with content representations. In line with previous findings we observed an attractive bias (i.e. serial dependence across trials) between current and past motion directions, in particular when their content was similar. Moreover, serial dependence across trials was also enhanced when items shared the same color or serial position across trials. In contrast, within a trial we observed a repulsive bias from S1 on S2 (i.e. within-trial serial dependence) that was attenuated by congruent context features. Taken together, our results confirmed our hypothesis that congruent context features promote integration by enhancing attraction between WM representations with similar contents across trials and by attenuating their repulsion within a trial. These findings suggest a context-dependent interplay of integration and separation in WM that helps to balance demands for stable object identity and object distinctiveness across or within a memory episode. Future experiments will aim at the identification of the neural mechanisms subserving integration and separation and their interaction with context congruency.

Title: Neurophysiological indices of the transfer of cognitive training gains to untrained tasks in multiple sclerosis patients

Authors: *T. J. COVEY, Z. TURTOLA, J. L. SHUCARD, X. WANG, D. W. SHUCARD; Neurol., Jacobs Sch. of Med. and Biomed. Sciences, Univ. at Buffalo, Buffalo, NY

Abstract: Multiple Sclerosis (MS) is a neurodegenerative disorder that can negatively affect cognition and day-to-day functions. Cognitive rehabilitation interventions may improve these functions in MS, but the research in this area has yielded mixed findings. The efficacy of cognitive rehabilitation may vary according to the specific cognitive domains that are targeted by a given protocol, and also based on individual differences in disease progression that can impact cognition and neural plasticity. Here we present preliminary analyses that sought to reveal the extent that a targeted cognitive training protocol could improve performance outcomes and change brain function for untrained cognitive tasks in MS patients. MS (n = 12) and healthy

control participants (n = 12) completed twenty sessions of adaptive working memory (WM) training (n-back task, visually presented letter stimuli), over 4-5 weeks. A WM training protocol was selected because it has been well-studied in healthy individuals, and WM and related processes (i.e., processing speed, executive functions) are commonly impaired in MS. All study participants completed a battery of cognitive tests at baseline (pretest) and after completing the training protocol (posttest). Event-related potential (ERP) indices of brain activity were derived from participants' ongoing EEG activity that was collected at pretest and posttest for untrained tests of spatial WM (spatial 3-back), cognitive control (Go/NoGo flanker task), and selective attention (visual search task). Both MS and control groups demonstrated significant improvements in a broad range of cognitive outcome measures. Furthermore, enhancements in ERP indices of target detection, attention, and executive control were observed for both groups after training. MS patients and controls both had pretest-to-posttest enhancement of N1 amplitude for the spatial WM task, and enhancement of P2 and N2 amplitude for the cognitive control and selective attention tasks. In contrast, the control group exhibited more pronounced pretest-to-posttest enhancement of P3 amplitude, overall, than the MS group. These analyses identified neural activity associated with the transfer of WM training gains in MS. These training-induced neural changes corresponded with pretest-to-posttest improvements in cognitive performance. The findings also indicate that some neural processes (i.e., P3) may be less responsive to cognitive training in MS, possibly due to the occurrence of disease processes.

Title: Sustained slow wave activity and alpha oscillations index distinct aspects of storage in working memory

Authors: *G. K. DIAZ, E. K. VOGEL, E. AWH;
Dept. of Psychology, Univ. of Chicago, Chicago, IL

Abstract: Multiple neural signatures have been implicated in the maintenance of information in visual working memory (WM). Using EEG recorded from parieto-occipital electrodes on human subjects, we replicated past observations that increasing WM load leads to monotonic increases in the amplitude of a sustained negative slow wave and monotonic declines in oscillatory brain activity in the alpha-band (8-12 Hz). Although both of these EEG signals track WM storage load, they appear to play separable functional roles. For example, previous research has found that these two signals have distinct time courses and explain unique variance in WM capacity across individuals (Fukuda et al., 2015). Our working hypothesis is that the negative slow wave is an item-based signal that tracks the number of individuated representations in WM, while alpha power indexes the locations of the stored items. In a prior study, we manipulated the number of perceived items using perceptual grouping, while holding constant the number of locations occupied by memoranda. We found that the negative slow wave, but not alpha power, tracked the number of perceived items. Here, we extended this work by using sequentially presented displays to manipulate the total number of locations occupied by a given number of memoranda. Alpha power, but not slow wave activity, tracked variations in the total number of locations when the number of items stored was held constant. By contrast, slow wave activity tracked the total number of items stored, but did not vary with the number of locations occupied by the memoranda. Overall, the current work provides additional evidence that alpha power and the negative slow wave from parieto-occipital electrodes track distinct aspects of WM storage, such that slow wave activity indexes the number of items stored, while alpha activity indexes the number of prioritized locations.

Title: Spatiotemporal dynamics of associative memory processing in patients with focal epilepsy

Authors: S. HENIN[1], A. SHANKAR[4], H. BORGES[1], D. FRIEDMAN[1], A. FLINKER[1], W. DOYLE[2], O. DEVINSKY[1], G. BUZSAKI[3], ***A. A. LIU**[1];

Abstract: BACKGROUND. Memory dysfunction impacts 40-50% patients with epilepsy, affecting work, school, and everyday life. Interictal spikes during verbal encoding have been associated with forgetting but their relationship to memory physiology is unclear. Epilepsy patients undergoing invasive electroencephalography (iEEG) for resective surgery provide an opportunity to dissect the fine-grained spatiotemporal dynamics of memory. OBJECTIVE. We describe the time course of high gamma activity (HGA), a measure of local population firing, across the brain during associative encoding. Next, we examined the impact of spikes on memory encoding in regional and network level analyses. METHODS. A computerized associative memory task was used to probe memory function in surgical epilepsy patients at NYU Langone Health. Electrode localization was performed using automated processes and expert review to identify spikes. Analysis focused on determining differences in the spectral-temporal features in the high-gamma activity (HGA) between successful and failed encoding as well as investigating the impact of spikes on successful encoding. RESULTS. Eight patients undergoing invasive EEG were included. Both successful and failed encoding trials demonstrated an early peak (<0.5 s) and sustained (0.5-2s) HGA in primary visual (occipital), visual association (inferior parietal), and high-level visual recognition (fusiform) cortex. Successful trials demonstrated greater HGA during late (1-2 s) encoding in bilateral medial temporal memory regions (entorhinal cortex, hippocampus, and amygdala) compared to failed trials. Late (1-2 s) differences in HGA in frontal executive and sensorimotor (primary motor, supplementary motor, pars triangularis/orbitalis, superior temporal gyrus) were associated with encoding performance. Right hemisphere demonstrated a different time course of HGA compared to left hemisphere, with greater differences in HGA distinguishing successful versus failed trials. Spikes occurring in bilateral medial temporal (L and R hippocampus, L entorhinal) during encoding were associated with a 2.0 greater odds of forgetting. CONCLUSIONS. In a cross-modal associative memory task, sustained neural activity in memory, executive/attentional, and sensorimotor networks characterized successful encoding. Differences in left and right hemisphere activity likely reflect specialization of word and face processing. Spikes in bilateral medial temporal lobe disrupt encoding.

Title: Distinct neural correlates underlie mean reward and reward variance in risky decision making: Evidence from eye-tracking and fMRI

Authors: *S. SUN[1], R. YU[2];
[1]Caltech, Pasadena, CA; [2]Psychology, Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Value-based decisions are influenced by both expected utility and potential risks of outcomes. However, most previous studies failed to separate the expected value from risks. Using a new incentivized reaction time (RT) task in which mean reward (expected utility) and reward variance (potential risks) of two values were parametrically manipulated and orthogonalized, we examined the neural correlates of expected utility and risk, and how these representations lead to subjective decisions. We show that RTs (n = 90) varied as a function of mean reward, suggesting that expected utility is the main driver of reward motivation. Moreover, gaze transitions (n = 68) tracked mean reward, indicating that participants shifted gaze more towards higher expected utility. Pupil size tracked the variability of RTs, possibly reflecting the emotional arousal induced by subjective risk preference. Neuronally (n = 22), the striatum tracked mean reward, and its connectivity with amygdala and SFG were correlated with expected utility. The insula tracked reward variance, and its connectivity with vmPFC and dACC was associated with potential risks. Computational modeling further shows that the putamen conveyed subjective utility by integrating both expected value and risks. We provide the first evidence that expected utility and risks were encoded differently at behavioral, attentional, and neural levels. These results extend existing evidence by showing that expected utility engages the striatal-cortical limbic motivational network in pursuing high reward, whereas risk associates with cingulo-insular salience network in detecting reward conflicts, together initiate subjective utility as conveyed by the pupil-linked arousal system and striatum. The results are discussed in terms of theory and application.
Key words: mean reward, reward variance, expected utility, risk, motivation, fMRI

Title: Competing decision making strategies in a fixed odds game: The subversive role of the reinforcement learning network

Authors: *C. R. STEINHARDT[1], S. V. SARMA[2];
[2]Biomed. Engin., [1]Johns Hopkins Univ., Baltimore, MD

Abstract: The underlying neural circuitry that a person uses to make decisions on a daily basis has evolved from millennia of evolutionary pressure on animals to make decisions about food, danger, and mate choice for the purpose of survival. The human brain performs reinforcement learning (RL), accumulation of evidence with repeated exposure to a stimulus that leads to an estimate of the amount and likelihood of reward gained from an object, as other animals do. Additionally, humans have developed other cognitive functions, including the ability to learn and make decisions based on instructions, rule-based learning (RBL). These strategies are both actively used for decisions on a personal level, such as choices of self-presentation or lifestyle (e.g. dietary choices), and, on larger scales, such as management of funds for a company. The adaptability of human cognition can be a disadvantage, as people can acquire biases towards dangerous behaviors, such as gambling, and show tendencies towards choices against known fixed odds. We hypothesize that these counter-factual decisions may be a result of RL overriding RBL in such situations. To test our hypothesis, we performed a study designed to elicit changes in decision strategy. Ten human subjects (3 M, 36.2 +- 3.8 years old) performed a sequential decision task in which on each trial a card was drawn from an infinite deck with fair probabilities, and they needed to bet $5 (low) or $10 (high) on the probability of the first card they are shown being higher than the next (which can be higher, lower, or the same). At the same time, EEG recordings were acquired from depth electrodes implanted for clinical purposes. Although the task had fixed probabilities, subjects show changes in betting behavior over time for the same card values. Additionally, some betting defies the optimal betting strategy (i.e., maximizing expected reward), such as betting high on a card with less than 50% chance of winning. To capture variability in each subject's betting behavior, we built subject-specific logistic regression models that predicted the probability of betting high as a function of RBL and RL variables. These models demonstrate which strategies (RBL vs RL) may be influencing changing beliefs and in turn gambles over trials. We concluded that certain subjects are consistently using RBL, while others are switching between betting using RBL and allowing RL

to outweigh the RBL choice. We then identified RL and RBL neural networks by examining power spectra of neural activity across the population, and found that the level activation of these networks explained variability in decision making observed.

Title: Humans over-expect from the future chances in finite sequential decision problems

Authors: Y. SHIN[1], H. SEON[2], Y. SHIN[3], ***D. CHUNG**[1], O.-S. KWON[1];
[1]Dept. of Human Factors Engin., [2]UNIST, Ulsan, Korea, Republic of; [3]Ctr. for Teaching and Learning, Univ. of Ulsan, Ulsan, Korea, Republic of

Abstract: Many decision problems in life are sequential and constrained by a certain time window. 'Secretary problem' is a classic example of this finite sequential decision problem; one has to make a choice whether to accept the current applicant, a rejected applicant does not get a second chance, and there are usually no chances to review other potential applicants when the position is filled. Although the problem can be mathematically solved, it is not clear whether and how humans deviate from the optimal behaviors. Here, we used one variant of a secretary problem to investigate (i) whether individuals make an optimal decision in a finite sequential decision problem, and (ii) if not, how their decisions are made. During the task, participants were asked to accept or reject after viewing a random number. On each round, they could have up to five chances to evaluate a new random number by selecting reject. When they accepted, the presented number was accumulated to their final payoff, and then they moved on to the next round (up to 200 rounds) that consisted of a new set of five chances. We computed a decision criterion for acceptance at each chance that best explained participants' choices. Participants showed higher threshold compared to optimal decision criteria indicating that they were expecting a higher payoff from the future chances than they could actually earn. This behavioral tendency was successfully explained by an optimal decision model with individuals' utility function parameterized by reference point and value sensitivity. We confirmed that difference between the presented values and the model estimated thresholds explains the speed of participants' responses at each chance. Furthermore, participants' physiological responses,

measured by their pupil dilation at keypress reflected the same pattern (a function of difference between value and the threshold rather than values *per se*). These results support our proposed model suggesting that individuals make threshold-based choices in a finite sequential decision problem, and seemingly suboptimal decision patterns (waiting for future chances) may be originated from the process of calculating thresholds using individuals' utility function.

Title: Menu complexity effects on attribute integration in risky multi-attribute decision making

Authors: *J. G. ELSEY[1], Y.-P. YANG[1], E. EMERIC[2], E. NIEBUR[3], V. STUPHORN[3]; [1]Psychological and Brain Sci., [2]The Zanvyl Krieger Mind/Brain Inst., [3]Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: When evaluating multiple risky alternatives, the values of each alternative's attributes are integrated such that preference dynamically evolves to form one's ultimate choice. Past studies have presented subjects with choice menus that are limited in alternative and attribute complexity, or where attributes were not parametrized. We therefore presented subjects with choice scenarios more complex than simple two-alternative risky choice menus, and more explicitly-defined than previous large choice menus. In this study, we investigate attribute integration strategies underlying preference formation in increasingly complex risky choice menus.

We tested subjects in variations of a decision making tasks that differed in the number of alternatives and attributes presented. In the first experiment, subjects were offered two or three alternatives with two attributes: reward amount and probability of earning reward. In the second experiment, subjects were presented with four alternatives that consisted of four attributes: reward amount, loss amount, probability of earning reward, and wait time for outcome feedback. Attribute stimuli are displayed in spatially separate locations within a boundary cue indicating that they belong to the same alternative. Each attribute's magnitude is masked by its corresponding color cue, which is only revealed when fixated upon. Subjects are allowed to freely inspect the attributes with no time constraint, before choosing. The eye movements provide temporal and spatial information about subjects' focus of attention during attribute

integration.
Subjects exhibited two different attribute integration strategies: (1) a within-alternative strategy (i.e. inspecting the attributes within one alternative, then inspecting the attributes within another alternative), and (2) a within-attribute strategy (i.e. inspecting the same attribute type across alternatives, then inspecting a different attribute type across alternatives). At the population level, subjects favored a within-alternative strategy in both the 2-alternative, 2-attribute (within-alternative: 44%, within-attribute: 29%) and 3-alternative, 2-attribute choice menus (within-alternative: 42%, within-attribute: 33%). However, past studies have shown that subjects faced with many more alternatives consisting of a greater number of attributes they predominantly use a within-attribute strategy. This aim of this study will to be to systematically investigate when the shift in integration strategy occurs as menu complexity increases.

Title: A computational model for cognitive fatigue in individuals with multiple sclerosis

Authors: *F. R. ERANI[1], J. D. MEDAGLIA[2];
[2]Psychology, [1]Drexel Univ., Philadelphia, PA

Abstract: Fatigue is experienced in up to 90% of individuals with multiple sclerosis (MS) and is a primary cause of disability in MS. Despite extensive research, the basic mechanisms that cause fatigue in MS are poorly understood, and as such, have slowed progress on interventions that target fatigue. The cognitive component of fatigue is generally the most distressing aspect of patients' fatigue because it limits their ability to sustain concentration and endure mental tasks. Reward and cognitive control research, along with corroborating neuroimaging findings, provide evidence that suggest the processes behind this symptom. This literature suggests that there is a reward/cognitive effort imbalance or a disruption in one or both of these functions in individuals with MS who experience cognitive fatigue. However, how the specific mechanisms of reward, cognitive control, and the anticipated rewards for exerting effort have not been clarified. To better characterize the processes behind cognitive fatigue, we introduce a model that builds upon the existing theories and include Shenhav and colleagues' (2013) expected value of control (EVC) theory. We use the model to demonstrate specific simulated cases in which fatigue would occur in individuals with 1) deficits in cognitive control, 2) deficits in reward processing, and 3) deficits in the ability to estimate the EVC. Our results indicate that model [1] less baseline

cognitive control or having less cognitive control to deploy due to MS pathology and model [2] baseline reward blunting or blunting due to MS pathology, result in early and fast increases in cognitive fatigue. Model [3] reveals that an inability to calculate the expected value of reward results in disengagement from the task altogether, preventing the ability to measure cognitive fatigue by avoiding it altogether. Moreover, dysfunctional cognitive control and reward processing, and subtle abnormalities in EVC interact to produce greater cognitive fatigue than each separately. Taken together, our results suggest that cognitive fatigue can result from one or more neurocognitive sources, and that similar levels of fatigue can imply differences in how interventions should be targeted in MS and potentially other neuropsychological syndromes.

Title: Modulation of 1/f noise emitted in reaction time: Independent effects of increasing uncertainty of "when" and "what" in stimulus presentation

Authors: *P. ALEFANTIS[1], C. SIETTOS[2], I. ALEFANTI[3], N. SMYRNIS[4,3];

Abstract: Measurement of Reaction Time (RT) in speeded decision processing tasks has shown a large intra-subject variability of RT (ISV-RT). Decomposing the frequency spectrum of the underlying time series of the RT have shown that ISV-RT may be rooted at a long memory process called 1/f noise. 1/f noise is theorized to be a characteristic signature for system complexity and has been associated with the most elementary aspect of cognitive process, the formation of representations. In this study we investigate how the emergence of 1/f noise is affected by different conditions of "stimulus time" and "stimulus type" predictability. 15 healthy volunteers performed the 1-Back working memory task, the Eriksen flanker spatial attention task and a two-choice simple visuomotor task. Six different task conditions were used for every task in which the inter-trial interval (ITI) was either fixed at 1s, or varied in a uniform distribution of ITI with a mean of 1s and range of.5, 1, 1.2, 1.5, 2s respectively. For the 1-Back task, the power spectrum was also investigated in three conditions of "stimulus type" predictability; more specifically the proportion of the two alternative responces was 50:50, 75:25 and 90:10 in different blocks. The spectrum density of RT confirmed the presence of 1/f noise measured as a

decreasing linear trend a in the log-log scale indicating higher power at low frequencies that was reduced in higher frequencies. More importantly this 1/f noise (alpha parameter)decreased significantly with increasing uncertainty regarding either the stimulus timing or the stimulus response-type, indicating two independent sources of 1/f noise (see figure1). These results suggest that the cognitive process of formation of stable representations revealed in the presence of 1/f noise in RT is sensitive to predictability of when and what in stimulus presentation.

Title: Identifying intuitive and reflective social decision processes

Authors: *S. NUMANO[1,2], T. NIHONSUGI[3,2], M. HARUNO[2,1];
[1]Grad. Sch. of Frontier Biosciences, Osaka Univ., Osaka, Japan; [2]Ctr. for Information and Neural Networks, Natl. Inst. of Information and Communications Technol., Osaka, Japan; [3]Fac. of Econ., Osaka Univ. of Econ., Osaka, Japan

Abstract: Our decision process has been postulated to comprise dual processes: intuitive (fast) and reflective (slow) ones (Sloman, 1996). The dual process theory is particularly important in social interactions (Evans, 2008) in which multiple neural processes need to be integrated. However, neural mechanisms underlying dual social decision processes remain poorly understood partly due to methodological limitations to model dual social processes. Here, we introduced a parametric drift-diffusion for social interactions, and used it to analyze behavioral and functional magnetic resonance imaging (fMRI) data of a trust game (Nihonsugi *et al*., 2015). In our online behavioral experiment (N=4043), we constructed parametric drift-diffusion which can include constant, self-reward, other-reward, inequity and guilt in its bias and drift terms and selected the best model based on predictive likelihood of unseen data which was not used for model estimation. In the fMRI experiment of the same trust game (N=45), we analyzed participants' behavior based on the best model selected in the online experiment. The best model includes a constant and inequity in the bias term, and a constant, self-reward, inequity, and guilt in the drift term, indicating that inequity comprises dual processes. Therefore, we conducted a clustering of participants based on the model's coefficients for bias inequity and drift inequity and identified two groups: "bias group" and "drift group". Next, we contrasted fMRI data correlated with inequity between the two groups (using SPM12). We found that the "bias" group exhibited activity in the ventral striatum and insula, and the "drift" group on the other hand, showed activity in the caudate nucleus, anterior cingulate, and dorsolateral prefrontal cortices (*P* < 0.001; uncorrected for multiple comparison). This result suggests that these two groups of brain structures play a critical role in intuitive and reflective inequity aversions, respectively.

Abstract: Critical resuscitation situations are very stressful for caregivers. Acute stress is known to decrease performance. Stress management training might help participants to improve performance and their stress management strategies. High-fidelity simulation (HFS) can help test this hypothesis, since HFS is known to induce acute stress in the participant through immersive and realistic situations. The objective was to test whether Tactics to Optimize the Potential (TOP), as a cognitive stress management program, could improve residents' performance during HFS and could have beneficial effects on the stress reaction. Each resident convened to formative HFS were randomized in two parallel-arms (TOP or control) and actively participated in one HFS scenario. Only residents from the TOP group had specific TOP training few weeks before the HFS and a four-minute TOP reactivation occurring just before the beginning of the scenario. 128 residents were included in the analysis. The overall performance was nine percent higher in the TOP group *vs.* the control group. Phasic EDA did not increase in the TOP group whereas it increased in the control group between the previous period of reactivation and the scenario period. Tonic EDA decreased during the scenario period with years of experience (resident skill) but was not influenced by TOP training. Thus, the TOP group was characterized by a decrease of phasic electrodermal activity, a marker of sympathetic system. This effect was different of effects induced by experience which only modified tonic electrodermal activity. It was at our knowledge the first time that two different processes were shown to influence independently one of the two components of the EDA. Benefits of TOP training should be considered in real clinical emergency settings.

Title: Changes-of-mind due to high decision uncertainty: An experimental and computational modelling study

Authors: *N. A. A. ATIYA[1], A. ZGONNIKOV[2], D. O'HORA[3], K. WONG-LIN[1];
[1]Sch. of Computing, Engin. and Intelligent Systems, Ulster Univ., Derry~Londonderry, United Kingdom; [2]Sch. of Computer Sci. and Engin., Univ. of Aizu, Aizu-Wakamatsu, Japan; [3]Sch. of Psychology, Natl. Univ. of Ireland Galway, Galway, Ireland

Abstract: Change-of-mind behaviour is considered a hallmark of cognitive flexibility. Previous perceptual decision-making studies have predominantly proposed that changes-of-mind are associated with fluctuations in noisy sensory information after the initial choice. These studies were supported by the extended drift-diffusion model (DDM) in which stimulus integration continues after the initial decision, taking into account delays in signal transduction and motor preparation (~400ms). In this work we challenge this concept by hypothesising that fluctuation in sensory evidence may not be the sole factor that contributes to changes-of-mind. In our experiment, four human participants observed a random dot kinematogram stimulus for a limited duration (800ms). In the vast majority of change-of-mind trials, hand responses were initiated only after the entire viewing duration. Furthermore, in such trials, after the initial response, the change in direction occurred later than 450ms. Importantly, such changes-of-mind, leaked into motor space, were associated with long initiation (i.e. response) times. Hence, these distinct 'signatures' strongly suggest a mechanism underlying change-of-mind behaviour that is different from sensory fluctuations after the initial choice. Such a mechanism cannot be readily accounted for by existing cognitive models, e.g. extensions of the DDM. To explain this mechanism, we

developed a biologically-motivated neuronal circuit model of decision making, in which decision uncertainty is continuously monitored through an uncertainty-monitoring cortical neuronal population. Our model without post-decision sensory evidence accumulation can account for the observed long initial response times in change-of-mind trials. Furthermore, the model revealed that long response times in change-of-mind trials are closely linked to high decision uncertainty (low decision confidence) levels. More specifically, during change-of-mind trials, high decision uncertainty leads to the appearance of a transient, choice-neutral, stable steady state that prolongs the initial decision. Such a mechanism is consistent with recent neurophysiological evidence of elevated neural activity in the frontal cortex being associated with changes-of-mind and error-correction behaviour. Taken together, our work provides a neuronal circuit computational framework that explains changes-of-mind in the absence of new post-decision evidence.

Abstract: Objective and rationale
Few study examined the conformity bias (e.g., people showing more susceptibility to negative or positive social influence, and exhibit more conformity on positive or negative evaluations). In this study, we aim to examine whether negative conformity exists and how this effect manifests in both behavioral and neural responses.
Method
Participants: 28 subjects were had normal or corrected-to-normal vision, no neurological history, and no color blinded was reported.
Task: The same as experiment 1 with 160 faces and trials in first round rating and second round rating.
EEG recoding and analysis: EEG data were recorded by a 64-channel NeuroScan system, sampled at 500 Hz/channel, with impedances lower than 5 kΩ. Traditional ERP analysis and time frequency analysis.

Results
We first confirmed a behavioral phenomenon that people showed a negative conformity bias in a value-based judgment task (present peer's ratings after their initial ratings to faces). Combined with reinforcement learning computational modeling in the first round ratings, we found the comparison of the two learning rate parameters representing positive and negative influence on norm updating showed that participants with higher update score for negative social influence than positive influence. The t-test between negative conformity score and positive conformity score indicated a significant difference, indicating a significant higher conformity score for peers-lower condition than peers-higher condition. The behavioral results indicate a bias to update ratings after more negative ratings from others in the first round ratings, and then people are more likely to adjust their rating towards negative direction in second round rating for peer-lower condition.
We also found EEG signatures (i.e., conflict-related N400 component and theta band EEG) of conformity is stronger for negative social influence direction compared with positive social influence direction. A further correlation confirmed that only theta band power for negative social influence can predict the whole social conformity to majority opinion.
Conclusions
The present investigation provide further perspective on how broadly valid it is that negative information is stronger than good. The present work also provided the temporal profile of social conflict processing as revealed by ERP (e.g., N400) and oscillation (theta band activity) patterns, which identified consistent evidence of stronger neural response to the peers-lower condition.

Title: Accumulation of evidence during decision making in obsessive-compulsive disorder patients

Authors: *Y. CHEN[1], Y. LIU[2], Q. FAN[2], T. YANG[1];
[1]Inst. of Neurosci., Shanghai, China; [2]Shanghai Mental Hlth. Ctr., Shanghai, China

Abstract: Decision making often entails the accumulation of evidence. Prior studies have suggested that the obsessive-compulsive disorder (OCD) patients' decision making differs from healthy controls. Both their compulsive behaviour and compulsive thoughts may influence the evidence accumulation process, yet the experimental investigations have been lacking. In the current study, a probabilistic categorization task paradigm has been employed to investigate the

evidence accumulation process during decision making in OCD patients. In the task, subjects made decisions by viewing a sequential presentation of visual stimuli, which were arrows of two directions at 5 different contrasts. In each trial, the stimulus sequence was generated by sampling with replacement from a pool of ten arrow stimuli, whose distribution depended on the correct answer. The subjects were asked to judge whether the overall contrast of the left arrows or the right arrows were higher and report their choices by pressing either the left or the right arrow key on a keyboard. Thus, each presentation of arrow stimulus furnished a piece of probabilistic evidence toward the corresponding choice with the contrast represented the strength of the evidence. Each arrow stimulus was presented for 150 ms and the subjects indicated their choices whenever they felt ready. The maximal length of stimulus sequence was 100. The subjects first took 20 practice trials and then completed a 100 trial session, which typically took less than 20 minutes. We collected data from 26 OCD patients and 23 healthy controls with matching gender, age, and education. Compared with the healthy controls, the OCD group achieved similar accuracy but at longer reaction times and with more accumulated evidence, suggesting that their decision making was less efficient. Interestingly, the anxiety level of the OCD patients, measured with the Hamilton Anxiety Scale, anti-correlated with their performance. The patients with higher HAMA scores had shorter reaction times and steeper psychometric curves, suggesting they were both more accurate and faster. These results suggested the evidence accumulation behavior of the OCD patients might be affected differently by distinguishable components of the disorder.

Title: Imposing inductive biases to solve general inference tasks in recurrent neural networks

Authors: *R. RAJALINGHAM[1], M. JAZAYERI[2];
[1]MIT, Cambridge, MA; [2]Brain and Cognitive Sci., Massachusetts Inst. of Technol. Dept. of Brain and Cognitive Sci., Cambridge, MA

Abstract: A key signature of primate intelligence is the ability to flexibly adapt to novel behavioral demands. In contrast, state-of-the-art deep neural network (DNN) models are notoriously brittle: while they can learn rich domain-specific knowledge via large labeled datasets, DNNs typically require massive amounts of training data, and often do not generalize. It has been hypothesized that the primate brain tackles the problem of generalization by making use of internal models that are capable of simulating external processes in the world. According to this hypothesis, neural network models that are optimized to simulate events and dynamics should be more adept at generalization. We sought to test this hypothesis by training recurrent neural network (RNN) models on a complex dynamic inference task reminiscent of the computer game called Pong.

The objective of the task is to control the vertical position of a paddle to intercept a ball moving across a two-dimensional frame with reflecting walls. Ball movement parameters (initial position, heading, speed) were randomly sampled on every trial. The frame additionally contained a large rectangular occluder right before the interception point such that the ball's trajectory was visible only during the first portion of the trial (prior to disappearing behind the occluder).

The RNNs received a two-dimensional subs-sampled pixel input reflecting moment-by-moment stimuli within the frame, and was trained to generate an output that controlled the vertical position of the paddle. As a first step, we verified that RNNs can learn to simulate the causal structure of this world: RNNs trained to predict key latent variables (ball position x,y) successfully generalized to held-out conditions. Next, we trained RNNs to solve the inference task, i.e. to predict the correct paddle position in order to intercept the ball. RNNs that were jointly optimized to represent the latent variables and intercept the ball could successfully solve this task, generalizing to held-out conditions. In contrast, RNNs that were only optimized for interception were unable to generalize. In other words, imposing an inductive bias mimicking mental simulation of the ball in RNNs was critical to solve this inference task. Finally, comparison of the behavior of RNNs to that of human subjects revealed a quantitative similarity between human and model error patterns. Taken together, these results suggest that imposing suitable inductive biases in RNNs may help uncover how the primate brain implements generalizable internal models.

Title: Rapid confidence-based hierarchical and counterfactual reasoning in humans

Authors: *M. RAMADAN[1], M. JAZAYERI[1,2];
[1]Brain and Cognitive Sci., Massachusetts Inst. of Technol. Dept. of Brain and Cognitive Sci., Cambridge, MA; [2]McGovern Inst. for Brain Res., Cambridge, MA

Abstract: A defining feature of human cognition is the capacity to process information hierarchically. This is evident in a wide range cognitive tasks such as language processing and intuitive physics. Recent experiments have used multi-stage decision-making tasks to highlight the role of confidence in hierarchical reasoning. Here, we used a novel task demanding multiple rapid and hierarchically organized decisions to further characterize the computational role of confidence in hierarchical and counterfactual reasoning.
Subjects had to track a ball mentally as it moved behind multiple occluded segments of an H-shaped maze (H-maze). At the beginning of each trial, the ball moved visibly down a vertical path towards its intersection with the horizontal segment of the H-maze. Immediately after reaching the H-maze, the ball was made invisible and changed direction toward the left- or right-end of the horizontal segment. After reaching the second branching point, the ball changed direction and moved toward the top or bottom of the vertical segment. After reaching one end of the vertical segment, subjects were asked to choose the point from which they thought the ball would exit the H-maze. To help subjects track the invisible ball, we played three auditory cues, one when the ball reached the horizontal segment, one when it reached the vertical segment, and one when the ball exited the H-maze. To create a challenging inference task, we varied the lengths of the three segments of the H-maze and the speed of the ball on a trial-by-trial basis. To perform the task, subjects had to use the geometry of the H-maze to choose the composite path that was most consistent with the intervals between consecutive auditory cues. Subjects received a binary feedback at the end of each trial.
We analyzed responses in relation to three models, one that relied on joint probabilities over multiple segments (i.e., not hierarchical), one that reasoned hierarchically, and one that used both hierarchical and counterfactual reasoning. Results provided strong evidence for the third model: subjects inferred the position of the ball hierarchically and used their confidence to consider counterfactual possibilities. Consistent with these finding, subjects' reaction times were significantly longer when counterfactual reasoning was warranted. Finally, eye-tracking data both during the ball movement and after the binary feedback exposed the dynamics of subjects' hierarchical and counterfactual reasoning on a trial-by-trial basis. Together, our behavioral and modeling results provide a quantitative account of the role of confidence in hierarchical and counterfactual reasoning during cognitive inference.

Title: The role of information lifespan and rate of information flow on decision making

Authors: *Y.-J. LIU, S.-W. WU;
Inst. of Neuroscience, Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: In many decisions we face, collecting more information is beneficial but comes at a cost of time and energy that can otherwise be spent on alternative actions that are equally – if not more – rewarding. Previously, we had shown that people tend to collect less information than they should in a task where information accumulates over time while the size of potential reward for making a correct decision decreases over time. It remains unclear, however, why people exhibit such suboptimal behavior. In this study, using the same task, we investigated two potential causes of suboptimality – information lifespan and rate of information flow.
Method. We examined the role of information lifespan by manipulating the amount of time a piece of information, once presented, stayed on the computer screen (0.2 sec, 0.5 sec, 2 sec and "always on"), while controlling for rate of information flow (20 Hz). We examined the rate of information flow by manipulating how fast a new piece of information is presented – 10 Hz, 20 Hz and 30 Hz – while controlling for information lifespan (always on). As a result, there were 6 conditions, with each condition having 20 participants in a between-subject design.
Results. We replicated previous findings by showing that subjects collected less information than they should have. Rate of information flow did not affect this pattern of suboptimal behavior, but information lifespan did – the shorter a piece of information stayed on the screen, the longer the subjects waited to collecting more information. This suggests that increasing the cost of integrating information over time, elicited by decreasing information lifespan, may promote optimal information collection in decision making.

Title: Dynamic value biases in decision making under time pressure

Authors: *E. A. CORBETT[1], A. MARTINEZ RODRIGUEZ[2], L. SPENCE[1], C. JUDD[1], R. G. O'CONNELL[1], S. KELLY[3];
[1]Trinity Col. Inst. of Neurosci., Trinity Col. Dublin, Dublin, Ireland; [3]Sch. of Electrical and Electronic Engin., [2]Univ. Col. Dublin, Dublin, Ireland

Abstract: In sequential sampling models, value biases in perceptual decisions are usually explained by a shift in starting point (SP) of evidence accumulation. In recent work, additional dynamic biases were needed to explain both behaviour and electrophysiology (EEG) in rapid colour discrimination (Afacan-Seref et al., 2018). Their data were well-described by a model with biases exerted on sensory evidence that increases over time, allowing the accumulator to shift from value to evidence driven over the course of the decision. Here we examined the role of drift rate (DR) and SP biases in a broader range of contexts to see if the findings generalized beyond perceptually easy rapid discrimination. We varied the difficulty of random dot motion direction discrimination in 3 conditions (high coherence, 365ms deadline; low coherence 475ms deadline; interleaved low and high coherence, 475ms deadline). We recorded EEG from 14 participants who were asked to maximise points when the value of each direction (30/10) was cued on a trial-by-trial basis. Responses were significantly faster and more accurate for high value trials (a, all $p<.03$).
We compared average BIC for several models with DR and SP biases and static or increasing evidence for each condition (b, models 1-8). Using Monte-Carlo simulations we minimized the G^2 between the simulated and real response time quantiles for correct and error high and low value trials. As in the colour task, the high-coherence data were best fit by models with increasing evidence. However, this may not be an appropriate model of sensory evidence in longer-timescale decisions, and the low-coherence condition was best fit by a model with static evidence and a biased variable SP. We then tested an alternative mechanism for the shift from value to evidence-driven accumulation—biased dynamic urgency initiated before evidence accumulation (with onset time free to vary). Such a model effectively incorporates both types of bias and provided the best fit of the data across all conditions (model 9). Future work will consider the electrophysiology in parallel with modelling results.

Title: Relationship between obesity dieting success and measures of decision-making

Authors: K. ALSTATT[1], T. HUYNH[1], A. O'DONOVAN[2,3,4], S. V. ABRAM[5], ***N. C. SCHMITZER-TORBERT**[1];

Cent, Univ. of California San Francisco, San Francisco, CA

Abstract: Obesity is associated with increased discounting of future monetary rewards, suggesting that altered decision-making may contribute to the risk for obesity. Here we examined the relationship between measures of decision-making, obesity and dieting success using an online sample (Amazon's Mechanical Turk service) and an undergraduate male sample. Participants completed monetary or food-based delay-discounting surveys, and a set of experiential foraging tasks (the Movie Row and Candy Row tasks). Rodent versions of the foraging tasks have also been used to demonstrate specific deficits in decision-making in drug-abstinent mice. In the foraging tasks (Movie Row and Candy Row), participants navigated

through a 3D virtual environment on a square track. Rewards (4-sec video clips displayed on a virtual movie screens in the Movie Row task or candy/snacks delivered to magazine for the Candy Row task) were available from four zones on the track. Only a subset of undergraduates completed the Candy Row task. As participants arrived at a zone, the reward category and a random delay were presented. Participants could accept the offer or move on to the next reward site. Behavior on the Candy Row task (using physical rewards) was similar to that of the Movie Row tasks (using videos as rewards), suggesting that these two versions of the task were sensitive to individual differences in rewards. Performance on the monetary and food-based versions of the delay-discounting measure were also positively correlated, but delay discounting measures were not well related to measures from the foraging tasks.
Obesity (determined from self-reported weight and height) was not related to delay discounting measures (k) for money or food, or to the number of rewards earned on the foraging tasks and delay thresholds (how long participants were willing to wait for a reward). Exploratory analyses found that obesity was associated with reduced regret on the Movie Row task. Self-reported change in body mass index (BMI) over the previous year was related to reported use of several dieting strategies (such as attempting to consume less food, avoiding carbohydrates), but not to measures of delay-discounting. However, several dieting strategies interacted with the discounting rate (k). Among participants who reported that they had attempted to eat less food to manage their weight, only participants with low discounting rates showed a reduction in BMI, while for participants who did not report using this strategy, there was no relationship between k and changes in BMI. These results suggest that obesity and dieting success may be related to several different disruptions in decision-making systems.

Title: Long term effects of nucleus accumbens deep brain stimulation reveal a causal contribution of ventral striatum to human self control

Authors: *B. J. WAGNER[1], C. B. SCHÜLLER[2], T. SCHÜLLER[2], J. BALDERMANN[2], D. HUYS[2], J. PETERS[3], J. KÜHN[2];
[1]Univ. of Cologne, Dept. of Psychology, Biol. Psychology, Cologne, Germany; [2]Univ. of Cologne, Med. Faculaty, Dept. of Psychiatry and Psychotherapy, Cologne, Germany; [3]Univ. of Cologne, Dept. of Psychology, Biol. Psychology, Cologne, Germany

Abstract: Multiple neural systems contribute to self-control in humans (Peters & Büchel 2011) including prefrontal networks involved in cognitive control, and regions of the mesolimbic and mesocortical dopamine system. Early studies on self-control mechanisms focused on characterizing potentially dissociable striatal and prefrontal value signals during inter-temporal choice (Kable and Glimcher 2007) a core behavioral maker of self-control impairments with high long-term stability (Kirby 2009). This debate has ultimately led to a revised view of self-control, according to which (lateral) pre frontal cortex (PFC) exerts top-down control over ventromedial PFC in support of self-controlled choices (Hare et al. 2009; Figner et al. 2010). However, despite the findings of that both striatal reward responses and cortico-striatal connectivity are robustly associated with temporal discounting in cross-sectional analyses, this model is largely silent with respect to the unique contribution of the ventral striatum. We directly addressed this issue by capitalizing on a rare opportunity to longitudinally follow n=7 patients who underwent deep brain stimulation (DBS) to nucleus accumbens for treatment-resistant obsessive-compulsive disorder (OCD). Patients underwent a standard delay discounting paradigm prior to-, after 6 months of continuous DBS and when DBS was turned off for one week. We analyzed subjects' choices using a hierarchical Bayesian modelling approach that accounts for the within-design of the data via JAGS (Plummer, 2003). 5 out of 7 patients showed increased choice impulsivity after 6 months of continuous DBS. Effects were quantified by examining the 95% highest density intervals of each patient's discount-parameter as well as of the corresponding hyperparameter distributions of all three conditions. Our results indicate a unique contribution of the ventral striatum to choice impulsivity in the face of reward availability.

Title: The dynamics of explore-exploit decisions reveals a signal-to-noise mechanism for random exploration

Authors: *S. F. FENG[1], S. WANG[2], S. C. ZARNESCU[2], R. C. WILSON[2];
[1]Khalifa Univ. of Sci. and Technol., Abu Dhabi, United Arab Emirates; [2]The Univ. of Arizona, Tucson, AZ

Abstract: When choosing classes for college, should you exploit the Psychology class you are sure to ace, or explore the Photography class you know less about? Exploiting the Psych class is the way to a 4.0, but exploring Photography could be the path to a better life. As with choosing classes in college, making optimal explore-exploit decisions is hard --- explore too much and you'll never major in anything, exploit too much and you might end up on the wrong path. This difficulty arises from the fundamental computational properties of explore-exploit problems: to make an optimal decision we need to consider all possible futures out to some time horizon, but simulating and optimizing over all possible futures is beyond what any brain can do. Work in machine learning has identified a number of heuristics that solve explore-exploit problems well in practice. These heuristics include an explicit bias for information ("directed exploration") and the randomization of choice ("random exploration"). Recent work in Psychology suggests that people actually use directed and random exploration, becoming more information seeking and more random in their responding when they have more opportunity to explore. In this work we focus on random exploration asking, in particular, how can behavioral variability be controlled by the brain? By modeling the explore-exploit choice using a drift diffusion process, we identify two distinct mechanisms by which behavioral variability could be controlled, and by fitting the diffusion model to human behavior, we determine which of these mechanisms humans actually use. More specifically, when applied to an explore-exploit choice, the drift diffusion model assumes that the decision is made by accumulating a noisy value based signal towards one of two bounds: one for explore and one for exploit. Behavioral variability can then be controlled by two different parameters: the signal-to-noise ratio of the accumulation process ("drift rate") and the separation between the decision bounds ("threshold"). By fitting humans' choices and reaction times in a popular explore-exploit task (the Horizon Task, Wilson et al. 2014) we find that while, statistically, both drift rate and threshold change as people have more opportunity to explore, numerically, it is the change in drift rate that has the main effect on random exploration. The provides evidence that random exploration is primarily driven by changes in the signal-to-noise ratio with which reward information is represented in the brain.

Title: Momentary changes in subjective feelings during conscious decision-making are explained by actual and counterfactual rewards and punishments

Authors: *L. P. SANDS, III[1], A. JIANG[2], K. T. KISHIDA[1,2,3];
[1]Neurosci. Grad. Program, [2]Physiol. and Pharmacol., [3]Neurosurg., Wake Forest Univ. Sch. of Med., Winston-Salem, NC

Abstract: What would you have done differently this week, and what might have changed as a result? Humans learn from experience by not only considering what rewards or punishments follow from their actions, but also by generating counterfactual thoughts (i.e., "what might have been") to evaluate alternative versions of past events (1). Humans compare actual and counterfactual information to improve decision-making by weighing both actual outcomes and foregone (counterfactual) actions in determining the relative values of different behavioral strategies. Recent evidence suggests that adaptive choice behavior may involve computing values of foregone actions in addition to computing values of chosen actions as predicated by temporal difference reinforcement learning (TDRL) theory (2,3). Indeed, sub-second measurements of dopamine (DA) release in human striatum (4) reveal that DA fluctuations combine reward prediction errors (RPEs) with counterfactual prediction errors (3), which represent how much better or worse an outcome could have been. This superposition of "actual" and "possible" outcomes is consistent with how humans should "feel" about their actions - "missing out" on an experience may elicit a sense of relief or regret depending on the outcome of the event in question. It remains unknown how humans combine actual and counterfactual rewards and punishments when evaluating their momentary subjective experience. To this end, human participants (n=51) completed a two-choice probabilistic reward/punishment task while reporting how they felt about recent outcomes. We employed a TDRL algorithm (Q-learning, 5) to model the series of participants' actions and outcomes to determine how participants assign value to different choices available in the task. We used these learned action values to construct a set of models that assessed the influence of actual and counterfactual rewards and punishments on self-reported feelings. Scoring the models across subjects by their Bayesian Information Criterion (BIC, 6) revealed that momentary changes in feelings are best explained by the combined influence of recent outcomes, expected values of chosen actions, and expected values of foregone (counterfactual) actions. In sum, our analysis shows that humans combine actual and counterfactual information when evaluating their moment-to-moment feelings, as opposed to using factual information alone. Our future directions include investigating the neural basis of counterfactual thinking and associated subjective feelings using noninvasive (fMRI and MEG) and invasive (human voltammetry) measurements of brain activity during conscious decision-making.

Title: The influence of action on explore-exploit decisions

Authors: *S. WANG, H. SADEGHIYEH, R. C. WILSON;
Univ. of Arizona, Tucson, AZ

Abstract: When deciding what to eat, will you order the pizza you always like or the new pasta on the menu? The tradeoff between exploiting the option you know and exploring new options is known as the explore-exploit dilemma. How far ahead one plans for the future, the "horizon", plays a key role in making such explore-exploit decisions. You will be more likely to try the new pasta if you know you are returning to the same restaurant again. Previous work has shown that humans can adapt the level of exploration to the horizon context (Wilson et al 2014). In this work we used a modified version of the same task to show that this horizon-adaptive exploration depends critically on how the value information is obtained.

In the original task, participants are instructed to choose between two one-armed bandits that give out random rewards from different Gaussian distributions whose means are initially unknown. Sometimes, they need to make 1 choice (short horizon) and sometimes 6 choices (long horizon). To give participants some information about the relative value of the two bandits before they make their own decisions, in the original task, participants are instructed to press the arrow keys according to a preset sequence to reveal some sample outcomes from the two bandits - these are referred to as "sample plays". After the sample plays, in their first free choice, people are more biased towards less-known option (known as directed exploration) and behave more randomly (known as random exploration) in longer horizon (Wilson et al 2014).

In our modified version, instead of actively pressing arrow keys to reveal the outcomes of the sample plays, all of the sample outcomes are presented passively to participants without key press. In this Passive condition, people show no horizon dependent directed or random exploration. This is true even if the same participant has played the Active version, i.e. the original Horizon Task, first.

To further investigate what kills the horizon-adaptive exploration in the passive condition, we performed a series follow up experiments in which: (a) the outcomes of sample plays were shown to people sequentially without a key press, and (b) outcomes of sample plays were revealed upon pressing a neutral key (space bar) instead of the arrow keys. In neither case did we find evidence for horizon-adaptive exploration. This suggests that the same information obtained by pressing the arrow keys which corresponds to the two options is registered differently than if obtained by pressing a neutral key or without key press. This work reveals a more complicated

nature of explore-exploit decisions and suggests the influence of action on how subjective utility is computed in the brain.

Abstract: Objective: Individuals with addictions are widely reported to be highly impulsive. While impulsivity is often thought of as a personality trait, this psychological construct entails many dimensions which may not all be fixed. Impulsive choice for instance, often studied via economic models of intertemporal choice, is the result of a neural value computation subject to poorly understood contextual modulation from external and internal signals. How does craving for drugs, for example, precipitate changes in decision-making that lead to reuse, relapse, and risk of overdose? Understanding how varying internal states like craving affect impulsive decision-making could be of significant clinical value. To address this, we followed a cohort of patients with Opioid Use Disorder (OUD) receiving treatment. We recorded variations in symptoms and changes in choice impulsivity with repeated sessions of a temporal discounting (TD) task. Patients also underwent the task in the fMRI scanner. This longitudinal approach allowed us to follow their dynamics in symptomatology, drug use, and impulsivity and test how these relate to neural measures.
Methods: 74 patients with OUD underwent 15 testing sessions over the course of 7 months after treatment initiation. Each session consisted of an symptomatology assessment (craving, pain, withdrawal, and anxiety), an incentive-compatible TD task (where participants chose between real immediate and delayed monetary rewards), and a drug use evaluation (by self-report and toxicology). 52 matched community controls (CC) performed similar sessions for a total of 5 visits. A subset of both OUD and CC participants performed the TD task in the fMRI scanner.
Results: Behaviorally, we found the TD task's discount rate to be more variable over time in the

OUD than in the CC group. This variability in OUD patients was in fact time-locked to changes in craving levels such that recent increases in craving (past 7 days) were predictive of increased impulsive decision-making (a steepening of the monetary discount curve.) Both craving and increased impulsivity contributed to predicting imminent opioid use events. Neurally, OUD patients with higher craving levels before the fMRI scan showed increased activity during the decision period of the TD task in a network of areas consisting of parietal association cortex and anterior insula. We hypothesize that craving, through its representation in proprioceptive and interoceptive cortex, affects decision making about future rewards. Next steps include exploring the interaction between areas like insula and subjective value representation in the ventral striatum and ventromedial prefrontal cortex.

Title: Large-scale brain oscillatory network dynamics of perceptual decision-making: An EEG study

Authors: *S. GHIMIRE, M. DHAMALA;
Georgia State Univ., Atlanta, GA

Abstract: Large-scale brain networks are believed to be involved in perceptual decision-making processes. Even though the dynamics of few brain areas in these networks are studied for their role in multi-step subprocesses, from sensory input to a perceptual decision and to a motor response, large-scale networks across the whole brain and their spatiotemporal oscillatory dynamics remain to be fully understood. In this study, using human scalp electroencephalography (EEG) recordings combined with source reconstruction techniques, we study how network oscillations functionally organizes all the Broadman areas and what temporal sequence of events in interactions occur during a face-house perceptual decision-making task. Each of these regions included multiple voxels. Single task trials of 26 participants were used to reconstruct source signals on those voxels and the singular value decomposition was used to estimate the representative orientation for dipoles in those voxels in each Broadman area. Spectral interdependency analysis showed that network oscillations in different frequency bands link many of these distributed areas during the task. Measures of network activity from the frontoparietal network were correlated with behavioural performance. These findings of whole-

brain network oscillations and timings of their peak activities broaden our understanding of the local and large-scale subprocesses leading to perceptual decisions.

Title: A Bayesian model explains intentional binding as precision-dependent, causality-based cue integration

Authors: *R. LEGASPI, T. TOYOIZUMI;
Neural Computation and Adaptation, RIKEN Ctr. for Brain Sci., Wakoshi, Japan

Abstract: Although Bayesian cue integration was proposed as a general principle behind sense of agency (SoA) (Moore & Fletcher, 2012), it was unknown if intentional binding experiments are consistent with Bayesian principles, and if indeed, the question is how. For example, it was pointed out that only indirect empirical evidence existed in support of Bayesian integration (Moore & Fletcher, 2012) and that Bayesian integration does not explain outcome binding (Wolpe et al., 2013). The fact that SoA, i.e., the feeling that we chose and intended an action that caused an external outcome (Haggard, 2017), is phenomenologically thin makes it hard to measure (Moore, 2016). However, intentional binding provides a robust implicit measure of SoA (Moore & Obhi, 2012): the time interval between an action and its sensory outcome is perceived to compress when the action is intentional and repulse when involuntary. We have introduced a Bayesian model that explains how action and outcome signals, in isolation or interacting with each other, may underlie SoA (Legaspi & Toyoizumi, SfN 2018). However, we have yet to propound specific predictions by our model on intentional binding.
Our Bayesian model accounts for the intentional binding effects reported by Haggard et al. (2002) and Wolpe et al. (2013). Specifically, our model judges the causation of the outcome by the action in both the binding and repulsion effects reported by Haggard et al. This means that causality is perceived regardless of whether the action is self-generated or unintended. However, binding happens when sensory signals are reliable (precise), hence, not by perceiving causation alone. Secondly, our model explains outcome binding in terms of cue-reliability that Wolpe et al. considered as non-Bayesian. As a consequence, our model gives two distinct testable predictions for future experiments on SoA: (1) perceptual binding or repulsion happen on a per-trial basis

and must correlate with the estimated causality between action and outcome, yielding a bimodal distribution of the perceived action-outcome interval that reflects the presence and absence of SoA, and (2) experimental manipulations that reduce the unreliability of sensory inputs would increase SoA even for unintended actions.

Title: Context effects on probability estimation

Authors: *S.-W. WU[1], W.-H. LIN[2], J. L. GARDNER[3];
[1]Natl. Yang-Ming Univ., Taipei, Taiwan; [2]Natl. Yang-Ming Univ., Taipei,Taiwan (ROC), Taiwan; [3]Psychology, Stanford Univ., Stanford, CA

Abstract: Many decisions we face rely on how we perceive potential outcomes associated with options under consideration and estimate their corresponding probabilities of occurrence. Decades of research from psychology indicate that outcome evaluation is subjective and context-dependent. However, despite its subjective nature, it remains unclear whether probability estimation is context-dependent. The purpose of this study therefore was to investigate how contexts impacts probability estimation at the behavioral and computational and neural implementation levels.
Method. In a simple stimulus-reward associative learning task, human subjects were asked to estimate probability of reward associated with visual stimuli. On each trial subjects saw a stimulus and had to estimate its probability of reward. After estimation, a feedback on whether they won a reward was provided. At the beginning of the experiment, subjects did not know the probabilities but can learn through feedback over the course of the experiment. Context was established by pairing two stimuli each carrying a unique probability of reward in a block of trials such that they appeared in random order. To investigate context effect, for a given probability of reward, we assigned two stimuli to it. These two stimuli were separately assigned to two different contexts where the reward probability of the other stimulus differed. A total of 4 behavioral experiments and one fMRI experiment were carried out so as to investigate the full dynamic range of probability.
Results. We found that probability estimation is context-dependent. Probability estimate of a

stimulus was affected by the reward probability of the other stimulus present in the same context such that it was biased away from the reward probability of the other stimulus. Further, the magnitude of such context effect appeared to be scaled by the estimated outcome uncertainty associated with the stimulus. Multivoxel pattern analysis on fMRI data revealed that dorsal anterior cingulate cortex and ventromedial prefrontal cortex – two regions implicated in uncertainty coding and valuation –represented context effect on probability estimate. Together, these results provide insights into the computational building blocks and neural mechanisms for probability estimation.

Title: Have you seen the ghost - Saccadic suppression in schizophrenia

Authors: *R. LENCER[1], I. MEYHOEFER[1], J. TRIEBSCH[2], K. SILLING[1], T. WATSON[3], M. LAPPE[2];
[1]Dept. of Psychiatry and Psychotherapy, [2]Inst. for Psychology, Univ. of Muenster WWU, Muenster, Germany; [3]Sch. of Social Scienes and Psychology, Western Sydney Univ., Sydney, Australia

Abstract: About 40% of patients with schizophrenia report discrete disturbances of visual perception, e.g. pseudo-movements of objects, which do not fulfil the criteria of hallucinations but nonetheless impact patient's well-being in daily life. One reason may be an impairment in saccadic suppression, the removal of disturbing visual input provoked by high saccade velocities up to 700°/s. Saccadic suppression can be understood as a reduction of visual sensitivity during saccades. Whether saccadic suppression is impaired in patients with schizophrenia has not been studied systematically. 17 patients with schizophrenia (mean 35.7 years) and 18 healthy controls (mean 34.2 years) performed 200 reflexive saccade trials with targets being apart by 7°. While saccades were in flight a Gabor stimulus (the "ghost") occurred for 11ms halfway (3.5°) to the target. After the saccade participants were asked to indicate whether they had seen the "ghost" by a button press. Prior to the experiment, Gabor contrasts were adjusted to 90% correct thresholds during fixation in each participant. Eye movements were recorded at 500 Hz. As expected, visual disturbances were present in patients but not in healthy controls ($p<0.01$). However, ghost detection rates were similar in both groups with saccadic suppression occurring between +/-

50ms around saccade onset, as typically observed with this task. Higher saccadic suppression rates were related to larger saccade amplitudes and shorter saccade latencies in both groups. Groups only differed on saccade amplitude, being smaller in patients (p=0.012). Patients' saccadic suppression performance was unrelated to symptom expression or dosage of antipsychotic medication. The finding of unimpaired saccadic suppression in patients bears important implications regarding basic visual information processing in schizophrenia. Saccadic suppression has been proposed to rely on the efference copy of the motor command indicating saccade onset as well as on backwards masking. Our present findings suggest both mechanisms are sufficiently intact in patients, as required for unimpaired saccadic suppression, and are unrelated to visual disturbances.

Title: Opioid antagonists are effective treatments for the symptoms of schizophrenia: A meta-analysis

Authors: *S. CLARK[1], J. VAN SNELLENBERG[2], J. M. LAWSON[3], A. ABI-DARGHAM[2]; [1]Terran Biosci. Inc, New York, NY; [2]Psychiatry & Behavioral Hlth., Stony Brook Med., Stony Brook, NY; [3]Neurosci., Columbia Univ. Med. Ctr., New York, NY

Abstract: Importance: Current treatments for the symptoms of schizophrenia, are only effective for positive symptoms in some individuals, and have considerable side effects that impact compliance. Thus, there is a need to investigate the efficacy of other compounds in treating both positive and negative symptoms. **Objective:** To conduct a meta-analysis to determine whether pan-opioid antagonists have therapeutic efficacy in patients with schizophrenia. **Data Sources:** Online databases Ovid Medline and PsychINFO, PubMed, EMBASE, Scopus, Cochrane library/CENTRAL, Web of Science, and Google Scholar from 1970 through Feb 2019, all of the bibliographies in identified trials, and a journal search. **Study Selection:** English language randomized placebo-controlled clinical trials of naloxone, naltrexone, nalmefene, and buprenorphine in patients with schizophrenia, that measured drug effects on positive, negative, or total symptoms. **Data Extraction and Synthesis:** Following PRISMA guidelines data were extracted from manuscripts with the following priority: means and SDs, test statistic (t or F), P value, means and SDs or raw data estimated from figures, an in-text description of whether the findings were statistically significant, an in-text description of the direction of effect. **Main**

Outcomes and Measures: Primary study outcomes were the within-subject change on any symptom assessment scale for positive, negative, or general symptoms of schizophrenia between active drug and placebo conditions. **Results:** Twenty nine studies were included. We found a significant effect of all drugs on total symptoms with both the random effects model: (g = 0.29; P = 0.024; k = 21) and the bootstrap effects model: (g = 0.26; P = 0.001; k = 29) and a significant effect on total scales (g = 0.25288; P < .0001; k = 18). We also observed a significant effect of all drugs on all positive scales combined with both the random effects model: (g = 0.37; P = 0.012; k = 17) and the bootstrap model (g = 0.3325; P < .0001; k = 21). **Conclusions and Relevance:** This evidence provides support for further testing in randomized clinical trials of a new class of non D2 receptor drugs, based on opioid mechanisms, for the treatment of positive and negative symptoms of schizophrenia.

Title: Perceived speed of illusory rotation for the Pinna Brelstaff Figure is linked to schizophrenia symptom severity

Authors: K. ZELJIC[1], Q. XIANG[2], Y. PAN[2], D. LIU[3], *Z. WANG[1];
[1]Inst. of Neurosci., Shanghai, China; [2]Shanghai Mental Hlth. Ctr., [3]Shanghai Key Lab. of Psychotic Disorders, Shanghai Jiao Tong Univ. Sch. of Med., Shanghai, China

Abstract: Motion perception deficits are a core perceptual impairment in schizophrenia. While their pathophysiology is unclear, psychophysical reports suggest aberrant motion integration at global rather than local processing stages, implicating extrastriate neural substrates medial superior temporal area (MST) and middle temporal area. However, to date, global motion integration in schizophrenia has only been studied using simple translational motion. Whether similar deficits exist in the integration of complex-flow motion such as real and illusory rotation is unknown. We recently showed that the Pinna-Brelstaff figure (PBF) can be physically manipulated to elicit such motion, which is encoded in MST, and can be parametrized to quantify perceptual variability in healthy subjects (Pan et al., 2016, Wang et al., 2016). Here, we use this stimulus and a modified illusion-free PBF to probe how individuals with schizophrenia perceive illusory and real complex-flow patterns. Data were collected from 102 schizophrenia patients and 90 controls, with simultaneous eye tracking also performed to monitor potential effects of eye movement on task performance. Schizophrenia symptoms were evaluated with the Positive and Negative Syndrome Scale. To quantify illusory perception strength, we use a previously validated nulling procedure in which the shift of the psychometric function corresponds to the illusory rotation induced by the expanding PBF (Luo et al., 2019). We found no significant group differences in perception of real rotation ($p>0.5$). However, perceived illusory strength was significantly lower in patients ($p<0.05$). For eye movement, patients had a significantly lower fixation count and fixation duration, and a significantly higher saccade count, although we found no effect of these on task performance. Interestingly, there was a significant effect of positive symptoms on perceived illusory strength in patients, which was mediated by angular speed of the PBF on the retina. Our preliminary results suggest that schizophrenia is characterized by alterations in global motion integration of complex illusory stimuli. Furthermore, the processes involved in this integration may be linked to those that underlie positive symptoms of this disorder.

Title: Deficits of multisensory integration in schizophrnenia and autism: Common or specific neural pathways?

Authors: M. TOYMAIAN[1], P. COVANIS[2], A. MANTAS[2], T. KARANTINOS[2], S. KAYAS[3], C. KLEIN[4], ***N. SMYRNIS**[1];
[1]Psychiatry, Natl. and Kapodistrian Univesrity of Athens Med. Sch., Athens, Greece; [2]Univ.

Mental Health, Neurosciences and Precision Med. Res. Inst. "COSTAS STEFANIS", Athens, Greece; [3]SKKA A LIFEPLAN, Athens, Greece; [4]Child and Adolescent Psychiatry, Univ. of Freiburg Med. Sch., Freiburg, Germany

Abstract: Complex decision making relies on the successful integration of sensory information from different modalities named Multi Sensory Integration (MSI). Evidence for deficits in MSI has been documented in autism spectrum disorder (ASD) and less so in schizophrenia (SZ). A target detection task with audio (A), visual (V) and audiovisual (AV) stimuli to examine the behavioural and neuropshysiological indices in MSI comparing these two neurodevelopmental disorders. 31 healthy controls (HC), 32 SZ patients and 19 ASD patients performed the task while Reaction times (RT) and scalp recorded electrophysiological (EEG) activity were measured. All groups had significantly faster RTs ($F_{2,82} = 4.33$, $p = 0.02$) and higher RT variability ($F_{2,82} = 51.9$, $p = 0.00001$) in the AV condition, with the SZ group showing the slowest reaction times ($F_{4,164} = 3.82$, $p = 0.005$) and highest reaction time variability (RTV) ($F_{4,164} = 3.39$, $p = 0.01$). We applied a novel bootstrap method to confirm the presence of true MSI for each subject. Application of this method confirmed the presence of MSI in 77% of HC, 47% of SZ patients and 16% of ASD patients ($F_{2,79} = 11.35$, $p < 0.0001$). At the neural level, we compared two auditory (N1, P2) and two visual (P1, N2) ERP's. All four components were larger in the Av compared to the corresponding A and V conditions. The control group showed significant enhancement of the auditory **N1** amplitude in the AV condition compared to the SZ group, while the N1 amplitude of the ASD group was between that of the other two groups ($F_{2,79} = 3.5$ $p = 0.03$). The auditory **P2** peak latency was faster in the AV condition compared to the A condition only for HC while patients with SZ and ASD showed the reverse effect ($F_{2,79} = 5.83$, $p = 0.004$). The visual P1 peak latency was slower for the AV condition compared to the V condition only for the ASD patient group ($F_{2,79} = 5.09$, $p = 0.008$). Importantly these effects did not correlate with the presence of MSI in all groups. These results show a complex relation of MSI deficits with sensory processing of visual and auditory stimuli in schizophrenia and autistic spectrum disorder and suggest the presence of specific neural substrates leading to MSI deficit in each disorder.

Title: Testing the brain-heart linkage in schizophrenia and obsessive compulsive disorder: The effect of cardiovascular activity on saccadic eye movement performance

Authors: M. LAZARIDI[1], P. COVANIS[2], G. PANAGIOTAROPOULOU[2], T. KARANTINOS[2], ***C. G. THELERITIS**[1], N. SMYRNIS[1];
[1]Psychiatry, Natl. and Kapodistrian Univesrity of Athens Med. Sch., Athens, Greece; [2]Univ. Mental Health, Neurosciences and Precision Med. Res. Inst. "COSTAS STEFANIS", Athens, Greece

Abstract: The neurovisceral integration model proposes a brain-heart linkage where prefrontal cortical brain areas related to executive functions are connected to midbrain areas that are responsible for the vagal control of the heart. There is evidence documenting autonomic dysregulation among patients with schizophrenia (SZ) while much less is known in patients with OCD. Both SZ and OCD patients present deficits in the inhibitory control of saccadic eye movements related to prefrontal cortical areas. The current study aims to examine the association between autonomic activity and inhibitory oculomotor control in SZ and OCD patients using indexes of heart rate variability (HRV) measured during the performance of saccade and antisaccade tasks. So far accumulated results from 10 healthy controls (HC) and 12 SZ patients confirmed the presence of a deficit in antisaccade task performance in schizophrenia (35% error rate for patients versus 15% error rate for controls, $t = 3.85$, $p < 0.001$) as well as increase in mean reaction time and reaction time variability for both voluntary saccades and antisaccades. Electrocardiographic (ECG) recordings were used in to determine autonomic activity five minutes before (baseline) and five minutes after (recovery), as well as during saccade and antisaccade task performance. RR intervals were detected in the ECG signal and used to measure indexes of sympathetic and parasympathetic activation in both time and frequency domains. Preliminary analysis of the RR intervals confirmed that lower error rate in the antisaccade task positively correlated with time domain measures of parasympathetic activation (root mean square differences between successive RR intervals $r = 0.32$, $p = 0.03$, integral of the RR interval histogram divided by the height of the histogram, $r = 0.31$, $p = 0.03$, and standard deviation perpendicular to the line of identity in Poincare plot, $r = 0.32$, $p = 0.03$) as well as frequency domain measures (high frequency component in power spectrum estimates of HRV, $r = 0.34$, $p = 0.02$). Further increase in sample size of HC and SZ patients as well as inclusion of OCD patients (currently not included in the analysis due to small sample size) will allow the investigation of the interaction of these effects with group to test the hypothesis of between HRV and cognitive control in schizophrenia and obsessive compulsive disorder.

Title: Differential effects of juvenile or adolescent stress in adult rats: Behavioral manifestation and neurophysiological correlates

Authors: *X. ZHU, A. GRACE;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Epidemiology studies overall implicate early-life stress as a risk factor for psychosis in adults. Childhood and adolescence are potential sensitive/critical periods for traumatic experiences. The present study sought to directly compare the vulnerability to the long-term consequence of stress in juvenility or adolescence.Male Sprague Dawley rats were exposed to various stress paradigms during juvenility (PD21-30), adolescence (PD30-40), and adulthood (PD65-74), including daily footshock (FS), occasional restraint stress (RS), and the combination (FS+RS). The long-term (>PD75 & >6 weeks after stress) stress consequence were assessed by (1) *in vivo* recording of dopamine (DA) neurons in the ventral tegmental area (VTA), (2) behavioral assays including elevated plus maze (EPM), novel object recognition (NOR), and amphetamine-induced hyperlocomotion (AIH). In addition, high-frequency stimulation(HFS)-induced medial prefrontal cortex (mPFC) - basolateral amygdala (BLA) circuit plasticity was assessed *in vivo* during development.Combined stress during adolescence increased DA neuron population activity in the VTA, produced persistent anxiety-like behaviors in EPM, deficits in NOR, and increased AIH. Our preliminary data suggested that similar effects were produced by juvenile FS+RS as well. Importantly, while FS or RS alone during adolescence produced long-lasting behavioral effects in NOR and EPM, adult DA-dependent AIH and DA population activity were not affected. This is distinct from that of juvenile stress, as FS alone induced a long-term increase in both DA neuron population activity and AIH, reminiscent of stress vulnerability in rats with mPFC lesion (Gomes et al., 2017). To examine whether the mPFC exerts differential control over BLA across development, HFS-induced mPFC-BLA plasticity was assessed. Preliminary data revealed that the plasticity of juvenile mPFC-BLA circuit is distinct from that of adolescence. Specifically, juvenile HFS produced a trend of increase in spike probability, whereas adolescent HFS produced an adult-like suppression of firing probability in the putative BLA projection neurons. In addition, single-pulse activation of mPFC induced differential latencies of response in the BLA, suggesting a difference in action potential propagation speed likely due to developmental myelination difference. Altogether, our results

suggest juvenile and adolescence represent distinct windows of stress vulnerability. This rapid change of behavioral/neurophysiological vulnerability is potentially mediated by progressive maturation of the mPFC to BLA circuit.

Title: Computerized social cognitive training for individuals with schizophrenia is associated with neural changes in the theory of mind network

Authors: *S. LOKEY[1,2], K. M. HAUT[3], A. LEE[2], B. GALINDO[2], S. PRIDGEN[2], A. SAXENA[2,5], M. NAHUM[6,7], C. I. HOOKER[4];

Abstract: Impaired social cognition (SC) in schizophrenia is a deficit that often persists throughout the course of the illness and is a strong predictor of everyday functioning. Functional neuroimaging studies have found that individuals with schizophrenia display lower activation during theory of mind and emotion processing tasks in social brain areas when compared to healthy controls. As a part of a randomized, double-blind, controlled trial to assess the efficacy of SocialVille, a novel, browser-playable treatment program designed to specifically address core SC deficits, we examined the effects of treatment on the underlying neural activity of theory of mind in individuals with schizophrenia. Sixty-four demographically matched participants with DSM-V diagnosis of schizophrenia participated in either SocialVille or active control games, comprising 3-5, 45-minute weekly sessions (~40 sessions) over twelve weeks. Pre- and post-training, subjects completed an untrained theory of mind fMRI task comprising reading vignettes about a person's thoughts (THO), emotions (EMO), or appearance (APP), and judging whether a subsequent action by that person would logically follow the story. Preliminary fMRI results indicate that the contrast hypothesized to be most associated with theory of mind (THO+EMO>APP), activated several regions, most strongly the anterior cingulate cortex and medial frontal gyrus. Additionally, initial whole-brain group analysis of treatment effects suggests that participants in the active training condition significantly increased activity in the

paracingulate gyrus, superior frontal gyrus, and bilateral orbitofrontal cortex, compared to baseline and compared to controls. Overall, these results demonstrate that computerized social cognitive training engages and enhances areas in the theory of mind network. This supports the potential efficacy of computerized training for social cognition deficits in individuals with schizophrenia.

Title: Increased functional coupling between VTA and hippocampus during rest in first-episode psychosis

Authors: *D. F. GREGORY[1], M. JALBRZIKOWSKI[2], W. FORAN[2], D. F. MONTEZ[3], B. LUNA[2], V. P. MURTY[1];
[1]Temple Univ., Philadelphia, PA; [2]Univ. of Pittsburgh, Pittsburgh, PA; [3]Washington Univ. in St. Louis, St. Louis, MO

Abstract: The development of psychosis is associated with increases in dopamine (DA) signaling, which have been strongly linked to positive symptoms (Heinz & Schlagenhauf, 2010). This neurobiological marker is present in prodromal individuals prior to the first-episode of psychosis (FEP), suggesting that dopamine-related deficits are core to the disorder's etiology (Howes et al, 2009). Psychosis is also reliably associated with deficits in hippocampal function (van Erp et al, 2015). Animal models have shown a positive-feedback loop between hippocampus and ventral tegmental area (VTA), the source of mesolimbic DA neurons; such that hippocampus regulates tonic VTA activation which can facilitate downstream plasticity within hippocampus (Lisman & Grace, 2005). The methylazoxymethanol acetate (MAM) model, a prominent rodent model of psychosis, suggests that early hippocampal dysfunction causes dysregulation of tonic VTA signaling (Lodge & Grace, 2011). These neurobiological deficits are thought to underlie the positive symptoms seen in psychosis. However, in psychosis, the study of hippocampal deficits and VTA signaling usually occur in isolation (but see Modinos et al, 2015). Importantly, open questions remain whether FEP individuals, who are proximal to the onset of psychosis, show deficits in VTA-hippocampal circuits. Using resting state fMRI (FEP: N=46; controls: N=32), we quantified functional coupling of extracted timeseries of VTA with right and left anterior hippocampus, respectively. We found a significant difference between groups, such that functional coupling between VTA and right anterior hippocampus was greater in FEP versus

controls ($p < 0.05$). A similar non-significant difference was found with left anterior hippocampus ($p = 0.15$). This pattern of results remained consistent when controlling for age and sex. These findings support that VTA-hippocampal circuits differ in FEP, which is consistent with predictions made by the MAM model, and could help provide a putative marker of psychosis risk. Future studies will extend these characterizations of VTA-hippocampal circuits into clinical high-risk populations.

Title: Investigation of the temporal dimension of prepulse inhibition of the acoustic startle response

Authors: M. DEBONO, N. PARENTELA, D. BITRAN, *A. C. BASU;
Col. of the Holy Cross, Worcester, MA

Abstract: Prepulse inhibition (PPI) of the acoustic startle response is a sensorimotor gating process in which the acoustic startle response is attenuated by pre-presentation of a sub-startle-threshold stimulus. PPI is disrupted in schizophrenia and autism spectrum disorders, and sex differences have been observed in both PPI and the incidence and onset of these disorders. Human and animal studies vary in the testing parameters used to assess PPI, and we believe that these differences may account for some of the inconsistency in results and conclusions drawn from these studies. The current study observes PPI in C57BL/6J mice when the prepulse is presented at 1, 5, 10, 50, 100, 500, and 2000 ms intervals preceding a startle stimulus. Our findings suggest that PPI is a threshold phenomenon with respect to inter-pulse interval, that there are no systematic sex differences in PPI across this temporal range of inter-pulse intervals, and that males may exhibit more variability than females in PPI. As such, these findings may provide insight into the neural mechanisms of PPI, as well as demonstrate a need to assess other relevant biological factors that may contribute to variability in PPI, such as litter effects and social dominance status.

Title: Machine learning approaches to characterize neurophysiological and cognitive measures predictive of schizophrenia diagnosis

Authors: *J. KNICKREHM[1], R. KIM[1], C. LAINSCSEK[1,2], A. L. SAMPSON[1], R. C. GUR[3,4], R. E. GUR[3], T. COGS INVESTIGATORS[5], T. J. SEJNOWSKI[1,2,6], G. A. LIGHT[5,7];

Abstract: Background: Schizophrenia (SZ) is a debilitating and heterogeneous neuropsychiatric disorder that affects multiple domains of neurophysiologic and cognitive functioning. Although SZ patients have robust impairments across domains, it is not clear which measures are optimally sensitive for correctly classifying SZ patients vs. nonpsychiatric comparison (NC) subjects. Machine learning is a rapidly growing field that allows algorithms to learn and extract salient features from data. The proposed study applied machine learning techniques to a large dataset of SZ and NC participants in order to identify measures that maximally discriminate groups. Methods :The Consortium on the Genetics of Schizophrenia (COGS-2), the largest of its kind, is a multi-center study that assessed Mismatch negativity (MMN) and P3a event related potential amplitudes and the Penn Computerized Neurocognitive Battery (CNB) measures in 877 SZ and 753 NC participants. Cognitive domains included executive control, episodic memory, complex cognition and social cognition. Elastic net regularized regression was first applied to the dataset to identify a subset of the measures most important for classifying SZ participants from NC participants. A multi-layer perceptron (MLP) model was then employed using the identified

features to evaluate classification performance.
Results: The elastic net regularized regression model revealed MMN and P3a as well as CNB measures of working memory (verbal and spatial working memory), executive control (mental flexibility and attention), and complex cognition (spatial ability and emotion identification) significantly contributed to classification. Using these features, an MLP model achieved a high classification accuracy (78.3%; average across 10-fold cross validation accuracy values).
Conclusions: Machine learning approaches identified an optimal set of neurophysiological and neurocognitive measures for identifying participants diagnosed with schizophrenia. Applying similar approaches to other modalities of data, such as imaging and genetic data, could help develop potential biomarker candidates for complex and heterogeneous psychiatric disorders.

Title: Mismatch negativity deficits in individuals at clinical high risk for psychosis

Authors: *R. B. SHAIK[1], M. A. PARVAZ[1], Z. BILGRAMI[1], C. SARAC[1], C. BENAVIDES MARTINEZ[1], J. LOPEZ CALDERON[2], C. CORCORAN[1];
[1]Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Industrial Engin., Facultad de Ingeniería, Univ. Autónoma de Chile, Talca, Talca, Chile

Abstract: BACKGROUND: Sensory processing deficits are core features of schizophrenia, reflected in impaired generation of event-related potential (ERP) measures such as auditory mismatch negativity (MMN). MMN is an EEG-derived ERP elicited by deviant stimuli in an auditory oddball paradigm, and it is a robust predictor of psychosis onset in clinical high risk (CHR) cohorts. Herein, we examined auditory MMN in a clinical high risk (CHR) cohort, using a paradigm developed by DC Javitt, and assessed which MMN deviants were abnormal in CHR patients, and the association of MMN with prodromal symptom severity.
METHODS: Participants included fifteen CHR participants and 9 healthy controls (HC), who completed an auditory MMN paradigm with deviants in duration, frequency, intensity, frequency modulation and “change of location”. Positive and negative symptom severity in CHR patients

were assessed using the Structured Interview for Psychosis-Risk Syndromes (SIPS).
RESULTS: In this small study, between-group independent t-tests showed significantly reduced MMN in CHR only for the duration deviant [t(22) =-2.40, p=.03]. Among CHR patients, duration MMN was associated with total positive symptom severity (r=.55, p=.03), whereas frequency modulation MMN was correlated with severity of unusual thought content/delusional ideas (SIPS P1; r=.74, p=.002). Decreased expression of emotion (SIPS N3) was correlated with frequency modulation MMN (r=.58, p=.02), increased pitch MMN (r=.55, p=.03), and decreased intensity MMN (r= .56, p= .03).
CONCLUSIONS: Data collection is ongoing. Our main finding to date is that duration MMN is significantly reduced in CHR patients, in whom it is associated with total positive symptom severity. Exploratory analyses showed that a specific negative symptom, decreased expression of emotion, was associated with a range of deviants, including frequency modulation, frequency and intensity. These findings replicate other studies that identify that duration MMN is among the most replicated biomarkers of psychosis risk.

Title: Investigating the relationship between paracingulate sulcus length and verbal source monitoring in clinical high risk for psychosis individuals

Authors: *A. LEE, S. LOKEY, K. HAUT, S. PRIDGEN, C. I. HOOKER;
Psychiatry, Rush Univ. Med. Ctr., Chicago, IL

Abstract: The paracingulate sulcus (PCS) shows considerable morphometrical variability and its absence has been associated with various forms of psychopathology. Reduced PCS length is associated with hallucinations in schizophrenia patients and with misattribution of self- vs other-generated speech in healthy individuals experiencing auditory perceptual disturbances. However, the relationship between PCS length and reality monitoring has not been examined in individuals at clinical high risk for psychosis (CHRp). This study uses a verbal source memory task to measure reality monitoring in CHR individuals with and without a PCS. We hypothesize that those with shorter or absent PCS will have impaired performance on the task compared to those with a present or prominent PCS.

55 CHR individuals were identified using the Structured Interview of Psychosis-risk Symptoms and completed a battery of clinical and cognitive measures. For the Source Memory task, subjects read a list of sentences, half of which must completed and half of which have a response provided. fMRI was acquired during a subsequent recall phase in which the subject indicates the source of each response. MPRAGE T1-weighted structural scans were also acquired and using a standardized protocol, the PCS was identified, traced, and categorized into prominent, present and absent.
Overall, participants had an 88.99% response accuracy (11.4% SD) with no significant differences between self- (88.3%) and other-generated words (89.7%) and no significant differences in reaction time. Analysis between the PCS categories showed similar accuracy rates across categories with no group differences in accuracy or reaction time. Furthermore, we found no significant relationships between task performance, PCS length, IQ or ratings of abnormal perceptual experiences.
These results suggest that individual differences in PCS morphometry may not be significantly related to the development of source monitoring impairments or perceptual abnormalities in CHR individuals. However, individuals' high accuracy on the Source Memory task suggests that the observed results may have been limited by ceiling effects. Further research may benefit from measures more sensitive to disruptions in reality monitoring early in the course of psychosis development.

Title: Increased functional connectivity of the insula during emotional face recognition in patients with schizophrenia

Authors: *S. E. PATEL[1], M. D. GREGORY[2], Y. TONG[3], D. P. EISENBERG[4], V. S. MATTAY[5,6], J. H. CALLICOTT, III[7], K. F. BERMAN[8];

Sch. of Med., Baltimore, MD; [7]DIRP, NIMH, NIH, Clin. and Translational Neurosci. Br., Bethesda, MD; [8]Clin. and Translational Neurosci. Br., NIH/National Inst. of Mental Hlth., Bethesda, MD

Abstract: Introduction Patients with schizophrenia (SZ) struggle with emotional face recognition. Although default mode network hypoconnectivity (Gohari et al., 2017) during facial emotion discrimination as well as altered insular connectivity to the salience network (Pang et al., 2017, Mikolas et al., 2016, Manoliu et al., 2013) in SZ have been reported, functional connectivity of the insula during recognition of faces showing emotion has not been explored in this population. **Methods** Here, we used an independently-derived insula parcellation to test whether SZ patients exhibit altered insular connectivity during recognition of faces showing emotion. 3T BOLD fMRI data were acquired during an emotional face matching task in 208 SZ patients (mean age 31.5+/-9.8, 147 males; 97%+/-7.4 task accuracy) and 766 healthy volunteers ([HVs], mean age 31.0+/-9.2, 322 males; 99%+/-3.1 accuracy). Using a two-cluster insula parcellation independently derived from multimodal neuroimaging data (Kelly et al., 2012), pathophysiological interactions (PPIs) of the anterior and posterior insula with facial emotion viewing were compared between patients and HVs, controlling for age, sex, task accuracy, and reaction time. **Results** Patients exhibited hyperconnectivity of the right anterior insula with the left orbitofrontal cortex, midcingulate cortex, and ventral striatum as well as of the right posterior insula with bilateral amygdalae, bilateral orbitofrontal cortices, left frontal operculum, and left DLPFC ($p<0.05$, FDR-corrected). Functional connectivity of left insula regions did not reach significance after FDR-correction but showed trend-level ($p<0.001$) hyperconnectivity patterns that were similar to findings in the right insula. For all regions, HVs exhibited anticorrelation with the insular seed regions while SZ patients showed positive connectivity with each region ($p's<0.05$, FDR corrected). No regions showed insular hypoconnectivity in SZ. **Conclusion** Here, we show that while matching emotional faces, SZ patients have abnormally increased functional connectivity between the insula and several regions involved in emotion processing. While we controlled for task accuracy, further investigation of whether such insular hyperconnectivity helps or hinders task performance within the SZ population may clarify the meaning of this aberrant connectivity pattern.

Title: Task-specific disruptions in theta oscillations associated with impaired working memory for temporal order in people with schizophrenia

Authors: *X. L. LIU[1,2], L.-T. HSIEH[1], M. HURTADO[1], C. RANGANATH[1], T. A. NIENDAM[1], T. A. LESH[1], C. S. CARTER[1], J. D. RAGLAND[1];
[1]Univ. of California, Davis, Davis, CA; [2]Xiamen Univ., Xiamen, China

Abstract: People with schizophrenia (SZ) have marked deficits in working memory (WM) that contribute to impairments in other cognitive domains and relate to poor functional outcomes. Previous research demonstrated that people with SZ are most impaired at WM tasks that require processing of, and memory for, relationships between items, such as temporal order. The goal of this study was to utilize EEG to examine the impact of SZ on frontal theta oscillations (4-7 Hz) during WM maintenance and its association with deficits in WM for temporal order. EEG data were acquired on 50 people with schizophrenia (SZ) and 61 demographically matched healthy controls (HC) while participants performed two WM tasks. Data were excluded for 7 SZ and 4 HC due to persistent artifacts or below chance performance, leaving a final sample of 43 SZ and 57 HC. On each trial, participants viewed 4 sequential fractal images and, after a 3000 ms delay, a test screen was shown. On “Order” trials they were shown two items from the memory set and they were to select the more recently presented item. On “Item” trials, they were shown one new item and one item from the memory set and asked to select the previously studied item. EEG analyses revealed that oscillatory power in the alpha (9-11 Hz) power was generally reduced in SZ, whereas SZ disruptions in theta (4-7 Hz) power were specific to Order trials. In addition to reduced theta power on Order trials, SZ also showed an altered relationship between theta oscillations and performance on the order task, such that stronger theta band activity predicted higher accuracy in the order task in HC, but not in SZ. These results suggest that reduced theta oscillations and disrupted brain-behavioral relationships during WM maintenance of temporal order are a candidate mechanism for temporal order WM deficits in people with SZ.

Title: Subjective language aptitude is linked to neural activity in Broca's area, but not to objective performance during a semantic priming task

Authors: *F. S. ZENGAFFINEN[1], S. FURGER[1], A. STAHNKE[1], A. FEDERSPIEL[1], T. KOENIG[1], K. STEGMAYER[1], S. WALTHER[1], R. WIEST[2], W. STRIK[1], T. DIERKS[1], Y. MORISHIMA[1];
[1]Translational Res. Ctr., Univ. Hosp. of Psychiatry and Psychotherapy, Bern, Switzerland; [2]Univ. Inst. of Diagnos. and Interventional Neuroradiology, Inselspital, Univ. of Bern, Bern, Switzerland

Abstract: Language, including speech and thought, is often affected in mental illnesses. In psychosis, the dimension of language symptoms shows a great variability between patients. A dimensional approach allows to study language as continuum from health to psychosis. Therefore, in the current study, we investigated the heterogeneity of a healthy population during a language task, additionally to a subjective rating of one’s language aptitude. The aim was to analyze the spectrum of inter-individual differences and its association with language-related brain networks, specifically Broca’s area. The observed heterogeneity in the healthy group would enable an extrapolation to clinical end of the spectrum. To this end, 102 healthy adult subjects performed a lexical priming task while measuring brain activity with fMRI. Subjects had to indicate whether a visually presented target word would form the generic term of a previously shown prime word, in terms of its category (e.g. Apple - Fruit) or its relation (e.g. Apple - Pear). To see the difference in language aptitude, we asked the participants to rate on 7-point Likert scale, how they thought their language abilities are. According to the rating they were then grouped into high, mid or low language aptitude groups. Although reaction time (RT) and accuracy showed no significant differences between all three groups, we found differences in brain activation in BA45 among the language aptitude groups. We looked at activation in the Broca areas (BA45, BA44) during preparation (waiting for the target after the indication of task type) and processing (target word processing) phases. We found differences between the groups in BA45 during the preparation and processing phases. The Post hoc analysis revealed that the high group showed significantly greater activation in BA45 compared to the low group, while there was no significant difference between the groups in BA 44. Furthermore, the RT was correlated with activation of BA 45 in the high language aptitude group during the preparation phase, indicating that increased activation in BA45 reflects faster responses in the high language aptitude group. Moreover, for the other two groups correlations with RT were found in BA44.

These results show that, according to subjective evaluation of their own language aptitude, one differently utilizes the language-related brain areas during the language task. These insights into the dimension of language is facilitating upcoming research, that compares these healthy population profiles to the profiles of a population with psychosis.

Title: Posterior striatal dopamine infusion increases striatal and auditory cortical Fos expression to a greater extent in proestrus than in metestrus female rats

Authors: T. J. ZAFAR[1], Z. YELLOWMAN[1], E. M. NIKULINA[1], *R. P. HAMMER, Jr.[2]; [1]BMS, Clin. Translational Sci., [2]BMS, Psychiatry, Clin. Translational Sci., Univ. of Arizona Col. of Med., Phoenix, AZ

Abstract: Brain mechanisms underlying the complex symptoms of schizophrenia are unknown, but the most supported theory involves excessive dopamine stimulation. For example, all major medications that treat schizophrenia symptoms, such as hallucinations, block D_2-like dopamine receptors in the brain. We have shown that the pattern of cortical activity resulting from a targeted infusion of dopamine into the posterior striatum of male rats resembles the pattern produced in response to auditory stimulation. Our recent studies suggest that females may be more sensitive to dopamine during proestrus. Therefore, we examined the effect of striatal dopamine infusion on Fos expression in female rats across the estrous cycle. We hypothesized that Fos expression would be enhanced by dopamine infusion in females during proestrus/estrus compared to metestrus/diestrus. Adult female Sprague Dawley rats were housed in reverse light-dark conditions (lights on 0900). Stereotaxic surgery was used to place unilateral guide cannulas, and vaginal smears were conducted to determine the estrous stage. Rats then received dopamine (50 nM) or saline vehicle through an infusion cannula targeting the posterior caudatoputamen (CP; AP: -1.80 mm, ML: 4.4 mm, and DV: 5.0 mm) at 0.2 µl/min for 5 min. Immediately thereafter, rats were placed into a sound-attenuated chamber with 75 dB background noise for 90 min. Twenty µm brain sections were collected for immunohistochemistry, and regional Fos labeling density was quantified in striatum and auditory cortex. Dopamine significantly increased Fos labeling in CP during both proestrus/estrus ($p< 0.01$) and metestrus/diestrus ($p < 0.01$) compared to saline infusion. Auditory cortex exhibited dopamine-induced increase of Fos

labeling compared to saline during proestrus/estrus ($p < 0.01$), but not during metestrus/diestrus. Dopamine infusion during proestrus/estrus increased Fos labeling significantly more than during metestrus/diestrus in both CP ($p < 0.01$) and auditory cortex ($p < 0.01$). Thus, dopamine infusion induced Fos labeling in the striatum, probably in direct projection neurons. Dopamine produced significantly greater Fos induction in auditory cortex during proestrus/estrus than during metestrus/diestrus. We conclude that striato-pallido-thalamo-cortical circuits affecting auditory cortex may be more sensitive to dopamine during proestrus/estrus, which could have implications for auditory symptoms in women with schizophrenia during the estrogen phase of the menstrual cycle.

Title: Neuro-behavioral multivariate markers for personalized patient segmentation, selection and treatment response prediction along the psychosis spectrum

Authors: ***J. JI**[1], M. HELMER[2], J. B. BURT[1], B. ADKINSON[1], A. KOLOBARIC[1], M. FLYNN[1], N. HILL[1], C. H. SCHLEIFER[1], Z. TAMAYO[1], A. SAVIC[4], Y. CHO[1], G. REPOVS[5], J. D. MURRAY[2], A. ANTICEVIC[3];
[2]Dept. of Psychiatry, [3]Psychiatry, [1]Yale Univ., New Haven, CT; [4]Univ. of Zagreb, Zagreb, Croatia; [5]Univ. of Ljubljana, Ljubljana, Slovenia

Abstract: One of the key challenges in psychiatry is selecting patients for effective treatments. Currently, there is no biologically-grounded framework for psychiatric diagnoses, patient segmentation or predicting a given patient's response to a treatment. While many studies of psychosis-spectrum disorders have found significant differences in behavioral or neural properties at the group level compared to healthy control cohorts, accurate inference and prediction at the single-subject level has remained a barrier for actionable personalized impact. Practically, patients with the same 'binary' DSM diagnosis exhibit a great deal of neural and behavioral heterogeneity. Understanding the mapping between specific symptoms and clinically meaningful neural variation is therefore critical to administering and developing effective individualized treatments.

Here, we build upon our prior work on the Neuro-Behavioral Relationships in Dimensional Geometric Embedding (N-BRIDGE) framework, under which behavioral variation can be mapped to variation in specific neural features in a clinically-informed manner. The neuro-behavioral (N-B) geometry was established using neural (fMRI-derived) and behavioral data from 436 psychosis-spectrum patients and 202 healthy controls. Previously we identified dimensions of behavioral variation in patients and showed that variation along these axes relate to variation in BOLD resting-state measures of global brain connectivity, revealing specific neural systems. These N-B relationships are robust and stable across sites, as well as in k-fold cross-validation, leave-one-out cross-validation, and split-half replication.
Critically, we show here that these behavioral dimensions can be used precisely predict clinically-meaningful neural variation at the individual patient level. Furthermore, we show that these predictions are robust in an independent out-of-sample dataset of patients diagnosed with schizophrenia (N=30) as well as patients with obsessive-compulsive disorder (N=39), a non-psychosis disorder. Lastly, we demonstrate how N-BRIDGE can be used to identify therapeutic targets for personalized patient-specific N-B profiles.
Using N-BRIDGE, we highlight a path for identifying molecular or behavioral targets in a neurobiologically-grounded, data-informed manner. In turn, this path allows for development of therapeutics that are rationally designed around person-specific N-B alterations. We show how multi-variate approaches like N-BRIDGE will be critical for developing rational, targeted, individualized, and maximally effective treatments for mental health symptoms.

Title: Functional connectivity changes in emotion processing network following social cognitive training in individuals with psychosis

Authors: *K. M. HAUT[1], B. GALINDO[1], A. LEE[1], S. LOKEY[2], M. NAHUM[3,4], C. I. HOOKER[1];

Abstract: Deficits in social cognition play a large role in functional impairments and disability in individuals with schizophrenia and are associated with altered activity in underlying functional networks. Cognitive training on abilities that support social cognition, such as emotion recognition, may improve these deficits. This study assesses changes in social cognitive functional networks following targeted cognitive training in individuals with schizophrenia. 52 individuals with schizophrenia spectrum disorders underwent a clinical evaluation and a functional MRI session prior to and subsequent to completing 40 hours (over ~8 weeks) of either targeted social cognitive training using SocialVille (brainhq.com)(N=27) or a computer game control condition (N=25). Resting state fMRI was acquired as well as fMRI during performance of an emotion recognition task and changes in emotion processing network activation and functional connectivity was evaluated. Individuals who received social cognitive training showed improved accuracy of emotion recognition compared to those in the control condition ($t(50)=2.16$, $p=.036$). Training was associated with altered activity within the emotion processing network, including the amygdala and superior temporal sulcus (STS). In addition, altered STS-medial prefrontal connectivity, amydala-orbitofrontal connectivity and amygdala-insula connectivity was found. These results suggest that targeted social cognitive training may be effective in altering functional network connectivity in networks associated with deficits in individuals with psychosis and may be a useful tool for intervention in individuals with psychotic disorders.

Title: Caudate connectivity and antipsychotic medication dose in psychosis patients

Authors: *E. HERMS[1], J. BISHOP[2], J. WREN-JARVIS[3], V. OKUNEYE[3], M. KESHAVAN[5], C. A. TAMMINGA[6], G. PEARLSON[7], J. SWEENEY[8], S. KEEDY[4];
[1]The Univ. of Chicago, Chicago, IL; [2]Univ. of Minnesota, Minneapolis, MN; [4]Psychiatry and Behavioral Neurosci., [3]Univ. of Chicago, Chicago, IL; [5]Harvard Med. Sch., Boston, MA; [6]Univ. of Texas Southwestern Med. Ctr. at Dallas, Dallas, TX; [7]Yale Sch. of Med., New Haven, CT; [8]Univ. of Cincinnati, Cincinnati, OH

Abstract: Background:
Antipsychotic medication influences resting brain network function as measured in fMRI studies. However, the influence of antipsychotic medication on brain function often is not examined directly, especially in studies of subjects taking different antipsychotic medications. Instead, antipsychotic medication is treated as an unexamined covariate, quantified via chlorpromazine dose equivalence estimates (CPZ). The current study aims to identify brain function effects associated with this common medication quantification approach. We focused our assessment on connectivity of the caudate; given this structure is a site of direct antipsychotic medication effect associated with efficacy at reducing psychosis symptoms.
Method:
We assessed connectivity in resting state functional MRI data collected from a subsample of participants of the multisite Bipolar Schizophrenia Network on Intermediate Phenotypes (BSNIP1) study. The subsample was selected for having adequate antipsychotic dose information available for CPZ calculation and for having fMRI data that passed stringent quality assessment criteria. The final sample included those diagnosed with schizophrenia (n = 82), schizoaffective disorder (n = 77), or bipolar disorder with psychosis (n = 91), and healthy controls (n = 173). Using the CONN toolbox, a bilateral caudate seed was used to generate connectivity maps for each subject. These connectivity maps were used in a whole brain regression analyses with CPZ, covarying for age, sex, and study site.

Results:
Higher antipsychotic dose was associated with greater connectivity of the caudate to the precuneus (cluster size = 286 mm^3, p= 0.0002) voxel threshold criteria of p<.001 uncorrected, and a cluster threshold of p <0.05 FWE.

Discussion:
We found that higher antipsychotic medication doses associated with greater connectivity between caudate and precuneus. The precuneus is a node of the default mode network (DMN), which has been reported to be altered in schizophrenia and other psychotic disorders. Specifically, greater connectivity has been found between DMN nodes including precuneus in schizophrenia compared to controls and to first degree relatives. Our findings suggest that such neural system alterations may be equally due to antipsychotic medication as well as illness effects. Future work will include assessments of alternative CPZ estimates and other metrics of resting state fMRI.

Title: Increased entropy of microstate sequences in first episode psychosis

Authors: *M. MURPHY, D. ÖNGÜR;
Harvard Med. Sch., Boston, MA

Abstract: Psychosis is commonly thought to be related to dysconnectivity between regions of the brain. We used microstate analysis to compress resting state high-density (hd-EEG) data from patients with first-episode psychosis and healthy controls into sequences of characteristic scalp topographies. We found that patients and controls produced similar sets of four microstates that agree with a canonical set of microstates widely reported in the literature. We found that microstate A was decreased in patients compared to controls. We then used sample entropy to calculate the complexity of the microstate sequences across a range of template lengths. For a

given template length *m*, the sample entropy is a measure of how likely two identical sequences of length will not be identical at length *m* + 1. We found that in controls, sample entropy decreased as template length increased, suggesting that control resting state data is self-similar. In patients, we found that sample entropy did not decrease. We show that this finding is unrelated to the length of the data or the topography of the microstates. We show that entropy is elevated in unmedicated patients and decreases with medication dosage. We also identify patterns of transitions between microstates that are overrepresented in control data and in patient data. Given previous work that has linked microstates with resting state networks, our findings suggest that, in addition to any disruption within brain networks, transitions between networks are abnormally chaotic in patients with first-episode psychosis.

Title: Non-parametric hyperdimensional analysis of multiscale phenotypic factors in intact cerebral organoids

Authors: ***J. SWANEY**[1], A. ALBANESE[2], D. YUN[2], N. EVANS[3], L. KAMENTSKY[4], M. KIM[4], C. SOHN[4], J. ANTONUCCI-JOHNSON[4], V. PHAM[4], C. DELEPINE[5], M. SUR[5], L. GEHRKE[4], K. CHUNG[5];

Abstract: Cerebral organoids are the most complex *in vitro* model of the developing human brain to date. At the single-cell level, cerebral organoids contain diverse cell populations with distinct expression patterns, and at the tissue level, cytoarchitectures observed during human cortical development begin to emerge. However, current techniques used to characterize cerebral organoids do not scale across these different length scales. Here, we present a tissue processing pipeline for whole-organoid antibody labeling and imaging as well as a computational framework for extracting and analyzing multiscale phenotypic factors from these images. SHIELD tissue processing preserves protein epitopes, mRNA, and endogenous fluorescence in

intact cerebral organoids and produces optically transparent samples that can be imaged using light-sheet microscopy. The computational framework segments all nuclei using a curvature-based seeded watershed algorithm and classifies cell types based on the mean fluorescence intensity of each cell type marker. The spatial proximity to progenitor cells (SOX2) and post-mitotic neurons (TBR1) revealed four distinct cellular niches within cerebral organoids cultured for 35 days. A clustering analysis of radial cell profiles identified five types of cortical cytoarchitectures corresponding to different layering patterns of progenitor cells and post-mitotic neurons. By concatenating descriptors of single-cells, cortical cytoarchitectures, and whole-organoid morphology, a hyperdimensional feature vector of multiscale phenotypic factors was constructed for each organoid. Correlation analysis between multiscale phenotypic factors quantified the interscale relationships between cerebral organoids cultured for 35 and 60 days. Permutation testing revealed differences in phenotypic factors corresponding to deficits in cortical development in cerebral organoid models of Zika virus and Rett syndrome. These results demonstrate how phenotypic factors observed from the single-cell level to the tissue level can be integrated into a single, unbiased analysis of intact cerebral organoids.

Title: An engram index permits brain-wide mapping of a specific memory

Authors: D. S. ROY[1], ***Y.-G. PARK**[1], S. K. OGAWA[1], J. CHO[1], H. CHOI[1], J. MARTIN[1], K. CHUNG[2,1], S. TONEGAWA[1,2];
[1]The Picower Inst. for Learning and Memory, [2]Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Neuronal ensembles that hold specific memory information (memory engrams) have been identified in the hippocampus, amygdala, and multiple cortical areas. It has been suggested that the engram for a specific memory is distributed among multiple brain regions that are functionally connected. Here, we generated a brain-wide putative engram cell ensemble map of 409 regions in contextual fear memory by applying activity-dependent cell labeling, optogenetics, and SHIELD-based tissue clearing. To circumvent the laborious optogenetic demonstration of engram cells, we devised an "engram index" based on the notion that memory engram cells are activated during learning and reactivated during recall, and applied it to rank-order the list of c-Fos$^+$ neuronal ensembles. We then subjected the high rankers to the established optogenetic procedures, which confirmed the previously demonstrated engram cell ensembles as well as revealed new engrams in thalamic nuclei. Crucially, optogenetic reactivation of not all c-Fos$^+$ neuronal ensembles resulted in memory retrieval, suggesting that these ensembles do not carry engrams for this memory. We also show that the engram cell ensembles reactivated by natural recall cues match well with those reactivated by optogenetics. Further, optogenetic reactivation of CA1 or BLA engram cells caused a pattern of increased activation of engram cell ensembles (both demonstrated and putative) in multiple brain regions, indicating functional connectivity of these ensembles. Finally, simultaneous chemogenetic reactivation of multiple engram cell ensembles, which mimics better the natural process of memory recall, resulted in a greater level of recall than a single engram ensemble reactivation. Overall, our study supports the hypothesis that a memory is stored in a specific pathway of multiple engram cell ensembles.

Title: Multiplexed organ-wide mapping of biomolecules using oligonucleotide labeling

Authors: *C. H. SOHN[1,2], Y. TIAN[3,2], M. E. KIM[1,2], N. P. TOWNSEND HASS[3,2], L. DELORENZO[1,2], K. CHUNG[1,2,3,4];

Abstract: Investigating biomolecules at cellular levels within the spatial context is key for understanding the brain function and dysfunction. Immuno-fluorescence (IF) staining and fluorescence *in situ* hybridization (FISH) of multiple targets are invaluable tools for cell type mapping but multiplexing has been challenging primarily due to the spectral overlap of fluorescent dyes and the limited antibody host variety. In addition, the methods used for highly multiplexed mRNA mapping is inapplicable to IF-based protein mapping. Finally, organ-scale samples often require several orders of magnitude more time for multi-round labeling, imaging, and registration, rendering the multiplexing strategy employed for thin single-cell layer samples nearly impractical for thick intact samples. Therefore, we sought a new approach to enable highly multiplexed three-dimensional volumetric staining and imaging of large-scale brain tissues. To take advantage of the barcoding strategy, we conjugated antibodies with short single-strand DNA oligonucleotides. The resulting oligo conjugates can be employed for simultaneous immunostaining of multiple targets without the host overlap issue. We optimized the antibody-oligonucleotide conjugation chemistry to be substantially low cost in comparison with expensive commercial kits, while allowing multiple oligo labeling without perturbation of antigen binding sites. The labeling method presented here is applicable to any antibody hosts and is scalable up to several mg quantities. In addition, we adopted multiplexed signal amplification methods with photostable dyes to minimize photobleaching and to enable ultrafast imaging of large-scale tissue using light-sheet microscopy. Overall, the tool kits presented here will allow high-throughput multiplexed mapping of biomolecules in organ-scale samples.

Abstract: Advances in intact tissue clearing and imaging modalities are enabling rapid visualization and 3D phenotyping of large tissues; however, molecular labeling of intact tissue remains laborious and low throughput. Here, we introduce an ultrafast method, eFLASH (electrophoretically driven Fast Labeling using Affinity Sweeping in Hydrogel), that permits organ-scale immunolabeling on the same time scale as conventional immunohistochemistry on thin tissue sections. eFLASH utilizes chemical strategy to modulate labeling reactions in the context of ultrafast probe transport mediated by Stochastic electrotransport (Kim, PNAS, 2015). With a universal 1-day protocol, eFLASH allows uniform labeling of mouse organ-scale tissues with a wide-range of antibodies, generating high-quality samples suitable for automated quantitative analysis of various proteins indicating cell types or functional activity. Universal nature of eFLASH allows labeling of disparate tissue types using the same protocol including models with restricted access to genetic labeling tools, and we have demonstrated its application on mouse brains, marmoset brain block, and human iPSC-derived cerebral organoid by achieving multi-probe labeling in each type. Finally, eFLASH leverages robust preservation of biomarkers and tissue architecture provided by SHIELD (Park, NBT, 2019), which allows repeated immunolabeling of rare or precious samples. We envision that eFLASH will spur multidimensional and holistic phenotyping of emerging animal models and disease models to help assess their functions and dysfunctions.

Title: Mechanical interlocking of biomolecules *in situ* preserves tissue architecture and integrity of biomolecules

Authors: *Y. TIAN[1], J. T. MARTIN[2], X. JIN[8,3], D. J. IRVINE[4,2,9,5,10], K. CHUNG[1,8,3,6,7]; [1]Chem. Engin., [2]Koch Inst. for Integrative Cancer Res., [3]Inst. for Med. Engin. and Sci., [4]Biol. Engin., [5]Material Sci. and Engin., [6]Picower Inst. for Learning and Memory, [7]Brain and Cognitive Sci., MIT, Cambridge, MA; [8]Broad Inst. of Harvard Univ. and MIT, Cambridge, MA; [9]Ragon Inst. of Massachusetts Gen. Hospital, Massachusetts Inst. of Technol. and Harvard Univ., Cambridge, MA; [10]Howard Hughes Med. Inst., Chevy Chase, MD

Abstract: Interrogating the spatial distribution and function of biomolecules in multicellular organisms is crucial for a wide range of biomedical research. However, chemical processes needed to preserve the physical structure of tissues often cause loss of biomolecular function. Most existing tissue preservation strategies use chemical fixatives to preserve spatial organization of biomolecules, but chemical modification in this process often sacrifices the integrity and activity of biomolecules and their dynamic interactions. Here we introduce a method for permanent mechanical interlocking of biomolecules across multiple scales, from the nanoscale of single biomolecules to the organ scale, without chemical damage. The method relies on the trapping and interlocking effect of polymer chains rather than the intense chemical crosslinking and modification mediated by fixatives in conventional tissue processing technologies. We confirm that the spatial distribution and the antigenicity of biomolecules are well preserved by mechanical interlocking of hydrogel. We show that the functionality of biomolecules is less affected due to the lack of aggressive fixation chemistry, and multiple functional assays can be easily applied after imaging. The new technology is applicable to a wide range of contents, from free proteins, nucleic acids, cells, to biological tissues, and ensures a good preservation of biomolecules and their functions. It has been applied to brain tissues and

lymph node tissues to study various questions that could not be addressed with conventional chemical fixation-based methods.

Abstract: Advances in tissue processing and preservation techniques have given rise to phenotyping capacity on a previously unprecedented scale. However, the scalability of such methods and the degree of molecular preservation have remained a challenge. Using SHIELD (**S**tabilization to **H**arsh conditions via **I**ntramolecular **E**poxide **L**inkages to prevent **D**egradation; Park, Nature Biotechnology, 2019), we have previously demonstrated that it is possible to preserve protein fluorescence, nucleic acids, antigenicity, and tissue architecture through the fixation of biological samples with a versatile polyepoxide crosslinker. SHIELD expands upon conventional fixative-based tissue preservation by using a five-arm polyepoxide crosslinker, P3PE. The macromolecules are uniformly dispersed throughout the tissue and simultaneously crosslinked into a tight network via a series of simple buffer changes. The preserved tissue can then be subjected to a variety of treatments, including whole-organ clearing, volumetric immunostaining, and high-throughput volumetric imaging. We show here that the SHIELD

protocol is easily scalable and has been successfully implemented in the analysis of embryonic and adult mouse brains, adult mouse organs, adult human brains, and cerebral organoids. Moreover, SHIELD can be combined with downstream processing methods such as MAP (Ku, Nature Biotechnology, 2016) and eFLASH to enable rapid and holistic interrogation of large-scale biological systems. We anticipate that SHIELD protocols will allow integrated structural and molecular phenotyping of a wide range of biological tissues.

Kubik Lab. for Neuropathology, Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA; [7]Broad Inst. of Harvard Univ. and MIT, Cambridge, MA

Abstract: Integrated, multi-scale mapping of the human brain is one of the most sought-after challenges in neuroscience. Due to the brain's size and complexity, state-of-the-art technologies for human brain interrogation must sacrifice either resolution or scalability -- low resolution 3D whole brain visualization (e.g. MRI) vs. molecular resolution nanometer-scale visualization (EM). Histology-based pipelines have also previously been implemented for cellular resolution visualization; however, these require many error-prone processing steps -- such as sectioning the brain into thousands of thin slices -- that also do not preserve 3D connectivity information.

Because of these current limitations, we aimed to develop a novel thick tissue processing, fluorescent labeling, and imaging pipeline that is reliable, able to preserve morphological integrity, and scalable to human brain length scales. Using custom-developed vibratoming, SHIELD-ELAST tissue-hydrogel transformation and clearing, kinetic-modulated immunolabeling, and high resolution selective plane illumination microscopy (SPIM) pipeline, we show that single neuronal axons can be manually traced within 3mm-thick coronal human brain hemisphere blocks. We are able to fix, clear, stain, and image each tissue slab with minimal tissue damage and deformation, high reproducibility, and sufficient image quality for manual long-range tracing of sparse neuronal fibers, demonstrating that this pipeline is scalable to a whole human brain, which would require processing 30-40 coronal slabs of this size. This proof of concept study suggests that single cell resolution mapping on the global human brain scale is possible and could facilitate the development of comprehensive human brain atlases in the future.

Title: Scalable cell phenotyping framework for microglial cells

Authors: ***M. E. KIM**[1,2], G. DRUMMOND[2], E. NICHOLS[5], N. B. EVANS[1], Y.-G. PARK[1], N. DINAPOLI[1], D. YUN[1,2], K. XIE[1], J. SWANEY[3], K. SAIJO[5], K. CHUNG[2,3,1,4];
[1]Inst. for Med. Engin. and Sci., [2]Dept. of Brain and Cognitive Sci., [3]Dept. of Chem. Engin., [4]Picower Inst. for Learning and Memory, MIT, Cambridge, MA; [5]Dept. of Mol. Cell Biol., Univ. of California Berkeley, Berkeley, CA

Abstract: Microglia play numerous important roles during the development and aging of the central nervous system (CNS). In response to changes in their surrounding micro-environment, microglia represent an impressive level of functional and morphological plasticity (AyoubAlbert E., 2003) (LawsonL.J., 1990) (LoaneDavid, 2016) (HutchinsKenneth, 1990). Therefore, characterizing their brain-wide organization and functional heterogeneity has become essential to understand the role of microglia in brain function and dysfunction. Yet, most currently available methods are either applied to limited regions or thin slices focused on specific questions (e.g. morphology profiles after neuroinflammation) (StenceNick, 2001), (Fernández-ArjonaMDM, 2017), or require manual analysis that is often biased, inaccurate, and extremely laborious, hence less scalable to broader regions (SwinnenNina, 2012). Here, we propose a scalable and fully automated cell phenotyping framework (S-CPF) that enables fast and comprehensive analysis of both spatial and morphological characteristics of microglia in 3D datasets acquired using SHEILD (ParkYoung-Gyun, 2018), eFLASH, and SPIM imaging. S-CPF achieves state-of-the-art accuracy and scalability in morphology prediction, allowing full analysis of microglia in an entire mouse brain within hours. Brain-wide analyses of microglial cell distribution and characterization of their morphology (e.g., ramified, amoeboid) in mouse brains at different developmental stages validate our framework and prove the high scalability and accuracy. We envision that S-CPF will enable scalable brain-wide phenotyping of microglia for a broad range of research.

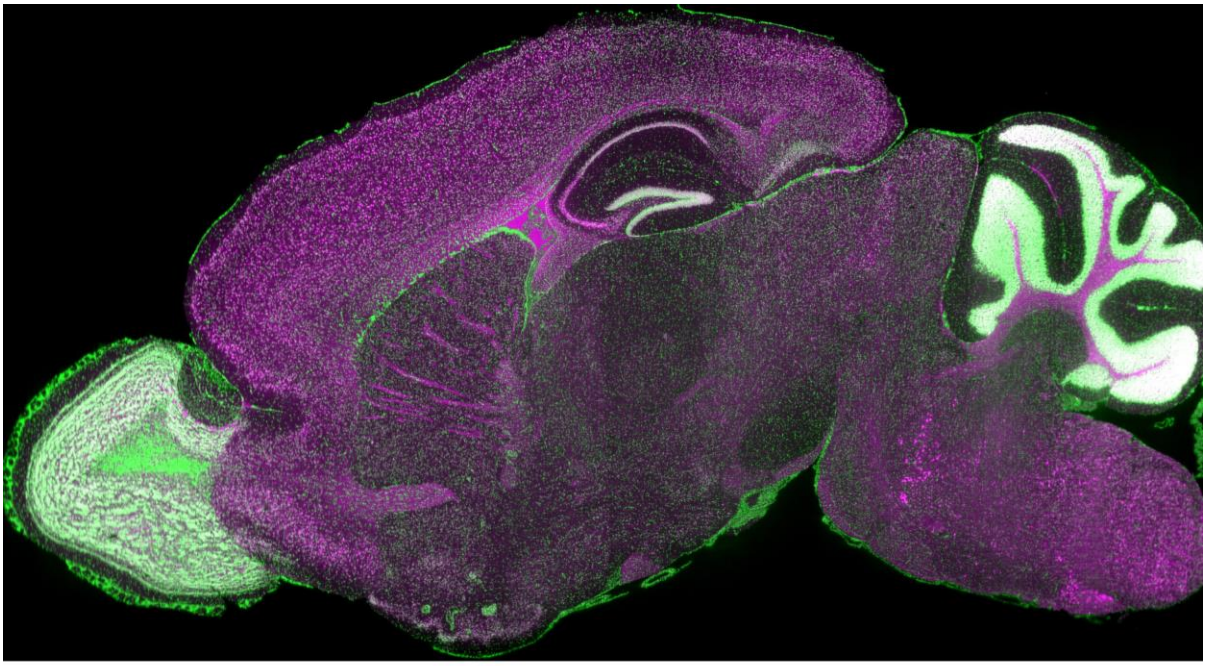
For Synthetic Biol., RIKEN Ctr. for Biosystems Dynamics Res., Osaka, Japan; [5]JST-PRESTO, Saitama, Japan

Abstract: Recent development of tissue clearing techniques have promised for researchers to visualize deep inside the nervous system. Light-sheet fluorescence microscopy (LSFM) is now a common method to explore a volumetric sample by less-invasive optical slicing. However, there have been few LSFM systems which cover a wide area of imaging with sufficient optical resolution (i.e. a whole brain with subcellular resolution). Thus, we designed a new LSFM system with spatially-uniform thin light-sheet illumination which provides a three-dimensionally isotropic resolution and covers a wide area of visualization; we visualized subcellular structures across entire area of mammalian brains and bodies. Isometric voxel data enable us to analyze the cell architecture based on the three-dimensional morphology regardless of illumination and imaging axis. Also, combined with a whole-brain immunostaining technique (CUBIC-HistoVIsion), each cell can be characterized by cell types and functions in nervous system. Finally, with those dataset, we renewed a point-based mouse brain atlas (CUBIC-Atlas) with annotations and classifications in addition to the position of cells.



Virtual sagittal section of a whole mouse brain reconstructed with horizontal optical slices.
The images were captured by a macroscopic LSFM with isotropic resolution (6.5 μm/voxel).
Neurons (magenta) and cell nuclei (green) are labeled by CUBIC-HistoVIsion.

Title: SeeNet: Hybrid hydrogel and tissue clearing for molecular and structural characterization of cerebral vasculature

Authors: *T. MIYAWAKI[1,2,4,5], E. A. SUSAKI[2,4,6], S. YAMAGUCHI[7,8], H. R. UEDA[2,3,4], Y. IKEGAYA[1,9];

Abstract: Cerebral vasculature is a 3D traffic network with blood-brain barrier, a molecularly heterogeneous interface regulating the flow of substances between blood and brain parenchyma. Although structural and molecular analyses of cerebral vasculature are promising for providing fundamental insights into cerebral circulation and cerebrovascular diseases, few studies have captured detailed structural information of molecularly identified vascular networks, due to technical limitations. Here, we introduce SeeNet, a method for near-complete three-dimensional visualization of intact cerebral vascular networks with high signal-to-noise ratios, compatible with molecular phenotyping. SeeNet employs perfusion of a novel multifunctional crosslinker, vascular casting by temperature-controlled polymerization of hybrid hydrogels, and a tissue clearing technique optimized for observation of vascular connectivity. SeeNet was capable of whole-brain visualization of molecularly characterized cerebral vasculatures at the single microvessel level. Moreover, SeeNet revealed a hitherto unidentified vascular pathway. This

technology will routinize large scale 3D tracing of molecularly characterized cerebral vasculature, and will facilitate the future investigation of cerebral circulation under health and disease.

Title: Advanced CUBIC pipeline in whole-organ cell profiling for biomedical research

Authors: *T. T. MITANI[1], K. MATSUMOTO[1], S. A. HORIGUCHI[1], J. KANESHIRO[1], T. C. MURAKAMI[2], T. MANO[2], H. FUJISHIMA[1], A. KONNO[3], H. HIRAI[3], H. R. UEDA[1,2]; [1]RIKEN Ctr. for Biosystems Dynamics Res., Osaka, Japan; [2]The Univ. of Tokyo, Tokyo, Japan; [3]Gunma Univ., Maebashi, Japan

Abstract: Whole-organ cell profiling pipeline coupled with CUBIC technologies is getting to be an effective tool to obtain comprehensive cell information throughout the organ. Recently, we reported a single-cell-resolution whole-brain atlas (CUBIC-Atlas), which was novel scalable and sharable format among research community for handling the whole-organ data by a point cloud. However, the positions of all detected cells in an organ had to be extracted from a large image data to compact the data size, and therefore the throughput of data collection and analysis remain a severe bottleneck for biomedical applications handling numerous samples. To overcome the obstacle, we developed a high-speed volumetric imaging system together with a high-speed cell detection algorithm for practical use. The stable and efficient imaging methods including adaptive focusing were integrated into a custom-built light-sheet fluorescence microscopy. The acquisition time was shortened to within a few hours per mouse whole organ. For example, using a ten-fold expanded adult mouse whole-brain sample, the throughput of 50 ms of exposure time

was measured as 0.56 TB/h and total data size was 6.3 TB using 10x objective lens with novel imaging system, comparing with 0.15 TB/h and 14 TB with previous imaging scheme (Murakami et al., 2018). Acquisition time per brain also became 8.5 times faster than the previous report. To analyze the large-scale imaging data in a rapid manner, we also developed a cell detection algorithm based on three-dimensional Hessian-based Difference of Gaussian and a highly parallelization of multiple CPUs and GPUs. Our cell-detection algorithm worked at 1 hour/TB and had over 90% F-scores of nuclear stained cell detection throughout the brain. Using a brain transduced with AAV-PHP.eB (NSE-H2B-mCherry) counterstained by nuclear stain dye, we demonstrated the usability of the developed imaging-analysis pipeline by quantification of mCherry positive cell number in each anatomical region and the ratio of positive cells in each 80 μm voxel. These results show that the cortex and hippocampus showed higher positive ratio than other areas. Thus, the pipeline provides a novel platform for the high-speed organ-scale analysis of cells and will promote next-generation biomedical research targeting a large number of samples in a feasible timescale.

Abstract: The recent development of various tissue clearing and three-dimensional (3D) imaging methods, including our CUBIC pipeline [1-3], allowed the comprehensive observation of whole organ/body with cellular resolution or more. However, in the long history of histology, whole-organ/body 3D staining and imaging have been still challenging due to the difficulty of adequate penetration of stains and antibodies. Even a small dye occasionally exhibits the resistance to penetration, implying the existence of a complex physicochemical environment in the staining system. Here, we report a universal whole-organ/body staining and imaging protocol named CUBIC-HistoVIsion. To dissect the complex physicochemical environment, we first conducted a precise characterization of biological tissue as an electrolyte gel. Then, we experimentally evaluated a broad range of 3D staining conditions by using a simplified tissue-mimicking artificial electrolyte gel. The combination of essential conditions allowed a bottom-up design of efficient 3D staining protocol which could uniformly label an adult whole mouse brain, an adult marmoset hemisphere, a ~1 cm^3 tissue block of adult human postmortem cerebellum, and an infant whole marmoset body with dozens of antibodies and cell-impermeant nucleic acid stains. We also demonstrate that our protocol enabled structural and functional neural circuit identification and analysis with Rabies virus tracing and whole-brain c-Fos immunostaining. Therefore, the CUBIC-HistoVIsion pipeline offers advanced opportunities for organ- and organism-scale histological analysis of multicellular systems in the brain and body. [Reference] 1. Title: Circadian change of whole-brain c-Fos immunoreactivity and its quantitative analysis by CUBIC-neural activity pipeline

Authors: *S. X. YOSHIDA[1], K. MATSUMOTO[1], T. MANO[2], H. FUJISHIMA[1], C. SHIMIZU[2], M. KURODA[2], E. A. SUSAKI[2], H. R. UEDA[2,1];

Abstract: The brain consists of various regions, which are associated with specific sensory, motor, memory, mental and arousal functions. These regions form complex networks and work in a highly interconnected manner. The recent advent of tissue clearing and three-dimensional (3D) imaging techniques potentially enables the understanding of such an organized brain function as a whole, when combined with whole-brain imaging and analysis of immediate early gene expressions[REF: Tatsuki Neuron 2016]. The previous study utilized a transgenic mouse expressing Arc-dVenus transgene reporter for labeling neural activities. However, it usually takes several months to prepare a sufficient number of animals for experiments by multiple crossing. Besides, Arc gene expressions are confined within cortex and hippocampus. To overcome those limitations, we recently developed whole-brain c-Fos immunostaining, imaging, and analysis in combination with CUBIC (Susaki and Mano et al.), which make it possible to analyze the whole brain neural activities with single-cell resolution in a rapid, easy and non-biased manner. Here, we mainly focus on the dynamical change of whole-brain c-Fos expression patterns associated with circadian rhythms to monitor the baseline activities of the brain regions during 24 h. For this purpose, we first analyzed the 3D c-Fos expression patterns in the suprachiasmatic nucleus of the hypothalamus (SCN), a center of the circadian clock in the body.

We collected a series of whole-brain c-Fos immunostaining and imaging data in the dark-dark (DD) condition. Signals of c-Fos in and around SCN were observed with single-cell resolution. Therefore, we are challenging to capture the changes of c-Fos signals quantitatively in and around SCN and expand the analysis to the brain regions throughout the brain. These collections of multiple brain data will provide crucial information on the circadian-related dynamics and state exchange of brain activities. We will finally develop a spatial and temporal atlas of c-Fos activity rhythms throughout 24 h. In this presentation, we report current situations and issues of the CUBIC-neural activity project.

Title: Ca^{2+}-dependent/-independent hyperpolarization pathway plays a role in sleep regulation - The first application of cubic in sleep research-

Authors: *S. SHI, H. R. UEDA;
The Univ. of Tokyo, Tokyo, Japan

Abstract: The timing and duration of sleep is an evolutionarily conserved process. The sleep-wake cycle accompanies with a global state change in brain and sleep duration seems to be regulated by networks of neural circuits. However, recent reverse and forward genetics have revealed several genes that regulate sleep duration and homeostasis, which suggests that sleep duration is regulated by molecular networks and the sleep-wake cycle might be triggered by a local state change. In this study, we focused a rhythmic firing pattern (slow-wave-sleep firing pattern, SWS firing pattern) with depolarized up states and hyperpolarized down states which are observed in cortical neurons during slow-wave EEG oscillations and attempted to identify

important genes in generating this firing pattern. Considering the tight correlation between SWS firing pattern and slow-wave EEG oscillations as well as behavioral states (e.g. sleep), the genes which are important in generating SWS firing pattern might also play a role in sleep duration regulation. A comprehensive bifurcation analysis against an averaged-neuron model, where a cortical neuron transmits its output to equivalent neurons (i.e., its output returns to itself as input), predicted that Ca^{2+}-dependent/-independent hyperpolarization is associated with SWS (Tatsuki et al 2016, Yoshida et al 2018). To validate the prediction, we generated KO mice for every gene included in the Ca^{2+}-dependent/-independent hyperpolarization pathway and analyzed their sleep phenotypes. As a result, we found that impaired Ca^{2+}-dependent K^+ channels (*Kcnn2* and *Kcnn3*), K^+ leak channels (*Kcnk9*), voltage-gated Ca^{2+} channels (*Cacna1g* and *Cacna1h*), or Ca^{2+}/calmodulin-dependent kinases (*Camk2a* and *Camk2b*) decrease sleep duration, while impaired plasma membrane Ca^{2+} ATPase (*Atp2b3*) increases sleep duration (Tatsuki et al 2016, Yoshida et al 2018). Pharmacological intervention validated the prediction that impaired NMDA receptors (glutamate- and voltage-gated Ca^{2+} channels) reduce sleep duration (Tatsuki et al 2016). CUBIC (Clear, Unobstructed Brain/Body Imaging Cocktails and Computational analysis) and FISH also verified that NMDA receptor down-regulation directly increases the excitability of cortex glutamatergic pyramidal neurons (Tatsuki et al 2016).

Abstract: Recent advancements of tissue clearing technologies have offered unparalleled opportunities for researchers to explore the entire neuronal system at cellular resolution. With the expansion of this research paradigm, however, there are ever growing demands for (1) integrated tools to analyze massive 3D images and (2) effective means to exchange whole-brain data, which together would enable community-driven comprehensive brain mapping. To deliver such computational platform, we opted to propose a cloud computing based solution, because of its accessibility, scalability and cost-effectiveness in carrying out intensive computations and connecting massive data. Thus, we designed and implemented CUBIC-Cloud, a cloud-based framework for single-cell-resolution whole-brain analysis. CUBIC-Cloud provides cloud-based image analysis package (CloudMap) which offers web-based graphical interface allowing any users to analyze massive 3D images without requiring expert knowledge on parallel computing. Analyzed data can be visualized and shared with the research community using CloudEye, a web-based whole-brain viewer and database manager. We then demonstrate the generality of CUBIC-Cloud by a variety of applications, including (1) whole-brain analysis of PV, Sst, ChAT, Th and Iba1 expressing cells (2) reconstruction of neuronal activity profile by c-Fos and (3) brain-wide connectivity mapping by pseudo-typed Rabies virus. Together, CUBIC-Cloud offers scalable and community-driven approaches to deconstruct whole-brain architecture.

Abstract: Super-resolution imaging has revealed nanoscale structures of various neuronal structures of the brain. However, the adaptation of super-resolution imaging techniques to the brain is still limited, as it generally requires special chemicals, apparatuses, or skilled personnel. Here, we demonstrate the super-resolution, volumetric, and three-dimensional imaging of various neuronal microstructures of the brain, including blood-brain barrier, synaptic receptors, and neuronal cytoskeletons. Among various super-resolution microscopy techniques, we use expansion microscopy as a imaging modality, as it can easily achieve 60-nm resolution imaging of thick tissue slices with a conventional microscopy system. In this work, we compare the diffraction-limited images and super-resolved images of the same structures to clearly show the nanoscale molecular detailed of those structures that can be revealed only with the super-resolution microscopy technique.

Title: Expansion microscopy imaging of various biomolecular species of the brain

Authors: *I. CHO, J.-B. CHANG;
KAIST, Daejeon, Korea, Republic of

Abstract: Visualizing multiple biomolecular species with nanometer-scale precision can provide essential knowledge to understand the molecular mechanisms of biological phenomenon. In 2015, a new super-resolution microscopy technique, called expansion microscopy, was reported; in this technique, higher lateral and axial resolution are achieved by physically expanding specimens via a swellable hydrogel (ExM; Science 347(6221):534-548, Nat. Biotechnol. 34(9):987-992). Briefly, target specimens, such as cultured cells or tissue slices, are embedded in a swellable hydrogel. During the embedding process, proteins of interest are chemically anchored to the hydrogel. Then, the specimen-hydrogel composite is isotropically expanded in de-ionized water. During the expansion, closely-located proteins move apart, resulting in 60-nm resolution when imaged with diffraction-limited microscopy. Here, we show that multiple biomolecular species of the brain can be visualized with the same resolution via expansion microscopy. We believe that this work will provide richer molecular information of the brain.

Title: Super resolution imaging of actin of the brain via expansion microscopy

Authors: *C. PARK, J.-B. CHANG;
KAIST, Daejeon, Korea, Republic of

Abstract: Actin is one of the most essential proteins of cells. In the past, super-resolution microscopy technique, such as STORM or STED, was used to visualize the nanoscale details of actin filaments of cultured cells. However, super-resolution imaging of actin in thick tissue slices is still challenging, as actin is highly expressed in almost all cell types, and it forms a very dense network structure. Here, we demonstrate the super-resolution, volumetric, and three-dimensional imaging of actin and associated proteins of the brain via expansion microscopy. Visualization of actin and various associated proteins of the brain would provide us the molecular information on how the mechanical properties of neurons are regulated and how molecular transportation inside neurons are controlled.

Title: Multiplexed super resolution volumetric imaging of substantia nigra via expansion microscopy

Authors: *K. MIN[1], S. KIM[2], Y. CHO[2], J. LEE[2], J. SEO[2], Y. SIM[2], Y. LEE[2], J.-B. CHANG[3];
[1]Sungkyunkwan Univ., Suwon, Korea, Republic of; [2]Sungkyunkwan Universiy, Suwon, Korea, Republic of; [3]KAIST, Daejeon, Korea, Republic of

Abstract: Parkinson's disease (PD) is the second most common neurodegenerative disease after Alzheimer's disease. Among multiple pathological features, the loss of dopaminergic neurons of substantia nigra is the most representative one. However, the molecular details of the loss have not been clearly understood. In this work, we demonstrate the super-resolution, multiplexed, volumetric, three-dimensional imaging of dopaminergic neurons and other associated cells of substantia nigra of the brain via expansion microscopy. To achieve multiplexed, volumetric, and super-resolution imaging of the brain, we screen multiple fluorophores and use the ones yielding the highest brightness. Super-resolution volumetric imaging of dopaminergic neurons and associated cells of the brain would help us to better understand the molecular mechanisms of PD.

Title: Multiplexed expansion microscopy imaging of the brain

Authors: *J.-Y. SEO[1], Y.-B. SIM[1], J.-B. CHANG[2];
[1]Sungkyunkwan Univ., Suwon, Korea, Republic of; [2]KAIST, Daejeon, Korea, Republic of

Abstract: Recently, multiple super-resolution microscopy techniques have been developed and adopted to neuroscience. However, the multiplexing capability of those techniques is limited, as those techniques achieve the higher resolution by precisely-tuning the chemical or physical properties of fluorophores and it is not trivial to tune multiple fluorophores simultaneously. Here, we demonstrate multiplexed super-resolution imaging of the brain based on expansion microscopy. In expansion microscopy, the higher-resolution is achieved by physically expanding specimens themselves, rather than fine-tuning fluorophores. As a result, multiple regular fluorophores can be used together to achieve multiplexed super-resolution imaging. In this work, we show that multiplexed expansion microscopy imaging can be used to reveal the cellular and molecular heterogeneity of the brain.

Title: Rapid super-resolution imaging of neural tissue with large-scale molecular sampling

Authors: *N. E. ALBRECHT[1], C. G. EBELING[2], R. HOBSON[2], M. A. SAMUEL[1];
[1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Bruker Nano Surfaces, Salt Lake City, UT

Abstract: Proper neural function depends on the correct arrangement and development of synapses, the primary site of communication between neurons. However, the molecular mechanisms that underlie synapse formation and specificity are only partially resolved in part because the internal landscape of synapse protein arrangement remains largely unknown. Two challenges have limited progress towards these goals: 1) synapses are beyond the resolution limit of light, and 2) nanoscopic approaches to visualize synapses are often time consuming and limited in their ability to see multiple proteins at once. To overcome these limitations, we present a rapid and optimized application of Stochastic Reconstruction Microscopy (STORM) for neural tissue that allows us to quickly screen for synaptic protein content and structure from relevant *in vivo* samples. With this workflow, we have successfully prepared tissue for STORM imaging using optimized cryosectioning techniques and imaged synapses and neurons, at nanometer resolution, in tissue sections that are 10µm thick in a protocol that takes 48 hours from tissue harvest to final image. This rapid approach enables high-throughput imaging and screening of neural tissue for the characterization of nanoscale synaptic structures. We are now applying these methods to synapse development and dysfunction to uncover the molecular regulators of synaptic formation and maintenance.

Title: Flexible high-density µLED-based implant with improved mechanical and optical performance for optogenetic stimulation of the cochlear

Authors: *E. KLEIN[1], A. DIETER[2], O. PAUL[1], T. MOSER[2], P. RUTHER[1];
[1]IMTEK, Univ. of Freiburg, Freiburg, Germany; [2]Inst. for Auditory Neurosci., Univ. Med. Ctr. Goettingen, Goettingen, Germany

Abstract: This paper reports on the latest achievements for flexible optical implants with integrated micro light-emitting diodes (µLED) on flexible substrates used to stimulate the cochlear neurons [1,2]. Optical cochlear implants (CIs) promise hearing restoration with improved frequency resolution as light can be better focused than electrical stimulation that is used in current clinical CIs. The process flow is based on 6-µm-thick GaN-µLEDs grown and processed on sapphire substrates. The µLEDs are transferred to a carrier wafer [3,4] and subsequently released from the sapphire substrate using a laser-lift-off (LLO) process [4]. The sophisticated wafer-level fabrication process is designed to realize highly flexible implants with up to 144 embedded µLEDs along slender probe shafts with lengths of up to 1.5 cm. To improve mechanical probe performance, the polymer process has been optimized in view of the applied materials minimizing thermo-mechanical stress. This improvement results in a pronounced suppression of implant bending due to pre-stress facilitating its implantation into the cochlea. A selective release mechanism based on a patterned sacrificial layer enables a stress-free probe release increasing the fabrication yield. The optical output power of the µLEDs is improved by roughening the µLED surface using wet etching. The optimized etching parameters enable a low temperature, polymer compatible as wells as time efficient etch process. The surface roughening process increases the optical power by >70%. In order to further improve the output power of the µLEDs, micro lenses and conical concentrators are integrated into the µLED probes. These optical components narrow and focus the emission cone of the µLEDs [5]. The µ-lenses are manufactured by silicone molding while the conical concentrators are integrated into the probe polymer by reactive ion etching. Upon µ-lens assembly, the etched cavities (sidewall angle 70°) are refilled with silicone. The combination of both components raised the light extraction and peak intensity by 115% and 145%, respectively. The capability of the innovative micro-optical probe to stimulate neurons in the cochlea is verified by *in-vivo* recordings from the auditory midbrain. They demonstrate that the optical activation of the auditory pathway with a µLED-based CI overcomes the frequency resolution limit of conventionally applied electrical CIs.

Title: Real-time visualization of acetylcholine in acute striatal slices using iAChSnFR; a new robust genetically-encoded fluorescent sensor

Authors: *J. A. CHOUINARD[1], J. S. MARVIN[2], P. M. BORDEN[2], L. L. LOOGER[2], J. R. WICKENS[1];

Abstract: The dawning availability of biosensors able to report the spatiotemporal dynamics of neurotransmitter levels *in vivo* opens new windows on chemical signaling in the brain. These sensors directly and specifically report synaptic signals as they are received by their receptors. A newly developed bacterial periplasmic binding protein (PBP) based acetylcholine (ACh) sensor, iAChSnFR, couples ACh-evoked conformational changes in the PBP to fluorescence changes of a fused, circularly permuted green fluorescent protein. Its high affinity for acetylcholine, millisecond response times, good signal-to-noise ratio, kinetics and targetability makes it suitable for use in live intact preparations. We tested iAChSnFR in acute brain slices after *in vivo* transfection using a CAGFlex AAV viral construct injected in the dorso-lateral striatum of male and female D1-Cre mice. All experiments were approved by the Animal Care and Use Committee of the Okinawa Institute of Science and Technology Graduate University and were conducted in accordance with Japanese law and the Public Health Service Policy on Humane Care and Use of Laboratory Animals of the National Institutes of Health in the United States of America. A minimal period of 4-weeks was allowed for *in vivo* expression, which was stable up to at least 6 months post-transfection. Animals were group housed and showed no abnormal behaviors. Confocal imaging in acute brain slices showed that iAChSnFR successfully detected post-synaptic ACh activity ex vivo. ACh kinetics were recorded following treatments with KCl, ACh and the GABA antagonist bicuculline (BIC) by either bath applications or local micropipette delivery of known concentrations. We observed traveling waves and local oscillations of ACh. Sensor response concentrated at axon plexus regions, displaying high extracellular ACh levels that were extremely responsive to our pharmacological manipulations. The spatiotemporal dynamics of ACh in the striatum are incompletely understood at present. Our data shows that iAChSnFR opens up a way toward a more complete understanding of ACh dynamics in the basal ganglia circuitry. With improved imaging and analysis methods, iAChSnFR could be a useful tool to decipher neural activity into its composite molecular signaling events.

Title: Rational engineering of an intensiometric, genetically encoded, indicator for quantifying CREB phosphorylation events *in vivo*

Authors: *T. YOKOYAMA[1], M. INOUE[1,2], T. ITO[1], Y. KONDO[1], H. FUJII[1], M. SAKAMOTO[1], H. BITO[1,3];
[1]Neurochemistry, Univ. of Tokyo Grad Sch. Med., Tokyo, Japan; [2]Bioengineering, Stanford Univ., Stanford, CA; [3]IRCN, Univ. of Tokyo, Tokyo, Japan

Abstract: Recent technological advances in genetically encoded calcium indicators (GECIs) now permit tracking of electrical signals in hundreds of neurons *in vivo*. On the other hand, visualizing dynamics of biochemical signals in a large neuronal population *in vivo* remains challenging due to lack of sensitive indicators. Here, we designed and validated a supersensitive, genetically encoded green fluorescent indicator, XCREB-G, which faithfully reported the phosphorylation state of cyclic AMP-responsive element binding protein (CREB), a key transcription factor required for excitation-transcription coupling, at single cell resolution *in vivo*. XCREB-G was expressed in layer 2/3 neurons of the mouse primary visual cortex using an adeno-associated virus (AAV) vector or via in utero electroporation (IUE). Using *in vivo* two-photon microscopy, we directly tested how rapidly and selectively CREB phosphorylation was triggered by visual input-selective stimuli, in hundreds of visual cortical neurons responding to orientation -selective moving gratings. The fastest CREB activation was shown within 10 sec, and the in vivo dynamics of CREB activation was overall consistent with previous reports using cultured neurons. Simultaneous dual-color imaging of calcium (using a red GECI XCaMP-R) and CREB phosphorylation activity (using XCREB-G) demonstrated that a sizable number of neurons showed an orientation-selective CREB activation, following a burst of orientation-selective neuronal activation. More interestingly, we found evidence that a subthreshold CREB activation after a first bout of orientation-selective neuronal activity could lead to a

suprathreshold CREB activation upon a second round of repetitive visual stimuli. Taken together, our findings suggest that nuclear CREB phosphorylation state indeed extracts and integrates information contained in synaptic input events *in vivo*. This technological advance will pave the way to better understand the complex dynamics and information processing elicited in vivo during excitation-transcription coupling, a privileged form of communication between electrical signals and nuclear gene expression via intracellular biochemical reactions.

Abstract: Analysis of the secretion of neurotransmitters in nervous system is important for elucidating the mechanism of neural network in nervous system. Thus, development of a probe which can track a specified neurotransmitter in real time with high selectivity has been required. Molecularly imprinted polymer (MIP), which is a molecular recognition material obtained by polymerization with a template-effect of the target molecule may be applicable for the probe. In this study, nanoparticle of MIP including fluorescent group (fMIP-NP) were developed as the probe of serotonin. The serotonin, as the template, was immobilized on glass beads by using mixed anchor of 3-aminopropyltrimethoxysilane (shorter chained) and 3- (2-aminoethylamino) propyltrimethoxysilane (longer chained) (1:1 in weight) with glutaraldehyde. The template-immobilized beads were fluidized in a mixed solution of a fluorescent monomer, a template-affinity monomer, and a crosslinking monomer under UV irradiation. The colloidal fMIP-NP was collected from the surface of the beads by washing with dimethylformamide. And the dispersion medium of the colloidal fMIP-NP was replaced with physiological phosphate buffer. The fluorescent intensity and the radius of the fMIP-NP was increased by addition of serotonin

but was insensitive to L-tryptophan which is the analogue of serotonin. The buccal ganglion of *Aplysia* sea snail was stained by the fMIP-NP by soaking in the dispersion. Spike oscillation in the fluorescent intensity were observed at the sensory neurons in the ganglion immediately after the taste of *Nori* seaweed was given to the radula connected with the ganglion. The oscillation was enhanced by addition of an inhibitor of monoamine oxidase which collects serotonins from the synapses. The results indicate that the serotonin secreted from neurons can be detected by imaging technology using the fMIP-NP templated by serotonin as a probe. Most of transmitters can be targets of MIPs, thus imaging with probes of fMIP-NPs would enable analysis of dynamism of neurotransmitters in central nerve system.

Title: Simultaneous detection of spikes and synaptic potentials with two-photon, two-color voltage and calcium imaging *in vivo*

Authors: *Y. BANDO[1,2], M. WENZEL[3,2], R. YUSTE[2];
[1]Dept. of Organ and Tissue Anat., Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan; [2]NeuroTechnology Center, Dept. of Biol. Sci., Columbia Univ., New York, NY; [3]Dept. of Epileptology, Univ. of Bonn, Bonn, Germany

Abstract: As a dream experiment, measuring simultaneously synaptic potentials and action potentials from populations of neurons could enable to better understand neuronal computations, as this would capture both the inputs and outputs of all the cells in a neural circuit. However, this has been difficult to achieve using conventional electrophysiological techniques. As a step towards measuring synaptic inputs and spikes in neuronal populations, we previously tested existing genetically-encoded voltage indicators (GEVIs) with two-photon (2P) imaging *in vivo*, and found that ArcLight-MT could detect subthreshold voltage change *in vivo* (Bando et al., Cell

Reports, 2019). However, its signal-to-noise ratio (SNR) was not large enough for reliable detection of synaptic potentials. Here, we modified ArcLight-MT, developing SynVolS (Synaptic Voltage Sensor), as a voltage indicator specialized to detect subthreshold synaptic inputs. We also added a soma-targeting signal peptide to improve its SNR (SynVolS-ST). We found that SynVolS-ST could detect subthreshold membrane potential change more accurately than ArcLight-MT with 2P imaging *in vivo*. We then co-expressed SynVolS-ST with jRGECO1a, a red calcium indicator, and performed simultaneous 2P voltage and calcium imaging *in vivo*. Using this method, we successfully recorded putative synaptic inputs and action potentials from multiple neurons simultaneously. As a practical application, we also used 2P SynVolS-ST voltage and jRGECO1a calcium imaging to pharmacological epilepsy model, and found different dynamics of propagation of voltage and calcium transients under seizures. In conclusion, we have rationally designed SynVolS as a specialized probe for subthreshold potentials measurements, and combined it with jRGECO1a to perform two-photon, two-color voltage and calcium imaging, successfully detecting both spikes and synaptic potentials *in vivo*. This technique could be useful to large-scale analysis of input-output relationship during sensory processing, learning and decision making in awake behaving animals.

Title: Optimization of genetically encoded voltage indicators for *in vivo* imaging

Authors: *I. KOLB, A. ABDELFATTAH, B. ARTHUR, G. CAO, V. JAYARAMAN, D. KIM, W. KORFF, L. LAVIS, Y. LIANG, L. LOOGER, D. MERRYWEATHER, D. REEP, E. SCHREITER, Y. SHUAI, K. SVOBODA, A. TSANG, G. TSEGAYE, G. TURNER, A. WONG, J. HASSEMAN;
Janelia Res. Campus, Ashburn, VA

Abstract: Measuring millisecond-scale activity of multiple individual neurons *in vivo* is a key technology for studying signal processing in neural circuits. Genetically encoded voltage indicators (GEVIs) are promising tools because they directly sense neuronal membrane voltage and report both action potentials and subthreshold fluctuations in spatially resolved groups of neurons. However, because of limitations of existing GEVIs and the short durations of voltage signals, it has been challenging to image voltage in intact tissue, especially in densely-labeled populations of neurons. Imaging membrane potential dynamics in subcellular compartments has also remained out of reach. We used a high-throughput mutagenesis and screening pipeline to

improve the sensitivity of existing GEVI scaffolds for *in vivo* imaging. We screened >10,000 variants of ASAP1 in HEK cells and 1,500 in dissociated neurons and discovered variants that have a two-fold improved $\Delta F/F_0$, as well as a variant with high sensitivity in the hyperpolarization and subthreshold activity range. The top-performing variants were tested by patch-clamp in cultured neurons and were found to exhibit improved performance compared to other ASAPs. The variants had sufficient $\Delta F/F_0$ and signal-to-noise ratio to report action potentials *in vivo* under one-photon and two-photon illumination in mouse visual cortex. The addition of a soma-targeting sequence further improved *in vivo* signal fidelity. We additionally screened 3,400 variants of the chemigenetic GEVI, Voltron (Abdelfattah *et al* Science 2019). Several mutations conferred a two-fold improvement in $\Delta F/F_0$ over the original scaffold without sacrificing fast kinetics.

Title: Engineering red and far-red genetically encoded Ca^{2+} indicators

Authors: *R. DALANGIN, Y. SHEN, R. E. CAMPBELL;
Chem., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Genetically-encoded calcium ion (Ca^{2+}) indicators (GECIs) make up an integral part of the optogenetics toolbox, enabling direct measurement of Ca^{2+} dynamics across small and large populations of neurons. The green GCaMPs represent the peak of CI engineering; however, red GECIs are more desirable as their longer excitation and emission wavelengths enable deeper penetration into the brain. Additionally, red GECIs can be used with other indicators for simultaneous multicolour imaging of multiple analytes. Currently, while there are multiple red GECIs, there is no red GECI that matches the performance of the best GCaMP variants in all criteria, and efforts are ongoing to produce bright red GECIs with large dynamic ranges, fast kinetics, good photostability and minimal cytotoxicity. Here, we present our work on

engineering two series of red GECIs, RCaMP3 and the Far Red (FR)-GECOs. RCaMP3 is an updated version of the RCaMP series using mRuby3, one of the brightest red fluorescent proteins to date. Preliminary results indicate that RCaMP3 has a larger dynamic range and higher affinity than jRCaMP1b. The FR-GECO series, which is based on the far-red fluorescent protein mKelly, is a more red-shifted line of red GECIs, with excitation peaks 600 nm and emission peaks ~640 nm. Our variants show high affinity for Ca^{2+} with dynamic ranges ranging from 7-fold to 18-fold response to Ca^{2+}. We anticipate that these GECIs will be valuable additions to the available repertoire of genetically-encoded fluorescent biosensors.

Title: Improved genetically encoded indicators for multi-spectral fluorescent voltage imaging

Authors: ***M. KANNAN**[1], G. VASAN[1], C. HUANG[2], S. HAZIZA[2], X. LIU[1], C. GARDINER[1], M. J. SCHNITZER[2], V. A. PIERIBONE[1];
[1]The John B Pierce Lab., Yale Univ., New Haven, CT; [2]Stanford Univ., Stanford, CA

Abstract: Recent advances in technologies such as single-cell transcriptomics and genetic tools are propelling neuroscientists to probe brain function with the finest detail possible. While newer cell types are being uncovered, newer approaches to access these distinct cell types are also being described. The field is now in active pursuit of functional tools to study the dynamic interplay of these individual cell types as they act concertedly to influence network activity and behavior. Here, we describe the development of multicolor genetically encoded voltage indicators (GEVIs) and the optical instrumentation for studying spiking dynamics in distinct cell types, simultaneously, in live animals. As recording tools, GEVIs exhibit clear advantages over electrode-based approaches and Ca^{2+} imaging. Like Ca^{2+} imaging, but unlike electrodes, GEVIs enable functional readouts at high-throughput, unambiguous identification of recorded cell types and longitudinal access to identified neurons in chronic preparations. But surpassing Ca^{2+} imaging, GEVIs offer millisecond-scale temporal resolution and report voltage oscillations, subthreshold activity and hyperpolarizations with much greater fidelity. FRET-opsin GEVIs combine the superior kinetics of opsins with enhanced brightness of engineered fluorophores. The newest members of this advanced generation, Ace-mNeon and Varnam, immaculately capture spike waveforms in live animals under routine imaging conditions. We further improve the dynamic range of these sensors and deliver them to individual cell types using intersectional strategies to study the dynamics of neural microcircuits in mice and flies. By expanding their applications to monitor activity across multiple cell populations, we will maximize their potential to behave as surrogate electrodes in neuroscience research.

Title: Engineering calcium- and voltage- sensitive bioluminescent systems for *in vivo* imaging in brain

Authors: S. SUNITA[1,2], *J. PLATISA[1,2], P. O'BRIEN[1], K. TRIEBEL[1], M. CONNOR[1], C. GARDINER[1], J. CHOI[3], A. J. TAAL[3], J. D. FABBRI[3], K. SHEPARD[3], V. A. PIERIBONE[1,2]; [1]The John B Pierce Lab., New Haven, CT; [2]Yale Univ., New Haven, CT; [3]Columbia Univ., New York, NY

Abstract: Bioluminescence is the production of light in many organisms that is mediated by an enzyme-substrate (luciferase-luciferin) reaction. This phenomenon is used by diverse species such as marine animals, bacteria and fungi to serve myriad functions (defense, predation and mating). For optical imaging, bioluminescence is emerging as an attractive alternative to traditionally used fluorescent approaches as it shows low background, high sensitivity and does not require an illumination source. The last decade has seen a surge in targeted protein engineering to enhance native luciferase properties alongside the synthesis of stable substrate homologs, making bioluminescent systems useful for a wide variety of imaging applications. In this work, we focus on development of calcium- and voltage- sensitive bioluminescent indicators that will allow for *in vivo* imaging of neuronal activity at cellular resolution. To this end, we have targeted a recently published firefly luciferase derivative that produces red-shifted glow-type bioluminescence ($\lambda_{max}$of ~650 nm) when combined with a modified substrate. Our current strategy is to introduce calcium- or voltage-sensitive sequences, amino acid substitutions and linker-length deletions within the native enzyme to produce probes capable of recording neuronal activity with optimal spatiotemporal resolution. High-throughput *in vitro* characterization of these modified probes is performed by differential scanning fluorimetry and luminometer assays to provide key information on pH and thermal stability. The newly developed constructs have also been assayed for calcium or voltage sensitivity through systematic screening in human embryonic kidney cells and neurons. We used adeno-associated viral vectors for expression of the most promising mutants in the mouse brain, followed by *in vivo* imaging of neuronal activity using commercially available EMCCD cameras or novel, custom-made implantable lensless imaging systems.

Title: Exploiting intra-protein electron transfer for optimal temporal resolution in *de novo* designed genetically encoded voltage indicators

Authors: *M. J. IWANICKI[1], C. MOSER[1], B. Y. CHOW[2], B. DISCHER[1];
[1]Dept. of Biochem. and Biophysics, [2]Dept. of Bioengineering, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Developing probes that can monitor voltage signaling events on the sub-microsecond timescale and can be targeted to specific cells and membranes is crucial to advance our understanding of the communication between neurons. Organic voltage sensitive dyes can report changes in membrane potential on appropriate timescales with high sensitivity; however, they cannot be genetically targeted to specific cell types. This lack of targetability is solved by using genetically encoded voltage indicators (GEVIs). GEVIs are typically constructed from the voltage-sensing domain of natural proteins, but they tend to be dimmer and slower than organic voltage sensitive dyes. Here, we present our progress on the development and characterization of a new family of genetically encoded voltage indicators called THOR (Transmembrane Hemoprotein Optical Reporter), a fusion protein of a *de novo* designed transmembrane 4-α-helical protein and a fluorescent optical reporter. THORs bind heme in the core of the 4-α-helical bundle, and the heme oxidation states change as a function of the transmembrane electric field. The oxidation state of one of the heme cofactors is then reported via FRET by an optical reporter, i.e. the fluorescent protein mOrange2. The speed of THORs is dependent on electron transfer between the cofactors, and therefore, tunable by their distance. Our simulations revealed that we will be able to achieve µs responses. A water-soluble prototype of THOR expressed in E. coli undergoes 18% fluorescent quenching of mOrange2 upon heme reduction. Several different variants of THOR were designed with two different lengths: one that closely matches the thickness of the membrane and one that extends into the cytoplasm. THORs have been expressed in both HEK293t cells and rat hippocampal neurons. The trafficking of THORs into plasma

membrane of HEK293t cells was improved with the sequential addition of export tag sequences from the potassium ion channel, Kir2.1. We have confirmed that THORs in rat hippocampal neurons decrease their fluorescence upon membrane potential changes induced by addition of valinomycin.

Title: JEDIs - improved genetically encoded voltage indicators for imaging membrane potential dynamics

Authors: Z. LIU[1], X. LU[1], Y. GOU[2], S. GUAN[2], J. LEE[1], E. FROUDARAKIS[2], J. REIMER[3], A. S. TOLIAS[3], *F. ST-PIERRE[2];

Abstract: A longstanding goal in neuroscience is to understand how spatiotemporal patterns of neuronal electrical activity underlie brain function, from sensory representations to decision making. An emerging technology for monitoring electrical dynamics is voltage imaging using Genetically Encoded Voltage Indicators (GEVIs) — light-emitting protein indicators whose brightness directly reports voltage. GEVIs are promising tools for monitoring voltage dynamics at high spatiotemporal resolution in genetically defined cell types *in vivo*. Indicator performance has steadily progressed since GEVIs were first reported; they have also been deployed in multiple animal systems. However, despite significant progress made so far by the GEVI community, the performance of current voltage indicators is usually insufficient for robust single-trial two-photon imaging of voltage dynamics of many individual neurons in behaving rodents. As a result, GEVIs have yet to be broadly adopted.
The mechanisms of voltage indicators are insufficiently understood to enable purely rational engineering of new GEVIs with predictable outcomes, motivating the evaluation of many candidates to identify improved variants. As screening by patch-clamp electrophysiology can only evaluate fewer than ~10 new candidates per day, we are developing a pipeline for high-throughput screening of GEVI libraries, followed by detailed characterization of the most promising candidates. Here, we will present our ongoing efforts to develop improved methods for screening GEVIs, using indicators of the Accelerated Sensor of Action Potential (ASAP)

family as a starting point. We also present preliminary data on promising candidates identified during our screens, which are now referred as Jellyfish-derived Electricity-reporting Voltage Indicators (JEDIs). We anticipate that these efforts will ultimately produce high-performing indicators of broad utility for imaging spontaneous voltage dynamics in the brains of behaving animals.

Title: Comparison between transgenic and AAV-PHP.eB mediated expression of GCaMP6s using *in vivo* wide field functional imaging of brain activity

Authors: *N. MICHELSON[1], M. VANNI[1,2], T. MURPHY[1];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Univ. of Montreal, Montreal, QC, Canada

Abstract: Mesoscale imaging of genetically encoded activity sensors, such as GCaMP6, is a powerful approach to assess cortical activity and functional connectivity *in vivo*. Expression of GCaMP6 in mice is typically achieved using transgenic models or by intracerebral injection of viral vectors. Recently, blood brain barrier (BBB) permeable adeno-associated virus (AAV) variants, AAV-PHP.B and AAV-PHP.eB, have been developed, allowing for widespread transduction of neural cells using non-invasive intravenous (IV) delivery. Currently, no comparison between this expression strategy and other classical transgenic approaches has been conducted. In this study, GCaMP6s was expressed in the cortex of negative C57BL/6J mice (n=3) using tail-vein injection of the AAV.PHP.eB viral vector under a pan-neuronal human synapsin promoter; and fluorescence, responsiveness, and connectivity mapping performance were compared against three transgenic lines: Thy1-GCaMP6s (n=4), TITL-GCaMP6s (n=3), and tetO-GCaMP6s (n=3) and two reference lines (negative, n=2 and GFP, n=2). GCaMP expression strategies were compared using transcranial wide field single-photon imaging in awake head fixed animals. Epifluorescence brightness of PHP.eB mediated expression was comparable to Thy1-GCaMP6s, but dimmer than tetO-GCaMP6s and TITL-GCaMP6s. Peak $\Delta F/F_0$ response to visual flash stimuli was evaluated between expression strategies (Fig 1).

Further, spontaneous variations and regionally correlated activity maps calculated from resting-state activity were compared between expression strategies. We show that expression strategies employing the BBB permeable virus, AAV-PHP.eB, yield comparable expression and function as those derived from transgenic mice. We recommend single photon wide-field imaging of visual responses in awake mice IV injected with AAV-PHP.eB for the testing of new genetically engineered activity sensors.

Title: Imaging acetylcholine dynamics by GPCR-based fluorescent indicators

Authors: *M. JING[1], Y. LI[4], J. ZENG[2], M. XU[5], Y. LI[3];
[1]Peking Univ., Peking, China; [2]Peking-Tsinghua Ctr. for Life Sci., [3]Peking Univ., Beijing, China; [4]Yale Univ., New Haven, CT; [5]Inst. of Neuroscience, Chinese Acad. of Scie, Shanghai City, China

Abstract: Acetylcholine (ACh) regulates diverse physiological processes throughout the body, yet further deciphering the function and regulation of cholinergic transmission requires precise monitoring of ACh *in vivo*. By tapping into the natural-evolved ACh sensing GPCRs as the scaffold, we previously developed the first genetically-encoded ACh sensors (GACh2.0) with sub-second kinetics, high molecular specificity as well as physiological-relevant affinity in detecting ACh. To further improve GACh sensors, we conducted site-directed mutagenesis to optimize the residues at the interface between GPCR and cpGFP, which resulted in an improved version of GACh sensors, named GACh3.0. Comparing with the GACh2.0 sensor, GACh3.0 shows significant increase in fluorescence response to ACh, while still retain fast kinetics and high molecular specificity. Taking advantage of the sensitive GACh3.0 sensor, we successfully tracked the dynamics of endogenous ACh release in *Drosophila* olfactory system in response to multiple physiological-relevant stimuli. We further real-time monitored the ACh release in hippocampus of mice during sleep-awake cycles by fiber photometry recording system. Finally, using the miniature two-photon microscope, we achieved the imaging of locomotion-induced cortical ACh dynamics in free-moving mice. In sum, the new GACh sensor provide a convenient, broadly applicable tool for monitoring cholinergic transmission underlying diverse biological processes.

Abstract: Purinergic transmitters, e.g. adenosine (Ado), ADP and ATP, are playing important roles in a plethora of physiological processes, including sleep-wake control, learning and memory, cardiovascular activity and immune response. Malfunction of the purinergic signaling is implicated in diseases such as pain, epileptic seizures and drug addiction. A major obstacle to decipher the function of purinergic transmission is the lack of a direct, sensitive, and non-invasive method to monitor structurally similar purinergic transmitters, ideally with high spatial and temporal resolutions *in vivo*. Here by tapping into human Ado and P2Y receptors, we developed a toolbox of genetically-encoded G-protein coupled Receptor Activation Based (GRAB) fluorescent sensors, with unique molecular specificity for Ado, ADP, ATP and UTP. Purinergic GRAB sensors have good plasma membrane localization and exhibit robust fluorescence increases upon cognate ligand binding, as well as inheriting their parental purinergic receptors' binding specificity and affinity. Using $GRAB_{Ado}$, we successfully monitored electrical and high-KCl stimulation evoked increases of extracellular Ado level in cultured hippocampal neurons. Aided by fiber photometry, we successfully detected the dynamic change of Ado levels during chemical induced seizures and sleep-awake cycles in mice *in vivo.* Furthermore, using $GRAB_{ATP}$, we successfully observed the mechanical-stimulation or laser ablation evoked ATP signals in astrocytes *in vitro* and *in vivo*. In sum, the development of purinergic GRAB sensors provides critical genetically-encoded imaging probes for investigating purinergic transmission in physiological and pathological processes with molecular specificity.

Abstract: Serotonin (also called 5-HT) is an important monoamine neuromodulator, critical for regulation of sleep, appetite control as well as learning and memory. Malfunction of 5-HT may result in depression, addiction, compulsivity and other neurological disorders. One major obstacle to understanding the physiological regulation of 5-HT is lack of sensitive methods to track the dynamics of 5-HT non-invasively with good cell specificity and high temporal resolution, especially *in vivo*. Here, for the first time, we developed a genetically-encoded 5-HT sensor by coupling cpEGFP with a human 5-HT receptor. Upon 5-HT binding, the chimeric receptor changes its conformation which leads to a subsequent fluorescent signal increase from the embedded cpEGFP, therefore reporting 5-HT. We named this sensor "the GPCR Activation Based sensor for 5-HT, or $GRAB_{5\text{-}HT}$. With iterative engineering, we developed a series of $GRAB_{5\text{-}HT}$ sensors with high specificity and sensitivity. Furthermore, we demonstrated $GRAB_{5\text{-}HT}$ could be applied in multiple organisms, including *Drosophila*, mice and monkey for reliable detection of 5-HT *in vivo*. Thus, this tool would enhance our understanding of complex neuromodulation in health and in diseases.

Abstract: Endocannabinoids (eCBs) and neuropeptides are essential signaling molecules in both nervous and endocrine system. By modulating on the related brain circuits, these molecules are the key regulators for many neural processes, including social behavior, sleep and circadian rhythm, food ingestion and pain sensation. Monitoring these neuromodulators' dynamics in live animals allow us to understand their diverse functions in both physiological and pathological status. eCBs mediate pre-synaptic inhibition by retrograde transmission, a process that is often hijacked by the recreational usage of marijuana to exert psychoactive experiences among human. Neuropeptides are synthesized and packaged in large-dense-core vesicles and their secretion dynamics, which remains largely unknown, is greatly different from that of the canonical synaptic vesicles. Currently, one major impediment to decipher the function and secretion dynamics of eCBs, as well as other neuropeptides, is the lack of direct, sensitive and non-invasive tools to monitor these compounds *in vivo*, with high spatial and temporal resolutions. Here by tapping into their innate G protein-coupled receptors (GPCR), we developed a toolbox of genetically-encoded fluorescent sensors for eCBs, cholecystokinin (CCK), vasoactive

intestinal peptide (VIP), somatostatin (SST), vasopressin/oxytocin, ghrelin and orexin. These novel fluorescent sensors utilize GPCR receptors as the ligand sensing modules and circular-permutated GFPs as the optical output. These sensors have good membrane localization and exhibit robust fluorescence increase (up to 700% $\Delta F/F_0$) upon cognate ligand application, when expressed in cultured neurons. In addition, these sensors retain the molecular specificity and affinity of the native receptors and have minimal downstream G protein coupling, compared to their original GPCR scaffolds. The eCB sensor could detect the evoked eCB release through electric stimulation in acute mouse brain slice from striatum, and enable to monitor the dynamics of eCB wave during epilepsy in the hippocampus of live mice. We plan to further validate these peptide sensors mentioned above in slice & *in vivo* and extend the sensor development strategy to cover all known peptide GPCRs in human genome. These novel eCB and neuropeptides sensors can be powerful molecular tools that lead to a deeper understanding of the physiological- and pathophysiological- roles of eCB and neuropeptides transmission.

Abstract: The basal ganglia circuit has long been recognized as an important regulator for movement in the brain. Dysfunction of this circuit can result in motor disorders such as Parkinson's and Huntington's disease. The striatum, the largest nucleus of the basal ganglia, is critical for normal motor control and is implicated in the pathology of various movement disorders. Recently, it has been reported that striatal neurons are modulated during movement and that spatially clustered striatal neurons may encode similar aspects of movement. Current techniques fall short of demonstrating how striatal neurons contribute to and modulate motor output, due to the inability to record both spiking and subthreshold activity from multiple cells

simultaneously during movement. Here, we report a novel genetically-encoded voltage sensor, SomArchon, which exhibits millisecond response times and compatibility with optogenetic control, and which increases the sensitivity, signal-to-noise ratio, and number of neurons observable, by several-fold (to approximately a dozen neurons at once) over previously published reagents. Under conventional one-photon microscopy, SomArchon enables population analysis of neural activity, both at subthreshold and spiking levels, in multiple brain regions—cortex, hippocampus, and striatum—of head-fixed awake, behaving mice. Using SomArchon in the striatum, we detected both positive and negative responses of striatal neurons during movement, previously reported by electrophysiology but not easily detected using modern calcium imaging techniques, highlighting the power of voltage imaging to reveal bidirectional modulation. We also observed that adjacent neurons did not respond to movement speed in identical ways. SomArchon may thus help disambiguate activity amongst spatially clustered striatal neurons.

Abstract: Proper brain functions require highly coordinated activities among large groups of pre- and postsynaptic neurons. Many studies have demonstrated precisely timed interactions between spiking activity and local field potential (LFP) oscillations during behaviors. However, how subthreshold intracellular membrane voltage dynamics of individual neurons impact spike

timing in the brain remains largely unclear. *In vivo* intracellular recording has provided some valuable information, but often with one neuron being recorded at a time. On the other hand, calcium imaging can capture dynamic changes of intracellular calcium concentrations of individual neurons from a large population of neurons, but lacks the temporal resolution of individual spikes, let alone subthreshold voltage activities.
Here we demonstrate the capability of a newly developed voltage sensor, SomArchon, in recording subthreshold voltage dynamics *in vivo* with wide-field microscope. With SomArchon, we are able to simultaneously observe the activities from multiple neurons in awake behaving animal, while recording LFPs at the same time. We examined individual neurons' spike timing relative to their own intracellular membrane voltage oscillations or to LFP oscillations, and found that, in most neurons, spikes were more phase-locked to intracellular oscillations than to LFP oscillations. We further calculated the coherence of intracellular oscillations among simultaneously recorded neuron pairs, and compared that to the coherence between intracellular oscillations and LFP oscillations. We noticed a great heterogeneity in coherence, and coherence of intracellular oscillations between neuron pairs show larger variations than that between intracellular oscillations and LFP oscillations. Together, these results demonstrate that SomArchon enable the analysis of subthreshold dynamics in awake behaving mice brains, and open up new frontiers on understanding the significance of subthreshold oscillations in neural network computation and behavior.

Title: Recessed traces for low-stress passivation of chronic penetrating silicon microelectrodes

Authors: *N. NOLTA, P. GHELICH, M. HAN;
Univ. of Connecticut, Storrs, CT

Abstract: Implantable microelectrode arrays are important tools for neuroscientific research and clinical neuroprosthetics, yet despite decades of research and development, reliable multi-year functionality remains elusive. One commonly observed failure mode is degradation of passivation materials. Passivation materials electrically isolate the conducting traces from each

other and the saline environment, and additionally provide a barrier against water and ions which corrode silicon and metals. Various passivation materials have been tried, including silicon oxide, silicon nitride, polyimide, Parylene, and SU-8, but all are vulnerable to degradation. However, material composition is not the only factor influencing materials degradation; mechanical stress can also play a role. Indeed, there is evidence to suggest that the non-planar topography created by conducting traces creates stress concentrations that become weak points for degradation. Therefore, we developed a method for recessing traces within the substrate, flush with the wafer surface, so that overlying passivation layers are planar. The traces were 5-10 µm wide, up to 6 mm long, 400 nm thick, and planar within ± 10 nm of the wafer surface. The technique is self-aligned and requires no additional masks or polishing steps. Furthermore, we incorporated the technique into the fabrication process of our multi-site, multi-shank silicon electrode array designed for 3D stimulation of cochlear nucleus and found no negative impact on connectivity or impedance *in vitro*. Accelerated soak testing is in progress to determine whether devices with recessed traces are more resistant to corrosion than controls.

Title: A portable neurostimulator with wirelessly adjusted constant-current waveforms and bias voltage

Authors: *A. ERSOZ[1], H. PHU[1], I. KIM[2], M. HAN[3];
[1]Univ. of Connecticut, Storrs, CT; [2]Dept. of Med., Univ. of Connecticut, Farmington, CT;
[3]Biomed. Engin. Dept., Univ. of Connecticut, Storrs, CT

Abstract: Neural interface electronics are essential in stimulation and recording of neuronal activities. Off-the-shelf and application specific integrated circuits (ASICs) approaches are common ways to design portable or implantable neurostimulator and recording systems. Typical off-the-shelf neurostimulator electronics are constructed from multiples of printed circuit boards (PCBs), connected with connectors, which may consume power and space. On the other hand, ASICs are time-consuming to design and incur high non-recurring engineering costs. We developed a compact embedded system using off-the-shelf components and 32-bit ARM® microprocessor to generate constant-current waveforms with wireless control of anodic voltage bias that enhances charge injection. The six-layer in a single board PCB (four signal and two

power plane layers) has the microprocessor controlled by a user-interface via Bluetooth and programmed with ARM® Keil® µVision®5 IDE and STM32CubeMX ToolChain. We integrated two 3.7 V Li-Ion rechargeable batteries and a power management block regulating at 3.3V, 5V, and -5V. Fabricated PCB had dimensions of 64.13 mm × 52.56 mm × 7.68 mm. In benchtop testing, stimulation signals were generated constant-current waveforms and resulting voltage transients were monitored to ensure safety stimulation. Evoked neural response recording circuit was successfully validated by a Plexon headstage testing unit whose signals were filtered, amplified, and analyzed. The user interface transmitted and received wirelessly, including stimulation parameters such as amplitude and polarity of biphasic signals. In particular, anodic bias voltages were adjusted remotely via Bluetooth which was not available in earlier work. Furthermore, it consumes slightly less power in active mode than other published off-the-shelf systems. We showed that the system could perform constant-current waveforms generation, Bluetooth communication, channel switching, and neural recording, all on a single PCB with off-the-shelf components. Additional testing with microelectrodes *in vitro* and *in vivo* are underway, and this portable neurostimulator system may ultimately be used in behavioral experiments.

Title: Comparison of sputtered iridium and sputtered iridium oxide on silicon-based neural microelectrodes

Authors: *P. GHELICH, N. NOLTA, M. HAN;
Univ. of Connecticut, Storrs, CT

Abstract: Neural microelectrodes have small electrode sites that allow for spatially-selective stimulation and recording, however these small site areas impose demanding constraints on the materials used. The ideal electrode material needs to have low impedance, high charge injection capacity, high mechanical/chemical stability, batch fabrication, and high biocompatibility. Two of the most extensively-validated materials *in-vivo* are sputtered iridium and sputtered iridium oxide film (SIROF). Previous studies have characterized the effects of various deposition conditions on each of these film's characteristics, but few have compared these materials head-to-head while keeping the geometry of the electrode sites constant. Here, we fabricated silicon microelectrodes designed for penetrating auditory brainstem and midbrain with electrode sites

55x37 um or 110x37 um coated with DC magnetron reactively-sputtered iridium deposited under pure argon, 1:4 oxygen:argon, or 1:1 oxygen:argon flow rates at 4 mTorr deposition pressure. Films were characterized using x-ray photoelectron spectroscopy, scanning electron microscopy, optical microscopy, focused ion-beam scanning electron microscopy, and electrochemical measurements including cyclic voltammetry, current pulsing, and electrochemical impedance spectroscopy in phosphate buffered saline at pH 7. Results confirmed stable and uniform film deposition thanks to a titanium adhesion layer. Electrochemical measurements confirmed functionality of the devices is in the expected range, although there were differences for each film depending on its oxygen content. This comparison will enable researchers to screen for the ideal film for their application and further refine vacuum-based deposition conditions for neural applications.

Abstract: Currently, the standard electrodes for recording from the peripheral nervous system are extraneural and are generally only capable of detecting compound action potentials. Commonly used intraneural devices are relatively large and can cause severe tissue responses, which are non-ideal for a chronic devices. The demand for advanced neural interfaces that can provide highly selective stimulation and recording is growing. Previously, we developed arrays of neuron-sized 8-µm carbon fibers for cortical interfacing, obtaining long-term, high-fidelity single unit recordings with minimal to no histological response. We are translating these carbon fiber microelectrode arrays (CFMAs) to peripheral interfaces. CFMAs (200-250 µm length, 132 µm pitch, 2x8 fiber layout) were inserted into sacral dorsal root ganglia of anesthetized felines. Procedures are also being developed for CFMA insertion into other species and ganglia, such as

rodent major pelvic ganglia. Neural activity was recorded for various stimuli, including cutaneous brushing, bladder volume modulation, distal electrical stimulation, and spontaneous activity.
Unique unit waveforms across CFMA fibers were observed for various stimuli. Signal amplitudes of up to 350 µV peak-to-peak were detected. Bladder units with a firing rate correlation coefficient to bladder pressure of up to 0.97 were observed in multiple experiments. We also determined that CFMAs can withstand multiple insertions, allowing for repositioning within an experiment.
These acute experiments demonstrate the potential of CFMAs for single-unit specificity in peripheral nerve interfacing. Further work, including the development of mounting and attachment procedures, are necessary before these arrays can be evaluated in survival experiments.

Abstract: Glucose regulation is a vital continuous process for maintaining a healthy biological state. This requires complicated coordination between the endocrine and nervous systems. An important pathway in the peripheral nervous system for glucose regulation is the vagus nerve, as it connects the relevant organs in glucose regulation to the central nervous system. However, limited information is available on the neural activity for glucose regulation that propagates through the vagus nerve. An electrode that has shown promising neural recording abilities with minimal tissue damage in the brain is the carbon fiber microelectrode array (CFMA). We

hypothesized that a modified version of the CFMA with sharpened fibers can capture glucose regulation neural activity in the vagus nerve. In this study, we performed non-survival experiments on anesthetized, female Sprague-Dawley rats. Through a midline ventral cervical incision, the left vagus nerve was isolated and placed on a custom 3D-printed nerve-holder. A CFMA (10-16 fibers; 200-250 µm in length; 132 µm pitch; 2-row layout) was inserted in the vagus nerve and connected to a neural interface processor that recorded at a sampling rate of 30 kHz. A bolus of glucose (1 g), or insulin (8 U) was administered intraperitoneally to modulate blood glucose levels. Measurements of blood glucose concentrations from the tail were obtained every 5 minutes using a glucometer. Glucose administration elevated blood glucose levels by 60.6%. Approximately 2 minutes after glucose administration, an initial unit with an average amplitude of 72.2 µV peak-to-peak began firing at a rate up to 24 spikes/sec. This initial unit may represent afferent activity due to the detection of the glucose bolus. Around 30 minutes after glucose administration, larger units with amplitudes over 140 µV peak-to-peak occurred at peak firing rates above 30 spikes/sec. These units may be efferent vagus nerve activity to the liver to modulate glucose storage and production, as reported in the literature. Insulin administration decreased blood glucose levels by 22.4%. Neural units were observed 15 minutes after administration, with average amplitudes over 160 µV peak-to-peak, and peak firing rates above 45 spikes/sec. This activity may be afferent signals to increase glucose intake. Overall, our results demonstrate that CFMA is a viable electrode for recording neural unit activity for glucose regulation in the vagus nerve. Furthermore, this study suggests that the CFMA can be used to monitor neural unit activity in peripheral nerves to help better understand the neural regulation pathways in various physiological and pathophysiological conditions.

Title: Fabrication and characterization of a carbon fiber peripheral nerve electrode appropriate for chronic recording

Authors: *E. J. WELLE[1], A. A. JIMAN[1], P. R. PATEL[1], J. WOODS[2], J. M. RICHIE[1], E. C. BOTTORFF[1], J. P. SEYMOUR[2], T. M. BRUNS[1], C. A. CHESTEK[1];
[1]Biomed. Engin., [2]Electrical Engin. and Computer Sci., Univ. of Michigan, Ann Arbor, MI

Abstract: State-of-the-art intraneural peripheral nerve electrodes are large, silicon-based structures that cause a large histological response and are ill-suited for recording from small autonomic nerves. The focus of this work is to adapt our minimally-scarring carbon fiber electrodes for brain to a chronic intraneural nerve array. We aim to increase the durability of the carbon fiber electrodes to withstand the surgical handling necessary for nerve implantation, while maintaining a cellular scale electrode that can insert through epineurium. Toward that end, we embedded carbon fibers in silicone to increase robustness, sharpened the fibers to penetrate epineurium, and tested fibers coated with poly(3,4-ethylene-dioxythiophene):sodium p-toluenesulfonate (PEDOT:pTS) *in vivo*.

We tested the durability of carbon fibers by embedding uninsulated fibers in a body of silicone and inducing a 90-degree bend to simulate the expected shear forces seen during surgery. We found that fibers of 175µm length were robust to thousands of bend cycles. After 3000 bends, 15 of 16 fibers remained intact. We blunt cut carbon fibers using a 532nm green laser and inserted fibers into silicone of stiffness similar to epineurium to determine a length for *in vivo* testing. We found that blunt fibers reliably insert into silicone without breaking when less than 200µm in length (N=8 fibers). We hypothesized that sharpened fibers would insert into tissue more easily, and therefore sharpened fibers with a 3mm butane flame when protruding from the surface of water. The dimensions of sharpened fibers were 224µm in length with 147µm of exposed carbon and a tip angle of 72 degrees (N=24 fibers).

We inserted functionalized sharpened carbon fibers coated with PEDOT:pTS into peroneal and cervical vagus nerves of anesthetized rats (N=5 arrays, 71 fibers, 7 animals). In all experiments, we observed that the sharpened carbon fiber electrodes penetrated the epineurium for successful insertion. The average 1kHz impedance of coated fibers prior to and upon insertion was 38kΩ and 56kΩ, respectively. In both cases, the Z_{1kHz} of roughly 90% of fibers measured below 100kΩ. We recorded spontaneous and evoked neural activity in each experiment and are analyzing the data for discernable single units. We also inserted sharpened fibers into anesthetized feline sacral dorsal root ganglia (N=3) and confirmed insertion with evoked neural recordings and 1kHz impedances (Z=59kΩ).

This work shows that the durable nature of csarbon fibers embedded in silicone can withstand surgical handling and insert into various types of nerves. Our next step will be the fabrication of an array for chronic implantation.

Title: Design and testing of an active 4096 channel micro-electrocorticography (μECoG) array

Authors: *G. SHULL[1], J. VIVENTI[1], J. ROGERS[2], J.-K. CHANG[3], J. LI[3], E. SONG[3];
[1]Biomed. Engin., Duke Univ., Durham, NC; [2]Northwestern Univ., Evanston, IL; [3]Univ. of Illinois Urbana-Champaign, Urbana, IL

Abstract: Electrocorticography (ECoG) is used clinically for evaluation prior to epilepsy surgery. High-density micro-electrocorticography (μECoG) provides the ability to resolve finer features of local field potentials from the cortex. Additionally, μECoG can be used to record action potentials from the cortex if the electrodes are smaller than ~250 μm^2. However, creating small, dense electrodes limits recording area and electrode channels due to constraints imposed by individually wired electrodes.

Active μECoG arrays use transistor multiplexing at the recording site to scale the number of channels without scaling the number of wires, which enables high-density recordings without compromising recording area. Fabricating transistors in university cleanrooms adds significant noise that limits the density of active μECoGs. Advances in post processing commercial CMOS devices opens the door to designing smaller transistors and more elaborate circuit architectures on the electrodes that can be used to create dense, high-channel-count, low-noise arrays. Encapsulating the arrays in thermally-grown silicon dioxide extends electrode lifetime to several years.

This work describes the design, simulation, and testing of a (4,096 channel) μECoG array with an electrode area of 15 μm x 15 μm, a pitch of 50 μm, and a recording area of 3.5 mm x 3.5 mm. To determine the smallest size of transistors that would perform with suitable noise and gain performance, we simulated noise, gain, and parasitics of transistor widths and electrode architectures including a source follower amplifier. We then designed and laid out the array and sent it to the foundry for production.

We plan to post process the device from the foundry and attach it to a polyimide substrate to achieve a total array thickness of 25 μm. We will use bench testing to quantify noise and gain performance of the array, *in vitro* soak testing to quantify lifetime of the array, and *in vivo* acute experiments of rat auditory cortex to asses frequency decoding capability of the array. We hypothesize the array will increase decoding accuracy.

This electrode array will expand the capabilities of μECoG, enabling chronic, high-channel-count recording from the cortex with low noise, and high resolution.

Title: High density, actively multiplexed μECoG array (HDAMA)

Authors: *I. RACHINSKIY[1], L. WONG[2], C.-H. CHANG[1], C. WANG[1], M. TRUMPIS[1], J. OGREN[2], Z. HU[2], B. MCLAUGHLIN[3], J. VIVENTI[1];

Abstract: Background: The study of brain function involves observation of coordinated firing from populations of neurons that spread across large brain regions. Sensing of electrical signals from dispersed neurons is vital for neuroscience research and can aid in the understanding of mechanisms of brain function and for the treatment of brain disorders. There emerges a demand for highly conformal devices, which span large cortical regions and have sufficient spatial resolution, chronic recording capability, and a small implantation footprint. We, therefore, developed an actively multiplexed electrode array using soft material to capture the fine spatiotemporal information on the cortical surface. **Method:** We have designed a high density, actively multiplexed μECoG array (HDAMA) using a reinforced silicone substrate that is ultra-soft, highly conformal, and resilient to repetitive mechanical strain. 61 electrode contacts are arranged in an 8 × 8 array covering ~3.4 × 3.4 mm^2 area. Electrode contacts are made of bulk PtIr to ensure low impedance and biocompatible, chronic implantability. We also developed a miniaturized custom integrated circuit multiplexing chip housed in a near-hermetic package within the ultra-thin (<500μm) silicone nano-mesh electrode array, to allow high-channel count multiplexing at the implant site. The longevity of silicone electrodes was evaluated by *in vitro* soak testing in PBS at 60℃, resulting in about five-fold aging acceleration compared to body temperature. We also implanted the HDAMA over the rat auditory cortex and compared the performance of signal quality to previous publications. **Results:** *In vitro* accelerated soak testing of the electrode demonstrated projected robustness for over a year. Electrodes maintained impedance values of 5-15kΩ throughout 3 months of accelerated soaking (15 month *in-vivo*

equivalent). The recording capabilities of the device in both acute and chronic animal experiments displayed an evoked auditory response from all 61 channels both during surgery and for the following 30 days in a chronically implanted subject. Analysis of the *in-vivo* auditory-evoked response yielded 60% decoding accuracy (chance level, 8%) during intra-operative recordings and comparable accuracy to past publications [BM1] in chronically implanted animals. The multiplexing IC and data acquisition system showed comparable performance to a single-chip Intan RHD 2164 recording system, but with far fewer connector wires. By combining the electrode and the multiplexing chip into a unified near-hermetic silicone package, we will produce an electrode array with direct multiplexing capability through a system-on-chip approach.

Title: Kiloscale neural interfaces for long-term recording

Authors: *C. CHIANG[1], S. M. WON[2], A. L. ORSBORN[3], K. YU[4], M. TRUMPIS[1], B. BENT[1], C. WANG[1], B. PESARAN[5], J. A. ROGERS[2], J. VIVENTI[1];

Abstract: Background: Long-lived, high-throughput neural interfaces are essential for precise brain mapping and high-performance neuroprosthetic systems. Ultra-thin (< 30 μm), flexible electrode arrays can maintain signal quality over long periods of time with little tissue injury or irritation after implantation. Electrode arrays that sample neural activity densely, such as those used in micro-electrocorticography (μECoG), reveal rich spatial and temporal information hidden by traditional approaches such as electroencephalography (EEG) and conventional ECoG. Scaling such devices to sample over a thousand sites across a relevant centimeter-scale brain region requires integrating powered electronics into the device. Active electrode arrays

(with integrated, powered electronics) can enable such kiloscale sampling by multiplexing many electrode sites to only a few external wire connections. However, existing active electrode arrays largely rely on encapsulation strategies that have limited implant lifetimes. To solve this problem, we have incorporated a thin layer of silicon dioxide (SiO_2) to act as the dielectric medium for capacitive sensing and as the bio-fluid barrier. This flexible, active µECoG array provides stable and long-term (over a year) neural recording from rat auditory cortex. A scaled version of this array with 1,008 electrodes captured detailed spatiotemporal patterns across sensorimotor cortices from a non-human primate (NHP).
Methods: Actively-multiplexed, capacitive arrays were fabricated using an in-house transfer printing process. The kiloscale array included 1,008 electrodes, with a sensing area of 9 × 9.24 mm^2. The rodent array included 64 electrodes, implanted epidurally over rat auditory cortex. The overall device was ~25 µm thick. The biofluid barrier and capacitive sensing dielectric was provided by a 900nm thick layer of thermally grown SiO_2 (t-SiO_2). Decoding of 13 different auditory pure-tone stimuli was used to measure the long-term performance of the neural interface in rats.
Result: We present evoked responses and decoding performance for over one year of implantation in five rats. Leakage current remained below cutoff for the duration of the implants. The long-term signal performance is similar to passive, faradaic electrodes, except for additional noise added by the transistors. Implanted arrays showed stable performance over the entire implantation period. This work demonstrates the feasibility of using a ultra-thin layer of t-SiO_2 as the dielectric medium for capacitive sensing of neural signals and as the biofluid barrier, with a projected lifespan up to 60 years.

Title: An approach for functional validation of connectivity in neuronal networks

Authors: *E. GUZMAN[1], K. R. TOVAR[3], K. S. KOSIK[2];
[1]MCDB, [2]Univ. of California Santa Barbara, Santa Barbara, CA; [3]Neurosci. Res. Inst., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Intracellular electrophysiological recordings using patch-clamp from pre and postsynaptic neurons have been invaluable in helping to describe the ways that a neuron responds to input stimulus and has revealed many of the adaptive phenomena that neurons exhibit when exposed to changing stimulus intensity. Local field potential recordings of neuronal activity using multi-electrode array (MEA) devices offers the opportunity to perform high throughput studies of electrophysiological networks from cultured neurons. MEA's have been used extensively to try to infer functional connectivity of random neuronal networks through the use of several statistical techniques. However, methods to validate such statistical techniques on MEA's has relied heavily on simulated data and fails to validate the real biological network connectivity. Our results demonstrate that multi-electrode arrays can be used to quantify functional connectivity of cultured mouse neurons. We outline 2 methodological approaches for quantification based on passive recordings and employing extracellular stimulation. We perform physical and pharmacological manipulations on cultures that result in quantifiable changes to interactions between detected units. These approaches are advantageous over previously described method(s) since there is no patch-clamp is required to identify or validate connectivity allowing for higher-throughput connectivity measurements. Finally, this method is generalized enough that it can be applied to recordings most commercial MEA's currently available.

Title: Real-time processing and visualization of high-channel-count electrophysiology data with the open ephys GUI

Authors: *P. KULIK[1], A. DOSHI[1], A. CUEVAS LOPEZ[2], J. VOIGTS[3], J. H. SIEGLE[4]; [1]Allen Inst., Seattle, WA; [2]Dept. de Ingeniería Electrónica, Univ. Politècnica De València, Valencia, Spain; [3]Brain and Cog. Sci., MIT, Cambridge, MA; [4]Allen Inst. for Brain Sci., Seattle, WA

Abstract: The Open Ephys Graphical User Interface (GUI) is an open-source, cross-platform, plugin-based application for acquiring multichannel electrophysiology data (open-ephys.org/gui). It is designed to facilitate experiments involving closed-loop feedback, which require custom event detection algorithms and a flexible data processing pipeline. Open Ephys is currently used by hundreds of scientists in over 30 countries, and has a vibrant community of

researchers contributing to its development (github.com/open-ephys/plugin-GUI). We have recently adapted the Open Ephys GUI for use with Neuropixels, a new type of silicon probe capable of recording single unit activity across dozens of cortical and subcortical structures simultaneously. We are currently working on optimizing this software for large-scale electrophysiological recordings—up to 6144 channels—by improving the efficiency of the signal-processing pipeline and creating novel visualizations for high-dimensional data streams. With funding from a BRAIN Initiative U24 award, we will provide community-wide support for the software, including simplifying the installation process, enhancing available documentation and tutorials, and creating a centralized repository for sharing and downloading plugins. This repository will host user-contributed plugins, written in C++ or Python, that extend the capabilities of the core application. The plugin architecture makes it straightforward to create modules that interface with different types of recording devices, giving the Open Ephys GUI the potential to be compatible with a wide variety of high-channel-count silicon probes.

Abstract: Experiments involving freely-moving animals have become increasingly important in recent times. They allow for more complex set-ups than their stationary counterparts and make it possible to study more natural behaviours. One of the biggest technical limitations for such experiments is the need to handle cabling from the headpieces to the acquisition equipment. Recently, there have been developments on electrophysiology headstages capable of transmitting neural data wirelessly. The main limitation of these technologies is power consumption due to the large amount of data being transmitted, usually either requiring large batteries for prolonged operation or limiting acquisition to fewer channels or lower rates than wired systems.
We have developed a wireless headstage focusing on low power and reduced size while maintaining characteristics similar to regular wired headstages. Our current prototype is able to

acquire 16 channels at 200KS/s while consuming less than 150mA, while targeting a size under 9mm^2. To that avail, we have designed a compression algorithm that reduces the amount of data to be transmitted up to 40% of its original size, thus reducing power requirements proportionally. The compression algorithm has been designed to run in an Igloo nano device, an ultra-low power, small-footprint FPGA from Microsemi, which also controls the chip responsible for neural acquisition. Due to its packaging of 25mm^2, the selected device allows for miniaturized designs. The overhead current consumption for the compression algorithm in this specific device has been measured in less 1mA. To transmit data from the FPGA to the wireless controller, we have developed a packet-based communication protocol focused on minimizing memory requirements. This protocol allows the wireless transmitter to use lower power datagram-based schemes while maintaining signal integrity in case of transmission errors.
The decompression algorithm has been developed as a plugin for the Open Ephys GUI, an open source electrophysiology suite that provides a perfect framework to visualize, analyze and record the neural signals acquired by the headstage.

Title: A non-contact multi-channel probe for monitoring network electrophysiology

Authors: ***T. SHARF**[1], M. HARI[1], Z. CHENG[2], L. PETZOLD[2], P. HANSMA[3], K. S. KOSIK[1]; [1]Neurosci. Res. Inst., [2]Computer Sci., [3]Physics, Univ. of California Santa Barbara, Santa Barbara, CA

Abstract: In the field of modeling and treating neurological and psychiatric disease, the goal of scientists is to have efficient and cost-effective assays of multi-cellular electrophysiology. Observing electrical activity of large multi-cellular populations with single-cell resolution is a crucial step towards uncovering basic principles that govern their function, which may transform our understanding of and approach to treating disease. (For example, over the course of the past two decades over US $1 billion has been invested on clinical trials which have ultimately failed

to produce effective drugs treatments for Alzheimer's disease.) Current state-of-the-art multi-cellular *in vitro* electrophysiology technologies require individual cell cultures to be grown on expensive electronic devices that often degrade at the cell-sensor interface. These difficulties introduce significant batch-batch variability and affect overall long-term cell viability, making it a challenge to generate reliable statistics. This variability has impeded the progress of developing effective pre-clinical models of disease *in vitro*. To solve this problem, we have developed a new electrophysiology technology that can measure extra-cellular fields generated by neurons in a non-contact configuration and resolve the electrical foot-print of an arbitrary number of neuron cultures grown on disposable glass coverslips, rapidly, reliably and in succession without degrading its sensitivity or performance. Our technology that could serve to dramatically improve the development of assays to aid in screening the effectiveness of human drug responses at the preclinical level using patient derived neurons from human induced pluripotent stem (iPS) cells.

Abstract: Developments in microelectrode technology has enabled deeper understanding of brain and nervous system function. The small size and low capacitance allow microelectrodes to sense neurotransmitters (NTs) at rapid rates on the sub-second time scale. These measurements have traditionally been executed using fast scan cyclic voltammetry (FSCV) with carbon-fiber microelectrodes (CFMEs). While CFMEs have exhibited the properties needed for *in vivo* neurochemical sensing, the need for a stable, batch-fabricated, and up-scalable microelectrode remains. Diamond is a material which exhibits excellent fabrication flexibility in conjunction with many other advantageous electrochemical properties such as good biocompatibility, low background current, and wide potential window. In this work we demonstrate the analytical capability of a novel, all-diamond microfiber (μ-fiber) electrode for neurochemical sensing. The all-diamond electrodes consist of a conductive boron-doped diamond (BDD) core encapsulated

by insulating layers of un-doped polycrystalline diamond (PCD). Analysis by scanning electron microscopy (SEM) revealed overall dimensions of 6 μm high x 25 μm wide and ~2 mm in length with an electroactive surface area of roughly 70 μm^2. The diamond μ-fibers were electrochemically characterized using model redox analytes such as ferri/ferrocyanide ($Fe(CN)_6^{3-/4-}$) and ruthenium hexaamine ($Ru(NH_3)_6^{2+/3+}$), among others; excellent steady state response was observed for each analyte using cyclic voltammetry (CV). The diamond μ-fibers were then assessed for their ability to several clinically-relevant analytes, including multiple NTs. Multiple FSCV parameters were investigated such as waveform, scan rate, and potential range. These were completed using the High Definition Cyclic Voltammetry (HDCV) interface developed at the University of North Carolina Chapel Hill. These novel all-diamond μ-fiber electrodes have commercial-scale potential, generating a powerful tool for neurochemical analysis.

Abstract: Mapping brain circuitry is one of the greatest scientific challenges currently facing the neuroscience community, and developing new technologies with improved electrical and chemical signal detection from single neurons is a critical step to achieve this grand goal. Microelectrode implantation, as a practical approach, has shown promising feasibility for neuronal recording. Recently, our group has developed an all diamond microfiber electrode, consisting of a conducting boron-doped polycrystalline diamond (BDD) fiber encapsulated by an insulating microcrystalline diamond (MCD) shell. The diamond microfiber was fabricated by chemical vapor deposition (CVD) of thin MCD and BDD films on a silicon wafer. Both layers were plasma etched using a Cu mask to form microfibers. A sealing layer of MCD was selectively grown on the patterned fibers, except for the contact pads where a Ti/Cu mask was applied to inhibit diamond growth. After being released from the Si substrate, the tip of the fiber was laser cut to expose the BDD electrode. Building upon our prior work, this work presents the experimental characterization of the as-fabricated diamond fibers using bench-top and *ex vivo*

methods. In particular, electrochemical impedance spectroscopy was used to measure the impedance of the fiber over broadband. The electrodes show low 1kHz impedance of less than 200 kΩ, indicating the high conductivity of heavily doped CVD BDD. The stability of MCD packaging was evaluated using an accelerated aging test in phosphate-buffered saline (PBS) and 10-20 mM H_2O_2/PBS solution that mimics acute post-surgery inflammatory reaction, for up to 7 days at 87 °C in absence of light. *Ex vivo* electrophysiology validates the efficacy of the diamond microfiber for extracellular recording of single unit response in neural culture. Future work will focus on *in vivo* validation of device functionalities for single unit recording in living brain tissues.

Title: A wearable, high channel count, digitizing, neural signal amplifier for microelectrode recordings in humans

Authors: *N. R. HALPER[1], C. DRYDEN[1], M. SORENSON[1], M. GERHARDT[1], F. SOLZBACHER[2], R. FRANKLIN[1];

Abstract: The BRAIN Initiative sets out seven primary areas for researchers all of which have some dependency on electrophysiology as a primary method of further understanding the brain. Particularly, the new focuses of the BRAIN Initiative are on applications in human health and ability. As part of the call to map the brain in new, holistic ways, new electrode technologies are emerging and scientists are pushing towards larger channel counts to sample greater numbers of areas of the brain simultaneously. Electrophysiology equipment, such as amplifiers and recording systems, need to be created to meet the needs of researchers seeking BRAIN Initiative goals.
Microelectrodes targeting cortical or deep brain structures are required for understanding circuit dynamics in the human brain. Current technologies limit researchers to lower channel counts that restrict the understanding of circuit interactions or regional interactions in the brain. We demonstrate a new amplifier that miniaturizes and expands upon current technologies used in the most common environment for exploring single unit activity and deep brain structures in humans: the epilepsy monitoring and resection cases in research hospitals.
The goal of this poster is to characterize the new amplifier and demonstrate its capability at

enabling new avenues electrophysiology research. The poster demonstrates benchtop testing of frequency response, signal to noise ratio, compatibility with neural stimulators, and interface testing with upcoming electrode technology. Further, the poster is bolstered by in-human recordings demonstrating functionality of the device and recording capabilities that it enables.

Title: Biomimetic, multi-modal platform to validate soft neuroprosthetic technology

Authors: *G. SCHIAVONE[1], I. FURFARO[1], B. BARRA[3], F. FALLEGGER[1], J. BLOCH[5], G. COURTINE[2], M. CAPOGROSSO[4], S. P. LACOUR[1];

Abstract: Soft bioelectronics leverages the mechanical compliance of soft materials to optimise the design of long-lasting electronic interfaces with biological tissue, for both sensing and modulation of neural activity. In the field of neuroengineering, numerous examples of soft neural interfaces have recently been reported in the scientific literature, indicating that mechanically compliant devices help mitigate foreign body reactions. Such shift towards soft technology, however, has not yet been complemented by a corresponding evolution in testing and validation of associated experimental protocols. Conventional methods are based on norms developed for clinical implants that become inadequate to the peculiar electromechanical characteristics of soft

bioelectronics. Materials and integrated interfaces now need to maintain electrical and electrochemical functionality while withstanding significant and complex strains.
We present here a biomimetic and multimodal in vitro platform that enables soft interfaces to be tested against simultaneous, anatomically relevant, mechanical and electrochemical stimuli in a temperature-controlled environment. As a case study, we have designed a system that mimics the mechanical environment of the cervical segments of the Non-Human Primate (NHP) spinal cord. We chose the neck region as this is the segment of the vertebral column that experiences the most demanding mechanical strain. Computed Tomography (CT) and Magnetic Resonance Imaging (MRI) scans of a NHP were acquired to build models of the vertebrae and spinal cord, respectively, and prepare synthetic mock-ups. Replicas of the vertebrae were 3D-printed and assembled to form an artificial spine; a model of the spinal cord was reproduced using a moulded hydrogel enveloped in a thin silicone "dura mater". CT scans of the NHP were taken at rest and maximum strain postures in order to record 3D positions of the spine during physiological movements. The extracted coordinates were translated in spatial positions within a Stewart platform to replicate the natural displacements of the cervical segments. Cyclic actuation controlled via software automation was then applied to test the function and integrity of soft implants inserted "epidurally" in the spine model.
This multimodal and biomimetic approach to in vitro characterization enables both more pertinent evaluation of new neurotechnologies compared to standard protocols, and more efficient and faster development cycles compared to in vivo only testing.

Abstract: Advances in prosthetic limb development have allowed persons with amputations to improve their quality of life by allowing them to regain lost functions in a natural way that previous prosthetics have not been able to achieve. Stimulating neural tissue to elicit sensory precepts and recording electrical signals to control device motion can combine to produce amazing results for both patients and their families. While these devices hold much promise, their development still has several areas that require attention from the scientific, engineering, and medical communities. One of these areas that our group focuses on is a communication problem between tissue and computer systems. As prosthetic devices advance, the amount of information they need to function properly increases on average. While there likely exists some threshold of information bandwidth needed to provide baseline functionality, it makes rational sense that accessing more of the information contained in the neural tissue of a patient could provide higher-resolution sensory precepts and finer motor control with the maximum limit being that of a natural limb. Our approach to improving the available "natural limb" information that a prosthetic limb has access to involves interfacing with the remaining peripheral nerves that once projected to the missing limb.
The peripheral nervous system, unlike the central nervous system, exhibits a high propensity for regeneration. In the event of an amputation, doctors clinically manage the exposed nerve endings which can grow unguided causing painful neuromas. Typically, these nerve endings are placed into denervated, living muscle tissue such that they can have a target to reinnervate resulting in reduced neuroma formation. If these nerves were placed in a tissue-engineered scaffold surrounding a high-density, soft neural interface array and allowed to regenerate towards a distal target, it may be possible to achieve high information bandwidths into and out of the tissue. This study evaluates our device design referred to as a Tissue Engineered Electronic Nerve Interface (TEENI) using traditional cryosection-based immunohistochemistry, CLARITY cleared tissue with light-sheet imaging, and electrophysiological analysis. Each rat in the study had a small segment of the right sciatic removed and was then implanted with a TEENI device. Electrophysiology was recorded until the animal was euthanized and the tissue extracted for histological analysis. Preliminary results indicate successful recording of multiple action potentials per recording sites across multiple recording sites with histology revealing axons in close proximity to the device surface.

Title: Modeling the impact of size, shape, distance, and dielectric width on the recording performance of microelectrodes in peripheral nerves

Authors: A. FURNITUREWALLA[1], P. RUSTOGI[1], J. W. JUDY[1], ***E. E. PATRICK**[2]; [1]Univ. of Florida, Gainesville, FL; [2]Uniuniversity of Florida, Gainesville, FL

Abstract: Single action potentials (APs) from peripheral-nerve axons have been recorded intraneurally using a variety of microelectrode technologies. Since the ability to record single APs from many nerve fibers can help amputees control prostheses with higher precision, there is a drive to increase the count and density of microelectrodes in nerve fascicles. However, to design large-scale neural interfaces rationally, engineers need to be able to predict not only an optimal size and shape of the recording electrodes but also an optimal distribution and density of electrodes. This design-optimization problem is multifactorial since it depends on neural anatomy and morphology as well as nerve-fiber electrophysiology and the physics of volume conduction. Due to this complexity, quantitative rational design of microelectrode arrays for large-scale peripherals-nerve interfaces has yet to be performed. Fortunately, computational modeling provides a means to simplify and parameterize this complex design problem. We present physics-based computational modeling results that explore the dependence of important geometric design elements for planar microelectrode arrays fabricated on thin-film polymer dielectrics. We couple biophysical models of nerve fibers in NEURON with finite-element-method simulation of volume conduction in COMSOL. First, we explore the effect of electrode size and electrode-to-fiber separation on the amplitude of APs recorded from nerve fibers of various size. Results show that spatial averaging on a planar disc electrode greatly decreases signal amplitudes when the electrode-to-fiber distance is small and is worse for large electrodes. For example, an 8-um-diameter electrode would sense a signal amplitude that is twice that (or greater) of a 64-um-diameter electrode. Although this dependence falls off for greater electrode-fiber separations, the recorded signal approaches recording noise floors (~10 uV). Second, we explore the dependence of recording performance given a fixed electrode size and electrode-fiber separation and a variable width of surrounding dielectric. Although a smaller width of surrounding dielectric can increase interface density, simulations show that the amplitude of recorded APs is reduced. In addition, we use probability theory estimate the number of recordable fibers within a realistic population of nerve fibers. Abstract: Neural implants such as electro-corticography devices (ECoGs) are used to identify the seizure foci in drug-resistant epilepsy, or eloquent brain regions in tumor resections. Current devices used in the clinic comprise a thick silicone shell (0.5-2 mm), which impedes conformal contact with the brain. The electrodes are thick metal disks embedded in silicone, millimeters in diameter and pitch, providing limited spatial resolution. Additionally, the presence of bulk metal is not compatible with magnetic resonance imaging (MRI), which prevents precise localization of the electrodes on the brain post-implantation and diagnosis of adverse post-operative effects. A technology enabling both increased conformability, spatial resolution and MRI compatibility is therefore highly desirable. Here, we present a soft microtechnology to fabricate MRI-compatible, conformable, large-scale neural interfaces that enable localized brain recordings. Soft microelectrode arrays are fabricated on 150 µm thick silicone layers using for the recording sites a composite of platinum particles dispersed in silicone, which creates a low-impedance soft contact to the neural tissue. The electrodes are accessed via a stretchable interconnect patterned in gold thin film. Soft µECoGs were used to record somatosensory evoked potentials on the cortex in a minipig model. The design versatility enables brain recordings with high spatial resolution and the conformal coating offers high signal-over-noise (SNR of 4-50). This technology is scalable and enables high channel counts and large area coverage (2-2400mm^2),

with a high yield (>95% functional contacts). Sample arrays laid on gel phantoms in saline solution have been tested for compatibility with a clinical 3 tesla MRI against artefact creation and induced radiofrequency (RF) heating. Compared to clinical arrays where the image artefact is extending several millimeters outside the device, the soft µECoGs do not produce artifacts larger than 0.6 mm. For the heating, after 15 minutes of a T2-weighted sequence, a maximum temperature increase of 0.54°C was recorded, well below the safety limit of 2°C.
With an outlook to adoption to the clinic, this technology could help mitigate the occurrence of adverse effects as well as provide improved diagnostic capabilities.

Title: Tissue-engineered electronic nerve interfaces (TEENI): Improved design, fabrication, and packaging using aggressive *in vitro* reactive-accelerated-aging reliability testing

Authors: C. A. KULIASHA, B. S. SPEARMAN, E. W. ATKINSON, K. J. OTTO, C. E. SCHMIDT, *J. W. JUDY;
Univ. of Florida, Gainesville, FL

Abstract: Peripheral neural interfaces (PNIs) for amputees should reliably capture the activity of motor neurons and stimulate activity in sensory neurons for the lifetime of the patient. Existing implants typically fail within months to a few short years. In order to achieve lasting success with PNIs, the must be engineered to properly interface with tissue and be rigorously tested to mitigate *in vivo* failure mechanisms. Our hybrid tissue-engineered electronic nerve interface (TEENI) consists of multi-electrode polyimide-based “threads” embedded into a biodegradable hydrogel composite scaffold that is wrapped in a bioresorbable small intestinal submucosa and sutured to the ends of a transected nerve. We have found that first-generation TEENI devices are susceptible to failure and can exhibit a consistent foreign-body response around the microelectrode threads. Herein, we report on design modifications to the TEENI microelectrodes and the use of aggressive *in vitro* reactive-accelerated aging (RAA) to facilitate rapid fabrication-process improvements of the device and the back-end packaging to better withstand the harsh implant environment. With RAA (7-days, 87 °C, 10 to 20 mM H_2O_2 in phosphate buffered

saline) we revealed that the epoxy-based polymeric packaging material used for first-generation TEENI implants was susceptible to oxidative degradation. Improved silicone encapsulation was found to be more resistant to this degradation and the resulting explants (3-months, rat sciatic nerve, $n = 3$) showed no signs of failure. First-generation TEENI devices also used an anisotropic-conductive-adhesive (ACA) connector technology to interface it with external electronics. Since the RAA testing revealed that ACA can rapidly fail due to moisture penetration into the package, we are pursuing improved connector strategies. We used RAA to improve the fabrication process to better resist polyimide-polyimide delamination, and we have successfully fabricated devices that can resist 3-days RAA (~3 months *in vivo*). We are now pursuing additional improvements to increase the duration of implant survival. Lastly, we are exploring the use of TEENI microelectrodes with reduced cross-sectional areas to reduce bending stiffness and foreign-body response. We are also using RAA to validate the robustness of the dimensionally reduced devices in preparation for *in vivo* implantation. This work was sponsored by the Defense Advanced Research Projects Agency (DARPA) Biological Technologies Office (BTO) HAPTIX program under the auspices of Drs. Doug Weber and Eric Van Gibson through the DARPA Contracts Management Office, Pacific Cooperative Agreement: No. HR0011-15-2-0030.

Title: A multifunctional microelectrode array for long-term, high-resolution intracortical recordings

Authors: *J. M. HERRERA-MORALES[1], M. HEUSCHKEL[2], F. MOR[2], A. ROUX[2], A. WOODTLI[1], L. STOPPINI[2], J. DONOGHUE[1];
[1]Wyss Ctr. For Bio and Neuroengineering, Geneva, Switzerland; [2]Haute Ecole du Paysage, d'Ingénierie et d'Architecture (HEPIA), Geneva, Switzerland

Abstract: High resolution, long lasting sampling of neural, optical, chemical, or other activity in the nervous system for evolving applications such as brain-computer interfaces (BCIs) requires the long-term implantation of recording devices suitable for humans. Such sampling for humans BCIs has mainly involved one type of penetrating (intraparenchymal) array of multiple microelectrodes. These human BCI studies has provided proof of concept that cortical signals recorded with such technologies in people with paralysis can provide useful command signals for

several years, allowing people to control computers, assistive robotic limbs or even their own paralyzed limbs. However, current intracortical microelectrode arrays (MEAs) exhibit issues with long-term usability after implantation because of biotic and abiotic failures. Those abiotic in nature are due mainly to poor biostability of materials and related boundary layers in the harsh body environment. Additionally, current MEAs have complex manufacturing processes that are difficult to control and introduces sources of variability and device failure. Also, they are so far constrained in possible geometry configurations including the length, pitch, and shape of the probes due to manufacturing limitations. Finally, their cost is very high due to the intense technical effort required to manufacture them. Therefore, there is a need for a penetrating microelectrode array that can function for many years in the body and that can be (1) manufactured in a more automated and reliable manner and (2) provide greater flexibility of design (length, shape and pattern of electrodes) at a cost suitable for a device that can be commercialized for humans. The penetrating MEA presented in this exploratory study (the *Geneva Array*) addresses the above issues of long term biostability and design flexibility through recent advances in materials science and 3D microfabrication technology. This Geneva Array and consists of a multifunctional penetrating MEA laser fabricated from biostable bulk (glass) materials for insulation and support, as well as long term biostability, in conjunction with optical, electrochemically active materials for array functionalization, which is designed and produced to form highly reliable material interfaces between them. We will present results of electrical recordings of this novel MEA in 3D engineered neural tissue (ENT) made of neurons derived from human embryonic stem cells, as well as mechanical insertion tests in relevant tissues and mediums as a next step to in vivo implementation.

Engin., [3]Dept. of Electrical and Computer Engin., Univ. of Minnesota, Twin Cities, Minneapolis, MN

Abstract: Electrocorticography (ECoG) is a neural sensing modality that measures field potentials at the surface of the brain. The minimally invasive nature of ECoG allows long term implantation and facilitates high SNR signals as compared to scalp electroencephalogram (EEG) recordings. Recently, flexible ECoG electrode arrays have been developed that enable recording from large areas of the surface of the cortex by conforming to the 3D topology of the brain. However, current flexible ECoG arrays require MEMS processing and clean room operations, which greatly lower the accessibility of ECoG to unequipped neuroscience facilities. Here we demonstrate that readily available desktop tools - inkjet printers and nail salon ultraviolet (UV) curing lamps - can be harnessed to fabricate functional and flexible ECoG electrode arrays. Devices were fabricated by first printing silver nanoparticle (AgNP) ink, or PEDOT:PSS ink, onto a flexible polyethylene terephthalate (PET) film. A second print layer of SU-8 was applied to encapsulate the electrode leads, followed by curing under a UV lamp. Using this process, we have realized a fully functioning, 9-channel flexible ECoG sensor with a minimum print feature size of less than 100 μm, interelectrode pitch of 400 μm, and an electrode contact area of 0.01 mm^2. Following five-day submergence in 1x PBS, flexible arrays yielded impedances of 0.876 - 3.11 kΩ at 1 kHz. *In vivo* testing revealed electrode impedances in the range of 2.42 - 3.11 kΩ at 0.1 to 500 Hz and successful capturing of surface field potentials in anesthetized mice. We are working towards multilayered printing and streamlining the fabrication process so that it can be robustly applied in any neuroscience laboratory. We expect that this novel approach will facilitate high-level customization, accessibility, and rapid prototyping of ECoG sensors that can promote new kinds of experiments in neuroscience.

Title: Separation of drug effects in human iPS cell-derived neurons using MEA system

Authors: Y. ISHIBASHI, M. SHIMIZU, S. TAKAHASHI, R. YOKOI, N. MATSUDA, A. ODAWARA, ***I. SUZUKI**;
Tohoku Inst. of Technol., Sendai, Japan

Abstract: In vitro human iPSC-derived neurons are expected to be applied to toxicity evaluations in nonclinical studies and drug screening. Microelectrode array (MEA) measurement system is suitable to evaluate the neuronal electrophysiological responses to drugs. We have previously reported the electrophysiological responses to several convulsive compounds using MEA in cultured hiPSC-derived neurons. (Elixirgen, LLC). In this study, we evaluated the responses to convulsants and anti-epilepsy drugs (AEDs) more than 15 compounds having different mechanism of actions in cultured hiPSC-derived neurons (Elixirgen, inc.). Among the 80 parameters, we identified a set of parameters that could separate the mechanism of action of the drug. Drug effects acting on GABA, Glycine, Glutamate, Dopamine, 5HT, Muscarinic receptors and Na channel, etc. were separated by principal component analysis and clustering analysis using identified parameters. It was suggested that spike data obtained by MEA measurement in cultured human iPS cell-derived neurons contained information on the efficacy of drugs having different mechanisms of action. Our analysis method of MEA data can be applied to elucidation of the mechanism of action of drugs, safety assessments of new drugs and screening.

Title: Extracellular recordings of peripheral nerve compound action potentials and consecutive-trace bioimpedance measurements

Authors: *T. M. SMITH[1], C. A. R. CHAPMAN[2], J. AVERY[2], N. THOMPSON[1], I. TAROTIN[1], M. KELLY[3], D. GOODWIN[4], K. ARISTOVICH[1], J. PERKINS[5], D. CHEW[6], D. HOLDER[1];

Abstract: In the peripheral nervous system, the complex organisation and heterogeneity of nerve fibres make the development of non-invasive imaging challenging and this limits the efficacy of

therapeutic interventions. Therefore, a technique to non-invasively image the neural activity of specific fibre types, especially unmyelinated fibres, is required to improve therapeutic efficacy. This research aims to develop a robust method, that is non-invasive to the nervous tissue, for recording neural activity from unmyelinated crustacean nerve fibres using bioimpedance. The Animal Welfare Act protects animals in the U.K. and suffering was minimised. Firstly, to ensure the validity of the model, the crustacean nerve model, fibre size and conduction velocity was characterised. Staining revealed that all fascicles showed a similar distribution of diameters with: 48% < 5 μm; 42% 5 - 13 μm and 10% > 13 μm (n = 3 crabs, 4 front and 4 rear leg nerves each). Then, hook electrodes were used to deliver a monophasic pulse to activate nerve fibres and the resulting compound action potential (CAP) was recorded and this revealed three distinct peaks at latencies of 2.83, 5.49, and 9.09 ms, corresponding to conduction velocities of 1.8, 1.05, and 0.61 m/s. These conduction velocities, reinforced by the histological fibre size distributions, strongly suggest these nerve fibres are a relevant model of unmyelinated C-fibres. To record bioimpedance changes due to the CAP, a 10 μA electrical impedance (EI) current was injected at 225 Hz between two electrodes, spaced 4 mm apart, 8mm from the supra-threshold neuronal stimulation. With the constant current sine wave applied at a frequency of 225 Hz and a novel randomised phase summation subtraction paradigm, a bioimpedance change of -0.377% ±0.072 (n = 4 crabs) and a maximal SNR of 13.2 ±4.3 were recorded, which was far greater than at 625, 825, 1000, 3000, 5000, 7000 Hz (n = 4 crabs at each frequency). The bioimpedance change became positive at 625 and 825 Hz. Using 225 Hz and 4 mm between electrodes resulted in bioimpedance changes up to a maximum distance of 56 mm away from the onset of the CAP (n = 5 crabs at 8, 20, 32, 44 and 56 mm), with a non-statistically significant change being recorded at 100 mm as the bioimpedance signal was -0.05 ±0.04 (n = 3 crabs at 100 mm). Together, these results indicate that, using the Crab peripheral nerve as a model of C-fibers, the optimal parameters for bioimpedance measurements are 225 Hz, with electrodes 4 mm apart, at a distance of 20 mm from the onset of activity. However, at longer distances from the onset of activity, the SNR of the bioimpedance change is not significant from noise, whereas the extracellularly recorded CAP is.

Title: A fully transparent, flexible μECoG array based on highly conductive and anti-reflective PEDOT:PSS-ITO-Ag-ITO thin films

Authors: *W. YANG, Q. H. FAN, W. LI;
Electrical and Computer Engin. Dept., Michigan State Univ., East Lansing, MI

Abstract: Integrative neural interfaces combine neurophysiology and optogenetics with neural imaging, providing numerous opportunities for neuroscientists to study the structure, function, and diseases in neural circuits. Such a comprehensive interface demands miniature electrode arrays that are highly transparent, mechanically flexible, and biocompatible. Compared to implanted electrodes, microscale electrocorticogram (μECoG) arrays are less invasive, therefore reducing the risk of stroke, hemorrhage, and infection. Conventional transparent μECoG electrodes made of a single material, such as indium tin oxide (ITO), ultrathin metals, graphene and poly-(3, 4-ethylenedioxythiophene)/poly(styrenesulfonate) (PEDOT:PSS), have limitations and hardly possess the desired combination of broadband transmittance, low electrical resistivity, mechanical flexibility, and biocompatibility. Herein, we designed and constructed an ultra-flexible, highly conductive, fully transparent, and peak-transmittance-tunable μECoG array using a PEDOT:PSS-ITO-Ag-ITO multilayer structure on a thin Parylene C substrate. Each array consisted of 32 transparent microelectrodes distributed uniformly and divided equally into two 2.5 mm× 2.5 mm panels. To fabricate the μECoG array, 10 μm Parylene C was deposited on a silicon wafer. ITO-Ag-ITO thin films were deposited using magnetron sputtering and were then patterned using a lift-off process. The thicknesses of the individual layers were optimized using admittance loci to maximize the optical transmittance at a targeted wavelength. Next, a 2 μm Parylene C was deposited on the substrate as an insulating layer, and the contact pads and microelectrode areas were subsequently exposed to air by dry etching. Finally, 500 nm copper was sputtered on the contact pads and PEDOT:PSS was spun on the recording sites. The transmittance of the PEDOT:PSS-ITO-Ag-ITO assembly under the targeted wavelength on the Parylene C substrate was ~7% higher than that of a single ITO layer of the equivalent thickness. The impedance of the microelectrodes at 1 kHz was ~8 kΩ, suitable for electrophysiology recording. Microelectrodes based on PEDOT:PSS-ITO-Ag-ITO also showed an enhanced signal-to-noise ratio compared with the plain ITO electrodes. *In vivo* recording from the primary visual cortex of anesthetized rats validated the efficacy of the transparent electrodes for electrical detection of ECoG activity in living brain tissues.

Title: Early recurrence enables figure border ownership

Authors: P. MEHRANI, *J. K. TSOTSOS;
York Univ., Toronto, ON, Canada

Abstract: Rubin's face-vase illusion demonstrates how one can switch between two different interpretations depending on how the figure outlines are assigned [1]. This border ownership assignment is an important step in the perception of forms. Zhou et al. [2] found neurons in the visual cortex whose responses not only depend on the local features present in their classical receptive fields, but also on their contextual information. Various models proposed that feedback from higher ventral areas or lateral connections could provide the required contextual information. While some [3, 4, 5] ruled out the plausibility of models exclusively based on lateral connections, further evidence [6] suggests that ventral feedback even from V4 is not fast enough to provide context to border ownership neurons in V1 and V2. Therefore, the border ownership assignment mechanism in the brain remains unclear. We tested, with computational simulations, the hypothesis that the dorsal stream provides the global information to border ownership cells in the ventral stream. A novelty of our model is its combination of global and local context by incorporating dorsal early recurrence and ventral lateral modulations. Computationally fast dorsal cells with large receptive fields provide global context while ventral lateral modulations present local context and enforce collinearity for border ownership. Our simulation experiments show that our model border ownership neurons exhibit the appropriately different responses to figures on either side of the border and are invariant to position, size, and solid/outlined figures as observed in biological cells. Furthermore, our model cells assign borders to the occluding figure along the occlusion boundaries of overlapping shapes. Interestingly, testing with Pokemon figures, our cells respond to the illusory occluding shape. In conclusion, neurophysiological evidence regarding latencies together with our simulations support the hypothesis that dorsal recurrent and ventral lateral modulations cooperatively enable border ownership assignment.

Title: Triplet motifs sustain activity in sparse recurrent networks

Authors: ***Y. ZHU**, K. R. BOJANEK, J. N. MACLEAN;
Neurobio., The Univ. of Chicago, Chicago, IL

Abstract: Activity propagation is the most basic function that arises from the structure of neocortex. However, synapses are weak and connections are both sparse and recurrent, making it unclear how local connectivity supports stable spike propagation in local circuits. Several lines of evidence suggest that higher order network interactions may be instrumental for spike propagation. Synaptic connectivity displays a prevalence of local neuronal cliques and motifs, and propagating activity in vivo displays elevated clustering dominated by specific triplet motifs. Here we algorithmically build and analyze spiking neural network (SNN) models to explore the role of higher-order interactions in activity propagation. These models are recurrent and sparsely-connected with conductance-based synapses and are comprised of excitatory and inhibitory adaptive exponential leaky integrate-and-fire (AdEx) neurons. Network topology parameters are optimized using grid search bounded by experimental measurements and result in naturalistic activity in our simulations - that is, networks display asynchronous, low-rate, and critical spiking regimes. We find that simulations of the same topological SNN can either spontaneously stop (truncate) or show sustained spike propagation on different runs despite identical initial conditions in the simulations. Using graph theoretic and probabilistic methods, we find that sustained activity requires cyclic higher-order coordination amongst excitatory neurons. In particular, the network cycles through epochs dominated in turn by three types of triangle motifs. The fan-in triangle motif is predominant, consistent with the need for nodes to integrate information from multiple sources. The network then cycles through middleman, a hallmark of recurrence, and fan-out triangles which distribute information. When a network fails to engage this dynamical regime, activity is not sustained and truncates. We also find that for each network, there exists a unique linear relationship between the probabilities of each of the three motif types being most dominant in the network at any point in time. Successful runs occupy a highly restricted range of values on this line of probabilities. Our results provide a mechanistic account and possible explanation for the widespread findings of clustered activity as well as synaptic connectivity in local neuronal circuits.

Title: Extended associative memory by inhibitory modulation

Authors: *T. HAGA[1], T. FUKAI[2];
[1]Ctr. for Brain Sci., RIKEN, Wako, Japan; [2]Okinawa Inst. of Sci. and Technol. Grad. Univ., Onna-Son, Japan

Abstract: Associative memory is one of fundamental functions in the brain. To model this function, attractor network models based on excitatory Hebbian learning, typically represented by Hopfield model (Hopfield, 1982), has been used. Hopfield model learns memory patterns as attractors through Hebbian learning within each pattern, which enables memory retrieval from incomplete stimulus (pattern completion). Griniasty, Tsodyks and Amit (1993) extended Hopfield model by adding inter-stimulus Hebbian learning terms, which makes the attractor patterns correlated to each other even if memory patterns (stimulus) are mutually uncorrelated. This model can explain experimental observations of correlation between neural representations for associated memory items. As described above, Hebbian learning of excitatory synapses has been extensively studied. However, although recent experimental findings strongly suggest the computational importance of inhibitory learning in associative memory (Barron et al., 2017), the contribution of inhibitory circuits and plasticity to associative memory has not been theoretically understood. Here, we report that introducing anti-Hebbian learning to Griniasty-Tsodyks-Amit model, which can be implemented by pattern-specific local inhibition, gives previously unknown attractor states. In this state, the range of temporal association between memory items significantly extends. In other words, an attractor is correlated with a larger number of memory patterns and attractors are correlated more in this state than the original model. Furthermore, this extension is accompanied by the increase of susceptibility of attractors to external inputs, that is, an attractor pattern in this state can be easily shifted to other patterns by much weaker inputs than the attractors in the original model. We show that this change of attractor states can be continuously controlled by changing the ratio of local/global inhibition in a neural network, and those inhibition weights can be optimized by the inhibitory plasticity rule for excitation-inhibition balance (Vogels et al., 2011). Functionally, this model can be related to cholinergic modulation of inhibitory circuits and uncertainty. Furthermore, with inhomogeneous association

between memory items, this model can perform multi-resolution grouping of memory items based on the associative network structure. In sum, our model suggests an essential role of inhibitory modulation and plasticity in associative memory.

Title: Predicting dynamics from connectivity patterns in networks of canonical neural oscillators

Authors: *A. RADULESCU, S. EVANS;
Mathematics, State Univ. of New York at New Paltz, New Paltz, NY

Abstract: A point of great interest in computational neuroscience has been to explain how the hardwired structure of a network (such as the brain) affects its temporal function. The question has crucial applications and has earned its own subfield of study (currently known as *dynomics*). However, the task of translating connectivity patterns to ensemble temporal behavior presents the difficulty of simultaneously addressing the complexity of the graph and the richness of the coupled dynamics. This may be computationally intractable, even for relatively small network sizes and for reduced models of node-wise neural dynamics. To shed light on this relationship, a recent strategy has been to investigate it in basic theoretical models, where one may more easily identify and pair specific structural patterns to their effects on dynamics. For example, in threshold linear networks (Curto and Morrison, 2016), complex ensemble behavior emerges from simple, almost linear node-wise dynamics. This makes it feasible to identify relationships between specific configurations and corresponding dynamic patterns. While this represents remarkable progress, it is important to establish whether this type of predictive analysis can be applied to other classes of models.
We use quadratic maps as a canonical way to model a neural response function in each of the network nodes. In this case, one can conveniently use the system's asymptotic (Julia and Mandelbrot) sets to calculate, visualize and interpret the long-term behavior of the system (in both phase and parameter spaces, with the network structure acting as a bifurcation parameter). The advantage is that of using clear topological markers (e.g., connectedness of a set) as the signature for the global dynamics of the system, amenable for prediction and classification. We

present our first robust classifications of ensemble behavior based entirely on the network architecture, independently on the node-wise dynamics.
We compare our results with those in other simplified models, proposing that some aspects may be universal to nonlinear networks, and hence could be further applied to physiological models with more complex dynamics. We discuss how our results compare with the classification of attractor sets in threshold linear networks, and with synchronization and clustering behavior in inhibitory Hodgkin-Huxley neuronal networks (Golomb and Rinzel, 1994). In each case, we use the appropriate measures of synchronization and stability to assess and classify long-term dynamics; then we check if there is any overlap (*universality*) in these classifications.

Title: Correlations, population dynamics, and structural connectivity

Authors: *S. SARAF, L.-S. YOUNG;
New York Univ., New York, NY

Abstract: This is a theoretical study of correlations in spiking activity between neuronal populations. We develop a metric for quantifying brief-timescale spiking correlations, designed to capture the population firing structure without regard for individual neuron spikes. We show that due to the random behavior of single neurons, a population-level metric is more robust. In addition, the correlation is subject to an intrinsic optimal delay between source firing and target response. This method can be used to shed light on the transference of gamma rhythms between populations in a multi-component network. Because of hypotheses of the importance of gamma-band activity in information transfer, stimulus representation, and cortical state, quantifying the similarity between rhythmic firing of two populations would be a logical step in studying communication within the brain and neurological disorders that manifest as abnormal firing patterns.

Title: Robustly encoding multiple variables on smooth manifolds in a spiking model of hippocampus

Authors: *E. P. FRADY[1], F. T. SOMMER[2];
[1]UC Berkeley, Berkeley, CA; [2]Univ. California, Helen Wills Neurosci Inst., Helen Wills Neurosci. Inst., Berkeley, CA

Abstract: It is often argued that sensory areas extract behaviorally meaningful variables, often organized on smooth manifolds. Here we ask how combinations of such variables, once extracted, should be encoded to enable the brain to carry out critical computations for memory, planning and action. A useful encoding scheme has to fulfill two fundamental requirements: (1) Distinguishability: Points far apart on a manifold, should be encoded by dissimilar (independent or orthogonal) "indexing" patterns so that the probability of confusion is low. (2) Smoothness: Points close to each other should be encoded by similar patterns such that the code is noise tolerant and points can be represented by interpolation of neighbors. Some evidence that population codes in the brain fulfill these properties has been recently provided (Stringer⋯Carandini, Harris, 2018). Here we propose a normative encoding model with properties (1)-(2), leveraging timing of individual spikes. Our approach is based on complex-valued connectionist models (Plate, 1993), and recent theoretical results on how dynamics in complex state spaces can be mapped onto the dynamics of spiking neural networks (complex phase represented by spike-timing; Frady & Sommer, 2019). Our coding model "tiles" a manifold such that each location is represented by a unique neural activity vector that can be used as an index (1), but also in a way that transitions between neighboring tiles are smooth (2). As we show, this is accomplished naturally in the complex domain, with the sinc function as a universal kernel. Our approach is demonstrated in a model of hippocampus neurons that encode location and heading direction. The behavioral variables are organized onto smooth manifolds with appropriate topology: linear topology for location, and ring topology for heading direction. The coding model combines these individual representations of location and heading-direction into a representation of their conjunction, satisfying conditions (1) and (2). The resulting representation enables computations that are essential for navigation, such as the coordinate

transform from an egocentric to allocentric reference frame. Our model helps to explain recent observations of conjunctional receptive fields (Hoydal⋯Moser, 2019), and how to relate computation with manifold structure observed in neural recordings (Low⋯Tank, 2018). Specifically, the model suggests the intrinsic structure of neural recordings is influenced by: (i) manifold dimensionality (number of variables), (ii) manifold smoothness and resolution (number of tiles), and (iii) redundant neural dimensions for robustness.

Title: Cognitive chimera and synchrony states in human brain networks

Authors: *K. BANSAL[1,2], J. O. GARCIA[2], J. M. VETTEL[3];
[1]Columbia Univ., New York, NY; [3]Future Soldier Technologies Div., [2]CCDC Army Res. Lab., Aberdeen Proving Ground, MD

Abstract: The human brain is a complex dynamical system, and it functions through the emergence of spatiotemporal patterns of coherent and incoherent activity as regional neuronal populations interact. To support cognitive processing, these patterns of activity need to balance successful segregation of information for localized processing while also maintaining efficient integration of information for global coordination. As different regions dynamically interact to perform cognitive tasks, variable patterns of synchrony can be observed, including chimera states with separate domains of synchronized and de-synchronized dynamics and metastable states with intermittent synchrony and desynchrony. We propose that the spatial patterning of these synchrony states, within the regions of the brain, plays a fundamental role in guiding the emergence of human cognitive abilities and individual variability. A chimera-based framework allows us to analyze this patterning and understand its implications for cognition. In our recent paper (Bansal et al. 2019, Sci Adv), we used this framework to study individual differences in structurally-constrained computational models. Our results identified that different cognitive networks within the human brain show different levels of subject-specific and region-specific structural variability, accounting for the functional role they serve. Here, we extend this work on structural models to study functional neuroimaging data. We hypothesized that the evolution of chimera and synchrony patterns in functional brain dynamics will capture variability between tasks. More specifically, patterns would capture the segregation or integration of cognitive

systems specific to the regions previously associated with task dynamics. Our results demonstrate that the spatial patterning of synchrony states not only shows task-dependent changes, but it can be used to dissociate individual variability in task performance.

Title: Do tuned responses in cerebral microvessels imply lateral interactions among vessels? A computational study

Authors: *B. S. KUMAR[1], N. MAYAKKANNAN[1], **S. V. CHAKRAVARTHY**[1], P. KARA[2]; [1]Dept. of Biotech., Indian Inst. of Technology, Madras (IITM), Chennai, India; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Studies on cat's visual cortex (O'Herron et al 2016) have shown the existence of orientation and direction sensitivity in cerebral microvessels. In some cases, interestingly, orientation tuning of the vessels is quite different from the orientation tuning of its neural neighborhood. In order to account for this discrepancy, the authors of that study speculate that there could be propagation of dilatory signals from adjacent neural functional columns along vessel walls. We investigate this question using a computational model of neurovascular network and explore the right pattern of lateral interactions among the vessels that can account for the orientation tuning of the cerebral vessels and the neurons they perfuse. To this end, we use a biologically plausible self-organizing network known as Gain Controlled Adaptive Laterally connected network (GCAL) to model orientation and direction sensitivity in visual cortical neurons. This neural network is bidirectionally connected with a network of vascular units. Each unit of the vascular network integrates vasodilatory signals from the neural network through weighted connections, while each neuron integrates the flux of metabolic signals from the vascular network. The vessels are assumed to have circularly symmetric, center-surround type of lateral interactions. Three alternative forms of lateral interactions among the vessel units are considered. (1) No lateral connection (2) Excitatory center and inhibitory surround (3) Inhibitory center and excitatory surround. The afferent and lateral connections of neural and vascular layers are trained using Hebbian learning for the above three cases of lateral connectivity in the vessels. The performance of the neural and vascular layer is compared with the experimental

observations (O'Herron et.al 2016) and the architecture of vascular network that best matches with the experimental observation is selected. The performance is evaluated in terms of orientation selectivity index (OSI) and directionality index (DI). It is observed that when the vessels have a lateral interaction comprising of inhibitory center and/or excitatory surround, the performance of the proposed neuro-vascular system closely matches the experimental observations. The model suggests that the vascular network has active signaling within itself in an OFF-center, ON-surround fashion. These model predictions are consistent with previously reviewed evidence for existence of dynamic signaling within microvascular beds (Secomb and Pries 2002; Pradhan and Chakravarthy 2011).

Title: Synaptic plasticity rules for maintenance of spatial working memory

Authors: *J. GU, **S. LIM**;
Ctr. of Neural Sci., New York Univ. Shanghai, Shanghai, China

Abstract: Persistent activity that lasts long after the stimulus offset has been thought to underlie working memory. Interactions between neurons in recurrent networks were suggested to support such a persistent activity beyond the scale of membrane time constant. However, with perturbations in network connectivity, memory performance can be impaired. Here, we explored synaptic plasticity rules which enable to recover the ability to maintain persistent activity in particular for spatial working memory. Previously, Xie and Seung (1999) [1] showed that an unsupervised learning rule that penalizes the sum of squared changes (time-derivative) of activities can recover memory performance to maintain a graded persistent activity. We found that the network with such a plasticity rule only maintains spatially uniform patterns and the network for spatial working memory requires an additional factor that reflects the spatial pattern such as a plasticity rule that penalizes time-derivatives weighted by their activity. Furthermore, we found a condition under which a spike-time dependent plasticity rule can be approximated by

this rate-dependent synaptic plasticity rule and demonstrated its performance in a spiking neural network. [1] Xie and Seung (1999) Spike-based learning rules and stabilization of persistent neural activity, NIPS

Title: Structural functional relationships in the human brain networks

Authors: *F. ZAMANI ESFAHLANI[1], J. FASKOWITZ[1], B. MIŠIĆ[2], R. BETZEL[1];
[1]Psychological and Brain Sci., Indiana Univ. at Bloomington, Bloomington, IN; [2]McConnell Brain Imaging Centre, Montréal Neurolog. Inst., McGill Univ., Montréal, QC, Canada

Abstract: Nervous systems are complex networks comprised of spatially-distributed regions. These regions are linked to one another by structural and functional connections that represent interregional white-matter fiber pathways and pairwise statistical relationships between regional activity, respectively. It is widely understood that functional connectivity (FC) reflects the outcome of an ongoing dynamical process and is constrained by the underlying structural connectivity (SC). However, the precise mapping of SC to FC is poorly understood, especially at the level of individual brain regions. Moreover, little is known about how this relationship is modified across the lifespan as the brain develops, matures, and enters senescence.
To better understand the relationship between SC, FC, age, and location in the brain, we analyzed neuroimaging data from the NKI-Rockland sample. This publicly available dataset includes structural, diffusion, and resting state-functional MRI data for >1000 subjects and includes ages ranging from 6 to 85 years. We preprocessed and used these data to generate structural and functional networks for a final sample of 587 subjects.
For each subject and for every pair of brain regions, we calculated 22 network measures that quantified the ease of information flow under different communication policies. These policies ranged from “communication-along-shortest-paths” (path length) to “communication-along-paths-of-all-lengths” (communicability). Next, we combined these network measures as predictors in a multilinear regression model to predict the strength of the FC from one region to all other regions. The goodness of fit between observed and predicted FC was quantified using the coefficient of determination measure, R-square. Finally, to assess age-related changes in model fitness, we computed the correlation of the R^2 value with age for every brain region.
In general, we found that R^2 was higher in visual networks ('VisPeri', 'VisCent': R^2= 0.33, 0.32) suggesting their higher correspondence in SC and FC and lowest in a sub-component of the

control network ("ControlA": R^2=0.2). Interestingly, we found that model fitness within both visual sub-networks as negatively associated with the subject's age (r=-0.37, -0.28, p<0.001). Our findings suggest that the relationship between SC and FC is not uniformly distributed in the brain. Rather, there are brain areas such as primary sensory cortices that their FC patterns are more likely to be explained in terms of their SC properties compared to the transmodal areas. The difference of SC-FC mapping in primary sensory areas with transmodal areas needs to be further investigated.

Title: The organization of functional connections without direct structural links

Authors: *Z.-Q. LIU[1], R. F. BETZEL[2], B. MISIC[1];
[1]McConnell Brain Imaging Centre, Montreal Neurolog. Institute, McGill Univ., Montreal, QC, Canada; [2]Dept. of Psychological and Brain Sci., Indiana Univ., Bloomington, IN

Abstract: INTRODUCTION
Human cognition is supported by a networked system of interacting brain areas operating on different hierarchies. Functional connections (FC) are thought to be emergent from and soft-constrained by the underlying sparse structural connections (SC). FCs without SC vastly outnumber those with direct SC links, but their organization is not completely understood. This study aims to describe the organizational principles of those structurally-unconnected FCs by studying their 1) spatial distribution, 2) topological arrangement, and 3) correspondence to cortical processing hierarchies.
METHODS
MRI-derived structural connectivity and functional time series data of 66 subjects are used to construct 1000-by-1000 group consensus SC and FC matrices. FCs were first binned by Euclidean distance. Within each distance bin, FCs with no direct SC link were then expressed as a z-score relative to the distribution of FCs with a direct SC link. This method uses the well-known relationship between spatial proximity and connection strength to identify FCs that are stronger than would be expected on the basis of their length. A robust z-score value is then

estimated by averaging over a spectrum of bin sizes. We then study the topological and hierarchical organization of the resulting z-scored FC ('ZFC') matrix.
RESULTS
The ZFC values represent an intuitive depiction of FC that accounts for the spatial embedding between brain regions. We find that a large proportion of FCs with no direct SC link are significantly stronger than expected on the basis of their length and display greater variability. Interestingly, transmodal areas at the top of a putative sensory-fugal hierarchy tend to participate in a disproportionately large number of unexpectedly strong (i.e. high-ZFC) connections. Finally, the ZFC matrix displays a rich modular structure with high ZFC values residing within resting-state networks, suggesting that this intrinsic network architecture is driven by functional interactions that transcend spatial embedding.
CONCLUSIONS
Our work examines organizational principles of structural-unconnected FCs, emphasizing the importance of studying the subset of FC without direct structural links. We demonstrate a distance-corrected baseline method that can be adopted for robust SC-FC relationship modelling, and shows a correspondence with functional hierarchies of the brain.

Title: Systematic computational ablation for identification of oxygen sensation functional pathways in *caenorhabditis elegans*

Authors: *J. KIM[1], E. SHLIZERMAN[2];
[1]Electrical and Computer Engin., [2]Electrical and Computer Engineering, Applied Mathematics, Univ. of Washington, Seattle, WA

Abstract: The nematode Caenorhabditis elegans (C. elegans) is known to perform aerotaxis, behavior in which locomotion is modulated according to the composition of air in the environment. Sensory neurons related to O2 aerotaxis have been proposed through experimental research. In particular, it was shown that the sensory AQR neuron, located in anterior body, is a possible trigger for changing O2 level. Here we utilize a recently introduced C. elegans neuromechanical model, which emulates the full nervous system response to stimuli, and

simulate muscles commands and body postures. We employ the model to investigate behavioral responses to O2 and identify associated functional pathways. Our approach is to introduce spatial gradients which incorporate information about stimulation into neurons depending on the body position. We validate the model by placing an AQR gradient as an obstacle for forward locomotion and observe a steering away response from the gradient, as observed in experiments. Consequently, we propose a computational ablation approach for examination and testing of the effective functionality of AQR's sensorimotor neural pathways.
In particular, we propose a Combinatorial Neighbor Ablation (CNA), in which for a given set of neurons, all possible combinations of connected neighboring neurons are enlisted and ablation is performed for each combination. Application of CNA to the AQR neuron identifies a command neuron, PVPL and (PVPR, DVC) pair, that have the highest correlation with AQR induced O2 sensation, i.e., their ablation masks motor response when introduced with AQR gradient. Furthermore, to discover additional pathways that lie beyond neighbors of AQR, we perform Conditional Group Ablation (CGA) algorithm. CGA surveys and ablates each and every neuron in particular group (e.g. interneurons) given ablations of particular neurons. From CGA, we uncover additional functional pathways utilized by AQR, such as interneurons RIH and RIGR. With this study we show that C. elegans in-silico model in conjunction with spatial stimulation and systematic ablation can assist in identifying behavioral functional pathways and circuits, even in a complex model that incorporates connectomics, dynamics and body postures, exhibiting intricate behaviors such as aerotaxis.

Title: A spiking neuron model of pharmacologically-biased fear conditioning in the amygdala

Authors: *P. DUGGINS[1], C. ELIASMITH[2];
[1]Univ. of Waterloo, Waterloo, ON, Canada; [2]Univ. Waterloo, Waterloo, ON, Canada

Abstract: Network models that reconstruct (a) the dynamics of individual neurons, (b) the anatomy of specific brain regions, and (c) the behaviors governed by these regions are important for understanding mental disorders and their pharmacological treatment. We present a spiking neuron model of the rat amygdala that undergoes fear conditioning, and is appropriately modulated by GABA agonists like oxytocin (OXY). The network includes neural populations for

the lateral (L), basal (B), central-lateral (CeL), and central-medial (CeM) amygdala; interneurons; inputs from cortex and hippocampus; and (Motor) output. The model is trained by pairing negative stimuli (footshocks) with neutral stimuli (auditory tones) within a prescribed context (conditioning cage). Prediction error signals drive associative learning of synaptic connection weights in L and B. Following an experimentally-vetted training regime, the model exhibits the fear response (freezing, via CeM inhibition of tonically driven Motor) to presentation of the conditioned tone or context. Furthermore, repeatedly presenting tones without shocks in a new context causes extinction of the fear response in that context, but not in others. To simulate the pharmacology of OXY, we excite L-, B-, and CeL-interneurons known to express the OXY receptor. Applying OXY during training and/or testing significantly impairs the model's fear responses (Figure 1, mean and 95% confidence intervals reported over n=10 simulated trials), consistent with the reduced freezing observed in rats injected with OXY or other GABA agonists (muscimol). These results demonstrate that the mechanisms underlying fear conditioning, including associative learning, extinction, and pharmacology, can be understood through the dynamic interactions between amygdala nuclei. Extensions to the model will allow targeted biophysical manipulations and anatomical reconstructions of human amygdala; experimental predictions made from this model may profitably inform human pharmacology and the treatment of conditions such as post-traumatic stress disorder.

Title: Solving the exploitation vs exploration dilemma of reinforcement learning using a network of spiking neurons with reward-modulated STDP

Authors: *M. V. BAZHENOV[1], G. P. KRISHNAN[1], Y. SOKOLOV[1], N. IMAM[2];

Abstract: One of the fundamental problems in reinforcement learning (RL) is the exploitation vs exploration dilemma. This dilemma can be observed in the multi-armed bandit task, a classic RL problem. Through continuous interaction with the environment, the agent has to learn a strategy to choose an optimal arm that maximizes the total expected reward. In this study, we considered a multilayer network model of spiking neurons that was capable of learning the unknown parameters of the Bernoulli bandits' reward distributions. Using reward-modulated spike timing-dependent plasticity (STDP) along with homeostatic mechanisms, the network was capable of learning the unknown information on a synaptic level and ultimately able to identify the arm with the highest reward. In this model, a switch from the mainly exploration phase to the mainly exploitation phase occurred when enough information about each arm had been gained. This phase switch was mediated by the homeostatic plasticity rules that operate to maintain a constant firing rate in the network by reducing synaptic weights to suboptimal arms. In addition, when reward distributions were allowed to vary throughout simulation, the intrinsic randomness of spiking neurons helped to increase performance by forcing the agent to explore the continually changing environment. We implemented this model on Intel's Loihi neuromorphic chip and demonstrated that it performs well with space and time limitations as compared to other existing methods. The study predicts the importance of homeostatic scaling for learning multiple reward distributions and, more importantly, for keeping the network in a state of high awareness, helping the network observe changes in the environment.

Title: Multistability in the global dynamic of inter-areal brain networks - A model comparison

Authors: *C. DIMULESCU, N. ROTH, K. OBERMAYER;
Technische Univ. Berlin, Berlin, Germany

Abstract: Computational modelling of the human brain has the potential of not only offering tremendous insight into its underlying functioning mechanisms, but also to provide a framework for testing and optimizing experimental protocols, in particular transcranial current stimulation, before delivering it to patients. The most powerful class of models revolves around the idea that the brain operates as a nonlinear dynamical system at the edge of criticality, which continually explores multiple functional states, only to collapse into a certain state given some task. In this context, it is important to have a thorough understanding of the system's dynamical landscape and the influence that each parameter has on it. In particular, we are interested in identifying the regions where the topology of the network supports multistability, meaning that the system can easily transition from one stable state to another. To this end, two models for the dynamic of individual nodes are employed in the current work. On the one hand we consider a computationally efficient, biophysically calibrated neural mass model [1], that supports various dynamical states, including low and high activity fixed points, bistability, and limit cycles. On the other hand, with the FitzHugh-Nagumo model we consider a much simpler dynamic, that phenomenologically still resembles the low and high fixed points, as well as a limit cycle. In a first step, the topology of the network is constrained based on healthy participant data from diffusion-tensor imaging, while resting-state functional resonance imaging is used to constrain the model parameters. Subsequently, the dynamical landscape is explored by varying four parameters of interest: external current input to the neural populations, coupling strength between different brain regions, delay in the network, and noise level. The results show the presence of several dynamical regimes: at a coarse level, this can be divided into a state of no (or constant low) activity, an oscillatory state, and a state of high constant activity. The phase boundaries between those states are of special interest. Here we observe both multistability, as well as chaotic activity. These parameter configurations close to the bifurcation are strong candidates for task-dependent "operating points" that allow neuronal networks to perform information processing tasks. Interestingly, we also observe phase transitions within the oscillatory regime, between regions of full synchrony and chaotic behaviour, as well as an

intermediate one.

Title: Applications of nonlinear control to the dynamics of the whole-brain network: A model study

Authors: *T. CHOUZOURIS, N. ROTH, K. OBERMAYER;
Tech. Univ. Berlin, Berlin, Germany

Abstract: Modulating and controlling neuronal activity is becoming increasingly important in clinical settings for the treatment of neurological disorders. In this study, we use a model-based approach to investigate the impact of external stimulation on the global dynamics of the brain. We implement a network model simulating spatiotemporal activity in the brain and, using methods from nonlinear control theory, we optimize the stimulation effects. The brain model's structural connectivity is constructed using Diffusion Tensor Imaging (DTI) data from the Human Connectome Project (HCP) divided into 90 cortical and subcortical regions according to the Automated Anatomical Labelling (AAL) atlas, each region corresponding to a node in the network. The node dynamics are defined by the phenomenological FitzHugh-Nagumo model, simulating the neuronal activity of each brain region. We systematically explore the network's state space for varying parameters, examine its dynamical landscape, and characterize the emerging dynamical network states. From there, we subsequently add external control to the nodes inducing transitions between these network states. Defining a minimization problem for the above system, we analyse the external stimuli that optimize the input energy and the deviation from the target state. We tune the number of controlled brain regions via applying sparse optimal control. This way, we transition from global to targeted, local stimulation. The sparse input signals allow us to examine the contributions of different brain regions to the network dynamics. We investigate the relation of these findings to the network topology and measures from linear control theory.

Title: Redundantly large networks can learn faster

Authors: *D. V. RAMAN, A. PEREZ ROTONDO, T. O'LEARY;
Dept. of Engin., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Large numbers of neurons often encode overlapping or identical task-relevant information. What is the reason for this apparent redundancy? We show how it allows for fast learning of generic tasks to high levels of performance, despite information-poor, noise-corrupted task feedback from teaching signals. More generally, we show how adding redundant neurons to an existing network architecture can increase robustness of the learning process to imperfect sensory information, synaptic noise, and task-irrelevant adaptive processes at the synapse. This allows redundantly large networks to achieve faster learning rates, and higher levels of performance post-learning. Our analysis does not rely on a particular choice of task or learning rule. Instead, we conceptualise learning a task as decreasing the value of an abstract task error function. This function can be visualised as a landscape, whose height represents the degree of error, and whose x-y co-ordinates represent the state of the adaptive network elements (e.g. synaptic weights). We show how adding redundancy 'flattens' the landscape in a mathematically quantifiable way, and how this allows for faster learning in the presence of task-independent plasticity processes (e.g. synaptic noise, the effect of learning other tasks, corrupted task-relevant sensory information).
Is every redundant neuron created equal? The degree to which an extra neuron improves learning performance depends on how it is incorporated architecturally into the network. We create an analysis template for comparing different ways of adding a neuron. We see that excessive redundancy can harm learning performance if synaptic strengths are intrinsically unreliable: the total degree of noisy synaptic plasticity then increases with network size. We also show that embedding a low-dimensional input signal into a very high dimensional space is a highly favourable form of redundancy. This corresponds to the cerebellar architecture, where low-dimensional input from mossy fibres undergoes a huge dimensionality expansion at the granule cell layer.

Title: Learning complex action representations for goal-directed tasks through neuromodulation of Hebbian plasticity in modular spiking networks

Authors: *S. AENUGU, A. SHARMA, S. YELAMARTHY, H. HAZAN, P. S. THOMAS, R. KOZMA;
Univ. of Massachusetts Amherst, Amherst, MA

Abstract: Motivation: The computational models of decision making in basal ganglia primarily invoke actor-critic architectures from reinforcement learning (RL) theory. The phasic firing of dopaminergic neurons in response to an external reward is likened to the functioning of the critic which delivers the temporal difference prediction error as a teaching signal to the actor. In this study, we present an actor-critic framework which provides a theory about how complex action representations are learned with respect to specific goal-directed tasks in the presence of a neuromodulatory signal.
Methods: In this study we consider an agent navigating a maze with obstacles and stochastic state transitions. The state of the agent at any time is encoded using the place cell neurons and the actions are represented by neurons tuned towards specific directions. We incorporate a modular structure where a group of cells act as an intermediary between the place cells and action cells forming complex action representations. Structural credit assignment in such a network is accomplished by the neurons acting in a hedonistic fashion by locally optimizing their firing policy in response to the global modulatory signal broadcast by the critic. We implement a local policy gradient framework developed for interacting agents in RL theory[1] to update synaptic strengths between the neurons. We further prove theoretically that such a policy update is fundamentally equivalent to Hebbian synaptic plasticity. We use leaky-integrate-and-fire spiking neuronal model to simulate firing patterns of the neurons.
Results: The above modular spiking agent network learns to traverse the maze in fewer than 100 episodes. We average the learning curve over 100 trials to validate the robustness in learning. The variance in learning over multiple trials is further eliminated by incorporating neuronal ensembles and redundancy through population coding.
Conclusions: We formalized the concept of hedonistic neuron by defining a spiking neuron as an RL agent to account for neural coding of decision making and behavior. We thus provide a new convergent approach for training spiking neural networks using RL theory to solve goal-oriented tasks.

Title: Incorporating domain knowledge as a strategy for minimizing training requirements and improving generalization performance in convolutional networks applied to visual object recognition tasks

Authors: *A. S. RIOS[1], G. C. MEL[2], V. AKOPIAN[3], L. ITTI[1], B. W. MEL[1];
[1]USC, Los Angeles, CA; [2]Stanford Univ., Palo Alto, CA; [3]Google, Los Angeles, CA

Abstract: "Deep networks" (DNs) are inspired by the ventral visual processing stream, and can perform as well as humans on object recognition benchmarks. In other respects their behavior is very un-biological: (1) they require vast amounts of labeled data in order to learn, and (2) their generalization behavior is often very brittle. In particular, DNs can misclassify stimuli in ways that seem inexplicable to human subjects, and often perform poorly in learning tasks that require transfer or continual learning.
Our main hypothesis is that these undesirable performance characteristics result from the fact that layered DN architectures contain too many parameters, while lacking the proper representational biases needed to support rapid learning and natural patterns of generalization. Following the example of biological evolution, we hypothesized that generous incorporation of 3 types of domain knowledge can significantly reduce training requirements and improve generalization. These are: (1) laws governing natural image statistics; (2) the peculiar computing properties of neurons and neural circuits; and (3) the nature of the viewpoint-invariant object recognition task.
To begin to explore these hypotheses, we developed a new shape-intensive classification benchmark consisting of a 40K image subset drawn from the iLab 3-D object dataset (consisting of 10 classes of toy vehicles – cars, boats, planes, etc.; Borji et al, 2016]. To suppress all cues other than object shape, we randomized the hue and light-dark polarity of every input image on every presentation both during training and testing – producing unpredictably colorized images that nonetheless contained all of the original shape information. We compared classification performance using a fixed RESNET-18 network that received as input either (1) raw RGB (false color/polarity) pixel values vs. (2) explicit object boundaries detected by a sophisticated – but

fixed – commercial-grade contour-detecting front end (that also received false color/polarity RGB images as input). We found the compound network with shape pre-processing outperformed the conventional network (65.41% vs. 58.12% accuracy), suggesting that fewer modifiable parameters *would* have been needed by the compound network to achieve similar classification performance, a conjecture we are in the process of testing. Rigorous generalization tests of the two networks are also underway, as is development of a second stage of biologically-inspired shape pre-processing that we believe will further significantly reduce training requirements.

Title: Neural networks with motivation

Authors: *S. SHUVAEV[1], N. TRAN[1], M. STEPHENSON-JONES[1,2], B. LI[1], A. KOULAKOV[1];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Sainsbury Wellcome Ctr., Univ. Col. London, London, United Kingdom

Abstract: Motivational salience is a mechanism that determines an organism's current level of attraction or repulsion from a particular object, event, or outcome. In reinforcement learning, motivational salience is described by modulating the reward function by an externally controlled parameter that remains constant within a single behavioral episode. For example, the perceived reward associated with water is dependent on the current level of thirst; reward of food is determined by the level of hunger, etc. The vector of perceived values of various outcomes determines motivation of an organism toward different goals. Organism's behavior should be able to reflect the varying in time motivation vector. How can an organism adapt to behave effectively in conditions of different motivational contexts? Here, we propose a reinforcement learning framework that relies on neural networks to learn optimal behavior for different motivation vectors. First, we show that Q-learning neural networks, through function approximation, can learn to navigate towards variable goals whose relative salience is determined by a multidimensional motivational vector. Second, we show that a Q-learning network based agent with motivation can learn complex behaviors towards several goals distributed in an environment. Finally, we show that firing patterns displayed by neurons in ventral pallidum, a basal ganglia structure playing a crucial role in motivated behaviors, are

reminiscent of the responses of neurons in recurrent neural networks trained in similar conditions. In particular, similarly to pallidum neurons, artificial neural nets contain two different classes of neurons, tuned to reward and punishment. Overall, we suggest that motivation-based networks may generate complex ongoing behaviors that can adapt to dynamic changes in an organism's demands. Thus, neural networks with motivation can both encompass more complex behaviors than networks with a fixed reward function, and can be mapped onto neuronal circuits that control rewarded behaviors. Since animal performance depends on the states of satiety, wakefulness, thirst, etc., our approach should help build more realistic computational models that include these variables.

Title: Relating information flow and causal interventions in neural circuits

Authors: *P. VENKATESH[1], P. GROVER[2];
[2]Electrical & Computer Engin., [1]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Objective and Rationale
We propose a theoretical framework for understanding information flows, as well as the effects of interventions upon these flows, in neural circuits. We restrict our attention to event-related experimental paradigms, and seek an understanding of how information about the stimulus flows in these tasks. We extend our previous work *[Venkatesh et al., ISIT'19]*, which defined and identified information flow, by exploring the effect of causal interventions on these flows.
Methods and Results
Our theoretical framework is based on a graphical model of the brain: we treat the brain as being composed of different computational areas, or nodes, which interact with one another by transmitting random variables upon edges. Within this framework, we systematically define stimulus-related information flow with the help of information-theoretic measures. Our definition is one that is based on conditional mutual information, and provably satisfies intuitively desirable properties. Specifically, our definition guarantees the existence of "information paths" between input and output nodes of the graphical model, wherein all edges on the path carry information flow as per our definition *[Venkatesh et al., ISIT'19]*.
We then use techniques developed in the field of causal inference to understand the effects of causal interventions upon these information paths. Since our framework intrinsically accounts for

computational nodes which compute functions of their inputs, the model fits well within the framework of "Structural Causal Models". We show that if interventions on the stimulus produce causal effects at any node in the graph, then these nodes are guaranteed to have information flow to them, from the input nodes. We also present counterexamples to show that intervening on an information path *may not* cause effects on downstream nodes in the path. Likewise, the presence of causal effects due to interventions at a particular node does not imply an information path between these pairs of nodes.

Conclusions

Our work takes a systematic approach to defining information flow and explores the effects of causal interventions upon these flows. Such an approach has hitherto been lacking in other works that deal with information flow, including those based on Granger causality and Transfer Entropy.

Title: A new method for encoding sequence of sounds as words: A computational model of speech perception

Authors: *M. TOPALIDOU, G. HICKOK;
Univ. of California, Irvine, Irvine, CA

Abstract: In previous work, we proposed a novel method of encoding sequences by the synaptic weights of a speech production model that results in reduced spatial and temporal complexity compared to the existing proposed models. For example, speech production models generally contain buffers or working-memory modules to encode sequences (Bohland et al, 2010; Grossberg, 1978a) or use slots to label the kind of the unit (Foygel and Dell, 2000). The goal of this work is to demonstrate how the proposed sequence encoding in the weights emerges as a result of an initial learning of auditory-lexical association. Thus, we present a computational model of speech perception that learns the mapping between sound sequences and representations of individual words. The proposed model contains a lexical and auditory-phonological structures bidirectionally connected to each, which map onto the cortical regions of mid-posterior superior temporal sulcus/middle temporal gyrus (pSTS/pMTG) and posterior superior temporal gyrus (pSTG) respectively. Initially, the lexical units are randomly connected

in an all-to-all manner with the auditory-phonological units. Furthermore, a soft winner-take-all mechanism is implemented through self-excitatory and lateral-inhibitory connectivity among the units at each level. On each trial, input is sent to the 'phonemes' of a word with a short delay between them. The lateral inhibition among the auditory units results to a higher activity of the unit receiving a preceding input compared to its following one. The random connectivity between the two levels results in activation of only a few of the lexical units by these auditory units. At the end of each trial, Hebbian-learning is applied among the active units of the two levels. Analysis of the network behavior shows that after a simulation is completed, the lexical unit that represents a word is more strongly connected with the first 'phoneme' than the second one, and so on. This results from (i) the different maximum activity of the auditory-phonological units on each trial, and (ii) Hebbian-learning, where the more active a pre- and a post-synaptic unit are, the stronger they will be connected. A limitation of the model is that multiple lexical units can learn the same sequence, but also, in rare cases, a unique unit can learn multiple sequences. This might be remedied by adding a mechanism for pattern separation, e.g., modeling the function of the dentate gyrus in the hippocampus. To conclude, our model proposes a new method for encoding sequences in speech perception, that can easily be expanded to the encode of sequences in speech production as we previously introduced.

Title: Balance of excitation and inhibition maximizes the coding capacity of a network

Authors: S. CHOWDHARY, *C. ASSISI;
Biol., Indian Inst. of Sci. Educ. and Res., Pune, India

Abstract: The sense of smell, movement patterning and selection, and episodic memories are all instantiated in the wetware of the brain as the spatiotemporal activity of networks of neurons. The capacity of a network to encode information may thus be thought of in terms of the number of stable spatiotemporal patterns it can generate. Purely excitatory networks often tend towards synchrony. Inhibitory networks, on the other hand, can generate elaborate and distinct patterns of activity. Earlier studies have mapped patterns of activity in an inhibitory network to a structural property of the network, namely its coloring[1]. Neurons associated with the same color do not

inhibit each other and fire in approximate synchrony, while those associated with different colors spike at different times. There are typically many ways to color a network. In fact, even determining all possible colorings of an arbitrary network is thought to be an intractable problem. This combinatorial explosion of possibilities also implies that a single inhibitory network can potentially generate a large number of spatiotemporal patterns. Here we ask, how many patterns can a network elicit (the capacity of the network), how stable are these patterns and can the network flexibly switch between different patterned outputs? To address these questions, we consider a small network (81 neurons) with a large number of possible colorings based on the popular puzzle, Sudoku. Each solution of the puzzle is a coloring of the network. We show that this, in turn, maps to a spatiotemporal pattern of activity generated by the network. There are nearly a trillion possible Sudoku puzzles (and a trillion possible spatiotemporal patterns). The stability of these patterns, thus the capacity of the network, is contingent upon the presence of excitatory interactions between the neurons. We show that a balance of excitation and inhibition maximizes the capacity of the network.
[1] A coloring of a network is a prescription that assigns different colors to nodes that are connected to each other.

Title: Memory and cognitive capabilities of heterogeneous neural structures

Authors: *Y. G. T. TIRAT-GEFEN[1], A. TIRAT-GEFEN[2];
[1]Maxwave Res. LLC, Rockville, MD; [2]US Government, Rockville, MD

Abstract: This project evaluated whether heterogeneous cognitive processing elements (e.g. in a heterogeneous neural networks) representing artificial or biological cognitive systems can outperform structures of homogeneous processing elements (e.g. identical or nearly identical neurons in a neural structure).
Objectives of this research included: (i) to understand how to measure the similarity between the elements in the neural structure and to find the optimal dissimilarity level for maximum memory and/or cognitive processing capability; (ii) to evaluate the impact of random differences versus deterministic differences among neurons; (iii) the development of an analytical model for trade offs between similarity, memory capacity, and cognitive capabilities.
The methods used included a computational modeling to represent heterogeneous cognitive structures; an analytical mathematical model to measure the similarity between processing

elements or structures; and use of time-delays differential models to better represent biological neural structures. An emphasis was given to small grain neural structures, but other machine learning models were deployed to represent coarse grain heterogeneous structures in the brain, e.g. using reservoir computing or reinforcement learning models to represent large neural structures in the Basal Ganglia. Evaluated learning tasks included pattern recognition in images and time series.
The computational results indicated that slightly dissimilar structures have better memory and processing capabilities than homogeneous ones in many of the tasks evaluated; however these advantages are progressively lost as the degree of dissimilarity increases. This seems to mimic biological neural structures who exhibit a high level of similarity but are not solely composed of identical neurons. These findings are expected to help researchers to better understand how biological neural structures evolved; and to the development of new family machine learning methods using ensembles of heterogeneous processing elements.

Title: Effects of temporal clustering on learning in neural networks

Authors: *T. RAHIMI-MOGHADDAM, C. J. HONEY;
Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: MOTIVATION. Information arriving from the world is temporally clustered: two images seen consecutively (e.g. two items when shopping, or two plants when hiking) will tend to be more similar to one another than two images seen hours apart. How does the temporal clustering of information (i.e. training data) affect the speed and quality of what we learn? Temporal ordering is known to affect category learning in humans and in neural networks: learning prototypical items first is advantageous ("curriculum learning"), and "spaced" learning is often superior to "massed" learning. We aimed (i) to measure the effects of temporal clustering not only in supervised category learning, but also in unsupervised representation learning; and (ii) to identify biologically plausible learning architectures in which temporal clustering is especially advantageous for learning.
METHODS. Feedforward networks were trained to categorize visual stimuli (supervised learning) and autoencoders were trained to reconstruct the same stimuli (unsupervised learning). Training was performed using both backpropagation and target propagation. Temporal clustering of training data was parametrically controlled by drawing *n* consecutive samples from each

category.
RESULTS. Clustering of the training stimuli slowed learning in both category-learning and representation-learning. The effect was observed for all standard neural network architectures and learning rules. Drawing stimuli at random (the standard approach in machine learning) was superior to sampling with 2, 3, 4 or more consecutive exemplars from the same category. This effect was magnified when training employed mini-batches. A training protocol that eliminated all clustering was superior even to drawing stimuli at random (i.e. superior to the standard approach in machine learning research). These results generalized across MNIST and artificial datasets containing low category overlap.
CONCLUSIONS. We found any level of temporal clustering in training data, even the clustering that arises by chance in random sampling, slows down both category learning and representation learning in standard network architectures. This finding suggests that learning in artificial networks is optimal when the novelty of received information is maximized. However, a more biologically realistic neural architecture might still benefit from temporal properties of the information. Thus, our ongoing work examines biologically plausible learning architectures for which network dynamics capture the temporal structure of information, and where temporal clustering may itself be usable as a learning signal (Wiskott & Sejnowski, 2002).

Title: Optimal or random?: How correlated variability impacts population neural coding

Authors: *J. A. LIVEZEY[1,2], M. DOUGHERTY[1], S. MADHOW[1,2], P. SACHDEVA[1,2], K. E. BOUCHARD[1,2];
[1]Biol. Systems and Engin., Lawrence Berkeley Natl. Lab., Berkeley, CA; [2]Redwood Ctr. for Theoretical Neurosci., Univ. of California, Berkeley, Berkeley, CA

Abstract: Neural computations take place in the presence of noise. Across repeated presentations of a fixed stimulus, neural measurements exhibit correlated variability (noise correlations). Measuring and understanding noise correlations are important for determining fundamental limits on the fidelity of neural representations. We address three outstanding issues in the field: what impact the choice of discriminability measure has on theoretical predictions, how to measure the optimality of observed noise correlations, and what correlational structures

in large networks should be experimentally observable.
Our first contribution is a prediction, based on theory, that noise correlations measured in areas of the brain that represent a set of stimuli as discrete or categorical, e.g., phonemes in STG (Chang, 2010), will have a different structure compared to those measured in areas of the brain that represent a set of stimuli as a continuous manifold, e.g., rotations of moving bars in retina (Franke, 2016, Zylberberg, 2016). Our second contribution is a new null model for testing whether observed noise correlations are optimal. Specifically, this null model tests whether there is optimal alignment between the principal axes of the observed noise correlations and the mean stimulus-responses for a given discriminability measure. By contrast, previously proposed null models only test whether measured correlations are more optimal than having no correlations but equal per-neuron statistics. When compared across diverse real and synthetic datasets, we observe a profound change in statistical significance, indicating that current null models cannot be used to test the optimality of observed correlations. Finally, we use simulations to determine what structured correlations in large networks of neurons (10^3 - 10^5) can be measured in experimentally realizable sub-populations (10 - 10^2). Together, these results provide an experimentally testable prediction for the structure of neural data and improved methods for testing hypotheses about the optimality of observed noise correlations.

Title: Continuous-time partitioning of neural variability

Authors: *A. S. CHARLES, J. PILLOW;
Princeton Univ., Princeton, NJ

Abstract: Neural variability is ubiquitous in the brain and poses fundamental limits on the accuracy of neural codes. Recent work has shown that spike count variability in the early visual system can be partitioned into a modulatory gain component and a Poisson spiking noise component (Goris et al. 2014, Charles & Pillow 2017). However, these approaches examined spike counts in large (~1s) bins, and assumed the modulator to be: *(i)* constant for the entire

duration of each trial; and *(ii)* sampled independently across trials. This treatment ignores the fact that modulatory signals evolve continuously in time, and makes estimates of modulator variability highly dependent on the bin size used to count spikes.To overcome this shortcoming, we propose a model-based framework for continuous-time partitioning of neural variability. Our model describes both the stimulus-dependent firing rate and the time-varying modulatory signal with Gaussian Processes (GP). The observed spiking at every trial is then the sum of the stimulus GP and a noise GP passed through a nonlinearity. Our model significantly generalizes previous over-dispersion models by allowing estimation of a continuous-time spike rates. Specifically, the continuous-time noise GP allows our model to explain the difference in statistics across bin sizes by accounting for temporal correlations. Conditioned on estimates of the noise parameters, we can estimate the stimulus GP via a maximum *a-posteriori* optimization, using a Laplace approximation to marginalize over the noise process. While our model assumes a particular form for the non-stimulus contribution to spiking (i.e. the noise GP), there are many mechanisms that could cause such a contribution. Regardless, our model allows for the exploration of the effect of the relevant time-scales of these "noise" contributions, illuminating potential clues as to their sources and computational roles.

Title: Simultaneous EEG acquisition framework towards the massive EEG hyperscanning

Authors: ***S. LEE**[1], H. CHO[2], S. C. JUN[1];
[1]Gwangju Inst. of Sci. and Technol., Gwangju, Korea, Republic of; [2]Div. of Translational Med., Wadsworth Ctr., New York State Dept. of Hlth., Albany, NY

Abstract: Social interaction is one of the important activities of human beings and there are various efforts to understand the social interaction of people in recent years. As part of these efforts, investigators attempted to apply advanced acquisition system which simultaneously measures brain activities from massive subjects during social interaction, which is called hyperscanning. There has been recent work on how the brain responds to a competitive or collaborative paradigm in dyadic social interaction. In reality, interactions between the multilateral are very common as well as dyadic social interaction. In addition, beyond communication, there are also phenomena that only occur in a group such as Asch effect.

However, since research on current social interactions is quite limited in their methodology, most studies have focused on one-to-one situations. There are several reasons hardly to find hyperscanning studies among many persons. For example, a well-controlled experimental paradigm among multi-users is not easy to develop at a reasonably cheap expense. It is difficult to find a system that can measure a large number of people for research on group interaction. Therefore, in this study, we designed and developed a framework to acquire EEG signals at the same time in a large scale environment such as ten or more persons. The designed framework was modified repeatedly in a trial and error basis. Finally, our developed framework could simultaneously acquire the EEG signal from twenty persons wirelessly. In order to verify the developed framework, we performed watching emotion-evoking video experiments under the developed framework and successfully acquired brain signals from twelve users. It is believed that our developed framework may enable researchers to build their own signal acquisition systems for multi-users. It is expected that this system is able to utilize various studies such as crowd psychology, massive hyperscannning, many-to-many interaction, interactive contents development, and new BCI paradigm development. *Acknowledgments.* This work was supported by the Institute of Information & Communications Technology Planning & Evaluation (IITP) grant funded by the Korea government (No. 2017-0-00451)

Title: The influence of white matter lesions on the electrical field during transcranial electric stimulation. Preliminary results of a computational sensitivity analysis

Authors: *B. KALLOCH[1,2], K. WEISE[1,3], P.-L. BAZIN[1,4], L. LAMPE[1], A. VILLRINGER[1], M. HLAWITSCHKA[2], B. SEHM[1];
[1]Max Planck Inst. For Human Cognitive and Brain Sci., Leipzig, Germany; [2]Leipzig Univ. of Applied Sci., Leipzig, Germany; [3]Ilmenau Univ. of Technol., Ilmenau, Germany; [4]Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: *Objective*: Individual simulation of transcranial electric stimulation (tES) holds the potential to predict the stimulation effect by providing insight into the subject-specific distribution of the electrical field. Transcranial direct-current stimulation is investigated as a means for facilitating recovery after a stroke. Numerical modeling on an inidividual basis becomes particularly important for this application due to the large variety in occurring stroke lesions. For this purpose, an accurate, individual head model is required. The influence of stroke

lesions on the electrical field was investigated before [Minjoli et al., 2017]. However, it is still unclear whether white matter lesions (WML), a phenomenon of the aging brain frequently found in stroke patients as well, must be considered for an accurate simulation. *Methods*: In this study, we are going to investigate the influence of WML on the distribution of the electrical field by a group-level sensitivity analysis of individual head models towards uncertainty in tissue conductivity based on [Saturnino et al., 2019]. We specifically focus on a high uncertainty in the conductivity of WML ([0.04,1.5] S m-1). Seventy-eight subjects, gender- (#: 39) and age-matched (yrs: 70.81 ± 3.39) are distributed across three groups according to their Fazekas score from 1 (F1) to 3 (F3) (mean, normalized, relative lesion volumes: F1=0.780 % ± 0.007 %, F2=2.550 % ± 0.024 %, F3=8.6800 % ± 0.0355 %). A dual electrode setup (10-20 coordinates: C3, C4) with 1 mA current strength is simulated. *Results*: We report the standard deviation of the computed the electrical field strength due to the uncertainty in tissue conductivity and analyze the individual contribution of the WML tissue uncertainty to the observed deviation. Preliminary results of one subject (F3) are reported from the mid-layer of the cortical gray matter. The electrical field strength (range: [0.015,0.258] V m-1) showed a 99th-percentile peak deviation of 0.038 V m-1 in the sulcal depths. The uncertainty in skull conductivity was the highest contribution to that deviation (47.55 %). The contribution of WML was 15.6 % and exceeded that of healthy white matter (5.47 %). *Conclusion*: Based on these preliminary results we expect a non-negligible contribution of WML to deviations in the electrical field strength, which we will confirm in our group study. Our results will inform whether changes of the aging brain must be considered for an accurate application of tES.

Title: BrainIAK education: User-friendly tutorials for advanced, computationally-intensive fMRI analysis

Authors: M. KUMAR[1], C. T. ELLIS[2], Q. LU[1], H. ZHANG[1], P. J. RAMADGE[1], N. B. TURK-BROWNE[2], ***K. A. NORMAN**[1];
[1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Psychology, Yale Univ., New Haven, CT

Abstract: Advanced brain imaging analysis methods, including multivariate pattern analysis (MVPA), functional connectivity, and functional alignment, have become powerful tools in cognitive neuroscience over the past decade. These tools are implemented in custom code and separate packages, each requiring different software environments and language proficiencies to deploy for data analysis. Although usable by expert researchers, novice users face a steep learning curve. These difficulties stem from the need to learn a new programming language (e.g., Python), challenges in figuring out how to apply machine-learning methods to high-dimensional fMRI data, and missing or inadequate documentation and training materials. Furthermore, most standard fMRI analysis packages (e.g., AFNI, FSL, SPM) focus on preprocessing and univariate analyses, leaving a gap in how to integrate with advanced tools. To address these needs in the field, we developed BrainIAK (brainiak.org), an open-source Python software package that seamlessly integrates several cutting-edge, computationally efficient techniques with other Python packages (e.g., nilearn, scikit-learn) for file handling, visualization, and machine learning. As part of ongoing efforts to disseminate these powerful tools, we have developed user-friendly tutorials (in Jupyter notebook format) and exercises for learning BrainIAK and advanced fMRI analysis in Python more generally. These materials cover cutting-edge techniques including: MVPA (pattern classification and representational similarity analysis); parallelized searchlight analysis; background connectivity; full correlation matrix analysis; inter-subject correlation; inter-subject functional connectivity; shared response modeling; event segmentation using hidden Markov models; and real-time fMRI. For long-running jobs, with large memory consumption, we have provided detailed guidance on using high-performance computing clusters. These notebooks were successfully deployed and have been extensively tested at multiple sites, including as problem sets for advanced fMRI analysis courses at Yale and Princeton universities and at workshops and hackathons at Princeton, Yale, and Virginia Tech. We are excited to announce that these materials are now freely shared, with the hope that they become part of a growing pool of open-source software and educational materials for large-scale, reproducible fMRI analysis and accelerated discovery.

Title: A mathematical framework to classify motivated mental states with EEG

Authors: *I. COS[1], N. IZAGUIRRE[3], M. GILSON[4], G. DECO[2];
[2]ETIC, [1]Univ. Pompeu Fabra, Barcelona, Spain; [3]Pompeu Fabra Univ., Barcelona, Spain; [4]Ctr. for Brain and Cognition, Barcelona, Spain

Abstract: How does social motivation influence motor behaviour? Although several studies have gradually dissected different aspects of motivation and have systematically probed specific brain areas responsible for them, we still lack a normative context capable of relating the expression of motivation on behaviour to its neural dynamics. Towards this end, here we investigate how social motivation influences movement parameters and decisions between actions, and investigate whether and how they reflect on changes of brain functional connectivity. Specifically, twelve human participants performed a decision-making paradigm, making choices between precision reaching movements. We manipulated the participants' motivated state by making the participant play either alone or with a simulated partner. In this context, the amount of reward obtained by the participant and by his/her partner was reported at the end of each trial, as a function of their end-point precision. No specific mention to competition was ever made to the participant. We simultaneously recorded kinematic, oculometric and EEG data. Our behavioural results show that end-point precision increased alongside with the partner's skill and that movement duration increased when playing with a partner, indicating a covert process of increased concern for performance whenever a partner was present. As a validation, we performed two complementary analysis of the subjects' electro-encephalographic recordings. First, a mental state discrimination analysis using several machine learning classifiers. Our results show that the mental states are best separable by means of the logistic classifier, with an 80-90% accuracy in most participants. Second, we performed an analysis of sources by means of a Functional Connectivity analysis, showing that the covert process of motivation includes significant changes on alpha-band sources in occipital areas. While these results require further testing, they clearly show that the presence of a partner modulates the participant's concern for performance, and that this responds to specific changes of functional connectivity typical consistent with the modulation of attentional load.

Title: NiBetaSeries: Assessing task connectivity

Authors: *J. KENT[1], M. VOSS[2];
[1]Neurosci., [2]Dept. of Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: Resting state functional magnetic resonance imaging (fMRI) has enjoyed a privileged position as an assay of the functional connectivity of the brain. Task fMRI, on the other hand, has not been given the same privilege. The dominance of resting state fMRI is partially be driven by the ease of analysis relative to task fMRI. There are few tools that are designed to analyze the correlations of task evoked responses in task fMRI, and none that use the burgeoning Brain Imaging Data Structure (BIDS) for organization of inputs and outputs. NiBetaSeries fills this gap by utilizing minimally preprocessed data and raw data stored using BIDS to generate task evoked region to region correlations across the brain. NiBetaSeries is an open source BIDS application for the analysis of task evoked correlations, otherwise known as betaseries correlations. To test the validity and functionality of NiBetaSeries, we used freely available and simulated data.The open data we tested shows biologically plausible correlations between regions (Figure 1). We tested the validity of NiBetaSeries under different task conditions with simulated data. The simulated data show that higher signal to noise ratios have a dramatic impact on the ability of NiBetaSeries to accurately report region to region correlations. The overall results demonstrate NiBetaSeries as a working application for the analysis of task evoked correlations. NiBetaSeries helps to level the playing field between resting state and task fMRI by easing the process of analyzing task fMRI for connectivity.

Figure 1.
region-region beta series correlations from sub-01 from ds000164 (Verstynen, 2014) performing the Stroop task. The trial types within the stroop task could either be congruent, incongruent, or neutral. The subject's data was downsampled to 10x10x10 mm voxels in the tutorial to reduce compute time. The Schaefer (2018) atlas was used to combine voxels into meaningful regions.

Title: Non-parametric discovery of population dynamics from large-scale activity recordings

Authors: *M. GENKIN, T. ENGEL;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Recent technological advances enabled activity recordings from hundreds of neurons simultaneously, opening an opportunity for neural population analyses. However, existing methods for extracting neural population dynamics from data lack either flexibility or interpretability. On one hand, methods fitting *ad hoc* parametric models to data are restricted to specific *a priori* hypotheses, which are not guaranteed to reflect the actual biological mechanism. On the other hand, the overparameterized models, such as artificial neural networks, are very flexible but difficult to interpret.

We develop an alternative non-parametric approach based on latent Langevin dynamics, which discovers an interpretable model of neural population dynamics from the data without *ad hoc* parametric assumptions. In our framework, changes of the neural population state over time are governed by a low-dimensional dynamical system, where driving forces can be continuously morphed to capture arbitrary non-linear dynamics. The activity of each neuron is related to the instantaneous population state via idiosyncratic firing-rate functions, which allow for heterogeneity of single-neuron responses. The driving forces and firing-rates are simultaneously optimized over the space of continuous functions to find a dynamical model that best describes the data. We develop a gradient-descent optimization algorithm that traverses the space of dynamical models of increasing complexity. To identify the model with the correct number of dynamical features, we develop a criterion based on a tradeoff between generalization accuracy and model complexity.

We show that our computational framework accurately recovers ground-truth population dynamics and firing-rate functions on synthetically generated datasets with biologically realistic amount of data. We demonstrate the scalability of our methods by recovering dynamics on large synthetic datasets (~150,000 spikes) of many neurons with diverse firing-rate functions. Our framework is suitable for analyzing multielectrode recordings with heterogeneous responses of

single neurons. It can be used to reveal mechanisms of neural computations on single trails and is broadly applicable to different behaviors and neural circuits in the brain.

Title: Generating personalized brain models at high spatial resolution using Mesoscale Individualized NeuroDynamic (MINDy) Modeling

Authors: *M. SINGH, S. CHING, T. BRAVER;
Washington Univ. In St. Louis, St. Louis, MO

Abstract: Several recent initiatives have produced innovative whole-brain dynamical systems models of neural activity. Unfortunately, there remains a gap in systems neuroscience communities between generative models of brain dynamics vs. descriptive/statistical models of brain activity. Statistical models such as the functional connectivity matrix (FC) have proven highly amenable to data-driven characterizations of individual differences but do not allow for the overt construction of mechanistic hypotheses. In the current work, we aim to bridge this gap with a procedure to rapidly fit large-scale dynamical-systems models to individual subjects using fMRI. We propose a novel procedure to parameterize networks of hundreds to thousands of nonlinear neural masses (parcels) each with their connections, intrinsic decay, and a transfer function which converts activation to output. The procedure contains three main ingredients: 1) a new set of transfer functions to allow regional variation, 2) the use of a recent extension of stochastic-gradients for optimization, and 3) a new decomposition of connectivity into sparse and low-dimensional components. The last contribution proves key for high spatial resolution. Resting state HCP scans were preprocessed and deconvolved with a canonical hemodynamic response. Ground-truth tests indicate that the fitted parameters are valid and robust to both measurement noise and hemodynamic uncertainty. Parameters are highly reliable across sessions and robust to the choice of preprocessing method. The fits retrieve the true simulated individual differences in connectivity and discriminate whether/how individuals differ in connectivity or intrinsic dynamics. By contrast, we found that despite FC's strong discriminatory power (detecting if two subjects differ), individual differences in FC mapped poorly onto the underlying

differences in connectivity and systematic changes in FC can result from individual differences in purely local decay parameters. Lastly, we used the model weight matrices to make new inferences regarding directed connectivity. We observed that the strongest inhibitory sources were bilateral inferior frontal gyrus (IFG) pars opercularis which exhibited inhibitory directed connections to default mode regions. In contrast, the strongest excitatory source was left IFG pars triangularis with strong outward connections to the "language network". The current work therefore is an advance on two fronts: we have generated spatially-detailed biophysically plausible models which span individual human brains and, in the process, we have generated a new measure of connectivity.

Title: Neurostimulation safety investigations performed with reference, posable anatomical models

Authors: A. M. CASSARA[1], ***B. A. LLOYD**[1], S. FARCITO[1], E. NEUFELD[1], N. KUSTER[1,2]; [1]IT'IS Fndn., Zurich, Switzerland; [2]ETH Zurich, Zurich, Switzerland

Abstract: Improved knowledge of the various parameters that influence unwanted peripheral nerve stimulation (PNS) during magnetic resonance imaging (MRI) is vital for the development of strategies to mitigate potential safety issues related to the latest generation of MRI scanners, which utilize higher gradients (e.g., for the Human Brain Connectome project [1]). Much better and more realistic virtual human models are needed to be able to achieve this goal. In this study, we evaluated the two recently developed anatomical phantoms for computational neurostimulation investigations, *Yoon-sun* (female) and *Jeduk* (male), created with high-resolution (0.1 – 0.2 mm) cryosection images from the Visible Korean Human project [2]. The phantoms feature more than 900 subject-specific nerve trajectories of separated sensory, motor (e.g., dorsal and ventral roots) and autonomic (e.g., vagus) nerves. The phantoms can also assume user-defined postures and can be morphed to permit model personalization, e.g., by changing the body-mass-index or by adapting morphology to target body shapes. Further, we extended our database of parameterized electrophysiological axonal models with recently developed separated models of myelinated sensory and motor fibers, and of an unmyelinated C-

fiber, to permit the development of customized neurostimulation models of nerves [3].
In a first step, PNS thresholds (slew rates and gradient field) and sites of stimulations were compared to experiments reported in the literature [4] to define experimental settings in terms of body positions and gradient pulse waveforms. This was complemented by investigating the effect of different electrophysiological models used to predict the threshold-pulse duration relationship described by Irnich [5] and Zhang [6]. We then identified via simulations three key combinations of body postures and positions that result in large variations in stimulation thresholds and sites of activations and used this information to perform validation experiments with volunteers in actual MRI environments.
Applications of our improved modelling pipeline include 1) scanning guidelines for, e.g., posture and position to reduce unwanted stimulation, 2) pulse sequence optimization – including stimulation reduction – as an additional goal or constraint, and 3) mechanistic inputs for low-frequency exposure guidelines.

Title: Multiple electroencephalographic reading system with linear depth control in small species

Authors: *R. BELTRAN-RAMIREZ;
Sistemas de Informacion, Univ. De Guadalajara, Zapopan, Mexico

Abstract: The present invention describes an electrode movement system that allows to control the depth to which these (electrodes) are placed in the brain of the animal, for the performance of a continuous electrical activity monitoring (electroencephalographic record) in the animal to be evaluated.Said invention has a bluetooth module (connected to a microcontroller which are attached to the animal's torso allowing the mobility of this, while the microcontroller is connected to a series of motors and placed in a structure which is mounted on the skull of the

animal.
The system consists of a mounting structure composed of an octagonal piece which has an opening in the center that allows access to the brain of the animal, in addition to a series of holes in the surface for fixing this piece to the skull. On the surface of this piece there is an arrangement of pivots on which, for each pivot, a support for the electrode movement system is placed giving a total of 6 movement systems in total.The system test was performed under the following specifications.
Adult male rats of the Wistar strain of approximately 250 g of weight were used, which were kept under bioterium conditions: light / dark cycles 12 X12 h, temperature 22 ± 20 C and relative humidity of 50 ± 4% , with free access to water and food. For the implantation of the dialysis cannula and recording electrodes, the animals underwent stereotactic surgery under anesthesia with a mixture of halothane: carbogen (O2: 95: 5% CO2). A dialysis probe of 0.5 mm diameter and 2 mm in length, previously washed with HPLC quality water at a flow of 10 µl / min for 10 min and stabilized with a Krebs-Ringer solution at a flow of 2 µl / min, was inserted in the middle dorsal hippocampus (AP, -5.6mm; L, 4.2mm; V, 5mm from the pial surface). Two recording electrodes were placed bilaterally in the hippocampus; one of them attached to the dialysis cannula and the other in the contralateral region placed at the same depth. Two other electrodes were placed on the right and left entorhinal cortex (AP, -7.6mm, L, 5.2mm, V, 5mm) the EEG recording was started simultaneously in each of the electrodes for the study and analysis of the different areas as they are. Right Hippocampus, Left Hippocampus and cortex.
The use of the Multi-Electrode System helps several tests can be performed simultaneously which allow correlating each of the regions of which the EEG is performed.

Title: Evaluation of the Japanese eye typing system with EEG

Authors: *I. MOTOYAMA[1,2], T. UDA[2], M. YAMAZAKI[3], N. OKAMOTO[4], Y. KURODA[5], H. EDA[1,6];
[1]Grad. Sch. For GPI, Hamamatsu-Shi, Japan; [2]ORANGEARCH Inc., Tokyo, Japan; [3]GRAND COEUR LAB LLC, Saitama, Japan; [4]Col. of Social Sciences, Ritsumeikan Univ., Kyoto, Japan; [5]Kyoto Univ. of Educ., Kyoto, Japan; [6]Photonics Innovations Co., Ltd., Hamamatsu, Japan

Abstract: Introduction
Eye typing system has new possibilities of communication. It consists of an eye tracker, a virtual

keyboard, and software. The eye tracker needs a correct reference file for exact gaze point calculation. We have developed a Japanese eye typing system. We previously evaluated the novel eye typing system by the behavioral data (input time duration and its error) (Motoyama et al., SfN 2018). This time, we will evaluate the eye typing system through brain evaluation.

Method

The eye tracker (Tobii Eye Tracker 4C, Tobii AB, Sweden) was attached to the display, on which the virtual keyboard was shown. The 11x5 matrix was used as a Japanese "hiragana" virtual keyboard. We prepared a Fixed type virtual keyboard (FixVKB) and a Moving type virtual keyboard (MoveVKB), subject's reference files (subRef) and an others' reference file (othersRef).

The subject performed the eye typing of six words with each of the four conditions (Fix+sub, Fix+others, Move+sub, Move+others). We attached EEG electrodes (Fp1,Fp2,F7,F8,Fz,O1,O2 and Pz) according to 10-20 system and recorded the data using polymate II AP216 (MIYUKI giken Corp., Japan). Time-frequency analysis was applied to EEG data (Fz) to evaluate Fm theta activity and beta activities as an index of the concentration.

Eye movement were evaluated by Fp1, Fp2, F7 and F8 electrodes.

The consent form was obtained from all subjects. The experiment ethics and private information protection were fully considered.

Results

Fm theta was decreased association with the error inputs during the most complicated word (7 characters required 10 input, "me-i-ji-ji-n-gu-u"). Beta activities showed the increased tendency when the input duration was shorter compared with other input methods. Alpha activities were shown no tendency in any trials. During FixVKB, the number of eye movements was increased and the amplitude of the eye movements got enlarged compared to MoveVKB.

Discussion

Compared to the FixVKB, MoveVKB enables us to type more quickly and accurately without the stress. EEG also suggests the difficulty of the maintaining the concentration in FixVKB. Our study also shows that the difficulty of the eye typing can be objectively evaluated by combining the behavioral data and EEG data.

Title: Web-based integrated database platform for exploring and sharing omics datasets

Authors: J. CHOI, N. KIM, Y.-J. JANG, J. HEO, B. HA, *S.-J. JEONG;
KBRI, Daegu, Korea, Republic of

Abstract: It has been recently increasing to demand the data base platform for analysis of big data such as brain images and omics including proteomics and transcriptomics data in neuroscience field. Many database open to be shared, but most of them just provide the data obtained from experiments on their own interests and purposes, not such a kind of the platform. In this study, we created a web-based database system for searching, sharing, and analyzing the multiple data integrated by the open resources which are already existed. This system includes proteomics data, especially secretomes from extracellular vesicles (EV) of either neurons or astrocytes. REST(Representational State Transfer) service were adapted in our system to integrate the open resource such as datasets of Allen Brain Atlas and STRING DB. It allows users to get the information and compare them with their own data as well as the information of protein interaction. We usually used the SDK library to store the data in a web service, but the server was slow and stopped because of the high traffic and memory usage. Web-based RESTful service was utilized to develop lightweight, fast, scalable, and easy to maintain, so we used it. In order to visualize integrated data on the web, we have parsed the resource represented in XML as a DOM(Document Object Model) method and obtained the objects and visualized them as PHP language. Consequently, we established fundamental database platform with the omics data integrated by open resources. It is expected to be useful for researchers who want to compare and analyze their own data and several open data.

Title: Logistic regression applications for machine learning and intelligent decision-making

Authors: *H. C. YUAN[1], M. V. CHAO[2];
[1]Independent Lab., San Marino, CA; [2]Independent Lab., Rancho Palos Verdes, CA

Abstract: This poster investigates the application of logistic regression in machine learning and intelligent decision making. Examples of how logistic regression may be applied are also given from avionic systems. Logistic regression is a classification algorithm that is used to predict the probability of a categorical dependent variable using input that is continuous or discrete. Logistic regression is a statistical method for predicting binary classes. The outcome or target variable is dichotomous yielding only two possible classes. Logistic Regression is similar to linear regression, analyzing the relationship between a dependent variable and either one or multiple independent variables. Linear regression uses regular least-squares approach to compute the line of best fit to predict the value of the dependent variable based on the knowledge of the independent variable. Logistic regression produces an estimate of the probability of a certain event occurring. It uses the knowledge of an independent variable to predict if it is probable whether an event denoted by the dependent variable will either occur, or not occur, rather than to predict the actual value of this dependent variable. The dependent variable will be either 0 or 1, rather than being distributed along a line of best fit as in linear regression. Odds ratios are important to logistic regression as it is based on the probability of the occurrence of an event. The dependent variable in logistic regression is also known as a 'logit' (natural log of odds). Logistic regression as a classifier is more a linear classifier which uses the calculated logits (score) to predict the target class. Avionics in air traffic control in airports or in search and rescue often make intelligent decisions based upon airborne target kinematics (velocity, altitude) measured from sensor inputs. Logistic regression is a way to input airborne kinematic target data from sensors and make intelligent, categorical decisions for actions based on airborne target type. This poster examines the use of Logistic Regression binary classifier through an example of how intelligent decisions can be made through applying binary logistic regression with one-vs-rest multi-class classification schemes to airborne target velocity and altitude kinematic data for categorical decisions. As an application, this poster examines how binary Logistic Regression and multi-classification strategy can be applied to fuse avionics data (aircraft range, velocity) in decision making for classification, surveillance, and early warning decisions.

Title: Automatic segmentation of anatomical structures based on high-resolution diffusion tensor imaging in the developing pig brain

Authors: *J. LI[1], T.-W. TU[2], C.-H. HSU[2], A. AGARONYAN[1], V. LAM[1], K. LYDIC[1], A. DAVIS[1], P. C. WANG[2], A. V. FARIA[3], S. MORI[3], R. JONAS[4], N. ISHIBASHI[4];
[1]Ctr. for Neurosci. Res., Children's Natl. Hlth. Syst., Washington, DC; [2]Dept. of Radiology, Howard Univ., Washington, DC; [3]Radiology, Johns Hopkins Univ., Baltimore, MD; [4]Children's Natl. Heart Inst. and Ctr. for Neurosci. Res., Children's Natl. Hlth. Syst., Washington, DC

Abstract: BACKGROUNG Magnetic resonance imaging (MRI)-based atlases have become widely available for the human and mouse brain, allowing quantitative image analysis on a large scale in clinical and preclinical studies. Unlike rodents, the pig brain is gyrencephalic and has gray/white matter composition similar to the human brain, which offers various advantages as a translational animal model. Diffusion tensor imaging (DTI) is capable of characterizing detailed white matter structures and revealing subtle white matter abnormalities. However, a brain atlas for DTI has not been established in the piglet brain. OBJECTIVE Our project aims to develop a DTI-based 3D piglet brain atlas that includes detailed white matter regions. Aim of the present study is to evaluate the feasibility of automatic parcellation of brain regions to perform regional quantitative image analysis using the unique piglet model. METHODS We used 7T MRI to acquire a high resolution ex-vivo DTI brain image of a 6-week-old female Yorkshire pig. All identified regions were traced and labeled manually using ROIEditor (Johns Hopkins University) based on a DTI directionally-encoded color map and anatomical information from previous atlases (Saikali, 2010). The acquired ROIs templates were applied on the brain images normalized by Diffeo Map (Johns Hopkins University) for automated parcellation. RESULTS We isolated 131 individual cerebral structures including 16 paired cortical and peripheral white matter areas, respectovely. Deep brain white matter regions such as coronal radiata, internal capsule, superior longitudinal fasciculus, and sagittal stratum were successfully differentiated. The quality of automatic delineation was validated by measurements of (1) dice index, (2) mean standard deviation, and (3) fractional anisotropy intensity of each region. The results showed a high correlation between the manual ROI-based and the automated approaches in most regions. CONCLUSION Our piglet brain atlas can facilitate group analysis of DTI data in a majority of brain regions. Introducing advanced meuroimaging technologies and an atlas-based approach to the piglet model will provide a wealth of bidirectional information to assist research directed toward complex human brain development and a wide range of neurodevelopmental disorders.

Title: Computational methods for registration and analysis of whole brain volumetric image data acquired via serial two-photon tomography

Authors: *A. D. AJAY[1,2], D. M.RAMIREZ[1,2], K. POINSATTE[1,2], M. P. GOLDBERG[1,2], J. P. MEEKS[1,2,3];
[1]Dept. of Neurol. and Neurotherapeutics, UTSouthwestern Med. Ctr., Dallas, TX; [2]Peter O'Donnell, Jr. Brain Inst., [3]Dept. of Neurosci., Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: The UT Southwestern Whole Brain Microscopy Facility (WBMF) provides access to a variety of automated microscopy platforms which enable acquisition of high resolution, volumetric images of the mouse brain. Such images can be used to interrogate the brain-wide distribution of labeled features of interest, including neuronal circuit connections which may be altered in models of brain injury or disease. We have developed a flexible and robust computational pipeline to effectively visualize and quantitate whole brain serial two-photon tomography (STPT) datasets acquired on the TissueCyte 1000 platform. The two main functions of the pipeline consist of signal segmentation and image registration. Various fluorescent signals of interest (*e.g.* neuronal somas or processes, vascular signals, etc.) are first segregated using an open-source machine learning based software toolkit (Ilastik; www.ilastik.org) to perform pixel classification using a supervised random forest classifier, which is then applied uniformly to large cohorts of whole brain datasets. Prediction probability maps indicating how accurately a pixel is classified into one of the user-defined classes are then exported. The segmented signals are displayed visually as a TIF stack for detailed 3D rendering and each experimental brain dataset can then be spatially aligned to the reference atlas (Allen Institute for Brain Science Common Coordinate Framework v3.0 (CCF v3.0)) for quantification. Applying the registration transform to the Ilastik-generated prediction probability maps and segmentation enables quantification of the voxel density in each segmented brain region. Our pipeline incorporates the SimpleElastix registration library, a collection of high performance medical image registration algorithms, which has allowed us to carefully choose transformation models and tune their parameter maps to achieve very good global and local registration results. Additionally, we have used an extension of the Insight Registration and Segmentation toolkit allowing registration of full resolution images. Validation measurements for Ilastik classification, image registration, and

measurements of regional volume changes are in process. The image analysis pipeline has been used to study circuit plasticity following ischemic stroke and we anticipate it will be useful for a wide variety of experimental paradigms including different injury and disease models as well as labeling strategies.

Title: Automated alignment and segmentation of mouse mesoscale brain images using machine learning

Authors: *D. XIAO, B. FORYS, R. TANDUN, T. MURPHY;
Dept. of Psychiatry, Kinsmen Lab. of Neurolog. Res., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Quantitative analysis of large scale brain images relies on accurate alignment and segmentation of regions of interest. Matching a reference atlas to the brain data are very labor- and time-intensive manual tasks and prevent high-throughput analysis. Furthermore, human error may occur when clicking the anatomical landmarks in different subjects. Machine learning-based alignment and segmentation approaches for brain images are gaining interest due to their self-learning and generalization ability when applied to large amounts of data. As machine learning architectures are becoming more mature, they gradually outperform previous state-of-the-art classical algorithms. Our aim is to develop an automated machine learning-based alignment and segmentation approaches for quantitative mouse mesoscale brain images. We first trained a deep learning model to identify specific landmarks (i.e. bregma, lamda) in a wide-field calcium imaging dataset from more than 200 transgenic mice. The model can then automatically label landmarks in a new dataset of calcium images with high accuracy. Furthermore, automated brain atlas segmentation onto the calcium images was then performed using a fully convolutional network based on previously labelled landmarks and sensory mapping (via visual/whisker/vibration stimulation). The model can be further optimised by training on a larger datasets and capable of processing large-scale brain images automatically under a few minutes. We propose to further demonstrate that our method significantly enhances the accuracy and robustness of alignment and segmentation of new data sets.

Title: Inference of decision-making strategy from high throughput animal training

Authors: ***M. QIAO**, T. ZHANG, C. SEGALIN, S. SAM, P. PERONA, M. MEISTER; Caltech, Pasadena, CA

Abstract: Understanding cognitive functions usually requires training animals to perform complicated decision-making tasks. During the course of training, the animal changes its strategy for decision-making. It is important to figure out the strategy each animal uses at any given trial in order to understand animal learning. Understanding how individual animals learn will require high-throughput standardized methods for behavioral training but also advances in the analysis of the behavioral data. In the course of training, an animal may change its behavior abruptly, and capturing such events calls for a trial-by-trial analysis of the animal's strategy. To address this challenge, we developed an integrated platform for automated animal training and analysis of behavioral data. A low-cost and space-efficient apparatus serves to train entire cohorts of mice on a decision-making task under identical conditions. A generalized linear model (GLM) analyzes each animal's performance at single-trial resolution. This model infers the momentary decision-making strategy and can predict the animal's choice on each trial with an accuracy of ~80%. We also assessed the animal's detailed trajectories and body poses within the apparatus. Unsupervised analysis of these features revealed unusual trajectories that represent hesitation in the response, reflect a behavioral adjustment to prevent further mistakes. We are now extending the study to behavioral paradigms in which the optimal decision-making strategies change from block to block, and preliminary results suggest that the model faithfully captures each animal's strategy in each block. These efforts promise to accelerate the understanding of animal learning and decision-making.

Title: Machine learning techniques for online decoding of single units activity and position during wakefulness or sleep reactivation

Authors: *T. BALENBOIS, S. LAVENTURE, D. BRYZGALOV, K. BENCHENANE;
Mobs Team, Lab. Plasticité Du Cerveau, ESPC, Paris, France

Abstract: The hippocampus is crucial for spatial navigation and place cells are considered to be the underlying neural substrate. Seminal studies have already shown that position can be decoded from place cell activity. Accessing this neural spatial information in real time would enable researchers to induce learning based directly on neural activity patterns by pairing the decoded position with rewarding or aversive stimulation. However this requires faster decoding methods than are currently available. A significant effort in the field right now is directed towards sorting spikes in real time in order to access the activity of single units which can then be used to decode position. Examples of this include using template matching or expectation maximization. Alternative methods consist of avoiding the spike sorting step and using a bayesian model to decode position based on unsorted spikes. Nevertheless, most of these tools present the usual trade-off between accuracy and efficiency. Using machine learning tools that can sustain both accuracy and computational efficiency is a mandatory condition for aversive or appetitive learning experiments based on decoded position. We used artificial neural networks to decode single unit activity ; this initial step is then followed by a classical approach consisting of a combination with a simple bayesian model to then decode the position of an animal given its place cell activity. We show that the accuracy is similar to that of offline decoding. The accuracy is a function of the number of active place cells recorded. Additionally, the integration of single unit activity has to be done on a biologically relevant time window. Our decoding device works with a time precision of 15 to 30 ms, which is consistent spatial coding in the hippocampus. Altogether, this shows the feasibility to use artificial neural networks as machine learning tools to decode position in real time.

Title: Automated atlas refinement in 3D

Authors: *D. M. YOUNG[1], S. FAZEL DARBANDI[1], G. SCHWARTZ[1], Z. BONZELL[1], D. YURUK[1], M. NOJIMA[1], J. RUBENSTEIN[1], W. YU[2], S. SANDERS[1];
[1]Psychiatry, Univ. of California, San Francisco, San Francisco, CA; [2]Inst. of Mol. and Cell Biol., Agency for Science, Technol. and Res., Singapore, Singapore

Abstract: We present Magellan, a suite of software tools to transform 2D organ atlases into consistent 3D atlases, and demonstrate the benefits by comparing the performance in cleared mouse brain samples at single nuclei resolution. Atlases are critical for mapping sample data into the correct anatomical space for quantification and comparison across multiple samples. Atlases across species and organs have been generated typically by serial labeling of 2D planes, a time-consuming task that can lead to inconsistencies and artifacts such as boundary misalignments between planes apparent in orthogonal dimensions. The expanding field of whole-organ volumetric microscopy necessitates complete, accurate, and fully 3D atlases, and variability across development mandates the generation of such atlases at specific developmental stages. To generate such atlases, while leveraging and cross-referencing existing atlases, we developed automated methods to extend atlases from serial 2D to fully 3D whole-organ maps. We employ 3D smoothing techniques to minimize region boundary artifacts in all dimensions while maintaining each region's overall shape and placement. To further refine labels, we automatically identify and incorporate gross anatomical boundaries into existing atlases to improve correspondence between labels and underlying anatomical markers, including those that may not have been as apparent along a single axis. Using the Allen Developing Mouse Brain Atlas series, we apply these methods to each atlas from prenatal to adult stages to demonstrate improved label coverage and anatomical correspondence across development as measured by distances between gross anatomical and label borders and within-region variability in 3D. Applying the atlas refinements to quantification of C57BL/6J mouse brains at age P0, we replicate these enhancements on intact tissue cleared brains including whole-brain nuclei detections with a 37% improvement in anatomical boundary match ($p_{adj} = 0.007$; n = 15 mice, 10 male and 5 female) to demonstrate closer atlas alignment and improved regional quantification at both the gross anatomical and cellular levels. Magellan-transformed atlases improve the analysis of whole-

organ volumetric microscopy data facilitating the direct comparison of 2D and 3D data registered to the Allen Brain Atlas and equivalent resources.

Abstract: Introduction: Experimental research in small animal disease models often require quantitative comparisons of cellular and molecular measures in large groups of specimens, with need for efficient and reproducible methods. We present a novel workflow for quantification and spatial analysis of labeling in large series of section images from mouse and rat brains, using Human Brain Project (HBP) tools and procedures. Method: As a first step, whole brain image series are anchored to a digital reference brain atlas, using the software tool *QuickNII*, to produce accurate anatomical maps adapted to the orientation of the images. Subsequently, we use advanced automated image segmentation using machine learning with *ilastik* based on Random Forest Algorithm for supervised classification. The classified images are subsequently analyzed on a whole brain and regional level with input from the atlas maps with the *Nutil* software. Results: The number of objects (extracted features) and areas occupied by the objects are identified at the whole brain and region level, enabling quantitative analysis. This workflow yields results comparable to expert manual delineations and to the output of a stereological method.

Title: Automatic ultrasound based neuronavigation approach for functional ultrasound imaging

Authors: M. NOUHOUM[1,2], J. FERRIER[2], B. OSMANSKI[2], M. TANTER[1], *T. DEFFIEUX[1]; [1]Physics For Med. Paris (Inserm / ESPCI Paris / CNRS / PSL Res.), Paris, France; [2]Iconeus, Paris, France

Abstract: Functional ultrasound (fUS) is a recent imaging technique capable of mapping cerebral vascular network but also to capture neuronal activity with very high sensitivity. One remaining hurdle is the expertise required to position the probe and identify brain structures solely based on 2D vascular images, especially when it comes to oblique non-coronal and non-sagittal slice. In this study, we developed and validated a fully automatic and integrated approach combining 3D multi-slice ultrasensitive Doppler imaging of the mouse brain and online automatic registration to the reference 3D anatomical atlas from the Allen brain institute. Using a prototype fUS scanner (Iconeus, Paris, France) equipped with a 15MHz ultrasonic probe (128 elements, 0.1-mm pitch) mounted on a motorized setup, successive 2D transcranial images were acquired in a male C57BL/6 mouse anesthetized with 1.5% isoflurane. Linear scans were repeated in several directions using a tomographic approach and reconstructed to obtain a high-resolution (100 x 100 x 100 µm3) 3D isotropic volume of the mouse brain vasculature. This 3D volume was first registered on a set of Magnetic Resonance Angiography scan acquired on a C57BL/6 mice along with T2-weighted images for anatomical correspondence and co-registered

scans were then aligned to the Allen Mouse Brain atlas.
The 3D Doppler volume was then used as a reference for automatic non-rigid datasets registration within experiments using an iterative optimization algorithm based on intensity matching of big vessels.
Validation was performed on C57BL/6 mice anesthetized with a Ketamine/Xylazine mixture. A caudal-to-rostral linear fUS scan has been acquired through the skin and skull (0.2 mm step, 8mm length, 60 s duration).
The prototype software was used to automatically register the scans onto the reference and thus on the atlas. An oblique 2D imaging plane was chosen to encompass both the left S1BF and right V1 cortex regions and the probe was moved automatically after selection. Functional imaging following whisker and visual stimulations revealed strong activation of both cortical seeds, validating the plane positioning. Secondly, automatic resting-state connectivity matrix could be constructed with 44 regions and demonstrating strong bilateral connectivity within the cortex as expected.
The proposed functional ultrasound online neuronavigation approach enables non-expert automatic brain navigation and positioning for standardized experiments and protocols and could also pave the way to software guided injection in deep structures.

Title: Braindrles: A crowd-sourcing tool for stroke lesion segmentation quality control

Authors: ***S.-L. LIEW**[1], A. SURI[1], M. P. NOTTER[2], K. ITO[1], P. RAAMANA[3], A. KESHAVAN[4];
[1]USC, Los Angeles, CA; [2]The LINE, Dept. of Radiology and Dept. of Clin. Sci., Ctr. for

Biomed. Imaging, Lausanne, Switzerland; [3]Baycrest Hlth. Sci., North York, ON, Canada; [4]Child Mind Inst., San Francisco, CA

Abstract: Understanding how a stroke affects the brain requires quantification of how the stroke infarct interferes with existing brain structures. For instance, stroke lesion overlap with the corticospinal tract is a robust predictor of sensorimotor recovery, while lesion overlap with Broca's area is a key predictor of recovery in the language domain. Although manual segmentation is the gold standard for lesion segmentation, this approach is extremely time consuming and requires expertise in neuroanatomy. Emerging big data approaches for stroke rehabilitation research requires automated approaches for analyzing hundreds to thousands of stroke MRIs (e.g., ENIGMA Stroke Recovery). A fast, accurate, and scalable pipeline for lesion segmentation is thus desperately needed. We generated a publicly-available dataset of 304 manually segmented lesion masks and used this to determine the best existing automated lesion segmentation algorithm (LINDA, Lesion Identification with Neighborhood Data Analysis). However, although LINDA performs well, there is still a significant need for manual visual inspection to ensure the automated lesion masks are correct, which creates a bottleneck. To this end, we developed a novel, crowd-sourced platform for gamified visual quality control of lesion masks called Braindrles (https://braindrles.us). Braindrles utilizes the same web-based platform as its predecessor Braindr, which harnessed the power of citizen scientists to provide over 80,000 human annotations on structural MRI motion artifacts. Braindrles provides a mobile optimized annotation interface in which citizen scientists are shown dynamic triplanar images of stroke MRIs with lesion segmentation overlays, which are animated to facilitate quick judgements of segmentation accuracy. Citizen scientists are asked to swipe right if the lesion segmentation accurately captures the lesioned territory and left if the segmentation is incorrect. Citizen scientists are onboarded with a tutorial, and images with ground truth segmentations are randomly included in the database to evaluate each individual's accuracy. Votes, weighted by individual accuracy, are aggregated and used to determine acceptable lesion segmentations versus those that need to be manually corrected. This information is used to inform and improve machine learning lesion segmentation algorithms. Overall, Braindrles employs a unique citizen-science approach to expediting visual quality control and has the potential to rapidly advance large-scale stroke rehabilitation research and lesion segmentation algorithm development.

Title: SBA composer: Web-based platform for interactive, multi-modal data visualization with Jupyter notebook control

Authors: R. BAKKER, N. TIMONIDIS, ***P. H. TIESINGA**;
Donders Ctr. for Neurosci., Radboud Univ., Nijmegen, Netherlands

Abstract: We present SBA Composer, an interactive online platform for visualizing brain volumes, tissue sections, region meshes, neuron morphologies and other 3d geometries inside a brain atlas. The platform uses brain atlases from the set collected by the Scalable Brain Atlas [Bakker et al (2015) Neuroinformatics, 13, 353-366]. They minimally consist of a brain region hierarchy, meshes for each brain area, one or more reference data volumes and a definition of the template space. Data can be imported into Composer either interactively by the user or programmatically from within a Jupyter notebook or via 3rd party websites, which can open SBA Composer as a separate tab in the browser and send data/receive messages from it.
A key challenge of multi-modal integration is the alignment of the various data sources. If they are pre-aligned to the selected atlas, they may still differ in the choice of units, orientation and origin. Composer offers a data import wizard to correct these settings, and uses the brain addressing system (brainaddress.org) to refer to location in the brain. For unregistered data, interactive tools for scaling, translation and rotation are available, as well as point-pair based registration.
A first use case is the Connectomic Composition Predictor (CCP), a service developed for the Human Brain Project (HBP) which predicts a mouse connectivity matrix on the basis of gene expression data. The service runs in the HBP Collaboratory, which provides Jupyter notebook environment in which python scripts can be run interactively. The CCP visualization module opens an SBA Composer window and loads the predicted connectivity as a volume, which is displayed as one or more section planes at arbitrary angles.
A second use case is the inspection of connectivity experiments from the Allen Institute. These experiments result in projection densities, which can be displayed as 'streamlines' and represent efferent connectivity from the injected area. In the figure, we inspect whether injections in the Anterior Cingulate Area are connected to the Basolateral Amygdalar nucleus.

Title: Deep learning for OCT angiogram vectorization

Authors: ***S. STEFAN**, C. POLUCHA, J. LEE;
Brown Univ., Providence, RI

Abstract: Optical coherence tomography (OCT) is a rapid, label-free, high resolution imaging tool that is becoming increasingly popular and useful for neuroscientific study. OCT may be particularly useful for the analysis of vascular networks, which are visualized based on dynamic scattering in vessels due to moving blood cells. One promising application of OCT is in the lifespan tracking of microvascular alterations in neurological diseases such as Alzheimer's Disease, without the need for contrast agents, additionally allowing measurements of blood flow in penetrating arterioles and venules using Doppler OCT as well as blood flow velocity in capillaries. However it is not realistic to semi-manually segment and vectorize a large number of longitudinal OCT datasets using existing methods. Additionally, many methods applied to the segmentation of the vasculature using other imaging modalities (for example two-photon

microscopy) are not as successful on OCT angiograms due to the effects of multiple-scattering which results in projection artifacts or “tails”. To combat this issue, we have trained a deep convolutional neural network to automatically segment OCT angiograms, using labeled data consisting of angiograms that are fully segmented and manually corrected. Application of our network to unseen test data of standard angiograms yields promising results, performing significantly better than standard methods of vessel segmentation without the need for empirical parameter optimization. Segmented data can now be vectorized more easily and accurately, making it possible to quantitatively investigate questions concerned with angioarchitecture, blood flow and neurovascular coupling.

Title: Introducing bioimage suite web: A simple, modern, & powerful software suite

Authors: ***S. NOBLE**, Z. SALTZMAN, C. LACADIE, H. GARBUS, J. ONOFREY, X. PAPADEMETRIS, D. SCHEINOST;
Yale Univ., New Haven, CT

Abstract: Neuroimaging research to dissect the functional organization of the brain is a rich and rapidly growing area of study, buoyed by support from major public initiatives. However, neuroimaging software infrastructure has lagged behind; notably, the most powerful software often require computational expertise beyond the scope of most neuroscience labs. Here, we introduce a state-of-the-art neuroimaging architecture that overcomes these limitations through an easy-to-use yet powerful design. BioImage Suite Web (BISWeb; www.bioimagesuite.org) is a point-and-click app that runs in any modern web browser without any installation necessary, yet with performance rivaling that of a locally installed software. Due to the general nature of its architecture (JavaScript, C++, WebAssembly), BISWeb works on most modern web-browsers (e.g., Chrome, Safari, Firefox), major operating systems (e.g., macOS, Windows, Linux), and devices (e.g., tablets, smartphones). BISWeb currently supports a range of functionality in human and animal fMRI: defacing, segmentation, registration, and more. New additions include visualizations that summarize the connectome, automatic brain segmentation via deep learning, and a DICOM to BIDS format converter. Furthermore, all BISWeb applications read and write

all data and parameters used in analyses to a JSON file, alongside software version, operating system, date, and user data. This enables a workflow in which a user can load data, create visualizations, and save their state to continue work later. These files can also be used to share "live figures" with collaborators or validate analyses and software across updates. A wealth of guidance is already available for new users, from YouTube video tutorials to developer documentation (all code is openly available on GitHub). In summary, BISWeb is a modern web-based neuroimaging software created not only to make state-of-the-art analysis accessible to users of any skill level, but also to ensure results are both transparent and reproducible. These goals promote rigor in the bourgeoning field of neuroimaging.

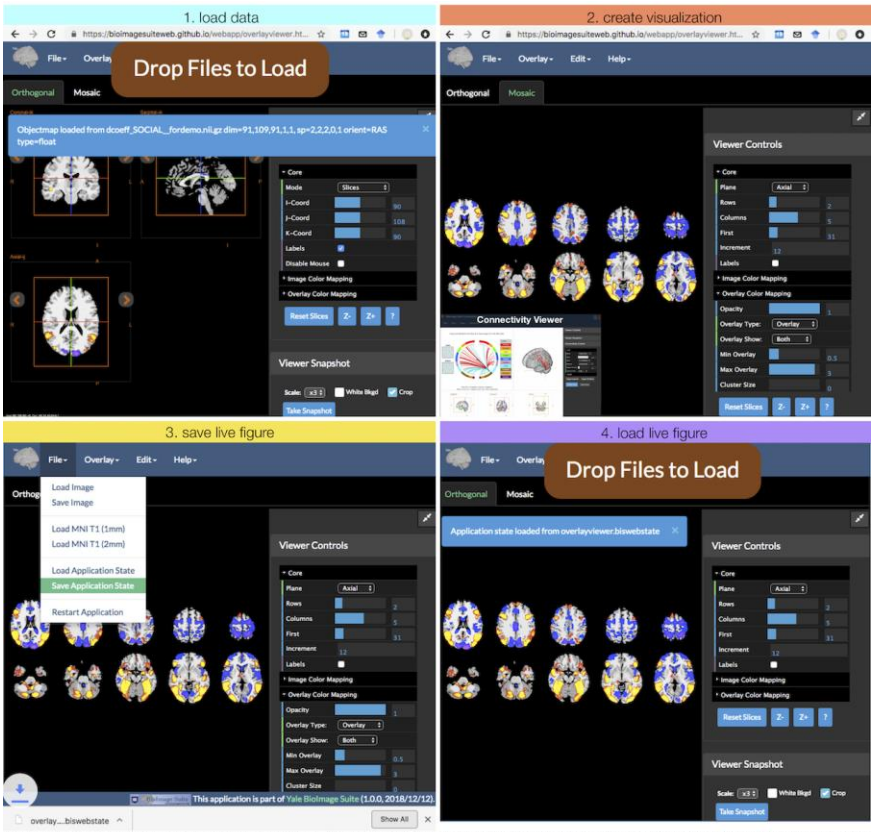

Figure 1. fMRI visualization and live figures in BISWeb. These screenshots demonstrate a typical process of fMRI image visualization in the Overlay Viewer application, resulting in a live figure that can be shared with a recipient (e.g., a collaborator). This example workflow demonstrates: (1) loading structural and overlay data, (2) creating a visualization of mosaic slices (inset: Connectivity Viewer application showing circle and glass brain plot), (3) saving the live figure, and (5) loading the live figure. Loading the live figure restores the full application state so that the user can continue where they left off, or a collaborator can adjust the figure.

Title: Cloud-enabled massively parallel structural and functional MRI preprocessing pipeline

Authors: *H. GONZALEZ, M. E. KOLLADA, M. S. MELLEM, Y. LIU, O. RODRIGUEZ, P. AHAMMAD;
Blackthorn Therapeut., San Francisco, CA

Abstract: The preprocessing of structural and functional MRI scans is a computationally-intensive operation, typically taking several hours per subject. This results in prohibitively long waits between MRI data acquisition and analysis, particularly in large datasets with many hundreds of subjects, when computation is performed using traditional infrastructure such as workstation units. Here we present our cloud-enabled massively-parallel MRI preprocessing pipeline, integrated from technologies widely used in the scientific community and capable of preprocessing an average of more than 150 scans per day.
We built a preprocessing pipeline, using the FreeSurfer and AFNI software suites, that takes raw structural and resting-state functional MRI data and outputs parcelated and voxel-level time series as well as functional connectivity matrices. Internally, we perform the following steps to preprocess the raw data: structural preprocessing, despiking, motion correction, skull-stripping, co-registration between structural and functional images, spatial smoothing, normalization by mean signal, nuisance signal regression, and normalization to the MNI space. Our pipeline follows the Brain Imaging Data Structure (BIDS) standard and was designed from the ground up to be used as a cloud service, retrieving and storing files on demand in AWS S3 and executing in Docker containers that require minimal support. Our pipeline is also compatible with AWS Batch, enabling us to preprocess complete large-scale datasets in parallel using a cloud-based cluster environment.
We tested our pipeline by preprocessing the resting-state scans from the following datasets: ABIDE I, CNP, and EMBARC. Our pipeline preprocessed the CNP dataset in 43 hours (N=251, 5.8 subjects/hour), the EMBARC dataset in 42 hours (N=326, 7.7 subjects/hour), and the ABIDE I dataset in 80 hours (N=1056, 13.2 subjects/hour).Our pipeline code was executed in "c5" AWS EC2 computers with 8GB of RAM per container. These results were obtained using up to 1300 concurrent AWS EC2 vCPUs.
Compared to traditional local non-parallel computation, our MRI preprocessing pipeline opens the door to big data analysis of MRI datasets. We have shown that by bringing state-of-the-art technology to neuro-imaging analysis, we can create a flexible on-demand high-performance computing infrastructure with minimal offline footprint, and potential for reducing long-term cost. Our approach significantly reduced the end-to-end preprocessing time for complete MRI datasets, and holds promise in enabling scientists to study the effect and sensitivity of parameter changes across datasets with many thousands of subjects.

Title: AISuite: A Python tool for morphometrical analysis

Authors: *J. ROOS, M. ENGELHARDT;
Inst. of Neuroanatomy, Med. Fac. Mannheim, Heidelberg Univ., Mannheim, Germany

Abstract: Morphometrical analysis of data obtained by immunofluorescent stainings after high resolution microscopic imaging has played a key role in our understanding of subcellular neuronal domains, such as the axon initial segment (AIS) and its plasticity. So far, morphometrical analysis of AIS parameters, particularly length, distance from soma or diameter has been accomplished with software tools such as Neurolucida or ImageJ and self-written macros or simply measuring “by hand” in the software supplied by the microscope manufacturer. These numerous applications have led to data acquisition with a varying degree of scientific precision. In today’s landscape of proprietary and barely interoperable software, it has become evident that there is a need for a solution that is open and easy to use. AISuite was designed to fill this gap. After evaluating the state of analytical tools in the literature, we developed a strategy for an open-source, user-flow centric and expandable application. Python - a potent scientific programming language - was selected as the basis of the software suite, integrating performant compiled libraries such as OpenCV, NumPy and the extensive ImageJ libraries. Regarding data handling, and due to the limitations of the proprietary landscape of microscope manufacturers, AISuite provides an initial conversion step of the raw microscopic data into NumPy arrays through the ImageJ Bioformats reader. This step also saves all of the OMEXML compliant metadata of the acquisition process into a hierarchical data format file (HDF5), which contains all future alterations and data acquisition within the same experiment. The HDF file format has been selected for its standardized and asynchronous accessibility from different programming languages. Accurate 3D to 2D projections are integrated with an implementation of a sliced Maximum Intensity Projection, which can be adjusted to the best fitting limits. However, AISuite is also undergoing further optimization of data analysis in 3D confocal stack data, which would further limit pre-analysis data manipulation. AISuite allows for different ROI selection modules utilizing a line drawing tool, which is supported by a graphical tablet and pen. Throughout the development, a constant feedback and feature request cycle was established

among members of the lab as well as others from the scientific community, providing various data sets to test and validate the software. Here, we present an open source, freely available solution providing a standardized workflow to analyze various morphological features in neurons and other cells. Additionally, we continue to develop the program for web-based applications.

Title: TMSmap software for analysis of transcranial magnetic stimulation mapping results - Demonstration of the new features

Authors: *P. NOVIKOV[1], M. NAZAROVA[1,3], K. KOZLOVA[1], E. IVANINA[2], V. NIKULIN[1,4,5];
[1]Ctr. for Cognition and Decision Making, Inst. for Cognitive Neurosci., [2]Dept. of Psychology, HSE Univ., Moscow, Russian Federation; [3]Dept. of Neurorehabilitation, Federal Ctr. for Cerebrovascular Pathology and Stroke, The Ministry of Healthcare of the Russian Federation, Federal State Budget Inst., Moscow, Russian Federation; [4]Dept. of Neurol., Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany; [5]Neurophysics Group, Dept. of Neurol., Campus Benjamin Franklin, Charité—Universitätsmedizin Berlin, Berlin, Germany

Abstract: Here we present a new version of free software for standardising quantitative analysis of the data obtained with transcranial magnetic stimulation (TMS) mapping procedure - TMSmap (a previous version is described here (Novikov et al., 2018), http://tmsmap.ru/). The program allows estimating standard TMS map parameters such as areas and volumes, locations of the hotspots and centres of gravity of the cortical representations, as well as excitability profiles of the cortical representations, the overlap between the cortical representations and other user-defined parameters. New version of the program has an option for co-registering TMS mapping data to Montreal Neurological Institute (MNI) space (Figure 1) and thus allowing group comparison of the TMS mapping results. For convenient group analysis it is possible to load data and compare TMS maps automatically using a predefined script. New version of TMSmap also includes the possibility to analyse only stimulation points corresponding to a specific brain structure visible on MRI image, for example analysing only the map based on the stimuli applied in the vicinity of the central sulcus.

Input data for the software includes the coordinates of the coil position or calculated locations of the induced electric field (depending on the neuronavigation system), structural MRI data and a response at each point of stimulation (motor evoked potentials, behavioural response etc.). TMSmap was developed for the versatile assessment and comparison of the cortical maps following different experimental interventions including but not limited to longitudinal studies (e.g., studying of cortical reorganization during rehabilitation after stroke).

Title: Cell detection and segmentation via persistent homology

Authors: *U. KILIC[1], M. VAIANA[2], E. M. GOLDBERG[3], S. E. MULDOON[4];
[1]Dept. of Mathematics, Univ. At Buffalo, SUNY, Buffalo, NY; [2]Mathematics, Univ. At Buffalo, Buffalo, NY; [3]Neurol., The Children's Hosp. of Philadelphia, Philadelphia, PA; [4]Univ. at Buffalo, SUNY, Buffalo, NY

Abstract: Analyzing neuroimaging data at the cellular level often involves the tedious task of localizing and/or segmenting cells in images. Although automated cell detection methods exist and can be utilized for certain types of data, in noisy images, cell localization can prove difficult and manual or semi-manual methods are often employed. Here, we present a new algorithm that draws from mathematical tools in applied topology, specifically persistent homology, to perform cell localization and segmentation in neuroimaging data. Importantly, this method is robust to small perturbations, and therefore advantageous for use in images with small amounts of noise. The method can be applied to images in which cells appear either as filled regions (using 0-dimensional homology) or as donut-shaped objects (using 1-dimensional homology). To verify the performance of the technique to detect filled regions, we apply the algorithm to a large set of images drawn from the 2018 KAGGLE Data Bowl: Nuclei Detection Competition and achieve high accuracy in localizing cells. We then provide examples of how 1-dimensional homology can be used to detect and segment neurons in calcium imaging data or to perform myelin segmentation in microscopy images.

Title: Advanced machine learning in Cellairus: The next generation of unbiased stereology

Authors: *W. D. PACK[1], N. ROUSSEL[1], A. D. LEDUC[1], B. S. EASTWOOD[1], C. R. BATES[1], H. L. KESSLER[1], J. MCMULLEN[1], S. J. TAPPAN[1], P. J. ANGSTMAN[1], F. DU[2], M. LIU[2], J. R. GLASER[1];
[1]MBF Biosci., Williston, VT; [2]FD NeuroTechnologies, Inc., Columbia, MD

Abstract: With the advent of Cellairus, automated stereology has risen to the forefront of object quantification research by leveraging artificial intelligence to reduce manual cell marking. The manual aspects of stereology have been a barrier to widespread utilization of unbiased stereology. Cellairus dramatically accelerates stereological cell counting through the use of

machine learning to replicate expert observer judgments of cell location and size. Once the machine learning algorithms are trained, Cellairus identifies cells in 3D volumes throughout 3D brain regions using the same observer criteria as a human expert. Additionally, automation avoids user fatigue and subjectivity by consistently applying the same cell counting criteria throughout the brain. The unbiased results can be audited and reviewed for every counting frame site. Cellairus makes stereology easier, more robust, and faster. In Cellairus, 3D image volumes are analyzed using the Optical Fractionator probe using 3D detection methods to ensure accurate cell detection and unbiased population estimates. Cellairus is trained to differentiate between cells and non-cell objects. Even dense populations of cells are counted correctly. Cellairus uses a patent pending technique to perform true 3D stereological analysis. In contrast, other 'automated stereology' counting technologies utilize methodical shortcuts, e.g., analyzing 2D images collapsed from 3D volumes, that reduce accuracy and introduce bias. In this study, we validated the cell counts from the Caudate-Putamen in mouse brains by comparing automated stereology results with ground-truth data collected by manual stereology. Coronal brain sections were prepared with two fluorescent labels, DAPI and NeuN. Manual and automated stereology were performed for both wide-field fluorescence and scanning laser confocal microscopy in order to assess the performance of Cellairus across multiple imaging technologies. Population estimates, coefficients of error, false positive, false negative, and true positive detection rates were quantified and compared between cell counting methods and imaging modalities.

Title: Data interface and apps for systems neurophysiology and imaging

Authors: D. GARCIA MURILLO[1], Z. WANG[1], O. ROGOVIN[2], S. CHEN[2], O. PAPAEMMANOUIL[1], *S. D. VAN HOOSER[2];
[1]Computer Sci., [2]Biol., Brandeis Univ., Waltham, MA

Abstract: Technology for recording from the brain is developing at a breakneck pace. But the digital integration of data acquired from different recording technologies is an impediment to the rapid adoption of these technologies across labs, and also makes analysis by interested 3rd parties, such as theorists, difficult. This lack of integration is a major barrier to scientific inquiry, as labs cannot easily analyze each other's data. Funding agencies are increasingly concerned with reproducibility, rigor, and distribution of data, even though there is no generally accepted "library" process for sharing these data. Common data interfaces would facilitate the development of common analysis code, leading to an increase in code testing and robustness, and an increase in reproducibility and rigor.
We present a data interface standard for neurophysiological and imaging data. The standard is not a file format but rather is a systematic means of specifying and accessing data used in the neurosciences, including voltage waveforms, imaging data, spike times of neurons, and intensity values in regions-of-interest within imaging data. The data interface standard can be implemented in any programming language. On the one hand, the interface includes tools for reading files from several Multifunction Data Acquisition Devices, 2-photon microscopes, and stimulus devices, and tools for handling the fact that different investigators often organize their data differently on disk. On the other hand, the interface contains a powerful extendible database so that the results of analyses and extracted quantities can be stored and queried. These features allow for an eco-system of best-of-breed "apps" to be developed or converted from existing open source tools, that store standardized results in the database.
The long-range goal of the project is to enable experimentalists, theorists, and even amateurs to exchange data easily and to begin meaningful analysis within the hour of download. This has the capability to transform neuroscience into a discipline more like astronomy, where data is widely shared and many theorists and amateurs contribute to new discoveries.

Title: ANTs-based pipeline for preprocessing structural neuroimaging data from stroke patients

Authors: *H. HECTOR[1], I. PAPPAS[3], K. HAWS[4], B. CURRAN[5], A. S. KAYSER[2], M. D'ESPOSITO[3];
[2]Neurol., [1]Univ. of California, San Francisco, San Francisco, CA; [3]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [5]Res., [4]VA Northern California Hlth. Care Syst., Martinez, CA

Abstract: Spatial normalization is a prerequisite to group-level analysis of neuroimaging data. Normalization transforms MR images of subjects' brains to a standard template, and thereby facilitates inter-subject comparisons. Standard normalization techniques, however, perform best on scans from healthy subjects and may perform poorly on scans from subjects with brain lesions.
Current methods for spatial normalization of MR images of brains with lesions include those that perform normalization through a cost-function that excludes the lesioned area as defined by a manually drawn "lesion mask" (Brett et al., 2001), and those that use tissue probability maps to perform normalization and segmentation simultaneously via "unified segmentation" (Ashburner and Friston, 2005). Despite their widespread use, these methods haves not been validated.
We offer a spatial normalization method tailored to MR images of brains with lesions using Advanced Normalization Tools ("ANTs") (Avants et al., 2011).
Specifically, we (1) create a group-level template and its corresponding prior probability images. The template is constructed using an iterative approach by tuning the ANTs pipeline to our stroke data. As each structural image is registered to the template, a new template that minimizes the diffeomorphisms between the template and the individual structural image is created. The process converges until it meets a tolerance criterion (Avants et al., 2010). (2) We perform a rigid transformation of each subject's structural image to the template, and (3) apply ANTs' cross-sectional cortical thickness pipeline (Tustison et al., 2016) to each structural image using the group template and its priors as input. (4) We normalize the extracted brain images to the MNI template using the nonlinear SyN registration method and a lesion mask for cost-function masking (Avants et al., 2011). This creates a group-specific template that reduces the cost of directly mapping the lesioned brains to MNI space.
We collected structural MRI data from patients with brain lesions following a stroke (160 slices, slice thickness 1 mm, TR = 2300 ms, TE = 2.98 ms, FA = 9°, matrix 256 × 230, field of view 256 mm x 230 mm). Lesion masks were drawn manually and approved by two board-certified neurologists (AK, MD). We assessed the quality of our method by calculating a normalized mutual information score between the normalized lesioned brains and the MNI template. Our method achieved higher normalized mutual information than the unified segmentation and cost-function masking methods. We propose that our preprocessing framework yields the most accurate spatial normalization of MR images from subjects with brain lesions.

Title: Brain platform: A step towards standardized analysis of neuroimaging data

Authors: *S. AGHAYEE[1], Z. BOWEN[2], G. MAGNUSSON[4], M. DIEP[4], M. LINDVALL[5], A. PORTER[5], W. LOSERT[3];

Abstract: Two photon calcium imaging has allowed for recording the activity of large populations of neurons simultaneously at single cell resolution. Over the years many analysis pipelines have been developed for extraction and inference of neuronal activity from neuroimaging data. However, a standardized data collection and analysis platform is still lacking in the field. Here we showcase the BRAIN platform that aims to act as a framework for neuroscience researchers to collaborate on reproducible experiments and perform their research in a more efficient way. The BRAIN platform will serve as a common platform for researchers to share algorithms, workflows, and data; enabling them to easily reproduce experiments and rapidly explore new ideas. Over time we expect the platform to assemble a large crowd sourced library of software packages and toolsets. Researchers will be capable of creating new workflows by chaining these software packages together. The NWB data format will be used to unify the difference in data inputs and formats between the lab instruments and software packages. The current iteration of the BRAIN platform has a few algorithms for the most common calcium imaging analysis operations such as motion correction, cell registration, signal extraction, and spike inference. The algorithms can be configured and arranged to form an image analysis pipeline. These algorithms come from open source packages such as Suite2p, and some provided by researchers at University of Maryland. Moving forward we plan to allow users to integrate their own software packages and toolsets across different data sources and programming languages.

Title: Cost effective open-source platform for the physiological data collection simultaneously with fMRI

Authors: P. T. SUMMERS[1], *S.-H. LEE[2], Y.-Y. I. SHIH[2];
[1]Biomed. Engin., [2]Dept. of Neurol., The Univ. Of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: In fMRI research, multiple devices are used to monitor resting state physiological conditions, including heart rate, body temperature, SpO_2, and $EtCO_2$. These conditions are known to contribute as nuisance noise, and many attempts have been made to find the correlation of these signals with Blood Oxygen Level-Dependent (BOLD) signal to regress out these nuisance components from the image data. There has yet to be a cost-effective platform allowing to collect physiological data from multiple devices facilitating efficient for synchronizing it with fMRI data. We designed a device integrating the open source platforms, Raspberry Pi and Arduino microcontrollers, to interface with measuring instruments to collect and store physiological data during MRI scans. The system implements Python and C++, enabling customization for different experimental setups and processing the signal. We used Arduino Uno as an analog-digital converter to deliver acquire analog signal at 9.6 kHz to the Raspberry Pi that is only allowing digital input though GPIO pins with a sample rate of 200 kHz. The trigger signal from the MRI scanner is used to synchronize these multi-modal data. The touchscreen monitor was used to couple with simplified Graphics User Interface (GUI) for easy interaction and monitoring of vitals. As a result, the Raspberry Pi and accessories can be bought from Adafruit for $180, and the Arduino Uno costs only $22, bringing the total cost of the final product can be around $200, which is highly cost-effective compared to the commercial platform. Also using the open source design enables each MRI group to optimize the system for their own needs. In conclusion, because our automated system is highly cost-effective and tunable, we expect our platform can be easily integrated into a wide variety of neuroscience MRI groups to collect physiological parameters concurrently with fMRI acquisition.

Title: A python package for quantitative classification and characterization of single neuron full morphology

Authors: *P. XIE[1], Y. WANG[1], L. LIU[2], Z. ZHOU[1], Y. YU[1], W. WAN[3], T. WANG[3], Q. WANG[1], L. QU[3], J. A. HARRIS[1], H. ZENG[1], H. PENG[1];

Abstract: Single cell morphology is a key feature for the definition of neuronal types since the specification of neuroanatomy. However, the complete morphological data of single neurons including intact local and long-range axon arbors, has just become available in recent years. Such data has paved the way to understanding the projection pathways of axons, density of axon/dendrite clusters, patterns of arborization and so on. Global efforts have been made to generate single neuron morphology data at large scales and there is an urgent need for methodologies for quantitative data analysis. Here, a python package is implemented for the purpose of feature quantification, cell type classification/characterization and flexible visualization. The package is designed for facilitating the community for efficient data exploration, interpretation and integration. The major analysis pipeline takes CCF-registered reconstructions as the input and includes the following modules:
1) Feature quantification of:
a. Arbor lengths across brain regions, based on the annotation of CCFv3.
b. Morphological features (defined by the L-measurement) of the shape, size and location of the dendrites and axon terminals.
c. Projection paths (defined by brain regions) of major axon branches.
2) Similarity metrics and clustering analysis:
a. Features normalization and selection.
b. Similarity measured for each feature sets by graph-based algorithms.
c. Co-clustering analysis through random resampling.
d. Consensus between feature sets for cluster calls.
3) Cluster characterization:
a. Differential feature detection for cluster separation at different levels.
b. Correspondence between objective and subjective classification.
4) Visualization:
a. Dimension reduction by PCA, tSNE or UMAP.

b. Interactive plotting and flexible sample/feature selection.
c. Visualization of neuron structures in the CCF template with flexible options of samples, features, neurite types and views.

Title: A robust intracranial electrode localization algorithm

Authors: ***T. ENDESTAD**[1], A.-K. SOLBAKK[2], J. IVANOVIC[3], P. LARSSON[3], R. T. KNIGHT[4], A. O. BLENKMANN[1];
[1]Univ. of Oslo, Oslo, Norway; [2]Univ. of Oslo, Bekkestua, Norway; [3]Oslo Univ. Hosp., Oslo, Norway; [4]Univ. of California Berkeley, Berkeley, CA

Abstract: The accurate localization of electrodes in relationship to the brain's anatomy is the foundation of the spatial resolution of intracranial EEG recordings. However, in "difficult cases" the localization needs to be done manually since automatic methods often fail. This could be high density arrays up to 3 mm inter-electrode distance, overlapping electrodes, low resolution CT images, or connection cables ovelaying grids. Here, we present a new fully automatic method that models a flexible array of electrodes and fits it to the artifacts observed in post implantation CT images.
We evaluated data from 18 adult patients with drug resistant epilepsy implanted with depth electrodes and/or subdural grids (18 patients, 3261 electrodes). The localization results of the automatic method were compared to manual localization.
The main processing steps (Fig. 1 A) were:
1) Thresholding and selection of a cloud of CT voxels containing the electrode artifacts
2) Assembling a model of the grid (depth) array of electrodes
3) Fitting the model to a smooth surface (line) approximation of CT artifacts
4) Fitting the model to the cloud of voxels by minimizing the energy function
$E = -Ec + Et + Ed$
Ec is the gaussian weighted spatial correlation between the electrodes and the cloud of voxels. Et

penalizes the translation of electrodes, and Ed penalizes the deformation of a spring grid connecting the electrodes.By using this energy minimization approach, all electrodes are localized simultaneously instead of the usual individual localization, and therefore less sensitive to noise.
Automatic localization resulted to be more precise than manual selection, observed as a significant reduction of the inter-electrode distance variance (Fig. 1 B).
We provide a robust method for intracranial electrode localization that is applicable to “difficult cases” were previous automatic methods fail (Fig. 1 C).
The method was implemented in the open-source iElectrodes toolbox and is available to the research community (Blenkmann et al., 2017).

Title: An affordable and accurate tool to target subcortical structures in non-human primate

Authors: *S.-E. PARK[1], Z. LIANG[2], C.-A. N. GUTEKUNST[2], M. J. CONNOLLY[2], A. DEVERGNAS[3], R. E. GROSS[2];
[1]Georgia Inst. of Technol., Atlanta, GA; [2]Neurosurg., Emory Univ. Sch. of Med., Atlanta, GA; [3]Yerkes Natl. Primate Res. Ctr., Atlanta, GA

Abstract: Despite great improvements in stereotactic navigation systems for human neurosurgery, most of the non-human primate (NHP) neurosurgeries are still planned using standard 2D brain atlases. When only relying on brain atlases, variance between NHP subjects can cause inaccurate implantation of electrodes and chambers. We developed a novel tool for stereotactic neurosurgical planning for chronic implantation of electrodes or chambers as well as for visualization of the recording trajectory after implantation. We describe here the use of this tool in a post-surgery condition for visualizing different structures of interest that could be reached through a chronic recording chamber. An MRI compatible chronic recording chamber aimed at the hippocampus was implanted using stereotaxic coordinates based on the Salim and Logothetis brain atlas. A post-surgical MRI scan was performed 1 week after the surgery. A grid loaded with vitamin E was inserted inside the chamber before the scan to visualize the center and possible angle of the chamber. The subcortical structures including subfields of basal ganglia and striatum as well as the hippocampus were identified by registering MRI to the pre-segmented 3D MRI brain atlas (Reveley-et-al, 2017) using FMRIB software library (FSL). The identified regions were then converted into the original coordinate space by using the inverse matrix of the registration. A predicted trajectory of the electrode at each location in the chamber was obtained using a homemade Matlab code. Electrophysiological single unit activities in the putamen, pallidum and the hippocampus were used to verify the predicted locations. LFP recordings further confirmed our prediction by showing the characteristic pattern of CA1 and CA3 in the hippocampus. This MRI-based tool provides accurate and fully automatized subject-specific identification of subcortical structures and is applicable for various designs of electrodes and chambers.

Abstract: A detailed census of the morphological, electrophysiological, molecular and connectional properties of cell types in the brain is being performed by a consortium of laboratories as part of the Brain Initiative Cell Census Network (BICCN). The Allen Institute for Brain Science is supporting the goals of BICCN by providing a foundational community resource for integrated cell-centric data with an open-access 3D digital brain cell reference atlas with molecular, anatomical, and physiological annotations of brain cell types in mouse and in human. To facilitate integration of diverse datasets generated by >30 different laboratories, a new integrated data framework has been implemented and continues to be developed. This flexible and powerful backend data architecture utilizes a graph database, and implements a unified data schema with supporting ontologies across all teams, experiments and datasets. The public web interface accesses the data through an API and services to support search, and enacts FAIR principles (finable, accessible, interoperable, reusable). By integrating different data modalities into a cell-centric framework, we will support the BICCN objectives by producing a scientifically cogent cell census. Essential to this integration is the adoption of semantic standards, spatial registration of all data to common brain coordinate systems, and to the extent possible, the use of standardized data processing pipelines and normalization to enable cross-modality comparison and analysis. The currently available Cell Registry product provides a centralized and archival record of all cells profiled or imaging experiments generated by the BICCN. This registry enables search by experimental parameters and points to data archive locations for high resolution data and protocols. The next evolution of this portal will provide access to spatial anatomic features, genetic and transcriptomic features, analytical annotation, morphological and electrophysiological feature through an integrated online viewer.

Title: Robust mapping of sectioned or 3D mouse brain images from multiple modalities using EM-LDDMM

Authors: *D. J. TWARD[1], B. C. LEE[1], X. LI[2], B. HUO[2], P. P. MITRA[2], M. MILLER[1]; [1]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [2]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: The Brain Initiative Cell Census Network (BICCN) aims to obtain molecular, anatomical, and functional data across the mouse brain, mapped to a reference brain (CCF). Laboratories throughout the network use a host of imaging modalities to acquire data, including serial two photon tomography (STPT), fluorescence micro-optical sectioning tomography (FMOST), MRI, and light microscopy of Nissl stained tissue processed with tape transfer. These present variety in contrast, tissue loss or damage, artifacts, and 3D or 2D sectioning, making traditional registration approaches insufficient. The objective of this work is to build robust computational tools for mapping these datasets, and to quantify tissue distortion so comparisonsof cell/process densities can be made between modalities. We developed a statistical model for generating observed images from a 3D atlas, including 3D changes in shape and pose, optional 2D sectioning and distortion, changes in image contrast and color, and presence of artifacts and damaged or missing tissue. An Expectation Maximization (EM) algorithm was employed to calculate penalized maximum likelihood estimates of unknown transformations, built using the Large Deformation Diffeomorphic Metric Mapping (LDDMM) framework. This method, named EM-LDDMM, results in estimates that are robust to imaging variability.From the determinant of Jacobian of mappings we computed median linear scale change for each modality and found that two STPT brains are smaller by 7% and 5% relative to the CCF, FMOST smaller by 16%, and Nissl larger by 2%. Examining in vivo to ex vivo MRI of the same specimen showed in 4% shrinkage due to fixation. The figure shows two axial slices of these modalities,

aligned to the CCF, with linear scale change overlayed, and demonstrates that registration is robust to tissue removed for RNA sequencing and other variability.These mapping tools are being used to atlas-map data, made public via brainarchitecture.org, which will accelerate research throughout the BICCN and neuroscience community.

Title: MorphoHub: An informatics platform for managing massive data production of neuron morphology

Authors: *S. JIANG[1], S. ZHAO[1], L. LIU[1], Z. ZHOU[3], Z. RUAN[1], Y. WANG[2], H. PENG[3]; [2]Southeast Univ. – Allen Inst. Joint Ctr. for Neuron Morphology, [1]Southeast Univ., Nanjing, China; [3]Allen Inst. For Brain Sci., Seattle, WA

Abstract: Obtaining complete morphology of neurons from whole-brain imaging data is commonly accepted as a critical step towards the deciphering of the brain mechanisms. Whole-brain imaging techniques (such as fMOST) and computational tools for volume image visualization and annotation (such as Vaa3D [1], TeraFly [2], TeraVR [3]) have recently become more accessible, which make it possible for launching large-scale whole-brain neuron

reconstruction projects using industrial approaches. However, as the size of the reconstruction repositories for such a project typically grows at increasing rates, new requirements occur during the course not only in organizing and storing the morphological data, but in managing the reconstruction procedures, monitoring the overall progress, and many other aspects as well.
To address the above problems, we designed MorphoHub, an integrated informatics platform for data management, annotation workflow control and monitoring, data profiling and analysis, information visualization, etc. The informatics platform is built upon a hierarchical database model to organize both the imaging data and reconstruction data. The Relational Database Management System (RDBMS) is adopted to ensure data warehouse security and offer robust data backup/recovery. Most major functions of MorphoHub are implemented as services mounted on top of the RDBMS. The Annotation Service is used to transfer annotation data of different levels between the data server and the annotation workstation, with the guidance of a clearly defined working protocol. The Data Management Service generates tracking tables for reconstruction status and permits an administrator to edit the database. The Data Visualization Service displays the real-time states of the overall reconstruction project on a wall-mount big screen system, such as the morphology of newly reconstructed cells, the progress of individual brains, and the analysis of the neuron reconstructions.
We assembled a team of 20 annotators at SEU-Allen and some other collaborating research centers. With the help of MorphoHub, several remarkable results, e.g. producing ~1,000 neuron morphologies of mouse brains, was achieved in about one year time.

Abstract: Normally extracted from microscopy imaging data, 3-D morphology is one of the most defining features for neurons. The process for obtaining morphology data is known as neuron reconstruction or neuron annotation, which is usually a nontrivial task especially for the cases of mammalian brains. Although promising automatic neuron reconstruction approaches emerged during recent years, manual efforts are nonetheless indispensable if precise and complete reconstructions are desired. Typically, the exhaustive reconstruction of full morphology from whole-mammalian brains could cost considerable time even for a team of experienced annotators. Thus, a methodology for accurate, efficient, scalable, organized, and manageable production of morphology data becomes a rising needed. In this work, we present a four-level protocol to systematically guide the neuron reconstruction process with clear standards. From lower to higher levels, the reconstruction criteria become stricter and the corresponding morphology data gets more refined with details. The easy-to-use protocol allows the combination of both automatic and manual procedures in a flexible order, and intuitively integrates several novel techniques including artificial intelligence and virtual reality. Based on such a protocol, a team of 20 annotators has smoothly reconstructed more than 700 neurons located in the thalamus, striatum, spiny claustrum, etc. of mouse brains. A large portion of the produced data have been released to the Brain Initiative Cell Census Network (BICCN).

Title: Automatic multi-scale neuron refinement for whole mouse brain reconstruction

Authors: *Z. ZHOU[1], L. LIU[2], Y. WANG[4], Z. RUAN[2], H. PENG[1,3];
[1]Allen Inst. For Brain Sci., Seattle, WA; [3]Southeast Univ. – Allen Inst. Joint Ctr. for Neuron Morphology, [2]Southeast Univ., Nanjing, China; [4]Allen Inst., Seattle, WA

Abstract: Currently, reconstruction of 3-D full morphology of neurons at the whole-brain scale still requires intensive manual curation and annotation in trillions of image-voxels of a brain. Manual reconstructions are considered the gold standard to evaluate automated reconstructions and to generate training sets for machine learning based algorithms. To further explore more detailed morphologies, these whole brain reconstructions could also be used forneurites radius estimation, spine detection, and/or synaptic boutons counting. Therefore, generating high quality, biologically meaningful annotations is in great demand. Here, we introduce an automatic multi-scale refinement system for whole mouse brain neuron reconstruction. The proposed system evaluates the reconstruction at two different scales (low/high resolutions). At each scale, a graph-augmented deformable (GD) model based approach is used to automatically refine manual curated reconstructions. Combing Euclidean distance, pixel intensity along the path, and closeness to local centers of image intensity distribution, the GD model is designed to find the optimal path between two end points. We applied an automatic refinement approach on 500+ manual curated full morphology reconstructions. Our preliminary results show the refined reconstruction highly reflects the overall neuronal structures of manual reconstruction. At the same time, each segment in refined reconstruction is fine-tuned to better represent the original neuron structure.

Title: Single neuron morphology heterogeneity from a whole brain perspective

Authors: *L. MANUBENS-GIL[1], P. XIE[2], L. LIU[1], H. PENG[2,1];

Abstract: Neuronal morphology is crucial for shaping brain connectivity. However, systematic analyses of the detailed morphology of full neurons from a whole brain perspective have not been possible due to a number of technical limitations. Using sub-micrometric resolution fMOST imaging of sparsely labeled neurons in whole mouse brains, the SEU-Allen Joint Center for Neuron Morphology started to release full neuron morphology reconstruction datasets at increasing pace. Here we reported an analysis of the dendritic and axonal trees of 95 neurons of a single mouse brain mainly distributed throughout the Thalamus and Caudoputamen. Our analysis shows a high degree of morphological variation within the studied brain regions, being higher in axons than dendrites. Neuron locations within the Thalamus and Caudoputamen brain areas do

not determine morphological types. However, thalamic neurons have smaller and less complex dendritic and axonal trees when located in lateral nuclei. Caudoputamen dendritic trees, conversely, show increased tree size and complexity for both posterior and lateral locations within the region. To assess whether neurons are segregated by their abilities to process and store information, we quantified the material cost, routing efficiency and connectivity repertoire of dendritic and axonal subtrees. Thalamus neurons have architectural traits maximizing storage capacity in both dendritic and axonal trees, while Caudoputamen neurons maximize routing efficiency. Moreover, thalamic dendrites seem to have segregated connectivity repertoire values in different nuclei. Thalamic neurons show distinct axonal projection patterns to the cortex, segregated in clusters throughout the antero-posterior axis that correspond to individual thalamic nuclei. Caudoputamen neurons mainly have local projections that do not vary depending on the location of the neurons within the region. Simulation of the axon potential propagation has shown diverse signal transmission dynamics among brain regions. Altogether our results show that (1) highly specific axonal projection patterns can follow discrete (Thalamus) or continuous (Caudoputamen) spatial distributions in distinc brain regions, and (2) currently defined anatomical parcellations account only for a small proportion of neuromorphological heterogeneity, which determines non-homogeneous information routing and storage capacities in brain circuits.

Title: The Brain Image Library

Authors: ***A. J. ROPELEWSKI**[1], A. WETZEL[1], G. HOOD[1], D. SIMMEL[1], K. BENNINGER[1], M. BRUCHEZ[2], A. WATSON[3], S. C. WATKINS[3];

Abstract: The Brain Image Library (BIL) is a unique resource of optical microscopy data for neuroscience investigators. The library is one of five NIH-designated repositories to receive BRAIN initiative data. Primary goals of the library are to preserve original research data from

brain studies that generate high-quality microscopy datasets at planar resolutions up to optical limits and sectional spacings from micron to hundreds of microns as dictated by their original experimental purpose. With single or multi-channel high-resolution data captures of mouse brains now exceeding 10 terabytes per specimen, these volumes have become increasingly difficult for research laboratories to store and exchange with remote sites. To make these datasets and data from larger mammalian species more widely available, the BIL provides a single site where data are stored once and then retrieved on-demand over nationwide high-speed networks for further research and academic uses. The library, now in its second year of operation, currently contains more than 750 contributed mouse full-brain volumetric datasets and is expected to grow to an aggregate store of 10 Petabytes over the next few years. The Brain Image Library also provides an extraordinary facility for both contributors and data users alike to interact with and select specific data subsets for further analyses from the BIL systems without requiring massive data downloads. This is achieved by BIL's support of a variety of remote-desktop mechanisms for remote visualization and data manipulations, including private virtual-machine environments capable of running commercial software and project-specific web portals. Allocations to high-performance computational resources are available for using PSC's large-scale Bridges computing system to directly interact with BIL data in-place using compute nodes with up to 12 Terabytes of shared memory, GPU nodes with P100 and V100 GPUs, and an NVIDIA DGX-2 to support high-bandwidth multi-GPU deep-learning applications. This design allows researchers to access these unique resources, bring their own software packages, and make use of software developed by other bio-imaging projects.

Title: Immersive visualization is a key enabler for precise whole-brain scale reconstruction of neurons

Authors: *Y. WANG[1,2,3,4], Q. LI[3], L. LIU[1,2], Z. ZHOU[5,2], Y. WANG[5], L. KONG[3], H. PENG[1,2,3,5];

For Brain Sci., Seattle, WA

Abstract: Neuron morphology, the 3-D digital representation of neurons, substantially helps neuroscientists to explore the underlying functions and mechanisms of brains. As techniques for sparse labeling and whole-brain imaging are more accessible, it now becomes feasible to reconstruct complete neuron morphology from whole-mammalian brains. For a complete morphology, both dendritic trees and axonal arborizations are expected to be precisely captured. Moreover, the reconstruction should be performed in an efficient way to achieve high-throughput data production. These requirements call for a powerful neuron reconstruction software that offers intuitive visualization and interaction.

We developed TeraVR [1], an open source virtual reality (VR)-based neuron reconstruction system. The software was quickly adopted by SEU-Allen and several other collaborating research teams to help fulfilling their goal in producing thousands or even millions of complete neuron morphologies. Integrated in Vaa3D [2], TeraVR natively gains the ability of handling imaging data of terabyte-scales [3], and can be readily enhanced by a broad line of Vaa3D plug-ins. Ever since its first release, TeraVR is continually being updated by adding more useful functionalities for neuron reconstruction and improving the human-computer interfaces to further boost productivity. In the meantime, morphology data generated using TeraVR was analyzed quantitatively to find out what really the strengths of TeraVR are. Analysis results firmly support the notion that TeraVR is the right tool to seek for when imaging data with complicated, weak, and/or noisy signals is encountered. With TeraVR, neuron reconstruction can be performed at an accuracy that has never been achieved before.

Recently, a dataset containing the complete morphology of 500+ neurons generated by TeraVR has been released to the public through BRAIN BICCN. Such data are expected to benefit the community in several ways, e.g. serving as defining features for discriminating cell types, or being used as gold standards for developing machine intelligence-based automatic neuron reconstruction approaches.

Title: Ultratracer2 on HPC for high-throughput neuron morphology reconstruction

Authors: *L. DING[1], Z. ZHOU[2], Z. DING[3], H. PENG[2,1];
[1]Southeast Univ., Nanjing, China; [2]Allen Inst. For Brain Sci., Seattle, WA; [3]Bournemouth Univ., Bournemouth, United Kingdom

Abstract: Neuron reconstruction at the whole-brain level is essential to the understanding and characterization of the 3D morphology of neurons. To facilitate the effort of obtaining such valuable data, a widely used platform, Vaa3D (Peng, et al, *Nature Biotechnology*, 2010, *Nature Protocols*, 2014), has been developed with visualization, auto-tracing and annotation functionality. Specifically, Vaa3D has been used as a key platform to enable the global *BigNeuron* initiative (Peng, et al, *Neuron*, 2015) that has produced the largest known archive of neuron reconstructions with over 3 million constructions in 2015. Also, an *UltraTracer* framework (Peng, et al, *Nature Methods* 2017) was developed to provide a generalized framework to enable reconstructing neurons from virtually unlimited large image volume. However, for mammalian brains, practically whole-brain neuron reconstruction has not been done in large-scale. In this work, we present a new framework with Vaa3D-UltraTracer2 and high performance computing(HPC) cluster employment for high-throughput reconstruction of whole-brain neuron reconstruction. In addition to UltraTracer's approach of divide-and-conquer and capability of using any basic tracer, UltraTracer2 adopts DeepNeuron(Z. Zhou et al., *Brain informatics*, 2018) to deal with the heterogenous background situation common in whole-brain image and employs confidence scores to help the determination of tracing process. UltraTracer2 also provides evaluation scores for the output reconstructions, which helps annotators to prioritize ones with good quality and thus improve the efficiency of annotation. We implemented the UltraTracer2 framework on HPC cluster to gain further computational efficiency. For each whole-brain data, a list of soma locations of the neurons are put through the system with one single command which runs all Ultratracer2 jobs. These jobs are distributed on the cluster nodes and are ran in parallel with job management system, hence HPC implementation speeds up UltraTracer2 framework. In this way, the UltraTracer2 on HPC framework increases the throughput of neuron reconstruction on whole brain level and thus facilitates the on-going effort of enlarging the data set of whole-brain neuron morphology reconstruction.

Abstract: Visualization and exploration of neuroimaging data are essential for the analysis of anatomical or functional images as well as statistical parametric maps. While two-dimensional orthogonal views of neuroimaging data are conventionally used to display activity and statistical analysis, real three dimensional (3D) depictions are useful for showing the spatial distribution of a functional network, as well as its temporal evolution. For these purposes, there is currently no open-source, 3D neuroimaging tool that can simultaneously visualize the following modalities: MRI, CT, EEG, MEG, fMRI, PET, and invasive electrodes (i.e., ECOG, depth electrodes, and DBS). Here we present the Multi-Modal Visualization Tool - MMVT (mmvt.org). This tool was built for researchers who wish to have a better understanding of their neuroimaging anatomical and functional data through simultaneous visualization of these existing imaging technologies. MMVT contains two separate modules: The first is an addon to the open-source, 3D-rendering program Blender. This addon is an interactive graphical interface which enables users to simultaneously visualize multi-modality functional and statistical data on the cortex and subcortical surfaces as well as the activity of invasive electrodes. This tool also enables highly accurate 3D visualization of neuroanatomy, including the location of invasive electrodes relative to brain structures. The second module includes stand-alone pre-processing full pipelines, from raw data to statistical maps. Each of the modules and module features can be integrated, separate from the tool, into existing data pipelines. This gives the tool a distinct advantage in both clinical and research domains as each has highly specialized visual and processing needs. MMVT leverages open-source programs and packages to build a comprehensive multimodal visualization tool for data visualization and exploration.

Title: Cortical atlas of the canine brain

Authors: *P. J. JOHNSON[1], W. LUH[2], J. P. LOFTUS[1], K. GRAHAM[3], A. WHITE[4], B. C. RIVARD[5], E. F. BARRY[1];
[1]Cornell Univ. Col. of Vet. Med., Ithaca, NY; [2]Natl. Inst. on Aging, Natl. Inst. of Hlth., Baltimore, MD; [3]Univ. of Sydney Sch. of Med., Syndey, Australia; [4]Univ. of Sydney Sch. of Med., Sydney, Australia; [5]Cornell Col. of Vet. Med., Ithaca, NY

Abstract: There is a need to identify and develop improved models for human neuroscience research. The dog has been bastioned as a potential unique model for comparative neuroscience research, an essential component of which is advanced neuroimaging. One limitation of the canine in this field is a lack of a brain atlas that includes a comprehensive myeloarchitectonic based cortical atlas for standardization and automation of cortical segmentation.

We created a canine brain atlas from isovolumetric T1-weighted MRI data generated in vivo from 30 neurologically healthy, mixed breed, mesaticephalic dogs. Data were preprocessed before registration and creation of a population template using Advanced Normalization Tools (ANTs). To assess the applicability of this template to other canine data sets with differing skull shapes an independent 3D T1-weighted MRI dataset of mesaticephalic, dolichocephalic, and brachycephalic neurologically healthy canines were recruited and, using non-linear registration, similarity metrics (mean normalized MI) were generated for each skull shape group. Delineation and parcellation of the cerebral cortex to create a cortical atlas was performed manually for each lobe in accordance with the myeloarchitectonic articles from Jerzy Kreiner. Region boundaries were established based on the myeloarchitectonic structure of the grey matter that is described in Kreiner's articles and depicted in images of cortical surfaces and transverse slices of the brain. In addition, subcortical structures were delineated using anatomic references and previous subcortical references.

The resulting atlas provides a mesaticephalic canine population template generated from healthy animals. When compared to other mesaticephalic dogs the similarity matrix of normalized MI had a mean value of -0.475 (st. dev. 0.0762) whereas for dolichocephalic and brachycephalic skull shape the normalized MI was increased to -0.449 (st. dev. 0) and -0.366 (st. dev. 0.0241) respectively. The myeloarchitectonic cortical parcellation resulted in generation of 108 cortical regions per hemisphere grouped into frontal, sensory-motor, perisylvian, parietal, cingulate and occipital lobar areas. Subcortical segmentations included olfactory lobe, hippocampus, cerebellum, amygdala, caudate, lateral and medial geniculate nuclei, and rostral and caudal colliculi.

This atlas provides intricate myeloarchitectonic based cortical segmentations which will function as a foundational tool for standardization and automation in future canine neuroimaging research.
